ADD. VOL.

ENCYCLOPÆDIA BRITANNICA.

ASSOCIATION, the act of associating, or constituting a society, or partnership, in order to carry on some scheme or affair with more advantage.—The word is Latin, *associatio;* and compounded of *ad*, to, and *socio*, to join.

Association of Ideas, is where two or more ideas constantly and immediately follow or succeed one another in the mind, so that one shall almost infallibly produce the other, whether there be any natural relation between them or not. See METAPHYSICS.

Where there is a real affinity or connexion in ideas, it is the excellency of the mind, to be able to collect, compare, and range them in order, in its inquiries: but where there is none, nor any cause to be assigned for their accompanying each other, but what is owing to mere accident or habit, this unnatural association becomes a great imperfection, and is, generally speaking, a main cause of error, or wrong deductions in reasoning. Thus the idea of goblins and sprights, it has been observed, has really no more affinity with darkness than with light; and yet let a foolish maid inculcate these ideas often on the mind of a child, and raise them there together, it is possible he shall never be able to separate them again so long as he lives, but darkness shall ever bring with it those frightful ideas. With regard to this instance, however, it must at the same time be observed, that the connection alluded to appears far from being either unnatural or absurd. See the article APPARITION.

Such wrong combinations of ideas, Mr Locke shows, are a great cause of the irreconcileable opposition between the different sects of philosophy and religion: for we cannot imagine, that all who hold tenets different from, and sometimes even contradictory to, one another, should wilfully and knowingly impose upon themselves, and refuse truth offered by plain reason: but some loose and independent ideas are, by education, custom, and the constant din of their party, so coupled in their minds, that they always appear there together: these they can no more separate in their thoughts, than if they were but one idea, and they operate as if they were so. This gives sense to jargon, demonstration to absurdities, consistency to nonsense, and is the foundation of the greatest, and almost of all the errors in the world.

Association forms a principal part of Dr Hartley's mechanical theory of the mind. He distinguishes it into synchronous and successive; and ascribes our simple and complex ideas to the influence of this principle or habit. Particular sensations result from previous vibrations conveyed through the nerves to the medullary substance of the brain; and these are so intimately associated together, that any one of them, when impressed alone, shall be able to excite in the mind the ideas of all the rest. Thus we derive the ideas of natural bodies from the association of the several sensible qualities with the names that express them, and with each other. The sight of part of a large building suggests the idea of the rest instantaneously, by a synchronous association of the parts; and the sound of the words, which begin a familiar sentence, brings to remembrance the remaining parts, in order, by successive association. Dr Hartley maintains, that simple ideas run into complex ones by association; and apprehends, that by pursuing and perfecting this doctrine, we may some time or other be enabled to analyze those complex ideas, that are commonly called the *ideas of reflection*, or *intellectual ideas*, into their several component parts, i. e. into the simple ideas of sensation of which they consist; and that this doctrine may be of considerable use in the art of logic, and in explaining the various phenomena of the human mind.

Association of Parliament. In the reign of King William III. the parliament entered into a solemn association to defend his Majesty's person and government against all plots and conspiracies; and all persons bearing offices civil or military, were enjoined to subscribe the association to stand by King William, on pain of forfeitures and penalties, &c. by stat. 7 and 8 W. III. c. 27.

Association, African. This is an institution which was formed in the year 1788, for the purpose of promoting discoveries in the interior parts of Africa. Out of the number of the members, of which this society consists, five are elected for the management of its funds and correspondence, and for the appointment of persons to whom the missions are assigned. Mr Ledyard was the first who was sent out, for accomplishing the object of the society. He undertook the adventurous task, of traversing from east to west, the widest part of the African continent, in the latitude which was ascribed to the Niger; and with this view he arrived at Cairo in August 1788. But before his projected journey commenced, he died, and the hopes that were entertained of this enterprising and persevering traveller were disappointed. Mr Lucas was next chosen by the committee,

Digitized by Google

committee. In October 1788, he embarked for Tripoli; and he was instructed to proceed over the desert of Zaara to Fezzan, to collect all the information that could be obtained, respecting the interior of the African continent, and to transmit it by way of Tripoli. He was then to return by way of Gambia, or the coast of Guinea. But his peregrinations terminated at Mesurata. The difficulties and dangers which presented themselves deterred him from proceeding farther. He transmitted to the society only the result of his conferences with the traders to Fezzan, with whom he was travelling; and soon after returned to England.

The society still persevered in its object, and in the year 1790, appointed Major Houghton, with instructions to sail for the mouth of the Gambia, and to traverse the country from west to east. He arrived on the coast in November the same year, immediately commenced his journey, ascended the river Gambia to Medina, 900 miles distant from his mouth, and thence proceeded to Bambouk, and to the adjoining kingdom of Kasson, where, in September the year following, he unfortunately terminated his travels with his life, near to the town of Jarra.

Mr Park was engaged by the society in the same service in 1795, and pursuing the route of Major Houghton, more successfully explored the banks of the Niger, to Sego and to Silla, the first of that great line of populous cities which divide the southern from the northern deserts of Africa. The information which Mr Park collected, during his adventurous journey, was communicated to the society in 1798. In a second journey, commenced in 1805, this enterprising traveller perished, after having reached the Niger; but the circumstances of his death have not been ascertained with perfect certainty.

Mr Horneman, who had offered himself to the committee in 1796, departed from London in July 1797, and proceeding by Cairo, commenced his journey westward with the caravan, in September 1798. In November following, he arrived at Mourzouk in Fezzan, from which his last despatches to the society were transmitted by way of Tripoli, but no accounts of his death ever reached the society.

John L. Burckhardt, the son of a citizen of Basle in Switzerland, was engaged by the society in 1808. After some preparatory steps, he set out in March 1809. He remained two years and a half at Aleppo; thence he went to Egypt. Unfortunately no caravan set out for the interior of Africa for a series of years. He was thus disappointed in his leading object; but he made two journeys up the Nile, and visited Mecca, Medina, and Mount Sinai. Diseases brought on by fatigue and the climate, at length put a period to his life in September 1817. See Africa, Supplement.

ASSOILZIE, in *Law*, to absolve or free.

ASSONANCE, in *Rhetoric* and *Poetry*, a term used where the words of a phrase or a verse have the same sound, or termination, and yet make no proper rhyme. These are usually accounted vicious in English; though the Romans sometimes used them with elegancy; as, *Militem comparavit, exercitum ordinavit, aciem lustravit.*

ASSONANT RHYMES, is a term particularly applied to a kind of verses common among the Spaniards, where a resemblance of sound serves instead of a natural rhyme. Thus *ligera, cubierta, tierra, mesa,* may answer each other in a kind of *assonant* rhyme, having each an *e* in the penult syllable, and an *a* in the last.

ASSUAN See Syene.

ASSUMPSIT, in the *Law of England*, a voluntary or verbal promise, whereby a person assumes, or takes upon him to perform or pay any thing to another.

A promise is in the nature of a verbal convenant, and wants nothing but the solemnity of writing and sealing to make it absolutely the same. If therefore it be to do any explicit act, it is an express contract, as much as any covenant; and the breach of it is an equal injury. The remedy indeed is not exactly the same: since, instead of an action of covenant, there only lies an action upon the case, for what is called an *assumpsit* or undertaking of the defendant; the failure of performing which is the wrong or injury done to the plaintiff, the damages whereof a jury are to estimate and settle. As, if a builder promises, undertakes, or assumes to Caius, that he will build and cover his house within a time limited, and fails to do it; Caius has an action on the case against the builder for this breach of his express promise, undertaking, or assumpsit; and shall recover a pecuniary satisfaction for the injury sustained by such delay. So also in the case of a debt by simple contract, if the debtor promises to pay it and does not, this breach of promise entitles the creditor to his action on the case, instead of being driven to an action of debt. Thus likewise a promissory note, or note of hand not under seal, to pay money at a day certain, is an express assumpsit; and the payee at common law, or by custom and act of parliament the indorsee, may recover the value of the note in damage, if it remains unpaid. Some agreements indeed, though never so expressly made, are deemed of so important a nature, that they ought not to rest in verbal promise only, which cannot be proved but by the memory (which sometimes will induce the perjury of witnesses. To prevent which, the statute of frauds and perjuries, 29 Car. II. c. 3. enacts, that in the five following cases no verbal promise shall be sufficient to ground an action upon, but at the least some note or memorandum of it shall be made in writing, and signed by the party to be charged therewith: 1. Where an executor or administrator promises to answer damages out of his own estate. 2. Where a man undertakes to answer for the debt, default, or miscarriage, of another. 3. Where any agreement is made upon consideration of marriage. 4. Where any contract or sale is made of lands, tenements, or hereditaments, or any interest therein. 5. And lastly, where there is any agreement that is not to be performed within a year from the making hereof. In all these cases a mere verbal assumpsit is void.

From these express contracts the transition is easy to those that are only implied by law. Which are such as reason and justice dictate, and which therefore the law presumes that every man has contracted to perform; and, upon this presumption, makes him answerable to such persons as suffer by his non-performance.

Thus, 1. If I employ a person to transact any business for me, or perform any work, the law implies that I undertook, or assumed, to pay him so much as his labour deserved; and if I neglect to make him amends, he has a remedy for his injury by bringing his action on the case upon this implied assumpsit: wherein he is at

Digitized by Google

at liberty to suggest that I promised to pay him so much as he reasonably deserved, and then to aver that his trouble was really worth such a particular sum, which the defendant has omitted to pay. But this valuation of his trouble is submitted to the determination of a jury; who will assess such a sum in damages as they think he really merited. This is called an *assumpsit* on a *quantum meruit*.

2. There is also an implied assumpsit on a *quantum valebat*, which is very similar to the former; being only where one takes up goods or wares of a tradesman, without expressly agreeing for the price. There the law concludes, that both parties did intentionally agree that the real value of the goods should be paid; and an action on the case may be brought accordingly, if the vendee refuses to pay that value.

3. A third species of implied assumpsit is when one has had and received money belonging to another without any valuable consideration given on the receiver's part; for the law construes this to be money had and received for the use of the owner only; and implies that the person so receiving, promised and undertook to account for it to the true proprietor. And, if he unjustly detains it, an action on the case lies against him for the breach of such implied promise and undertaking; and he will be made to repair the owner in damages, equivalent to what he has detained in such violation of his promise. This is a very extensive and beneficial remedy, applicable to almost every case where the defendant has received money which *ex æquo et bono* he ought to refund. It lies for money paid by mistake, or on a consideration which happens to fail, or through imposition, extortion, or oppression, or where undue advantage is taken of the plaintiff's situation.

4. Where a person has laid out and expended his own money for the use of another at his request, the law implies a promise of repayment, and an action will lie on this assumpsit.

5. Likewise, fifthly, upon a stated account between two merchants, or other persons, the law implies that he against whom the balance appears has engaged to pay to the other; though there be not any actual promise. And from this implication it is frequent for actions on the case to be brought, declaring that the plaintiff and defendant had settled their accounts together, *insimul computassent* (which gives name to this species of assumpsit); and that the defendant engaged to pay the plaintiff the balance, but has since neglected to do it. But if no account has been made up, then the legal remedy is by bringing a writ of *account, de computo;* commanding the defendant to render a just account to the plaintiff, or show the court good cause to the contrary. In this action, if the plaintiff succeeds, there are two judgments; the first is, that the defendant do account (*quod computet*) before auditors appointed by the court; and when such account is finished, then the second judgment is, that he do pay the plaintiff so much as he is found in arrear.

6. The last class of contracts, implied by reason and construction of law, arises upon this supposition, that every one who undertakes any office, employment, trust, or duty, contracts with those who employ or intrust him, to perform it with integrity, diligence, and skill: and if by his want of either of those qualities any injury accrues to individuals, they have therefore their remedy in damages by a special action on the case. A few instances will fully illustrate this matter. If an officer of the public is guilty of neglect of duty, or a palpable breach of it, of non-feasance, or of mis-feasance; as, if the sheriff does not execute a writ sent to him, or if he wilfully makes a false return thereof; in both these cases the party aggrieved shall have on action *on the case* for damages to be assessed by a jury. If a sheriff or gaoler suffers a prisoner who is taken upon mesne process (that is, during the pendency of a suit) to escape, he is liable to an action *on the case*. But if, after judgment, a gaoler or sheriff permits a debtor to escape, who is charged in execution for a certain sum; the debt immediately becomes his own, and he is compellable by action of *debt*, being for a sum liquidated and ascertained, to satisfy the creditor in his whole demand. An advocate or attorney that betray the cause of their client, or, being retained, neglect to appear at the trial, by which the cause miscarries, are liable to an action on the case, for a reparation to their injured client. There is also in law always an implied contract with a common innkeeper, to secure his guest's goods in his inn; with a common carrier or barge-master, to be answerable for the goods he carries; with a common farrier, that he shoes a horse well, without laming him; with a common taylor, or other workman, that he performs his business in a workmanlike manner: in which if they fail, an action on the case lies to recover damages for such breach of their general undertaking. Also, if an innkeeper, or other victualler, hangs out a sign and opens his house for travellers, it is an implied engagement to entertain all persons who travel that way; and upon this universal assumpsit an action on the case will lie against him for damages, if he without good reason refuses to admit a traveller. In contracts likewise for sales, if the seller doth upon the sale warrant it to be good, the law annexes a tacit contract to this warranty, that if it be not so, he shall make compensation to the buyer; else it is an injury to good faith, for which an action on the case will lie to recover damages.

ASSUMPTION, a festival in the Romish church, in honour of the miraculous ascent of the Virgin Mary into heaven: the Greek church, who also observe this festival, celebrate it on the 15th of August with great ceremony.

ASSUMPTION, in *Logic*, is the minor or second proposition, in a categorical syllogism.

ASSUMPTION is also used for a consequence drawn from the proposition whereof an argument is composed.

ASSUMPTION, an island in North America, in the gulf of St Lawrence, at the mouth of the great river of the same name. It is covered with trees. W. Long. 60. 40. N. Lat. 49. 30.

ASSUMPTION, a large and handsome town of Proper Paraguay, on the river of the same name in South America. It is a bishop's see, is well peopled, and seated in a country fruitful in corn and fruits, whose trees are always green. There is likewise a quantity of pasture, and the air is temperate and salutary. W. Long. 58. 40. S. Lat. 24. 50.

ASSUMPTIVE ARMS, in *Heraldry*, are such as a person has a right to assume, with the approbation of his sovereign, and of the heralds: thus, if a person who has no right by blood, and has no coat of arms, shall

Digitized by Google

shall captivate in any lawful war any gentleman, nobleman, or prince, he and his heirs are, in that case, entitled to bear the shield of that prisoner for ever.

ASSURANCE, or INSURANCE, in *Commerce*. See INSURANCE. See also ASSURANCE in the SUPPLEMENT.

ASSUROR, a merchant, or other person, who makes out a policy of assurance, and thereby insures a ship, house, or the like.

ASSUS, or Assos, in *Ancient Geography*, a town of Troas (though by others supposed to be of Mysia), and the same with Apollonia (Pliny); but different from the Apollonia on the river Rhyndacus. Ptolemy places it on the sea-coast, but Strabo more inland; if he does not mean the head of an inland bay, as appears from Diodorus Siculus. It was the country of Cleanthes the Stoic philosopher, who succeeded Zeno. St Luke and others of St Paul's companians, in his voyage (Acts xx. 13. 14), went by sea from Troas to Assos: but St Paul went by land thither, and meeting them at Assos, they all went together to Myteleue. It is now called Bairam. E. Long. 26. 20. N. Lat. 39. 10.

ASSYRIA, an ancient kingdom of Asia, concerning the extent, commencement, and duration of which, historians differ greatly in their accounts. Several ancient writers, in particular Ctesias and Diodorus Siculus, have affirmed, that the Assyrian monarchy, under Ninus and Semiramis, comprehended the greater part of the known world. Had this been the case, it is not likely that Homer and Herodotus would have omitted a fact so remarkable. The sacred records intimate, that none of the ancient states or kingdoms were of considerable extent; for neither Chedorlaomer, nor any of the neighbouring princes, were tributary or subject to Assyria; and we find nothing of the greatness or power of this kingdom in the history of the judges and succeeding kings of Israel, though the latter kingdom was oppressed and enslaved by many different powers in that period. It is highly probable, therefore, that Assyria was originally of small extent. According to Ptolemy, it was bounded on the north by Armenia Major; on the west by the Tigris; on the south by Susiana; and on the east by Media.

It is probable, that the origin and revolutions of the Assyrian monarchy were as follows.—The founder of it was Ashur, the second son of Shem, who went out of Shinar, either by the appointment of Nimrod, or to elude the fury of a tyrant; conducted a large body of adventurers into Assyria; and laid the foundation of Nineveh (Gen. x. 11.). These events happened not long after Nimrod had established the Chaldæan monarchy, and fixed his residence at Babylon. The Persian historians suppose that the kings of Persia of the first dynasty were the same with the kings of Assyria, of whom Zohah, or Nimrod, was the founder of Babel. (Herbelot Orient. Bibl. v. *Bagdad*). It does not, however appear, that Nimrod reigned in Assyria. The kingdoms of Babylon and Assyria were originally distinct and separate (Micah, v. 6.); and in this state they remained until Ninus conquered Babylon and made it tributary to the Assyrian empire. Ninus the successor of Asher (Gen. x. 11. Diod. Sic. lib. 1.), seized on Chaldæa, after the death of Nimrod, and united the kingdoms of Assyria and Babylon. This great prince is said to have subdued Asia, Persia, Media,

Playfair's Chronology.

Egypt, &c. If he did so, the effects of his conquests were of no duration; for in the days of Abraham, we do not find that any of the neighbouring kingdoms were subject to Assyria. He was succeeded by Semiramis; a princess of an heroic mind; bold, enterprising, fortunate; but of whom many fabulous things have been recorded. It appear, however, that there were two princesses of the same name, who flourished at very different periods. One of them was the consort of Ninus; and the other lived five generations before Nitocris queen of Nebuchadnezzar (Euseb. Chron. p. 58. Herod. lib. i. c. 184.). This fact has not been attended to by many writers.

Whether there was an uninterrupted series of kings from Ninus to Sardanapalus, or not, is still a question. Some suspicion has arisen, that the list which Ctesias has given of the Assyrian kings is not genuine; for many names in it are of Persian, Egyptian, and Grecian extraction.

Nothing memorable has been recorded concerning the successors of Ninus and Semiramis. Of that effeminate race of princes it is barely said, that they ascended the throne, lived in indolence, and died in their palace at Nineveh. Diodorus (lib. ii.) relates, that, in the reign of Teutames, the Assyrians, solicited by Priam their vassal, sent to the Trojans a supply of 20,000 foot and 200 chariots, under the command of Memnon, son of Tithonus president of Persia: But the truth of his relation is rendered doubtful by the accounts of other writers.

Sardanapalus was the last of the ancient Assyrian kings. Contemning his indolent and voluptuous course of life, Arbaces, governor of Media, withdrew his allegiance, and rose up in rebellion against him. He was encouraged in this revolt by the advice and assistance of Belesis, a Chaldean priest, who engaged the Babylonians to follow the example of the Medes. These powerful provinces, aided by the Persians and other allies, who despised the effeminacy, or dreaded the tyranny of their Assyrian lords, attacked the empire on all sides. Their most vigorous efforts were, in the beginning, unsuccessful. Firm and determined, however, in their opposition, they at length prevailed, defeated the Assyrian army, besieged Sardanapalus in his capital, which they demolished, and became masters of the empire, B. C. 821.

After the death of Sardanapalus, the Assyrian empire was divided into three kingdoms, viz. the Median, Assyrian, and Babylonian. Arbaces retained the supreme power and authority, and fixed his residence at Ecbatana in Media. He nominated governors in Assyria and Babylon, who were honoured with the title of *kings*, while they remained subject and tributary to the Median monarchs. Belesis received the government of Babylon as the reward of his services; and Phul was intrusted with that of Assyria. The Assyrian governor gradually enlarged the boundaries of his kingdom, and was succeeded by Tiglath-pileser, Salmanasar, and Sennacherib, who asserted and maintained their independency. After the death of Assar-haddon, the brother and successor of Sennacherib, the kingdom of Assyria was split, and annexed to the kingdoms of Media and Babylon. Several tributary princes afterwards reigned in Nineveh; but no particular account of them is found in the annals of ancient nations. We hear

Digitized by Google

hear no more of the kings of Assyria, but of those of Babylon. Cyaxares king of Media assisted Nebuchadnezzar king of Babylon, in the siege of Nineveh, which they took and destroyed, B. C. 606. The Chaldean or Babylonish kingdom was transferred to the Medes, after the reign of Nabonadius, son of Evilmerodach, and grandson of Nebuchadnezzar. He is styled Belshazzar in the sacred records, and was conquered by Cyrus, B. C. 538.

ASSYTHMENT. See ASSITHMENT.

ASTA, an inland town of Liguria, a colony (Ptolemy) on the river Tanarus: now *Asti.* E. Long. 8. 15. N. Lat. 44. 40.

ASTA *Regia*, a town of Bætica, (Pliny); situated at the mouth of the Bætis which was choked up with mud, to the north of Cadiz: 16 miles distant from the port of Cadiz, (Antonine). Its ruins show its former greatness. Its name is Phœnician, denoting a *frith* or arm of the sea, on which it stood. It is said to be the same with XERA; which see.

ASTABAT, a town of Armenia, in Asia, situated near the river Aras, 12 miles south of Nakshivan. The land about it is excellent, and produces very good wine. There is a root peculiar to this country, called *ronas;* which runs in the ground like liquorice, and serves for dyeing red. It is very much used all over the Indies, and in it they have a great trade. E. Long. 46. 30. N. Lat. 39. 0.

ASTANDA, in antiquity, a royal courier or messenger, the same with ANGARUS.—King Darius of Persia is said by Plutarch, in his book on the fortune of Alexander, to have formerly been an *astanda.*

ASTAROTH, or ASHTAROTH, in antiquity, a goddess of the Sidonians.—The word is Syriac, and signifies *sheep*, especially when their udders are turgid with milk. From the fecundity of these animals, which in Syria continue to breed a long time, they formed the notion of a deity, whom they called *Astaroth*, or *Astarte.* See ASTARTE.

ASTAROTH, in *Ancient Geography*, the royal residence of Og king of Bashan; whether the same with Astaroth Carnaim, is matter of doubt: if one and the same, it follows from Eusebius's account, that it lay in Bashan, and to the east of Jordan, because in the confines of Arabia.

ASTARTE, in Pagan mythology, (the singular of Astaroth), a Phœnician goddess, called in scripture the *queen of heaven*, and the *goddess of the Sidonians.* —Solomon, in compliment to one of his queens, erected an altar to her. In the reign of Ahab, Jezebel caused her worship to be performed with much pomp and ceremony; she had 400 priests; the women were employed in weaving hangings or tabernacles for her; and Jeremiah observes, that "the children gathered the wood, the fathers kindled the fire, and the women kneaded the dough, to make cakes for the queen of heaven."

ASTARTE, in *Ancient Geography*, a city on the other side Jordan; one of the names of Rabbath Ammon, in Arabia Petræa, (Stephanus).

ASTEISM, in *Rhetoric*, a genteel irony, or handsome way of deriding another. Such, e. gr. is that of Virgil:

Qui Bavium non odit, amet tua carmina, Mævi, &c.

Diomed places the characteristic of this figure, or species of irony, in that it is not gross and rustic, but ingenious and polite.

ASTELL, MARY, an English lady who was an eminent writer, was born at Newcastle-upon-Tyne in the year 1668. Her father, who was a merchant, committed the education of his daughter to her uncle, who was a clergyman. Convinced of the general injury done to young ladies at that period by the deficiency of their education, he taught her the Latin and French languages, and instructed her in the principles of logic, mathematics, and natural philosophy. Having spent 20 years of her life in Newcastle, she retired to London, where she continued the pursuit of her studies; and, deeply affected with the general ignorance of her sex, she employed the first fruits of her pen to rouse them to a proper emulation, in a work, "A serious Proposal to the Ladies, wherein a Method is offered for the Improvement of their Minds," printed in 12mo, at London 1697. The chief object of that book was to erect a seminary for female education. A certain lady, supposed to be the queen, formed the design of devoting 10,000l. to this honourable purpose; but Bishop Burnet having suggested, that it would have too much the appearance of a nunnery, the design did not take effect.

Disappointed in the article of marriage with an eminent clergyman, she next wrote a book entitled "Reflections on Marriage," which was published in 1700. This lady was a zealous advocate for the religious system commonly called *orthodox;* and in politics, defended the doctrine of nonresistance. About this time she published some controversial pieces, among which are the following: "Moderation truly stated;" "A Fair Way with the Dissenters;" "An Impartial Enquiry into the causes of the Rebellion;" and "A Vindication of the Royal Martyrs;" all printed in 4to in 1704. Her most finished performance was, "The Christian religion as professed by a Daughter of the Church of England," published in 1705, in a large octavo volume. Dr Waterland speaks of this book in very favourable terms; and such was the intrepidity of this lady, that she has attacked both Locke and Tillotson in the controversial part. In the evening of her life Mrs Astell was attacked with the severe disease of a cancer in her breast; the amputation of which she bore with singular fortitude. At the advanced age of 63 she died in the year 1731.

Mrs Astell appears to have been a woman of uncommon talents as a writer and scholar; rigid in her principles, and austere in her manners. Since a new era of female education has commenced, such an author as Mrs Astell would have attracted little notice; but at a period of society when few women could read, and scarcely any could write, it was highly honourable for a female to suggest hints, however imperfect, for the improvement of female education. It may farther be remarked, that it deserves to be mentioned, that about a century ago a lady informed the public by her pen, that "women, who ought to be retired, are for this reason designed for speculation," and that "great improvements might be made in the sciences, were not women enviously excluded from this their proper business." Deeming her time more valuable than to be wasted by trifling visitors, and abhorring the practice

of

Digitized by Google

of teaching servants to lie, she would humorously accost such visitors by saying, "Mrs Astell is not at home." (*Gen. Biog.*).

ASTER, STARWORT. See BOTANY *Index*.

ASTER, or *Stella Marina*, in *Zoology*. See ASTERIAS, HELMINTHOLOGY *Index*.

ASTERABAD, a small province in the north-east part of Persia, sometimes included in that of Mazanderan. It is bounded by the Caspian sea on the west, by lofty mountains on the south, on the north by the river Ashor, and extends to the 58th degree of longitude on the east. It nearly coincides with the ancient Hyrcania, and is the native province of the present king of Persia. It is a mountainous country, in some parts fruitful, in others sandy and barren. Asterabad is the chief town. E. Long. 54. N. Lat. 36. 50.

ASTERIA, in *Zoology*, a name by which some authors have called the *falco palumbarius*, or *goshawk*. See FALCO, ORNITHOLOGY *Index*.

ASTERIA is also the name of a gem, usually called the *cat's eye*, or *oculus cati*. It is a very singular and very beautiful stone, and somewhat approaches to the nature of the opal, in having a bright included colour, which seems to be lodged deep in the body of the stone, and shifts about, as it is moved, in various directions; but it differs from the opal in all other particulars, especially in its want of the great variety of colours seen in that gem, and in its superior hardness. It is usually found between the size of a pea and the breadth of a sixpence; is almost always of a semicircular form, broad and flat at the bottom, and rounded and convex at the top; and it is naturally smooth and polished. It has only two colours, a pale brown and a white; the brown seeming the ground, and the white playing about in it, as the fire colour in the opal. It is considerably hard, and will take a fine polish, but is usually worn with its native shape and smoothness. It is found in the East and West Indies, and in Europe. The island of Borneo affords some very fine ones, but they are usually small; they are very common in the sands of rivers in New Spain: and in Bohemia they are not unfrequently found immersed in the same masses of jasper with the opal.

ASTERIA is also the name of an extraneous fossil, called in English the *star-stone*. The fossils are small, short, angular, or sulcated columns, between one and two inches long, and seldom above a third of an inch in diameter: composed of several regular joints; when separated, each resembles a radiated star. They are, not without reason, supposed to be a part of some sea-fish petrified, probably the asterias or sea-star. The asteria is also called *astrites*, *astroites*, and *asteriscus*. They may be reduced to two kinds: those whose whole bodies make the form of a star; and those which in the whole are irregular, but are adorned as it were with constellations in the parts. Dr Lister, for distinction's sake, only gives the name *asteria* to the former sort, distinguishing the latter by the appellation of *astroites*; other naturalists generally use the two indiscriminately. The asteria spoken of by the ancients, appears to be of this latter kind. The quality of moving in vinegar, as if animated, is scarce perceivable in the astroites, but is signal in the asteria. The former must be broken in small pieces before it will move; but the latter will move, not only in a whole joint, but in two or three knit together. The curious frequently meet with these stones in many parts of England: at Cleydon in Oxfordshire they are found rather larger than common, but of a softer substance; for, on being left a small space of time in a strong acid, they may easily be separated at the joints in small plates.

ASTERIAS, STAR-FISH, or SEA-STAR. See HELMINTHOLOGY *Index*.

ASTERIAS, the ancient name of the bittern. See ARDEA, ORNITHOLOGY *Index*.

ASTERISK, a mark in form of a star (*), placed over a word or sentence, to refer the reader to the margin, or elsewhere, for a quotation, explanation, or the like.

ASTERIUS, or ASTURIUS, a Roman consul, in 449. We have under his name, "A Conference on the Old and New Testament," in Latin verse: in which each strophe contains, in the first verse, an historical fact in the Old Testament; and in the second, an application of that fact to some point in the New.

ASTERN, a sea phrase, used to signify any thing at some distance behind the ship; being the opposite of AHEAD, which signifies the space before her. See AHEAD.

ASTEROPODIUM, a kind of extraneous fossil, of the same substance with the asteriæ or star-stones, to which they serve as a base. See ASTERIA and STAR-STONE.

ASTHMA. See MEDICINE *Index*.

ASTI, a city of Montferrat in Italy, seated on the Tanara, and capital of the county of the same name. It is a bishop's see, and well fortified with strong walls and deep ditches; and is divided into the city, borough, citadel, and castle, which contain altogether 22,000 inhabitants. There are a great many churches and convents, as well as other handsome buildings; and its territory is well watered, beautiful, and fruitful. It was repeatedly taken and retaken by the French and Austrians during the late wars. E. Long. 8. 15. N. Lat. 44. 58.

ASTIGI, in *Ancient Geography*, a colony, and conventus juridicus, of Bætica, surnamed *Augusta Firma*, situated on the Singulus, which falls into the Bætis; called also *Colonia Astigitana* (Pliny): Now *Ecya*, midway between Seville and Cordova. W. Long. 5°. N. Lat. 37. 20.

ASTOMI, in anthropology, a people feigned without mouths. Pliny speaks of a nation of Astomi in India, who lived only by the smell or effluvia of bodies taken in by the nose.

ASTORGA, a very ancient city of Spain, in the kingdom of Leon, with a bishop's see, is seated on the river Tuerta, and well fortified both by art and nature. It stands in a most agreeable plain, about 150 miles north-west of Madrid. There are excellent trouts in the river. W. Long. 6. 20. N. Lat. 42. 20.

ASTRACAN, a province of Russia, and the most easterly part of Europe; bounded on the north by Bulgaria and Baskiria; on the south by the Caspian sea; on the west, by the Volga, which divides it from the Nagayan Tartars and Don Cossacks; and on the east, by the great ridge of mountains which part it from Great Tartary. The province extends from the 46th to the 52d degree of latitude. The summer is long, and intensely hot: the winter continues about three

Digitized by Google

months so severe, that the Volga is frozen hard enough to bear loaded sledges. The soil is rich and fertile; but the Tartars who inhabit it are strangers to agriculture. On the western and southern sides of the Volga, are heaths of a prodigious extent, sandy, desert, and uncultivated; these, however produce vast quantities of fine transparent salt in pits, where the sun bakes and incrustates it to the thickness of an inch on the surface of the water. There are pits in the neighbourhood of Astracan which yield this excellent salt in such abundance, that any person may carry it off, paying at the rate of one farthing a poost, which is equal to forty pounds. The metropolis, Astracan, is situated within the boundaries of Asia, on an island called *Dolgoi*, about 60 English miles above the place where the Volga disembogues itself into the Caspian sea. The city derives its name from Hadgee Tarkan, a Tartar, by whom it was founded. It was conquered by Iwan Basilowitz, recovered by the Tartars in the year 1668, and retaken by the czar, who employed for this purpose a great number of flat-bottomed vessels, in which he transported his forces down the Volga from Casan.

The city of Astracan is about two miles and a half in circumference, surrounded by a brick wall, which is now in a ruinous condition: but, if we comprehend the suburbs, the circuit will be near five miles. The number of inhabitants amounts to 70,000, including Armenians and Tartars, as well as a few Persians and Indians. The garrison consists of six regiments of the best Russian troops, who, when this place was alarmed from the side of Persia, had in the adjacent plain erected a great number of small batteries, to scour the fields, and obstruct the approach of the enemy. The houses of Astracan are built of wood, and generally mean and inconvenient. The higher parts of the city command a prospect of the Volga, which is here about three miles in breadth, and exhibits a noble appearance. The marshy lands on the banks of it render the place very sickly in the summer: the earth, being impregnated with salt, is extremely fertile, and produces abundance of fruit, the immoderate use of which is attended with epidemical distempers. Sickness is likewise the consequence of those annual changes in the atmosphere produced by the floods in spring and autumn. All round the city of Astracan, at the distance of two miles, are seen a great number of gardens, orchards, and vineyards, producing all sorts of herbs and roots. The grapes are counted so delicious, that they are preserved, in sand, and transported to court by land-carriage at a prodigious expence: yet the wine of Astracan is very indifferent. The summer being generally dry, the inhabitants water their gardens by means of large wheels worked by wind or horses, which raise the water to the highest part of the garden, from whence it runs in trenches to refresh the roots of every single tree and plant. The neighbouring country produces hares and partridges, plenty of quails in summer, with wild and water-fowl of all sorts in abundance.

About ten miles below Astracan is a small island called *Bosmaise*, on which are built large storehouses for the salt, which is made about twelve miles to the eastward, and, being brought thither in boats, is conveyed up the Volga, in order to supply the country as far as Moscow and Twere. The quantity of salt annually dug for these purposes amounts to some millions of pounds, the exclusive property of which is claimed by the crown, and yields a considerable revenue; for the soldiers and bulk of the people live almost entirely on bread and salt. The neighbourhood of these salt-works is of great advantage to the fisheries, which extend from hence to the Caspian sea, and reach to the south-east as far as Yack, and even 100 miles above Zaritzen. The principal fish here caught are sturgeon and belluga. These, being salted, are put on board of vessels, and sent away in the spring, for the use of the whole empire, even as far as Petersburg: but as fish may be kept fresh as long as it is frozen, the winter is no sooner set in, than they transport great quantities of it by land through all the provinces of Russia. Of the roes of the fish called *belluga*, which are white, transparent, and of an agreeable flavour, the fishers here prepare the caviare, which is in so much esteem all over Europe. These fisheries were first established by one Tikon Demedoff, a carrier, who settled in this place about 60 years ago, his whole wealth consisting of two horses. By dint of skill and industry, he soon grew the richest merchant in this country: but his success became so alluring to the crown, that of late years it hath engrossed some of the fisheries as well as the salt works.

From the latter end of July to the beginning of October, the country about Astracan is frequently infested with myriads of locusts, which darken the air in their progression from the north to the southward; and, wherever they fall, consume the whole verdure of the earth. These insects can even live for some time under water: for when the wind blows across the Volga, vast numbers of them fall in clusters, and are rolled ashore; and their wings are no sooner dry, than they rise and take flight again.

Heretofore the inhabitants of Astracan traded to Khuva and Bokhara; but at present these branches are lost, and their commerce is limited to Persia and the dominions of Russia. Even the trade to Persia is much diminished by the troubles of that country; nevertheless, the commerce of Astracan is still considerable. Some years ago, the city maintained about 40 vessels, from 100 to 200 tons burden, for the Caspian traffic. Some of these belong to the government, and are commanded by a commodore, under the direction of the admiralty. This office is generally well stocked with naval stores, which are sold occasionally to the merchants. The trading ships convey provisions to the frontier towns of Terkie and Kislar, situated on the Caspian sea; and transport merchandise to several parts of Persia. The merchants of Astracan export to Persia, chiefly on account of the Armenians, red leather, linens, woollen cloths, and other European manufactures. In return, they import the commodities of Persia, particularly those manufactured at Casan; such as silk sashes intermixed with gold, for the use of the Poles; wrought silks and stuffs mixed with cotton; rice, cotton, rhubarb, and a small quantity of other drugs; but the chief commodity is raw silk. The government has engrossed the article of rhubarb, the greater part of which is brought into Russia by the Tartars of Yakutski, bordering on the eastern Tartars belonging to China. They travel through Siberia to Samura, thence to Casan, and lastly to Moscow. The

revenue

Digitized by Google

revenue of Astracan is computed at 150,000 rubles, or 33,000l. arising chiefly from salt and fish. The city is ruled by a governor, under the check of a chancery. He is nevertheless arbitrary enough, and exercises oppression with impunity. The officers of the admiralty and custom-house having very small salaries, are open to corruption, and extremely rapacious. At christening feasts, which are attended with great intemperance, the guests drink a kind of cherry-brandy out of large goblets; and every person invited throws a present of money into the bed of the mother, who sits up with great formality to be saluted by the company.

The Indians have a Pagan temple at Astracan, in which they pay their adoration, and make offerings of fruit to a very ugly deformed idol. The priests of this pagod use incense, beads, cups, and prostrations. The Tartars, on the contrary, hold idol-worship in the utmost abomination.

ASTRÆA, in *Astronomy*, a name which some give to the sign Virgo, by others called *Erigone*, and sometimes *Isis*. The poets feign that Justice quitted heaven to reside on earth, in the golden age; but, growing weary of the iniquities of mankind, she left the earth, and returned to heaven, where she commenced a constellation of stars, and from her orb still looks down on the ways of men.

ASTRAGAL, in *Architecture*, a little round moulding, which in the orders surrounds the top of the shaft or body of the column. It is also called the *talon* and *tondino;* it is used at the bottoms as well as tops of columns, and on other occasions: it properly represents a ring, on whatever part of a column it is placed; and the original idea of it was that of a circle of iron put round the trunk of a tree, used to support an edifice, to prevent its splitting. The astragal is often cut into beads and berries, and is used in the ornamented entablatures to separate the several faces of the architrave.

ASTRAGAL, in *Gunnery*, a round moulding encompassing a cannon, about half a foot from its mouth.

ASTRAGALOMANCY, a species of divination performed by throwing small pieces, with marks corresponding to the letters of the alphabet; the accidental disposition of which formed the answer required. This kind of divination was practised in a temple of Hercules, in Achaia. The word is derived from αστραγαλος, and μαντεια, *divination*.

ASTRAGALUS, MILK-VETCH, or LIQUORICE-VETCH. See BOTANY *Index*.

ASTRAGALUS. See ANATOMY *Index*.

ASTRANTIA, MASTERWORT. See BOTANY *Index*.

ASTRICTION, in *Law*. See THIRLAGE.

ASTRICTION, among physicians, denotes the operation of astringent medicines.

ASTRINGENTS, in the *Materia Medica*, substances distinguished by a rough austere taste, and changing solutions of iron, especially those made in the vitriolic acid, into a dark purple or black colour; such are galls, tormentil root, bistort root, balaustines, terra japonica, acacia, &c. See MATERIA MEDICA *Index*.

ASTROGNOSIA, the science of the fixed stars, or the knowledge of their names, constellations, magnitudes, &c.

ASTROITES, or STAR-STONE, in *Natural History*. See ASTERIA and STAR-STONE.

ASTROLABE, the name for a stereographic projection of the sphere, either upon the plane of the equator, the eye being supposed to be in the pole of the world; or upon the plane of the meridian, when the eye is supposed in the point of the intersection of the equinoctial and horizon.

ASTROLABE is also the name of an instrument formerly used for taking the altitude of the sun or stars at sea.

ASTROLABE, among the ancients, was the same as our armillary sphere.

ASTROLOGY, a conjectural science, which teaches to judge of the effects and influences of the stars, and to foretel future events by the situation and different aspects of the heavenly bodies.

This science has been divided into two branches, *natural* and *judiciary*. To the former belongs the predicting of natural effects; as, the changes of weather, winds, storms, hurricanes, thunder, floods, earthquakes, &c. This art properly belongs to natural philosophy; and is only to be deduced, *à posteriori*, from phenomena and observations. Judiciary or judicial astrology, is that which pretends to foretel moral events; i. e. such as have a dependency on the free will and agency of man; as if they were directed by the stars. This art, which owed its origin to the practices of knavery on credulity, is now universally exploded by the intelligent part of mankind.

The professors of this kind of astrology maintain, "That the heavens are one great volume or book, wherein God has written the history of the world; and in which every man may read his own fortune, and the transactions of his time. The art, say they, had its rise from the same hands as astronomy itself: while the ancient Assyrians, whose serene unclouded sky favoured their celestial observations, were intent on tracing the paths and periods of the heavenly bodies, they discovered a constant settled relation or analogy between them and things below; and hence were led to conclude these to be the Parcæ, the Destinies, so much talked of, which preside at our births, and dispose of our future fate.

"The laws, therefore, of this relation being ascertained by a series of observations, and the share each planet has therein; by knowing the precise time of any person's nativity, they were enabled, from their knowledge in astronomy, to erect a scheme or horoscope of the situation of the planets at this point of time; and, hence, by considering their degrees of power and influence, and how each was either strengthened or tempered by some other, to compute what must be the result thereof."

Thus the astrologers.—But the chief province now remaining to the modern professors, is the making of calendars or almanacks.

Judicial astrology is commonly said to have been invented in Chaldea, and thence transmitted to the Egyptians, Greeks, and Romans; though some will have it of Egyptian origin, and ascribe the invention to Cham. But it is to the Arabs that we owe it. At Rome the

Astrology. the people were so infatuated with it, that the astrologers, or, as they were then called, the *mathematicians*, maintained their ground in spite of all the edicts of the emperors to expel them out of the city. See GENETHLIACI.

Add, that the Bramins, who introduced and practised this art among the Indians, have thereby made themselves the arbiters of good and evil hours, which gives them great authority: they are consulted as oracles, and they have taken care never to sell their answers but at good rates.

The same superstition has prevailed in more modern ages and nations. The French historians remark, that in the time of Queen Catherine de Medicis, astrology was so much in vogue, that the most inconsiderable thing was not to be done without consulting the stars. And in the reigns of King Henry III. and IV. of France, the predictions of astrologers were the common theme of the court conversation. This predominant humour in that court was well rallied by Barclay, in his *Argenis*, lib. ii. on occasion of an astrologer, who had undertaken to instruct King Henry in the event of a war then threatened by the faction of the Guises.

ASTRONIUM. See BOTANY *Index*.

ASTRONOMICAL, something relating to ASTRONOMY.

ASTRONOMICAL Calendar, an instrument engraven on copperplates, printed on paper, and pasted on a board, with a brass slider carrying a hair: it shows by inspection the sun's meridian altitude, right ascension, declination, rising, setting, amplitude, &c. to a greater degree of exactness than the common globes.

ASTRONOMICAL Sector, a very useful mathematical instrument, made by the late ingenious Mr Graham; a description of which is given in the course of the following article.

ASTRONOMY.

ASTRONOMY is that science which treats of the motions of the heavenly bodies, and explains the laws by which these motions are regulated.

It is the most sublime and the most perfect of all the sciences. No subject has been longer studied, or has made greater progress. There is a vast interval between the rude observations of the earlier astronomers, and the precision and general views which direct our present observers. To ascertain the apparent motions of the heavenly bodies was a difficult task, and required the united observations of ages. To unravel these intricate mazes, and detect and demonstrate the real motions, demanded the most patient perseverance, judgment, and dexterity. To ascertain the laws of these motions, and to resolve the whole of them into one general fact, required the exertions of a sagacity scarcely to be expected in human nature. Yet all this has been accomplished; and even the most minute movement of the heavenly bodies has been shewn to depend upon the same general law with all the rest, and even to be a consequence of that law. Astronomy, therefore, is highly interesting, were it only because it exhibits the finest instance of the length that the reasoning faculties can go. It is the triumph of philosophy and of human nature. But this is not all. It has conferred upon mankind the greatest benefits, and may truly be considered as the grand improver and conductor of navigation.

The following treatise will be divided into four parts. In the *first* part, we shall give a sketch of the history of astronomy; in the *second*, we shall treat of the apparent motions of the heavenly bodies; in the *third*, of their real motions; and in the *fourth*, of gravitation, or of that general fact to which all their motions may be referred, and from which they proceed.

PART I. HISTORY OF ASTRONOMY.

History. THE antiquity of this science may be gathered from what was spoken by the Deity at the time of creating the celestial luminaries, "Let them be for signs and seasons," &c. whence it is thought probable that the human race never existed without some knowledge of astronomy among them. Indeed, besides the motives of mere curiosity, which of themselves may be supposed to have excited people to a contemplation of the glorious celestial canopy, as far as that was possible, it is easily to be seen that some parts of the science answer such essential purposes to mankind, that they could not possibly be dispensed with.

1 Astronomy supposed to be understood by Adam and the Antediluvians.

By some of the Jewish rabbins, Adam, in his state of innocence, is supposed to have been endowed with a knowledge of the nature, influence, and uses of the heavenly bodies; and Josephus ascribes to Seth and his posterity an extensive knowledge of astronomy. But whatever may be in this, the long lives of the Antediluvians certainly afforded such an excellent opportunity for observing the celestial bodies, that we cannot but suppose the science of astronomy to have been considerably advanced before the flood. Josephus says, that longevity was bestowed upon them for the very purpose of improving the sciences of geometry and astronomy. The latter could not be learned in less than 600 years: "for that period (says he) is the *grand year*." By which it is supposed he meant the period wherein the sun and moon came again into the same situation as they were in the beginning thereof, with regard to the nodes, apogee of the moon, &c. "This period (says Cassini), whereof we find no intimation in any monument of any other nation, is the finest period that ever was invented: for it brings out the solar year more exactly than that of Hipparchus and Ptolemy; and the lunar month within about one second of what is determined by modern astronomers. If the Antedilu-

History.

Digitized by Google

History.

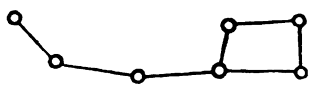
vians had such a period of 600 years, they must have known the motion of the sun and moon more exactly than their descendants knew them some ages after the flood."

2 Astronomical knowledge of the Chinese.

On the building of the tower of Babel, Noah is supposed to have retired with his children born after the flood, to the north-eastern part of Asia, where his descendants peopled the vast empire of China. "This (says Dr Long) may perhaps account for the Chinese having so early cultivated the study of astronomy; their being so well settled in an admirable police, and continuing so many hundred years as they did in the worship of the true God." The vanity of that people indeed has prompted them to pretend a knowledge of astronomy almost as early as the flood itself. Some of the Jesuit missionaries have found traditional accounts among the Chinese, of their having been taught this science by their first emperor Fo-hi, supposed to be Noah; and Kempfer informs us, that this personage discovered the motions of the heavens, divided time into years and months, and invented the twelve signs into which they divide the zodiac, which they distinguish by the following names.

3 Their names for the signs of the zodiac.

1. The mouse. 2. The ox or cow. 3. The tiger. 4. The hare. 5. The dragon. 6. The serpent. 7. The horse. 8. The sheep. 9. The monkey. 10. The cock or hen. 11. The dog; and, 12. The bear. They divide the heavens into 28 constellations, four of which are assigned to each of the seven planets; so that the year always begins with the same planet; and their constellations answer to the 28 mansions of the moon used by the Arabian astronomers. These constellations, in the Chinese books of astronomy, are not marked by the figures of animals, as was in use among the Greeks, and from them derived to the other European nations, but by connecting the stars by straight lines; and Dr Long informs us, that in a Chinese book in thin 4to, shown him by Lord Pembroke, the stars were represented by small circles joined by lines; so that the Great Bear would be marked thus,



To the emperor Hong-ti, the grandson of Noah, they attribute the discovery of the pole-star, the invention of the mariner's compass, of a period of 60 years, and some kind of sphere. This extraordinary antiquity, however, is with good reason suspected, as is likewise their knowledge in the calculation of eclipses; of which Du Halde assures us, that 36 are recorded by Confucius himself, who lived 551 years before Christ; and P. Trigault, who went to China in 1619, and read more than 100 volumes of their annals, says, "It is certain that the Chinese began to make astronomical observations soon after the flood; that they have observed a great number of eclipses, in which they have noted down the hour, day, month, and year, when they happened, but neither the duration nor the quantity; and that these eclipses have been made use of for regulating their chronology."

"But out of this abundance (says Dr Long), it is much to be regretted, that so very few of their observations have been particularized; for beside what has been mentioned above, we meet with no very ancient observations of the Chinese, except a winter solstice in the year 1111, and a summer solstice in the year 882, before Christ. Martini indeed speaks of a summer solstice 2342 years before that period. But M. Cassini, who calculated it, found that there must have been an error in the Chinese computation of 500 years at least. An error of equal magnitude appears to have been committed in the conjunction of the five planets, which it is pretended they observed between the years 2513 and 2435 before Christ. In short, some have supposed, that none of these are real observations, but the result of bungling calculations; and it has been hinted, but surely on too slight a foundation, that even those good fathers themselves were greatly to be suspected. But let us come to things which are not contested.

"P. Gaubil informs us, that at least 120 years before Christ, the Chinese had determined by observation the number and extent of their constellations as they now stand; the situation of the fixed stars with respect to the equinoctial and solstitial points; and the obliquity of the ecliptic. He farther says, he cannot tell by what means it is that they foretel eclipses: but this is certain, that the theory by which they do predict them was settled about the same time; and that they were acquainted with the true length of the solar year, the method of observing meridian altitudes of the sun by the shadow of a gnomon, and of learning from thence his declination and the height of the pole, long before. We learn, moreover, from the same missionary, that there are yet remaining among them some treatises of astronomy, which were written about 200 years before Christ, from which it appears, that the Chinese had known the daily motion of the sun and moon, and the times of the revolutions of the planets, many years before that period.

"We are informed by Du Halde, that, in the province of Honan, and city Teng-foang, which is nearly in the middle of China, there is a tower, on the top of which it is said that *Tcheou-cong*, the most skilful astronomer that ever China produced, made his observations. He lived 1200 years before Ptolemy, or more than 1000 years before Christ, and passed whole nights in observing the celestial bodies and arranging them into constellations. He used a very large brass table placed perfectly horizontal, on which was fixed a long upright plate of the same metal, both of which were divided into degrees, &c. By these he marked the meridian altitudes; and from thence derived the times of the solstices, which were their principal epocha."

Dr Long represents the state of astronomy in China as at present very low; occasioned, he says, principally by the barbarous decree of one of their emperors*, to have all the books in the empire burnt, excepting such as related to agriculture and medicine. We are informed, however, by the Abbe Grosier, in his description of China, that astronomy is cultivated in Pekin in the same manner as in most of the capital cities of Europe. A particular tribunal is established there, the jurisdiction of which extends to every thing relating to the observation of celestial phenomena. Its members are, an inspector; two presidents, one of them a Tartar and the other a Chinese; and a certain number of mandarins who perform the duty of assessors; but for near a century and a half the place of the Chinese president has been filled by an European. Since that time particular attention has been paid to the

* See *China*.

Digitized by Google

History.

the instruction of the astronomical pupils; and the presidents have always considered it as their duty to make them acquainted with the system and method of calculations made use of in Europe. Thus two-thirds of the astronomical pupils, maintained at the emperor's expence, in all about 200, have a tolerable notion of the state of the heavens, and understand calculation so well as to be able to compose ephemerides of sufficient exactness. The missionaries have never been the authors of any of these ephemerides: their employment is to revise the labours of the Chinese mathematicians, verify their calculations, and correct any errors into which they have fallen. The Portuguese mission still continues to furnish astronomers for the academy, as it did at the first.

The astronomical tribunal is subordinate to that of ceremonies. When an eclipse is to be observed, information must be given to the emperor of the day and hour, the part of the heavens where it will be, &c. and this intelligence must be communicated some months before it happens; the eclipse must also be calculated for the longitude and latitude of the capital city of every province of the empire. These observations, as well as the diagram which represents the eclipse, are preserved by the tribunal of ceremonies, and another called the *calao*, by whom it is transmitted to the different provinces and cities of the empire. Some days before the eclipse, the tribunal of ceremonies causes to be fixed upon a public place, in large characters, the hour and minute when the eclipse will commence, the quarter of the heavens in which it will be visible, with the other particulars relating to it. The mandarins are summoned to appear in state at the tribunal of astronomy, and to wait there for the moment in which the phenomenon will take place. Each of them carries in his hand a sheet of paper, containing a figure of the eclipse and every circumstance attending in. As soon as the observation begins to take place, they throw themselves on their kness, and knock their heads against the earth, and a horrid noise of drums and cymbals immediately commences throughout the whole city: a ceremony proceeding from an ancient superstitious notion, that by such a noise they prevented the luminary from being devoured by the celestial dragon; and though this notion is now exploded in China, as well as everywhere else, such is the attachment of the people to ancient customs, that the ceremonial is still observed. While the mandarins thus remain prostrated in the court, others, stationed on the observatory, examine, with all the attention possible, the beginning, middle, and end of the eclipse, comparing what they observe with the figure and calculations given. They then write down their observations, affix their seal to them, and transmit them to the emperor; who, on his part, has been no less assiduous to observe the eclipse with accuracy. A ceremonial of this kind is observed through the whole empire.

The Japanese, Siamese, and inhabitants of the Mogul's empire, have also, from time immemorial, been acquainted with astronomy; and the celebrated observatory at BENARES, is a monument both of the ingenuity of the people and of their skill in the science.

4 Indian astronomy.

Mr Bailly has been at great pains to investigate the progress of the Indians in astronomical knowledge, and gives a splendid account of their proficiency in the science, as well as of the antiquity of their observations. He has examined and compared four different astronomical tables of the Indian philosophers. 1. Of the Siamese, explained by M. Cassini in 1689. 2. Those brought from India by M. le Gentil of the Academy of Sciences. 3. and 4. Two other manuscript tables found among the papers of the late M. de Lisle. All of these tables have different epochs, and differ in form, being also constructed in different ways; yet they all evidently belong to the same astronomical system: the motions attributed to the sun and the moon are the same, and the different epochs are so well connected by the mean motions, as to demonstrate that they had only one, whence the others were derived by calculation. The meridians are all referred to that of Benares above mentioned. The fundamental epoch of the Indian astronomy is a conjunction of the sun and moon, which took place at no less a distance of time that 3102 years before the Christian era. Mr Bailly informs us, that, according to our most accurate astronomical tables, a conjunction of the sun and moon actually did happen at that time. But though the bramins pretend to have ascertained the places of the two luminaries at that time, it is impossible for us at this time to judge of the truth of their assertions, by reason of the unequal motion of the moon; which, as shall afterwards be more particularly taken notice of, now performs its revolution in a shorter time than formerly.

Our author informs us, that the Indians at present calculate eclipses by the mean motions of the sun and moon observed 5000 years ago; and with regard to the solar motion, their accuracy far exceeds that of the best Grecian astronomers. The lunar motions they had also settled, by computing the spaces through which that luminary had passed in 1,600,984 days, or somewhat more than 4383 years. They also make use of the cycle of 19 years attributed by the Greeks to Meton; and their theory of the planets is much better than that of Ptolemy, as they do not suppose the earth to be the centre of the celestial motions, and they believe that Mercury and Venus turn round the sun. Mr Bailly also informs us, that their astronomy agrees with the most modern discoveries of the decrease of the obliquity of the ecliptic, the acceleration of the motion of the equinoctial points, with many other particulars too tedious to enumerate in this place.

5 Astronomy of the Americans.

It appears also, that even the Americans were not unacquainted with astronomy, though they made use only of the solar, and not of the lunar motions, in their division of time. The Mexicans have had a strange predilection for the number 13. Their shortest periods consisted of 13 days; their cycle of 13 months, each containing 20 days; and their century of four periods of 13 years each. This excessive veneration for the number 13, according to Siguenza, arose from its being supposed the number of their greater gods. What is very surprising, though asserted as a fact by Abbé Clavigero, is that having discovered the excess of a few hours in the solar above the civil year, they made use of intercalary days, to bring them to an equality: but with this difference in regard to the method established by Julius Cæsar in the Roman calendar, that they did not interpose a day every four years, but 13 days (making use even here of this favourite num-

History.

ber) every 52 years, which produces the same regulation of time.

6
Of the Chaldeans and Egyptians.

Among those nations who first began to make any figure in ancient history, we find the Chaldeans and Egyptians most remarkable for their astronomical knowledge. Both of them pretended to an extravagant antiquity, and disputed the honour of having been the first cultivators of the science. The Chaldeans boasted of their temple of Belus; and of Zoroaster, whom they placed 5000 years before the destruction of Troy: the Egyptians boasted of their colleges of priests, where astronomy was taught; and of the monument of Osymandyas, in which we are told was a golden circle 365 cubits in circumference and one cubit thick. The upper face was divided into 365 equal parts, answering to the days of the year; and on every division were written the name of the day, and the heliacal rising of the several stars for that day, with the prognostications from their rising, principally, as Long conjectures, for the weather.

The Chaldeans certainly began to make observations very soon after the confusion of languages; for when Alexander the Great took Babylon, Calisthenes, by his order, inquired after the astronomical observations recorded in that city, and obtained them for 1903 years back. Nothing, however, now remains of the Chaldean astronomy, excepting some periods of years which they had formed for the more ready computation of the heavenly bodies. But though they must have laboured under great disadvantages for want of proper instruments, in those early ages, Gemina, as quoted by Petarius in his Uranologion, informs us, that they had determined, with tolerable exactness, the length both of a synodical and periodical month. They had also discovered that the motion of the moon was not uniform, and even attempted to assign those parts of her orbit in which it was quicker or slower. Ptolemy also assures us, that they were not unacquainted with the motion of the moon's nodes and that of her apogee, supposing that the former made a complete revolution in $6585\frac{1}{3}$ days, or 18 years 15 days and 8 hours; which period, containing 223 complete lunations, is called the Chaldean *Saros*. The same author also gives us, from Hipparchus, several observations of lunar eclipses which had been made at Babylon about 720 years before Christ; but though he might very probably meet with many of a more ancient date, it was impossible to mention them particularly, on account of the imperfect state of the Chaldean chronology, which commenced only with the era of Nabonassar, 747 years before Christ. Aristotle likewise informs us, that they had many observations of the occultations of fixed stars and planets by the moon; and from hence, by a very natural and easy inference, they were led to conclude that the eclipses of the sun were occasioned also by the moon, especially as they constantly happened when the latter was in the same part of the heavens with the sun. They had also a considerable share in arranging the stars into constellations. Nor had the comets, by which astronomers in all ages have been so much perplexed, escaped their observation: for both Diodorus Siculus and Appollinus Myndius, in Seneca, inform us, that many of the Chaldeans held these to be lasting bodies, which have stated revolutions as well as the planets, but in orbits vastly more extensive; on which account they are only seen by us while near the earth, but disappear again when they go into the higher regions. Others of them were of opinion, that the comets were only meteors raised very high in the air, which blaze for a while, and disappear when the matter of which they consist is consumed or dispersed. Dialling was also known among them long before the Greeks were acquainted with any such thing.

History

It is evident, indeed, that the countries both of Chaldea and Egypt were exceedingly proper for astronomical observations, on account of the general purity and serenity of the air. The tower or temple of Belus, which was of an extraordinary height, with stairs winding round it up to the top, is supposed to have been an astronomical observatory; and the lofty pyramids of Egypt, whatever they were originally designed for, might possibly answer the same purpose. Indeed these very ancient monuments show the skill of this people in practical astronomy, as they are all situated with their four fronts exactly facing the cardinal points. Herodotus ascribes the Egyptian knowledge in astronomy to Sesostris, whom Sir Isaac Newton makes contemporary with Solomon; but if this was the case, he could not be the instructor of the Egyptians in astronomical matters, since we find that Moses, who lived 500 years before Solomon, was skilled in all the wisdom of the Egyptians, in which we are undoubtedly to include astronomy.

From the testimony of some ancient authors, we learn that they believed the earth to be spherical, that they knew the moon was eclipsed by falling into its shadow, and that they made their observations with the greatest exactness. They even pretended to foretel the appearance of comets, as well as earthquakes and inundations; which extraordinary knowledge is likewise ascribed to the Chaldeans. They attempted to measure the magnitude of the earth and sun; but the methods they took to find out the latter were very erroneous. It does not indeed appear with certainty that they had any knowledge of the true system of the universe; and by the time of the emperor Augustus, their astronomical knowledge was entirely lost.

From Chaldea the science of astronomy most probably passed into Phenicia; though some are of opinion that the Phenicians derived their knowledge of this science from the Egyptians. They seem, however, to have been the first who applied astronomy to the purposes of navigation; by which they became masters of the sea, and of almost all the commerce in the world. They became adventurous in their voyages, steering their ships by one of the stars of the Little Bear; which being near the immoveable point of the heavens called the *Pole*, is the most proper guide in navigation. Other nations made their observations by the Great Bear: which being too distant from the pole could not guide them in long voyages; and for this reason they never durst venture far from the coasts. 7 Of the Phenicians.

8
Astronomy of the Greeks.

The first origin of astronomical knowledge among the Greeks is unknown. Sir Isaac Newton supposes that most of the constellations were invented about the time of the Argonautic expedition: but Dr Long is of opinion that many of them must have been of a much older date; and that the shepherds, who were certainly

Digitized by Google

History.

certainly the first observers, gave names to them according to their fancy; from whence the poets invented many of their fables. Several of the constellations are mentioned by Hesiod and Homer, the two most ancient writers among the Greeks, who lived about 870 years before Christ: Hesiod desiring the farmer to regulate the time of sowing and harvest by the rising and setting of the Pleiades; and Homer informing us, that observations from the Pleiades, Orion, and Arcturus, were used in navigation. Their astronomical knowledge, however, was greatly improved by

9 Improved by Thales.

Thales the Milesian, who travelled into Egypt, and brought from thence the first principles of the science. He is said to have determined the height of the pyramids by measuring their shadows at the time the sun was 45 degrees high, and when of consequence the lengths of the shadows of objects are equal to their perpendicular heights. But his reputation was raised to the highest pitch among his countrymen, by the prediction of an eclipse, which happened just at the time that the armies of Alyattes king of Lydia, and Cyaxares the Mede, were about to engage; and being regarded as an evil omen by both parties, inclined them to peace. To him Callimachus attributes the forming of the constellation of the Little Bear; the knowledge of which he certainly introduced into Greece. He also taught the true length of the year; determined the cosmical setting of the Pleiades in his time to have been 25 days after the autumnal equinox; divided the earth into five zones by means of the polar circles and tropics; taught the obliquity of the ecliptic; and showed that the equinoctial is cut by the meridians at right angles, all of which intersect each other at the poles. He is also said to have observed the exact time of the solstices, and from thence to have deduced the true length of the solar year; to have observed eclipses of the sun and moon; and to have taught that the moon had no light but what she borrowed from the sun. According to Stanley, he also determined the diameter of the sun to be one-720th part of his annual orbit. "But (says Dr Long) these things should be received with caution. There are some reasons which might be assigned for supposing that the knowledge of Thales in these matters was much more circumscribed: and indeed it is not unreasonable to suppose, that that veneration for the ancients which leads authors to write professedly on the history of ancient times, may have induced them to ascribe full as much knowledge to those who lived in them as was really their due."

10 By Anaximander, &c.

The successors of Thales, Anaximander, Anaximenes, and Anaxagoras, contributed considerably to the advancement of astronomy. The first is said to have invented or introduced the gnomon into Greece; to have observed the obliquity of the ecliptic; and taught that the earth was spherical, and the centre of the universe, and that the sun was not less than it. He is also said to have made the first globe, and to have set up a sun-dial at Lacedemon, which is the first we hear of among the Greeks; though some are of opinion that these pieces of knowledge were brought from Babylon by Pherycides, a contemporary of Anaximander. Anaxagoras also predicted an eclipse which happened in the fifth year of the Peloponnesian war; and taught that the moon was habitable, consisting of hills, valleys, and waters, like the earth. His contemporary, Pythagoras, however, greatly improved not only astronomy and mathematics, but every other branch of philosophy. He taught that the universe was composed of four elements, and that it had the sun in the centre; that the earth was round, and had antipodes; and that the moon reflected the rays of the sun; that the stars were worlds, containing earth, air, and ether; that the moon was inhabited like the earth; and that the comets were a kind of wandering stars, disappearing in the superior parts of their orbits, and becoming visible only in the lower parts of them. The white colour of the milky-way he ascribed to the brightness of a great number of small stars; and he supposed the distances of the moon and planets from the earth to be in certain harmonic proportions to one another. He is said also to have exhibited the oblique course of the sun in the ecliptic and the tropical circles, by means of an artificial sphere; and he first taught that the planet Venus is both the evening and morning star. This philosopher is said to have been taken prisoner by Cambyses, and thus to have become acquainted with all the mysteries of the Persian magi; after which he settled at Crotona in Italy, and founded the Italian sect.

11 Doctrines of Pythagoras.

About 440 years before the Christian era, Philolaus, a celebrated Pythagorean, asserted the annual motion of the earth round the sun; and soon after Hicetas, a Syracusan, taught its diurnal motion on its own axis. About this time also flourished Meton and Euctemon at Athens, who took an exact observation of the summer solstice 432 years before Christ; which is the oldest observation of the kind we have, excepting what is delivered by the Chinese. Meton is said to have composed a cycle of 19 years, which still bears his name; and he marked the risings and settings of the stars, and what seasons they pointed out: in all which he was assisted by his companion Euctemon. The science, however, was obscured by Plato and Aristotle, who embraced the system afterwards called the *Ptolemaic*, which places the earth in the centre of the universe.

Eudoxus the Cnidian was a contemporary with Aristotle, though considerably older, and is greatly celebrated on account of his skill in astronomy. He was the first who introduced geometry into the science, and he is supposed to be the inventor of many propositions attributed to Euclid. Having travelled into Egypt in the earlier part of his life, and obtained a recommendation from Agesilaus to Nectanebus king of Egypt, he, by his means, got access to the priests, who had the knowledge of astronomy entirely among them, after which he taught in Asia and Italy. Seneca tells us that he brought the knowledge of the planetary motions from Egypt into Greece; and Archimedes, that he believed the diameter of the sun to be nine times that of the moon. He was also well acquainted with the method of drawing a sun-dial upon a plane; from whence it may be inferred that he understood the doctrine of the projection of the sphere: yet, notwithstanding what has been said concerning the observations of Eudoxus, it is not certain that his sphere was not taken from one much more ancient, ascribed to Chiron the Centaur. The reason given for this supposition is, that had the places of the stars been taken from his own observations, the constellations must have been half a sign farther advanced than they are said to be in his writings.

Soon

Digitized by Google

Soon after Eudoxus, Calippus flourished, whose system of the celestial sphere is mentioned by Aristotle; but he is better known from a period of 76 years, containing four corrected metonic periods, and which had its beginning at the summer solstice in the year 330 before Christ. But about this time, or rather earlier, the Greeks having begun to plant colonies in Italy, Gaul, and Egypt, these became acquainted with the Pythagorean system, and the notions of the ancient Druids concerning astronomy. Julius Cæsar informs us, that the latter were skilled in this science; and that the Gauls in general were able sailors, which at that time they could not be without a competent knowledge of astronomy: and it is related of Pythoas, who lived at Marseilles in the time of Alexander the Great, that he observed the altitude of the sun at the summer solstice by means of a gnomon. He is also said to have travelled as far as Thule to settle the climates.

12 State of astronomy in Egypt after the death of Alexander.

After the death of Alexander the Great, science flourished in Egypt more than in any other part of the world; and a famous school was set up at Alexandria under the auspices of Ptolemy Philadelphus, a prince instructed in all kinds of learning, and the patron of all those who cultivated them; and this school continued to be the seminary of all kinds of literature, till the invasion of the Saracens in 650. Timocharis and Arystillus, who first cultivated the astronomical science in this school, began to put it on a new footing; being much more careful in their observations, and exact in noting down the times when they were made, than their predecessors. Ptolemy assures us, that Hipparchus made use of their observations, by means of which he discovered that the stars had a motion in longitude of about one degree in an hundred years; and he cites many of their observations, the oldest of which is before the erection of this school, in the year 295, when the moon just touched the northern star in the forehead of the Scorpion; and the last of them was in the 13th year of Philadelphus, when Venus hid the former star of the four in the left wing of Virgo.

From this time the science of astronomy continued greatly to advance. Aristarchus, who lived about 270 years before Christ, strenuously asserted the Pythagorean system, and gave a method of determining the distance of the sun by the moon's dichotomy. Eratosthenes, born at Cyrene in 271 B. C. determined the measure of a great circle of the earth by means of a gnomon. His reputation was so great, that he was invited from Athens to Alexandria by Ptolemy Euergetes, and made by him keeper of the royal library at that place. At his instigation the same prince set up those armillas or spheres, which Hipparchus and Ptolemy the astronomer afterwards employed so successfully in observing the heavens. He also found the distance between the tropics to be eleven such parts as the whole meridian contains eighty-three. About the same time Berosus a native of Chaldea, flourished at Athens. He is by some said to have brought many observations from Babylon, which are ascribed to the Greeks; while others contend, that the latter owe little or nothing of their astronomical knowledge to the Babylonians. The celebrated Archimedes, who next to Sir Isaac Newton holds the first place among mathematicians, was nothing inferior as an astronomer to what he was as a geometrician. He determined the distance of the moon from the earth, of Mercury from the moon, of Venus from Mercury, of the sun from Venus, of Mars from the sun, of Jupiter from Mars, and of Saturn from Jupiter; as likewise the distance of the fixed stars from the orbit of Saturn. That he made astronomical observations, is not to be doubted; and it appears from an epigram of the poet Claudian, that he invented a kind of planetarium, or orrery, to represent the phenomena and motions of the heavenly bodies.

13 Discoveries of Archimedes.

14 Of Hipparchus.

Hipparchus was the first who applied himself to the study of every part of astronomy, his predecessors having chiefly considered the motions and magnitudes of the sun and moon. Ptolemy also informs us, that he first discovered the orbits of the planets to be eccentric, and on this hypothesis wrote a book against Eudoxus and Calippus. He gives many of his observations: and says, that by comparing one of his with another made by Aristarchus 145 years before, he was enabled to determine the length of the year with great precision. Hipparchus also first found out the anticipation of the moon's nodes, the eccentricity of her orbit, and that she moved slower in her apogee than in her perigee. He collected the accounts of such ancient eclipses as had been observed by the Chaldeans and Egyptians. He formed hypotheses concerning the celestial motions, and constructed tables of those of the sun and moon, and would have done the same with those of the other planets if he could have found ancient observations sufficient for the purpose; but, these being wanting, he was obliged to content himself with collecting fit observations for that purpose, and endeavouring to form theories of the five planets. By comparing his own observations on the Spica Virginis with those of Timochares at Alexandria made 100 years before, he discovered that the fixed stars changed their places, and had a slow motion of their own from west to east. He corrected the Calippic period, and pointed out some errors in the method laid down by Eratosthenes for measuring the circumference of the earth. By means of geometry, which was now greatly improved, he was enabled to attempt the calculation of the sun's distance in a more correct manner than any of his predecessors; but unhappily it required so much accuracy in observation as was found impracticable. His greatest work, however, was his catalogue of the fixed stars, which he was induced to attempt by the appearance of a new star. The catalogue is preserved by Ptolemy, and contains the longitudes and latitudes of 1022 stars, with their apparent magnitudes. He wrote also concerning the intervals between eclipses both solar and lunar, and is said to have calculated all that were to happen for no less than 600 years from his time.

15 Makes the first catalogue of fixed stars.

16 System of Ptolemy.

Little progress was made in astronomy from the time of Hipparchus to that of Ptolemy, who flourished in the first century. The principles on which his system is built are indeed erroneous: but his work will always be valuable on account of the number of ancient observations it contains. It was first translated out of the Greek into Arabic in the year 827, and into Latin from the Arabic in 1230. The Greek original was unknown in Europe till the beginning of the 15th century,

Digitized by Google

History. century, when it was brought from Constantinople, then taken by the Turks, by George a monk of Trapezond, who translated it into Latin. Various editions were afterwards published: but little or no improvement was made by the Greeks in this science.

17 Astronomy of the Arabians.

During the long period from the year 800 to the beginning of the 14th century, the western parts of Europe were immersed in deep ignorance and barbarity. However, several learned men arose among the Arabians. The caliph Al Mansur was the first who introduced a taste for the sciences in his empire. His grandson Al Mamun, who ascended the throne in 814, was a great encourager of the sciences, and devoted much of his own time to the study of them. He made many astronomical observations himself, and determined the obliquity of the ecliptic to be 23° 35′. He employed many able mechanics in constructing proper instruments, which he made use of for his observations; and under his auspices a degree of the earth was measured a second time in the plain of Singar, on the border of the Red sea. From this time astronomy was studiously cultivated by the Arabians; and Elements of Astronomy were written by Alferganus, who was partly cotemporary with the caliph Al Mamun. But the most celebrated of all their astronomers is Albategnius, who lived about the year of Christ 880. He greatly reformed astronomy, by comparing his own observations with those of Ptolemy. Thus he calculated the motion of the sun's apogee from Ptolemy's time to his own; determined the precession of the equinoxes to be one degree in 70 years; and fixed the sun's greatest declination at 23.35′. Finding that the tables of Ptolemy required much correction, he composed new ones of his own fitted to the meridian of Aracta, which were long held in estimation by the Arabians. After his time, though several eminent astronomers appeared among the Saracens, none made any very valuable observations for several centuries, excepting Ebn Younis astronomer to the caliph of Egypt; who observed three eclipses with such care, that by means of them we are enabled to determine the quantity of the moon's acceleration since that time.

Other eminent Saracen astronomers were, Arzachel a Moor of Spain, who observed the obliquity of the ecliptic, and constructed tables of sines, or half chords of double arcs, dividing the diameter into 300 parts; and Alhazen, his cotemporary, who first showed the importance of the theory of refractions in astronomy; writing also upon the twilight, the height of the clouds, and the phenomenon of the horizontal moon.

Ulug Beg, a grandson of the famous Tartar prince Timur Beg, or Tamerlane, was a great proficient in practical astronomy. He is said to have had very large instruments for making his observations; particularly a quadrant as high as the church of Sancta Sophia at Constantinople, which is 180 Roman feet. He composed astronomical tables from his own observations for the meridian of Samarcand his capital, so exact as to differ very little from those afterwards constructed by Tycho Brahe; but his principal work is his catalogue of the fixed stars, made from his own observations in the year of Christ 1437. The accuracy of his observations may be gathered from his determining the height of the pole at Samarcand to be 39° 37′ 23″.

Besides these improvements, we are indebted to the Arabians for the present form of trigonometry. Menelaus, indeed, an eminent Greek astronomer who flourished about the year 90, had published three books of Spherics, in which he treated of the geometry necessary to astronomy, and which show great skill in the sciences; but his methods were very laborious, even after they had been improved and rendered more simple by Ptolemy: but Geber the Arabian, instead of the ancient method, proposed three or four theorems, which are the foundation of our modern trigonometry. The Arabians also made the practice still more simple, by using sines instead of the chords of double arcs. The arithmetical characters they had from the Indians. 18

Revival of astronomy in Europe.

During the greatest part of this time, almost all Europe continued ignorant not only of astronomy but of every other science. The emperor Frederick II. first began to encourage learning in 1230; restoring some universities, and founding a new one in Vienna. He also caused the works of Aristotle, and the Almagest or Astronomical Treatise of Ptolemy, to be translated into Latin; and from the translation of this book we may date the revival of astronomy in Europe. Two years after its publication, John de Sacro Bosco, or of Halifax, an Englishman, wrote his four books *De Sphæra*, which he compiled from Ptolemy Albategnius, Alferganus, and other Arabian astronomers: this work was so much celebrated, that for 300 years it was preferred in the schools to every other; and has been thought worthy of several commentaries, particularly by Clavius in 1531. In 1240, Alphonso king of Castile caused the tables of Ptolemy to be corrected: for which purpose he assembled many persons skilled in astronomy, Christians, Jews, and Moors; by whom the tables called *Alphonsine* were composed, at the expence of 40,000, or according to others 400,000 ducats. About the same time Roger Bacon, an English monk, published many things relative to astronomy; particularly of the places of the fixed stars, solar rays, and lunar aspects. Vitellio, a Polander, wrote a treatise on Optics about 1270, in which he showed the use of refractions in astronomy. 19

Improvements of Purbach.

From this time to that of Purbach, who was born in 1423, few or no improvements were made in astronomy. He wrote a commentary on Ptolemy's Almagest, some treatises on Arithmetic and Dialling, with tables for various climates. He not only used spheres and globes, but constructed them himself; and formed new tables of the fixed stars, reduced to the middle of that age. He composed also new tables of sines for every ten minutes, which Regiomontanus afterwards extended to every single minute, making the whole sine 60, with 6 ciphers annexed. He likewise corrected the tables of the planets, making new equations to them, because the Alphonsine tables were very faulty in this respect. In his solar tables he placed the sun's apogee in the beginning of Cancer; but retained the obliquity of the ecliptic 23° 33½′, to which it had been reduced by the latest observations. He made new tables for computing eclipses, of which he observed some, and had just published a theory of the planets, when he died in 1461. 20

Of Regiomontanus.

John Muller of Monteregio (Koningsberg), a town of Franconia, from whence he was called *Regiomontanus*,

Digitized by Google

History.

nus, was the scholar and successor of Purbach. He completed the epitome of Ptolemy's Almagest which Purbach had begun; and after the death of the latter, went to Rome, where he made many astronomical observations. Having returned to Nuremberg in 1471, he was entertained by a wealthy citizen named *Bernard Walther*, who having a great love for astronomy, caused several instruments to be made under the direction of Regiomontanus, for observing the altitude of the sun and stars, and other celestial phenomena. Among these was an armillary astrolabe, like that which had been used by Hipparchus and Ptolemy at Alexandria, and with which many observations were made. He also made ephemerides for 30 years to come, showing the lunations, eclipses, &c. He wrote the Theory of the Planets and Comets, and a Treatise of Triangles yet in repute for several extraordinary cases. He is said to have been the first who introduced the use of tangents into trigonometry; and to have published in print (the art of printing having been lately invented) the works of many of the most celebrated ancient astronomers. After his death, which happened at Rome, Walther made a diligent search for all his instruments and papers which could be found: and continued his observations with the instruments he had till his death. The observations of both were collected by order of the senate of Nuremberg, and published there by John Schoner in 1544; afterwards by Snellius at the end of the Observations made by the landgrave of Hesse in 1618; and lastly, in 1666, with those of Tycho Brahe. Walther, however, as we are told by Snellius, found fault with his armilla, not being able to give any observation with certainty to less than ten minutes. He made use of a good clock, which also was a late invention in those days.

21 Of Werner.

John Werner, a clergyman, succeeded Walther as astronomer at Nuremberg; having applied himself with great assiduity to the study of that science from his infancy. He observed the motion of the comet in 1500; and published several tracts, in which he handled many capital points of geometry, astronomy, and geography, in a masterly manner. He published a translation of Ptolemy's Geography, with a commentary, which is still extant. In this he first proposed the method of finding the longitude at sea by observing the moon's distance from the fixed stars; which is now so successfully put in practice. He also published many other treatises on mathematics and geography; but the most remarkable of all his treatises, are those concerning the motion of the eighth sphere or of the fixed stars, and a short theory of the same. In this he showed, by comparing his own observations of the stars Regulus, Spica Virginis, and the bright star in the southern scale of the Balance, made in 1514, with the places assigned to the same stars by Ptolemy, Alphonsus, and others, that the motion of the fixed stars, now called *the precession of the equinoctial points*, is one degree ten minutes in 100 years, and not one degree only, as former astronomers had made it. He made the obliquity of the ecliptic 23° 28′, and the first star of Aries 26° distant from the equinoctial point. He also constructed a planetarium representing the celestial motions according to the Ptolemaic hypothesis, and made a great number of meteorological observations with a view towards the prediction of the weather. The obliquity of the ecliptic was settled by Dominic Maria the friend of Copernicus, at 23° 29′, which is still held to be just.

22 Pythagorean syst restored Copernic

The celebrated Nicholas Copernicus next makes his appearance, and is undoubtedly the great reformer of the astronomical science. He was originally bred to the practice of medicine, and had obtained the degree of doctor in that faculty: but having conceived a great regard for the mathematical sciences, especially astronomy, he travelled into Italy, where he for some time was taught by Dominic Maria, or rather assisted him in his astronomical operations. On his return to his own country, being made one of the canons of the church, he applied himself with the utmost assiduity to the contemplation of the heavens, and to the study of the celestial motions. He soon perceived the deficiency of all the hypotheses by which it had been attempted to account for these motions; and for this reason he set himself to study the works of the ancients, with all of whom he also was dissatisfied excepting Pythagoras; who, as has been already related, placed the sun in the centre, and supposed all the planets, with the earth itself, to revolve round him. He informs us, that he began to entertain these notions about the year 1507; but not being satisfied with stating the general nature of his hypothesis, he became desirous of determining the several periodical revolutions of the planets, and thence of constructing tables of their motions which might be more agreeable to truth than those of Ptolemy and Alphonsus. The observations he was enabled to make, however, must have been extremely inaccurate: as he tells us, that if with the instruments he made use of he should be able to come within ten minutes of the truth, he would rejoice no less than Pythagoras did when he discovered the proportion of the hypothenuse to the other two sides of a right-angled triangle. His work was completed in the year 1530; but he could not be prevailed upon to publish it till towards the end of his life, partly through diffidence, and partly through fear of the offence which might be taken at the singularity of the doctrines set forth in it. At last, overcome by the importunities of his friends, he suffered it to be published at their expence, and under the inspection of Schoner and Osiander, with a dedication to Pope Paul III. and a preface, in which it was attempted to palliate as much as possible the extraordinary innovations it contained. During the time of its publication the author himself was attacked with a bloody flux, succeeded by a palsy; so that he received a copy only a few hours before his death, which happened on the 23d of May 1543.

After the death of Copernicus, the astronomical science was greatly improved by Schoner, Nonius, Appian, and Gemma Frisius. Schoner survived Copernicus only four years; however, he greatly improved the methods of making celestial observations, reformed and explained the calendar, and published a treatise of cosmography. Nonius had applied himself very early to the study of astronomy and navigation; but finding the instruments at that time in use excessively inaccurate, he applied himself to the invention of others which should be less liable to inconvenience. Thus he invented the astronomical quadrant, in which he divided the degrees into minutes by a number of concentric circles.

Digitized by Google

History.

circles. The first of these was divided into 90 equal parts, the second into 89, the third into 88, and so on, as low as 46; and thus, as the index of the quadrant would always fall upon one or other of the divisions, or very near it, the minutes might be known by computation. He published many treatises on mathematical subjects, particularly one which detected the errors of Orontius, who had imagined that he could square the circle, double the cube, &c. by finding two mean proportionals betwixt two right lines. Appian's chief work was entitled *The Cæsarean Astronomy;* and was published at Ingolstadt in 1540, dedicated to the emperor Charles V. and his brother Ferdinand. In this he showed how to resolve astronomical problems by means of instruments, without either calculations or tables; to observe the places of the stars and planets by the astrolabe; and to foretel eclipses and describe the figures of them: the whole illustrated by proper diagrams. In his second book he describes the method of dividing an astronomical quadrant, and of using it properly. His treatise concludes with the observation of five comets. Gemma Frisius wrote a commentary on a work of Appian entitled his *Cosmography*, with many observations of eclipses. He invented also the astronomical ring, and several other instruments, which, though they could not boast of much exactness superior to others, were yet of considerable utility in taking observations at sea; and he is also memorable for being the first who proposed a time-keeper for determining the longitude at sea.—George Joachim Rheticus was a scholar of Copernicus, to attend whose lectures he gave up his professorship of mathematics at Wittemberg. For the improvement of astronomical calculations, he began to construct a table of sines, tangents, and secants, for every minute and ten seconds of the quadrant. In this work he first showed the use of secants in trigonometry, and greatly enlarged the use of tangents, first invented by Regiomontanus; but he assigned for the radius a much larger number of places than had been done before, for the greater exactness of calculation. This great work he did not live to accomplish; but it was completed by his disciple Valentine Otho, and published at Heidelberg in 1594.

23
Several illustrious persons apply to the study of astronomy.

During this century, the list of astronomers was dignified by some very illustrious names. About the year 1561, William IV. landgrave of Hesse Cassel, applied himself to the study of astronomy. With the assistance of Rothman and Burgius, the former an astronomer, the latter an excellent mathematical instrument-maker, he erected an observatory on the top of his palace at Cassel, and furnished it with such instruments as were then in use, made in the best manner the artists of that age could execute. With these he made a great number of observations, which were by Hevelius preferred to those of Tycho Brahe, and which were published by Snellius in 1618. From these observations he determined the longitudes and latitudes of 400 stars, which he inserted in a catalogue where their places are rectified to the beginning of the year 1593.

24
Observations of Tycho Brahe.

Tycho Brahe began his observations about the same time with the landgrave of Hesse, already mentioned. He observed the great conjunction of Saturn and Jupiter in 1563; and finding the instruments he could procure very inaccurate, he made a quadrant capable of showing single minutes, and likewise a sextant four cubits radius. In 1571, he discovered a new star in the chair of Cassiopeia; which induced him, like Hipparchus, to make a catalogue of the stars. This contained the places of 777 stars, rectified to the year 1600; but instead of the moon, which was used by the ancients to connect the places of the sun and stars, Tycho substituted Venus, as having little or no parallax, and yet being like the moon visible both day and night. By the recommendation of the landgrave of Hesse, he obtained from the king of Denmark the island of Huenna, opposite to Copenhagen, where an observatory was built. The first stone of this building, afterwards called *Uraniburg*, was laid in the year 1576. It was of a square form, one side of it being about 60 feet in length; and on the east and west sides were two round towers of 32 feet diameter each. The instruments were larger and more solid than had ever been seen before by any astronomer. They consisted of quadrants, sextants, circles, semicircles, armillæ both equatorial and zodiacal, parallactic rulers, rings, astrolabes, globes, clocks, and sun-dials. These instruments were so divided as to show single minutes; and in some the arch might be read off to 10 seconds. Most of the divisions were diagonal: but he had one quadrant divided according to the method invented by Nonius; that is, by 47 concentric circles. The whole expence is said to have amounted to 200,000 crowns. The method of dividing by diagonals, which Tycho greatly admired, was the invention of Mr Richard Chanceler, an Englishman: Tycho, however, shows, that it is not accurately true when straight lines are employed, and the circles at equal distances from each other; but that it may be corrected by making circular diagonals, which if continued would pass through the centre.

25
Account of Uraniburg, his observatory.

Tycho employed his time at Uraniburg to the best advantage; but falling into discredit on the death of the king, he was obliged to remove to Holstein, and at last found means to get himself introduced to the emperor, with whom he continued to his death. He is well known to have been the inventor of a system of astronomy, which bears his name; and which he vainly endeavoured to establish on the ruins of that of Copernicus: but the simplicity and evident consonancy to the phenomena of nature, displayed in all parts of the Copernican system, soon got the better of the unnatural and complicated system of Tycho. His works, however, which are very numerous, discover him te have been a man of vast abilities. After his death the castle of Uraniburg quickly fell to decay, and indeed seems to have been purposely pulled down; for, in 1652, when Mr Huet went to Sweden, it was almost level with the ground, and few traces of the walls could be discerned. None of the neighbouring inhabitants had ever heard of the name of Tycho or Uraniburg, excepting one old man, whom Mr Huet found out with great difficulty, and who had been a servant in the family! All the discoveries of Purback, Regiomontanus, and Tycho, were collected and published in the year 1621, by Longomontanus, who had been Tycho's favourite scholar.

26
Discoveries of Kepler.

While Tycho resided at Prague with the emperor, he invited thither John Kepler, afterwards so famous for his discoveries. Under the tuition of so great an astronomer, the latter quickly made an amazing progress.

Digitized by Google

progress. He found that his predecessors had erred in supposing the orbits of the planets to be circular, and their motions uniform: on the contrary, he perceived, from his own observations, that they were elliptical, and their motions unequal, having the sun in one of the foci of their orbits; but that, however they varied in absolute velocity, a line drawn from the centre of the sun to the planet, and revolving with it, would always describe equal areas in equal times. He discovered, in the year 1618, that the squares of the periodical times are as the cubes of the distances of the planets; two laws which have been of the greatest importance to the advancement of astronomy. He seems to have had some notion of the extensive power of the principle of gravity: for he tells us, that gravity is a mutual power betwixt two bodies; that the moon and earth tend towards each other, and would meet in a point nearer the earth than the moon in the proportion of the superior magnitude of the former, were they not hindered by their projectile motions. He adds also, that the tides arise from the gravitation of the waters towards the moon: however, he did not adhere steadily to these principles, but afterwards substituted others as the causes of the planetary motions.

Cotemporary with Kepler were Mr Edward Wright, and Napier baron of Merchiston. To the former we owe several very good meridional observations of the sun's altitude, made with a quadrant of six feet radius, in the years 1594, 1595, and 1596; from which he greatly improved the theory of the sun's motion, and computed more exact tables of his declination than had been done by any person before. He published also, in 1599, an excellent treatise, entitled, "Certain Errors in Navigation discovered and detected." To the latter we are indebted for the knowledge of logarithms; a discovery, as was justly observed by Dr Halley, one of the most useful ever made in the art of numbering. John Bayer, a German, who lived about the same time, will ever be memorable for his work, entitled, *Uranometria*, which is a very complete celestial atlas, or a collection of all the constellations visible in Europe. To this he added a nomenclature, in which the stars in each constellation are marked with the letters of the Greek alphabet; and thus every star in the heavens may be referred to with the utmost precision and exactness. About the same time also, astronomy was cultivated by many other persons; abroad, by Maginus, Mercator, Maurolycus, Homelius, Schultet, Stevin, &c.; and by Thomas and Leonard Digges, John Dee, and Robert Flood, in England: but none of them made any considerable improvement.

27 **Invention of telescopes, and consequent discoveries.**

The beginning of the 17th century was distinguished not only by the discovery of logarithms, but by that of telescopes; a sort of instruments by which astronomy was brought to a degree of perfection utterly inconceivable by those who knew nothing of them. The question concerning the inventor is discussed under the article OPTICS; but whoever was entitled to this merit, it is certain that Galileo was the first who brought them to such perfection as to make any considerable discoveries in the celestial regions. With instruments of his own making, Galileo discovered the inequalities in the moon's surface, the satellites of Jupiter, and the ring of Saturn; though this last was unknown to him after he had seen it, and the view he got made him conclude that the planet had a threefold body, or that it was of an oblong shape like an olive. He discovered spots on the sun, by means of which he found out the revolution of that luminary on his axis; and he discovered also that the milky way and nebulæ were full of small stars. It was not, however, till some time after these discoveries were made, that Galileo and others thought of applying the observations on Jupiter's satellites to the purpose of finding the longitude of places on the surface of the earth; and even after this was thought of, astronomers found it so difficult to construct tables of their motions, that it was not till after many observations had been made in distant places of the world, that Cassini was able to determine what positions of the satellites were most proper for finding out the longitude. At last he perceived that the entrance of the first satellite into the shadow of Jupiter, and the exit of it from the same, were the most proper for this purpose: that next to these the conjunctions of the satellites with Jupiter, or with one another, may be made use of; especially when any two of them, moving in contrary directions, meet with each other: and lastly, that observations on the shadows of the satellites, which may be seen on the disk of Jupiter, are useful, as also the spots which are seen upon his face, and are carried along it with greater velocity than has hitherto been discovered in any of the other heavenly bodies.

28 **Logarithmic tables composed.**

While astronomers were thus busy in making new discoveries, the mathematicians in different countries were no less earnestly employed in constructing logarithmic tables to facilitate their calculations. Benjamin Ursinus, an excellent mathematician of Brandenburg, calculated much larger tables of logarithms than had been done by their noble inventor, and published them in 1625. They were improved by Henry Briggs, Savilian professor of Oxford; who by making unity the logarithm of ten, thus rendered them much more convenient for the purposes of calculation. Logarithmic tables of sines and tangents were also composed by Mr Briggs and Adrian Vlacq at Goude, so that the business of calculation was now rendered nearly as easy as possible.

29 **Transit of Venus first observed by Mr Horrox.**

In 1733, Mr Horrox, a young astronomer of very extraordinary talents, discovered that Venus would pass over the disk of the sun on the 24th of November 1639. This event he announced only to one friend, a Mr Crabtree; and these two were the only persons in the world who observed this transit the first time it had ever been viewed by human eyes. Mr Horrox made many useful observations at the time; and had even formed a new theory of the moon, so ingenious as to attract the notice of Sir Isaac Newton: but the hopes of astronomers from the abilities of this excellent young man were blasted by his death in the beginning of January 1640.

30 **Foundation of the Academy of Sciences at Paris and Royal Society at London.**

About the year 1638 many learned men began to assemble at Paris in order to hold conferences on different scientific subjects, which was the first foundation of the Royal Academy of Sciences in that capital. This practice was introduced in France by Mersennus, and soon after at London by Oldenburg; which laid the foundation of the Royal Society there. About this time also the celebrated astronomer Hevelius flourished at Dantzic, building an observatory in his own house,

Digitized by Google

History.

house, and furnishing it with excellent instruments of his own construction; particularly octants and sextants of brass of three and four feet radius, as well as telescopes, with which he constantly observed the spots and phases of the moon, and from which observations he afterwards compiled his excellent and beautiful work entitled *Selenographia*. This noble building, together with all the books and instruments it contained, was consumed by fire on the 26th of September 1679; but the memory, as well as the form and construction of the instruments, is preserved in a curious work of the ingenious inventor, entitled *Machina Cœlestis;* though almost the whole impression of this book was involved in the same fate with the instruments it describes. The damage sustained on this occasion was estimated at 30,000 crowns.

The celebrated English mechanic Dr Hooke, who was cotemporary with Hevelius, had in the mean time invented instruments with telescopic sights, which he preferred to those used by Hevelius so much, that a dispute commenced, which procured Hevelius a visit from Dr Halley. The latter had at that time taken a voyage to St Helena, at the desire of the Royal Society, in order to observe and form a catalogue of the stars in the southern hemisphere. The result of his observations with Hevelius's instruments was, that three several observations on the Spica Virginis and Regulus differed only a few seconds from each other. They were the invention of Tycho Brahe, and are described under the article OPTICS. At this visit Halley and Hevelius observed an occultation of Jupiter by the moon, and determined the diameter of the latter to be 30′, 33″.

In 1671 the royal observatory in Paris was finished, and the use of it assigned to Mr Cassini, after it had been furnished with instruments at a very great expence: and the observatory at Greenwich being likewise built five years after, Mr Flamstead was appointed astronomer-royal. The observations in both these places, however, have been so numerous, that it is in vain to attempt any account of them.

31
Improvements in telescopes.

Before the middle of the 17th century the construction of telescopes had been greatly improved, particularly by Fontana and Huygens. The latter constructed one of 123 feet, which is still preserved in the museum of the Royal Society at London. With this he observed the moon and planets for a long time, and discovered that Saturn was encompassed with a ring. The French, however, still outdid the English artists; and by means of telescopes of 200 and 300 feet focus, Mr Cassini was enabled to see all the five satellites of Saturn, his belts, and the shadows of Jupiter's satellites passing over his body. In 1666 Mr Azout applied a micrometer to telescopes, for the purpose of measuring the diameters of the planets, and small distances in the heavens; however, an instrument of this kind had been before invented by Mr Gascoigne, though it was but little known abroad.

Notwithstanding all these discoveries by means of telescopes, it was evident that they still continued in a very imperfect state, and their imperfections at the time appeared to be without remedy. One defect was the enormous length requisite to admit of any very considerable magnifying power; and another was the incorrectness of the image arising from the aberration of the rays, as was then supposed, by the spherical figure of the glass. To obviate these inconveniences, Mersennus is said to have first proposed, in a letter to Descartes, the use of reflectors instead of lenses in the construction of telescopes; but this he did in such an obscure manner, that the latter laboured to persuade him of the falsehood of the principle on which his scheme was founded. In 1663, however, James Gregory of Aberdeen showed how such a telescope might be constructed. He showed also, that, in order to form a perfect image of an object in this manner, the figure of the speculum ought to be parabolic; but Sir Isaac Newton, who applied himself to the framing of telescopes of the reflecting kind, found it impracticable to grind them of the desired figure. Laying aside the idea of reflecting telescopes, therefore, he applied himself to the execution of a scheme formed by Descartes, viz. that of grinding lenses of the figure of one of the conic sections. In prosecuting this plan, he discovered, that the greatest errors to which telescopes were subject arose from the different refrangibility of the rays of light, for which he could not then find any remedy. He therefore returned to the scheme he had just abandoned; and, in the year 1672, presented to the Royal Society two reflectors which were constructed with spherical speculums, as he could not procure any other. The inconveniences arising from the different refrangibility of the rays of light, have since been in the fullest manner corrected by Mr Dollond, the excellency of whose achromatic telescopes is too well known to need any encomium.

About the beginning of the 18th century, the practical part of astronomy seemed to languish for want of proper instruments. Roemer, indeed, had invented some new ones, and Dr Hooke had turned his attention towards this subject in a very particular manner; but either through want of skill in the artists, or some other unfortunate circumstance, it happened that nothing effectual was done. But at the very time when this was the case with practical astronomy, the speculative part was carried in a manner to its utmost pitch by the labours of the immortal Newton, whose Principia gave an entire new face to the science. It was not, however, for many years relished by the foreign philosophers, though almost immediately adopted at home, and has continued ever since to spread its reputation farther and farther, so that now it is in a manner established all over the world. "But (says Dr Long) that, after Newton's system had for so long a time been neglected, it should all at once be universally received and approved of, is not to be attributed to chance, or the caprice of fashion, as some who are ignorant of it are apt to think, and from thence to expect that some other system will hereafter take its place, and bury it in oblivion. The system of Newton, like that of Copernicus, is so agreeable to the phenomena of nature, and so well put together, that it *must* last as long as truth and reason endure, although some may perhaps bring the word attraction into disuse; and though it may no longer be thought inherent in matter, yet the laws of gravitation, as they are now called, and on which this system is founded, will never be forgotten."

It was also in Britain that the first improvements in astronomical instruments took place. The celebrated

Digitized by Google

mechanic and watchmaker, Graham, carried the accuracy of his instruments to a degree which surprised every one.

32 Astronomical instruments first improved in England.

He also greatly improved the principles of watch-work, and made clocks to go with much greater regularity than before. The old eight-feet mural arch at Greenwich was also constructed by him; as was a small equatorial sector for making observations out of the meridian; but he is chiefly remarkable for contriving the zenith sector of 24 feet radius, and afterwards one of $12\frac{1}{2}$ feet, by which Dr Bradley discovered the aberration of the fixed stars. The reflecting telescope, which had been invented by Gregory, and executed by Newton, was greatly improved by Mr Hadley, and a very complete and powerful instrument of that kind was presented to the Royal Society in 1719. The same gentleman has also immortalized his memory by the invention of the reflecting quadrant, which he presented to the Society in 1731, which is now in universal use at sea; and without which all improvements of the lunar theory would have been useless for determining the longitude, through the want of an instrument proper to make the observations with. It however appears, that an instrument, exactly similar to this in its principles, had been invented by Sir Isaac Newton, and a description of it, together with a drawing, given by the inventor to Dr Halley, when he was preparing for his voyage to discover the variation of the needle in 1701. About the middle of this century, the constructing and dividing of large astronomical instruments was carried to a great degree of perfection by Mr John Bird; reflecting telescopes were equally improved by Mr Short, who first executed the divided object-glass micrometer. This had indeed been thought of by M. Louville, and several other persons long before; and a description of one nearly agreeing with that of Mr Short had been published in the Philosophical Transactions for 1753: but had it not been for the great skill of Mr Short in figuring and centering glasses of this kind, it is very probable the scheme might never have been executed. About this time also Mr Dollond brought refracting telescopes to such perfection, that they became superior to reflectors of equal length; though all of them are now excelled by those of Mr Herschel, whose telescopic discoveries have been far more numerous and surprising than those of any other astronomer.

33 Improvements within this last century.

We shall close this history with a short account of the labours of the principal astronomers since the building the royal observatories at Paris and Greenwich, and the appointment of Mr Flamstead to the office of astronomer royal. This gentleman not only made observations on the sun, moon, planets, and comets which appeared in his time, but on the fixed stars also, of which he gave a catalogue of 3000; many of them so small that they cannot be discerned without the help of a telescope: he also published new solar tables, and a theory of the moon according to Horrox. He published a very curious tract on the doctrine of the sphere, in which he shewed how to construct eclipses of the sun and moon, as well as occultations of the fixed stars by the moon, geometrically; and it was upon his observations that Halley's tables and Newton's theory of the moon were constructed. Mr Cassini also distinguished himself very considerably. He erected the gnomon, and drew the famous meridian line in the church of Petronia at Bologna. He enjoyed his office more than 40 years, making many observations on the sun, moon, planets, and comets, and greatly amended the elements of their motions; though the result of his labours was much inferior to Mr Flamstead's. The office was continued in his family, and his grandson still enjoys it. Rœmer, a celebrated Danish astronomer, first discovered the progressive motion of light by observing the eclipses of Jupiter, and read a dissertation upon it before the Royal Academy of Sciences at Paris in the year 1675. He was also the first who made use of a meridional telescope.

Mr Flamstead was succeeded in 1719 by Dr Halley, "the greatest astronomer (says M. de la Lande) without contradiction in England;" and, adds Dr Long, "I believe he might have said in the whole world." He had been sent, at the age of 21, by King Charles II. to the island of St Helena, in order to make a catalogue of the southern stars, which was published in 1679. In 1705, he published his *Synopsis Astronomiæ Cometicæ*, in which, after immense calculation, he ventured to predict the return of one in 1758 or 1759. He also published many learned dissertations in the Philosophical Transactions concerning the use that might be made of the next transit of Venus in determining the distance of the sun from the earth. He was the first who discovered the acceleration of the moon, and gave a very ingenious method of finding her parallax by three observed phases of a solar eclipse. He composed tables of the sun, moon, and all the planets; and, in the nine years in which he was at Greenwich, made near 1500 observations of the moon; all which he compared with the tables, and noted the differences; and these, he thought, would return in about 18 years. He recommended the method of determining the longitude by means of the moon's distance from the sun and certain fixed stars. He was convinced of its superior excellence; and it has since been adopted by all the most eminent astronomers in Europe. It is at present the only sure guide to the mariner; and the great perfection to which it is now brought is much owing to the industry and exertions of Dr Maskelyne, the present astronomer-royal, to whom we are indebted for the publication of the Nautical Almanack, the Requisite Tables, and other works of the utmost service to practical astronomy.

34 True figure of the earth discovered.

In the mean time an attempt was made in France to measure a degree of the earth, which occasioned a very warm dispute concerning the figure of it. Cassini, from Picart's measure, concluded that the earth was an oblong spheroid; but Newton, from a consideration of the laws of gravity and the diurnal motion of the earth, had determined the figure of it to be an oblate spheroid, and flatted at the poles. To determine this point, Louis XV. resolved to have two degrees of the meridian measured; one under, or very near the equator; and the other as near the pole as possible. For this purpose the Royal Academy of Sciences sent M. Maupertuis, Clairault, Camus, and Le Monier, to Lapland. They were accompanied by the abbé Outhier, a correspondent of the same academy. They were joined by M. Celsius professor of anatomy at Upsal; and having set out from France in the spring of the year 1736, returned to it in 1737, after having fully

Digitized by Google

History.

fully accomplished their errand. On the southern expedition were despatched M. Godin, Condamine, and Bouguer, to whom the king of Spain joined Don George Juan and Don Anthony de Ulloa, two very ingenious gentlemen and officers of the marine. They left Europe in 1735; and after enduring innumerable hardships and difficulties in the execution of their commission, returned to Europe at different times, and by different ways, in the years 1744, 1745, and 1746. The result of this arduous task was a confirmation of Newton's investigation. Picart's measure was revised by Cassini and De la Caille; and, after his errors were corrected, it was found to agree very well with the other two. On this occasion too it was discovered, that the attraction of the great mountains of Peru had an effect on the plumb-line of one of their largest instruments, drawing it seven or eight seconds from the true perpendicular.

Dr Halley, dying in 1742, was succeeded by Dr Bradley, who, though inferior as a mathematician, greatly exceeded him as a practical astronomer. He was the first who made observations with an accuracy sufficient to detect the lesser inequalities in the motions of the planets and fixed stars. Thus he discovered the aberration of light, the nutation of the earth's axis, and was able to make the lunar tables much more perfect than they had ever been. He also observed the places, and computed the elements of the comets which appeared in the years 1723, 1736, 1743, and 1757. He made new and most accurate tables of the motions of Jupiter's satellites, from his own observations and those of Dr Pound; and from a multitude of observations of the sun, moon, and stars, was enabled to give the most accurate table of mean refractions yet extant, as well as the best methods of computing the variations of those refractions arising from the different states of the air as indicated by the thermometer and barometer. In 1750, having procured a very large transit instrument made by Mr Bird, and a new mural quadrant of brass eight feet radius, he began to make observations with redoubled industry; so that betwixt this time and his death, which happened in 1762, he made observations for settling the places of all the stars in the British catalogue, together with near 1500 places of the moon, much the greater part of which he compared with the tables of Mr Mayer.

35 Improvements by the French astronomers.

In the mean time the French astronomers were assiduous in their endeavours to promote the science of astronomy. The theory of the moon, which had been given in a general way by Sir Isaac Newton, began to be particularly considered by Messrs Clairault, D'Alembert, Euler, Mayer, Simpson, and Walmsly; though Clairault, Euler, and Mayer, distinguished themselves beyond any of the rest, and Mr Euler has been particularly happy in the arrangement of his tables for the ease and expedition of computation. He was excelled in exactness, however, by Mayer, who published his tables in the Gottingen Acts for 1753. In these the errors in longitude never exceeded two minutes; and having yet farther improved them, he sent a copy to the lords of the British admiralty in 1755; and it was this copy which Dr Bradley compared with his observations, as already mentioned. His last corrections of them were afterwards sent over by his widow; for which she and her children received a reward of 3000l.

Accurate tables for Jupiter's satellites were also composed by Mr Wargentin, a most excellent Swedish astronomer, and published in the Upsal Acts in 1741; which have since been corrected by the author in such a manner as to render them greatly superior to any ever published before.

36 Of M. de la Caille.

Amongst the many French astronomers who contributed to the advancement of the science, we are particularly indebted to M. de la Caille, for a most excellent set of solar tables, in which he has made allowances for the attractions of Jupiter, Venus, and the moon. In 1750 he went to the Cape of Good Hope, in order to make observations in concert with the most celebrated astronomers in Europe, for determining the parallax of the moon, as well as of the planet Mars, and from thence that of the sun; from whence it appeared that the parallax of the sun could not greatly exceed 10 seconds. Here he re-examined and adjusted the places of the southern stars with great accuracy, and measured a degree of the meridian at that place. In Italy the science was cultivated with the greatest assiduity by Signior Bianchini, Father Boscovich, Frisi, Manfredi, Zanotti, and many others; in Sweden by Wargentin already mentioned, Blingenstern, Mallet, and Planman; and in Germany, by Euler elder and younger, Mayer, Lambert, Grischow, &c. In the year 1760 all the learned societies in Europe began to prepare for observing the transit of Venus over the sun, foretold by Dr Halley upwards of 80 years before it happened, showing, at the same time, the important use which might be made of it. Unfortunately, however, for the cause of science, many of the astronomers sent out to observe this phenomenon were prevented by unavoidable accidents from reaching the places of their destination, and others were disappointed by the badness of the weather. It happened also, that the circumstances of the phenomenon were much less favourable for the purpose of determining the sun's parallax than had been expected by Dr Halley, owing to the faults of the tables he had made use of: so that, notwithstanding all the labours of astronomers at that time, they were not able to determine the matter: and even after their observations in 1769, when the circumstances of the transit were more favourable, the parallax of the sun remained still uncertain.

Dr Bradley was succeeded in his office of astronomer-royal by Mr Bliss, Savilian professor of astronomy at Oxford; who, being in a very declining state of health at the time of his accession to the office, did not enjoy it long. He was succeeded by the learned Nevil Maskelyne, D. D. the present astronomer-royal, whose name will be rendered immortal by his assiduity and success in bringing the lunar method of determining the longitude at sea into general practice.

Such was the general state of astronomy, when Dr Herschel's great discovery of augmenting the power of telescopes, beyond the most sanguine hopes of astronomers, opened at once a scene altogether unlooked for. By this indefatigable observer we are made acquainted with a new primary planet attended by six secondaries belonging to our solar system; so that the latter now appears to have double the bounds formerly assigned to it; this new planet being at least twice the distance of Saturn from the sun. In the still farther distant celestial regions, among the fixed stars, his observations

vations

Digitized by Google

History. vations are equally surprising; of which we shall only say with Dr Priestley*, "Mr Herschel's late discoveries in and beyond the bounds of the solar system, the great views that he has given of the arrangement of the stars, their revolutions, and those of the immense systems into which they are formed, are peculiarly calculated to inspire an ardent desire of seeing so great a scene a little more unfolded. Such discoveries as these give us a higher idea of the value of our being, by raising our ideas of the system of which we are a part; and with this an earnest wish for the continuance of it."

* Exper. and Observ. vol. vi. Pref.

PART II. OF THE APPARENT MOTIONS OF THE HEAVENLY BODIES.

WHEN we cast our eyes up towards the heavens, we perceive a vast hollow hemisphere at an unknown distance, of which our eyes seem to constitute the centre. The earth stretches at our feet like an immense plain, and at a certain distance appears to meet and to bound the heavenly hemisphere. Now the circle all around, where the earth and the heavens seem to meet and touch each other, is called the *horizon*. We can scarcely avoid supposing, that besides the hemisphere which we perceive, there is another, exactly similar, concealed from our view by the earth, and that the earth, therefore, is somehow or other suspended in the middle of this heavenly sphere, with all its inhabitants. A little observation turns this suspicion into certainty. For in a clear evening the heavenly hemisphere is seen studded with stars, and its appearance is changing every instant. New stars are continually rising in the east, while others in the mean time are setting in the west. Those stars, that, towards the beginning of the evening, were just seen above the eastern horizon, late at night are seen in the middle of the starry hemisphere, and may be traced moving gradually westward, till at last they sink altogether under the horizon. If we look to the north, we soon perceive that many stars in that quarter never set at all, but move round and round, describing a complete circle in 24 hours. These stars describe their circles round a fixed point in the heavens; and the circles are the smaller, the nearer the star is to the fixed point. This fixed point is called the *north pole*. There must be a similar fixed point in the southern hemisphere, called the *south pole*. Thus the heavenly sphere appears to turn round two fixed points, called the poles, once every 24 hours. The imaginary line which joins the points is called the *axis* of the world.

37 Appearance of the heavens.

In order to have precise notions of the motions of the heavenly bodies, it is necessary to be able to assign precisely the place in which they are. This is done by means of several imaginary lines, or rather circles, supposed described upon the surface of the sphere; and these circles, as is usual with mathematicians, are divided into 360 equal parts called degrees. Every degree is divided into 60 minutes: every minute into 60 seconds, and so on. That great circle of the sphere, which is perpendicular to the axis of the world, and of course 90° distant from either pole, is called the *equator*. The smaller circles, which the stars describe in consequence of their diurnal motions, are called *parallels*, because they are obviously parallel to the equator.

The equator divides the heavenly sphere into two equal parts, the north and the south; but to be able to assign the position of the stars, it is necessary to have another circle, passing through the poles, and cutting the equator perpendicularly. This circle is called a *meridian*. It is supposed, not only to pass through the poles, but to pass also through the point directly over the head of the observer, and the point of the sphere exactly opposite to that. The first of these points is called the *zenith*, the second is called the *nadir*.

The meridian divides the circles described by the stars into two equal parts; and when they reach it they are either at their greatest height above the horizon, or they are at their least height. The situation of the pole is easily determined; for it is precisely half way between the greatest and least height of those stars which never set. When we advance towards the north we perceive that the north pole does not remain stationary, but rises towards the zenith, nearly in proportion to the space we pass over. On the other hand it sinks just as much when we travel towards the south. Hence we learn that the surface of the earth is not plane, as one would at first suppose, but curved.

All the heavenly bodies appear to describe a complete circle round the earth in 24 hours. But besides these motions which are common to them all, there are several of them which possess motions peculiar to themselves. The sun, the most brilliant of all the heavenly bodies, is obviously much farther to the south during winter than during summer. He does not, therefore, keep the same station in the heavens, nor describe the same circle every day. The moon not only changes her form, diminishes, and increases; but if we observe the stars, near which she is situated one evening, the next evening we shall find her considerably to the eastward of them; and every day she removes to a still greater distance, till in a month she makes a complete tour of the heavens, and approaches them from the west. There are eight other stars, besides, which are continually changing their place; sometimes we observe them moving to the westward, sometimes to the eastward, and sometimes they appear stationary for a considerable time. These stars are called *planets*. There are other bodies which appear only occasionally, move for some time with immense celerity, and afterwards vanish. These bodies are called *comets*. But the greater number of the heavenly bodies always retain nearly the same relative distance from each other, and are therefore called *fixed stars*. It will be necessary for us to consider the nature and apparent motions of all these bodies. We shall, therefore, divide this first part of our treatise, into the following heads: 38

38 Arrangement.

1. Of the Sun.
2. Of the Moon.
3. Of the Planets.
4. Of the Comets.
5. Of the Fixed Stars.
6. Of the figure of the Earth.

These topics shall be the subjects of the following chapters.

CHAP.

Chap. I. *Of the Sun.*

The sun, as the most conspicuous and most important of all the heavenly bodies, would naturally claim the first place in the attention of astronomers. Accordingly its motions were first studied, and they have had considerable influence on all the other branches of the science. We shall subdivide this part of our subject into three parts. In the first, we shall give an account of the apparent motions of the sun; in the second, we shall treat of the division of time, which is regulated by these apparent motions; and in the third, we shall consider the figure and structure of the sun, as far as they have been determined by astronomers. These shall be the subjects of the following sections.

Sect. I. *Apparent Motions of the Sun.*

39 Annual motion of the sun.

That the sun has a peculiar motion of its own, independent of the diurnal motion common to all the heavenly bodies, and in a direction contrary to that motion, is easily ascertained, by observing with care the changes which take place in the starry hemisphere during a complete year. If we note the time at which any particular star rises, we shall find that it rises somewhat sooner every successive day, till at last we lose it altogether in the west. But if we note it after the interval of a year, we shall find it rising precisely at the same hour as at first. Those stars which are situated nearly in the track of the sun, and which set soon after him, in a few evenings lose themselves altogether in his rays, and afterwards make their appearance in the east before sunrise. The sun then moves towards them in a direction contrary to his diurnal motion. It was by observations of this kind that the ancients ascertained his orbit. But at present this is done with greater precision, by observing every day the height of the sun when it reaches the meridian, and the interval of time which elapses between his passing the meridian and that of the stars. The first of these observations gives us the sun's daily motion northward or southward, in the direction of the meridian; and the second gives us his motion eastward in the direction of the parallels; and by combining the two together, we obviously obtain his orbit: But it will be necessary to be somewhat more particular.

40 Method of drawing a meridian line.

These observations cannot be made without drawing a meridian line, or a line, which, if produced, would pass through both the poles of the earth, and the spot where the observer is placed. It is obvious, that such a line is in the same plane with the meridian as the heavenly hemisphere. A meridian line may be found thus: On an horizontal plane describe three or four concentric circles, as E, G, H, fig. 1. Plate LIX. and in the common centre fix perpendicularly a wire CB, having a well-defined point. When the sun shines in the morning, observe where the shadow of the top of the wire, as CD, touches one of the circles; and in the afternoon mark where the extremity of the shadow CF just touches the same circle: then through the centre C draw the line CE, bisecting the arc DF, and CE will be a meridian, as required. If the same be done with as many of the circles as the shining of the sun will admit of, and the mean of all the bisecting lines CE be chosen as a meridian, there will be no doubt of its accuracy, particularly if the observations be made about midsummer, which is the best time. After a meridian line is thus found, another parallel to it may be readily drawn at any convenient distance: the method is this: Hang a thread and plummet exactly over the south end of the known meridian line, and let another thread and plummet be hung over the south end of the plane upon which a meridian is to be drawn; then let a person observe when the shadow of the thread falls on the given meridian, and immediately give a signal to another person, who must at that moment mark two points on the shadow of the second thread, through which two points the new meridian must be described.

Apparent Motions of the Heavenly Bodies.

41 Altitude of the sun.

The height of the sun from the horizon, when it passes the meridian, or the arch of the meridian between the sun and the horizon, is called the *sun's altitude*. The ancients ascertained the sun's altitude in the following manner: They erected an upright pillar at the south end of a meridian line, and when the shadow of it exactly coincided with that line, they accurately measured the shadow's length, and then, knowing the height of the pillar, they found, by an easy operation in plane trigonometry, the altitude of the sun's upper limb: whence, after allowing for the apparent semidiameter, the altitude of the sun's centre was known. But the methods now adopted are much more accurate. In a known latitude, a large astronomical quadrant, of six, eight, or ten feet radius, is fixed truly upon the meridian; the limb of this quadrant is divided into minutes, and smaller subdivisions, by means of a vernier; and it is furnished with a telescope (having cross hairs, &c. turning properly upon the centre). By this instrument the altitude of the sun's centre is very carefully measured, and the proper deductions made.

42 Method of ascertaining the sun's motion.

With a similar instrument we may ascertain the apparent motions of the sun in the following manner, beginning our observations about the 20th of March. On this day we must note some fixed star which comes to the meridian exactly at the same time as the sun does; for the stars may be seen in the daytime with an astronomical telescope. On the following day, both the altitude of the sun, and the situation of the stars when the sun is on the meridian, must be observed; the sun's meridian altitude will be about 23′ 40″ greater than on the former day, and the star will be found on the meridian about 3 m. 39 sec. in time before the sun. Make similar observations for a few days, and it will be found, at the end of a week, that the sun's meridian altitude will be increased 2° 46′, and the star will be on the meridian 25 m. 26 sec. in time before the sun, or it will be $6^\circ\ 21\frac{1}{3}'$ westward of the meridian when the sun is upon it. During this period of seven days, therefore, the sun has been moving towards the east, and has increased his altitude by regular gradations. In fig. 2. let EQ represent a portion of the equator, QS the meridian on which the sun is, QS his altitude above the equator, E the place of the star, and ES part of the path of the sun: then, in the spherical triangle EQS, right-angled at Q, there are given $EQ = 6^\circ\ 21\frac{1}{3}'$, and $QS = 2^\circ\ 46'$, to find the angle E. By the rules of spherical trigonometry, we have, tangt. of $E = \frac{\text{tangt. of SQ}}{\text{sine of QE}} = \frac{\cdot 0483250}{\cdot 1107463} = \cdot 4364479$,

Apparent Motions of the Heavenly Bodies.

·4364479=tangt. of 23° 34′ 43″, the angle E required.

43 Ecliptic.

The orbit in which the sun moves is called the *ecliptic*. It does not coincide with the equator, but cuts it, forming with it an angle, which in the year 1769 was determined by Dr Maskelyne, at 23° 28′ 10″, or 23°.46944. This angle is called the *obliquity of the ecliptic*.

44 Seasons explained.

The different seasons of the year are occasioned by the combination of this proper motion of the sun with his diurnal motion. The two points in which the ecliptic cuts the equator, are called the *equinoxes*, or *equinoctial points;* because on the days that the sun is in them, he describes by his diurnal motion the equator, which being divided into two equal parts by the horizon, the day is then equal to the night in every part of the earth. One of these equinoxes is called the *vernal*, because the sun is in it about the 20th of March, or the beginning of the spring. As the sun advances in his orbit from that point, his meridian altitude becomes greater and greater every day. The visible arches of the parallels which it describes, become continually greater; and with them the length of the day increases, till the sun reaches his greatest altitude, or distance from the equator: then the day is the longest of the year. And as at that period the variations in the sun's altitude are scarcely sensible for some time, as far at least as it affects the length of the day; the point of the orbit, where the sun's altitude is a maximum, has for that reason been called the *summer solstice*. The parallel which the sun describes when in that point, is called the *tropic of Cancer*. From the solstice the sun descends again towards the equator, crosses it again at the autumnal equinox, and goes southward till its altitude becomes a minimum. This point of the orbit is called the *winter solstice*. The day is then the shortest of the year, and the parallel which the sun describes, is called the *tropic of Capricorn*. From the winter solstice the sun again approaches the equator, and returns to the vernal equinox.

Such is the constant course of the sun and of the seasons. The interval between the vernal equinox and the summer solstice, is called the *spring;* the interval between this solstice and the autumnal equinox, is called *summer;* that between the autumnal equinox and the winter solstice, is *autumn;* and that between this solstice and the vernal equinox, is *winter*.

The different altitudes of the pole in different climates, occasion remarkable peculiarities in the seasons, with which it is proper to be acquainted. At the equator the poles are situated in the horizon, which last circle cuts all the parallels into two equal parts. Hence the day and the night are constantly of the same length all the year round. On the equinoxes the sun is in the zenith at noon. His altitude is the least possible at the solstices, and is then equal to the complement of the inclination of the ecliptic. During the summer solstice, the shadows of bodies illuminated by the sun are directed towards the south; but they are directed towards the north at the winter solstice; changes which never take place in our northern climates. Under the equator then there are in reality two summers and two winters. The same thing takes place in all countries lying between the tropics. Beyond them there is only one summer and one winter in the year. The sun is never in the zenith. The length of the longest day increases, and that of the shortest day diminishes, as we advance toward the poles; and when the distance between the zenith and the pole is only equal to the inclination of the ecliptic, the sun does not set at all on the days of the summer solstice, nor rise on that of the winter solstice. Still nearer the pole, the period in which he never sets in summer, and never rises in winter, gradually increases from a few days to several months; and, under the pole itself, the equator then coinciding with the horizon, the sun never sets when it is upon the same side of the equator with the pole, and never rises while it is in the opposite side.

The intervals of time between the equinoxes and solstices are not equal. There are about seven days more between the vernal and autumnal equinox, than between the autumnal and vernal. Hence we learn, that the motion of the sun in its orbit is not uniform. Numerous observations, made with precision, have ascertained, that the sun moves fastest in a point of his orbit situated near the winter solstice, and slowest in the opposite point of his orbit near the summer solstice. When in the first point, the sun moves in 24 hours 1°.01943; in the second point, he moves only 0°.95319. The daily motion of the sun is constantly varying in every place of its orbit, between these two points. The medium of the two is 0°.98632, or 59′ 11″, which is the daily motion of the sun about the beginning of October and April. It has been ascertained, that the variation in the angular velocity of the sun, is very nearly proportional to the mean angular distance of it from the point of its orbit where its velocity is greatest. 45 Motion not uniform.

It is natural to think, that the distance of the sun from the earth varies as well as its angular velocity. This is demonstrated by measuring the apparent diameter of the sun. Its diameter increases and diminishes in the same manner, and at the same time, with its angular velocity; but in a ratio twice as small. About the beginning of January, his apparent diameter is about 32′ 39″, and at the beginning of July it is about 31′ 34″, or more exactly, according to De la Place, 32′ 35″=1955″ in the first case, and 31′ 18″=1878″ in the second. 46 Diameter varies.

Opticians have demonstrated, that the distance of any body is always reciprocally as its apparent diameter. The sun must follow the same law; therefore, its distance from the earth increases in the same proportion that its apparent diameter diminishes. That point of the orbit in which the sun is nearest the earth, is called *perigeon*, or *perigee;* and the point of the orbit in which that luminary is farthest distant from the earth, is called *apogee*. When the sun is in the first of these points, his apparent diameter is greatest, and his motion swiftest; but when he is in the other point, both his diameter and the rapidity of his motion are the smallest possible. 47 Sun's distance varies.

From these remarks it is obvious that if the orbit of the sun be a circle, the earth is not situated in the centre of that circle, otherwise the distance of the sun from the earth would remain always the same, which is contrary to fact. It is possible therefore, that the variation in his angular velocity may not be *real*, but only apparent. Thus in fig. 3. let AMPN be the orbit

Apparent Motions of the Heavenly Bodies.

orbit of the sun, C the centre of that orbit, and E the position of the earth at some distance from the centre. It is obvious that P is the sun's perigee, and A its apogee. Now as the sun's apparent orbit is a circle having the earth in its centre, it is evident that this orbit must be AMPN, and that the angular motion of the sun will be measured upon that circle. Suppose now that the sun in his apogee moves from A to A′, it is obvious that his apparent or angular motion will be the segment *a a′* of the apparent orbit, considerably smaller than AA′, so that at the apogee the angular motion of the sun will be less than his real motion. Again: let the sun in his perigee move from P to P′, describing a segment precisely equal to the segment AA′. This segment as seen from the earth will be referred to *p p′*, which in that case will be the sun's angular motion, evidently considerably greater than his real motion.

Hence it is obvious that even on the supposition that the sun moved equably in his orbit, his angular motion as seen from the earth would still vary, that is, would be smallest at the apogee, and greatest at the perigee; and that the angular and real motion would only coincide in the points M and N, where the real and apparent orbits cut each other. From the figure it is obvious also, that the angular velocity would increase gradually from the apogee to the perigee, and diminish gradually from the perigee to the apogee, which likewise corresponds with observation. Now the line EC, which is the distance of the earth from the centre of the sun's orbit, is called the *eccentricity* of that orbit. The variation in the angular motion of the sun may be owing to this eccentricity.

48 Sun's motion varies.

But if it were owing to this cause alone, it is easy to demonstrate that in that case the diminution of his angular velocity would follow the same ratio as the diminution of his diameter. The fact however is, that the angular velocity diminishes in a ratio twice as great as the diameter of the sun does. The variation of the angular velocity cannot then be owing to the eccentricity alone. Hence it follows, that the variation of the motion of the sun is not merely apparent, but real; and that its velocity in its orbit actually diminishes, as his distance from the earth increases. Two causes then combine to produce the variation in the sun's angular velocity; namely, 1. The increase and diminution of his distance from the earth; and, 2. The real increase and diminution of his velocity in proportion to this variation of distance. These two causes combine in such a manner that the daily angular motion of the sun diminishes as the square of his distance increases, so that the product of the angular velocity multiplied into the square of the distance is a constant quantity. But this law is so important that it will be necessary to be more particular.

The observation that the sun's angular motion in his orbit is inversely proportional to the square of his distance from the earth, was first made by Kepler. The discovery was made by a careful comparison of the sun's diurnal motion with his apparent diameter, which were found to follow that law; and it is evident that the one is the angular motion of the sun, and the other his distance from the earth, which is inversely proportional to his apparent diameter. Let ASB (fig. 4.) be the sun's orbit, E the earth, and S the sun. Suppose a line ES joining the centres of the earth and sun to move round along with the sun. This line is called the *radius vector*. It is obvious, that when S moves to S′, ES, moving along with it, is now in the situation ES′, having described the small sector ESS′. In the same time that S performs one revolution in its orbit, the radius vector ES will describe the whole area ABS, enclosed within the sun's orbit. Let SS′ be the sun's angular motion during one day. It is obvious that the small sector ESS′ is proportional to the square of ES, multiplied by SS′: for the radius vector is the sun's distance from the earth, and SS′ his angular motion. Hence this sector is a constant quantity, whatever the angular motion of the sun be; and the whole area SEA increases as the number of days which the sun takes in moving from S to A. Hence results that remarkable law, first pointed out by Kepler, that *the areas described by the radius vector are proportional to the times*. Suppose the sun to describe SS′ in one day, and SA in 20 days, then the area SES′ is to the area SEA as 1 to 20; or the area SEA is 20 times greater than the area SES′.

49 Describes areas proportional to the times.

The knowledge of these facts enables us to draw upon paper, from day to day, lines proportional to the length of the radius vector of the solar orbit, and having the same relative position as these lines. If we join the extremity of these lines, by making a curve pass through them, we shall perceive that this curve is not exactly circular. Let E in fig. 5. represent the earth, and E *a*, E *b*, E *c*, E *d*, E *f*, &c. the position and length of the radius vector during every day of the year: if we join together the points *a*, *b*, *c*, *d*, *e*, *f*, *g*, *h*, *i*, *k*, *l*, *m*, *n*, *o*, by drawing the curve *a e i m*, through them, it is obvious that this curve is not a circle, but elongated towards *a* and *i*, the points which represent the sun's greatest and least distance from the earth. The resemblance of this curve to the ellipse induced Kepler to compare them together, and he ascertained their identity. Hence it follows, that the orbit of the sun is an *ellipse*, having the earth in one of its foci. The centre C of the ellipse is the point where its greater axis is cut perpendicularly by its smaller axis. The distance CE, between the earth and that centre, is the eccentricity of the sun's orbit. The eccentricity of this orbit is not great. Let the earth's mean distance from the sun be represented by 10,000; it has been ascertained that the eccentricity is equal to 168 of these parts. Hence the sun's orbit does not differ much from a circle.

50 His orbit an ellipse.

To form a precise notion of the elliptical motion of the sun, let us suppose a point to move uniformly in the circumference of a circle, whose centre coincides with the centre of the earth, and whose radius is equal to the sun's distance from the earth when in his perigee. Let us suppose also, that the sun and the point set out together from the perigee, and that the motion of the point is equal to the sun's mean angular motion. While the radius vector of the point moves uniformly round the earth, the radius vector of the sun moves with unequal velocity, describing always areas proportional to the times. At first it gets before the radius vector of the point, and forms with it an angle, which, after having increased till it reached a certain limit, diminishes again and becomes equal to zero, when the sun is in apogee; then the radius vector of the sun and of the point

Apparent Motions of the Heavenly Bodies.

point coincide both with each other, and with the greater axis of the ellipse. After passing the apogee the radius vector of the point gets before that of the sun, and forms with it angles exactly equal to the angles formed by the same lines in the former half of the ellipse, at the same distance from the perigee. At the perigee, the radius vector of the sun and of the point again coincide with each other, and with the greater axis of the ellipse. The angle which the radius vector of the sun makes with that of the point, which indicates how much the one precedes the other, is called the *equation of the centre*. It is always greatest when the motions of the point and of the sun are equal, and it vanishes altogether when there is the greatest difference between these motions. The angular motion of the point is called the *mean motion*, and that of the sun the *real motion*. The place of the point in the orbit is called the *mean place*. Now, if to the mean place in the orbit, we add or subtract the equation of the centre, it is obvious that we have the sun's real place for any given time. The angular motion of the point is known with precision for a given time, a day for instance, by ascertaining the exact length of time which the sun takes in making a complete revolution round its orbit. For if we ascertain how many days that revolution requires, we have only to divide the whole orbit by that number to prove the portion of it traversed by the point in one day. The equation of the centre can only be found by approximation. Its maximum in the year 1750 was $1^{\circ}.9268$.

51 Equation of the centre explained.

In computations we begin always at that part of the orbit where the motion of the sun is slowest. The distance of the imaginary point from that part, is called the *mean anomaly*. A table is made of the equation of the centre, corresponding to each degree of the mean anomaly. By adding or subtracting these equations from the mean anomaly, we obtain the true anomaly or place of the sun for any given time.

52 Signs of the zodiac.

The ecliptic is usually divided, by astronomers, into 12 equal parts, called signs, each of which of course contains 30 degrees. They are usually called the signs of the zodiac; and beginning at the equinox, where the sun intersects and rises above the equator, have these names and marks: Aries ♈, Taurus ♉, Gemini ♊, Cancer ♋, Leo ♌, Virgo ♍, Libra ♎, Scorpio ♏, Sagittarius ♐, Capricornus ♑, Aquarius ♒, Pisces ♓. Of these signs, the first six are called *northern*, lying on the north side of the equator; the last six are called *southern*, being situated to the south of the equator. The signs from Capricornus to Gemini are called *ascending*, the sun approaching or rising to the north pole while it passes through them; and the signs from Cancer to Sagittarius are called *descending*, the sun, as it moves through them, receding or descending from the north pole.

The *longitude* of the sun is his distance in the ecliptic from the first point of Aries. His *right ascension* is the arch of the equator intercepted between the first point of Aries, and the meridian circle which passes through his longitude. The distance of the sun from the equator, measured upon a meridian circle, is called his *declination*, and it is either north or south according to the situation of the sun.

53 Orbit varies in position.

It has been observed that the position of the larger axis of the elliptical orbit of the sun, is not constant. The angular distance of the perigee from the vernal equinox, counted according to the sun's movement, was $278^{\circ}.6211$ at the beginning of 1750; but it has, relative to the stars, an annual motion of about $11''.89$ in the same direction as the sun.

The orbit of the sun is gradually approaching to the equator. Its obliquity diminishes in a century at the rate of about $1''.50$.

The precision of modern astronomers has enabled them to ascertain small irregularities in the sun's elliptical motion, which observation alone would scarcely have been able to bring under precise laws. These irregularities will be considered afterwards.

54 Distance of the sun.

To determine the distance of the sun from the earth, has always been an interesting problem to astronomers, and they have tried every method which astronomy or geometry possesses in order to resolve it. The amplest and most natural, is that which mathematicians employ to measure distant terrestrial objects. From the two extremities of a base whose length is known, the angles which the visual rays from the object, whose distance is to be measured, make with the base, are measured by means of a quadrant; their sum subtracted from 180°, give the angle which these rays form at the object where they intersect. This angle is called the *parallax*, and when it is once known, it is easy, by means of trigonometry, to ascertain the distance of the object. Let AB, in fig. 6. be the given base, and C the object whose distance we wish to ascertain. The angles CAB and CBA, formed by the rays CA and CB with the base, may be ascertained by observation; and their sum subtracted from 180° leaves the angle ACB, which is the parallax of the object C. It gives us the apparent size of the base AB as seen from C.

When this method is applied to the sun, it is necessary to have the largest possible base. Let us suppose two observers on the same meridian, observing at the same instant the meridian altitude of the centre of the sun, and his distance from the same pole. The difference of the two distances observed, will be the angle under which the line which separates the observers will be seen from the centre of the sun. The position of the observers gives this line in parts of the earth's radius. Hence, it is easy to determine, by observation, the angle at which the semidiameter of the earth would be seen from the centre of the sun. This angle is the sun's *parallax*. But it is too small to be determined with precision by that method. We can only conclude from it, that the sun's distance from the earth is at least equal to 10,000 diameters of the earth. We shall find afterwards, that other methods have been discovered for finding the parallax with much greater precision. It amounts very nearly to $8''.8$: hence it follows, that the distance of the sun from the earth amounts to 23,405 semi-diameters of the earth.

Sect. II. *Of the Division of Time.*

Motion is peculiarly adapted for measuring time. For, as a body cannot be in different places in the same time, it can only arrive from one part to another, by passing successively through all the intermediate spaces. And if it be possible to ascertain, that in every point of the line which it describes it is actuated by the very same force, we can conclude with confidence, that it will

Apparent Motions of the Heavenly Bodies.

will describe the line with a uniform motion. Of course the different parts of the line will be a measure of the time employed to traverse them. When a pendulum at the end of every oscillation is precisely in the same circumstances, the length of the oscillations is the same, and time may be measured by their number. We might employ also, for the same purpose, the revolutions of the heavenly sphere, which appear perfectly uniform. But all nations have agreed to employ the revolutions of the sun for that purpose.

55
Astronomical day.

In common language, the *day* is the interval of time which elapses from the rising to the setting of the sun; the *night* is the interval that the sun continues below the horizon. The *astronomical day* embraces the whole interval which passes during a complete revolution of the sun. It is the interval of time which passes from 12 o'clock at noon, till the next succeeding noon. It begins when the sun's centre is on the meridian of that place. It is divided into 24 hours, reckoning in a numerical succession from 1 to 24: the first 12 are sometimes distinguished by the mark P. M. signifying *post meridiem*, or after noon; and the latter 12 are marked A. M. signifying *ante meridiem*, or before noon. But astronomers generally reckon through the 24 hours from noon to noon; and what are by the civil or common way of reckoning, called morning hours, are by astronomers reckoned in the succession from 12, or midnight, to 24 hours. Thus 9 o'clock in the morning of February 14th, is, by astronomers, called February the 13th at 21 hours.

56
Sidereal day.

An astronomical day is somewhat greater than a complete revolution of the heavens, which forms a *sidereal day*. For if the sun cross the meridian at the same instant with a star, the day following it will come to the meridian somewhat later than the star, in consequence of its motion eastward, which causes it to leave the star; and after a whole year has elapsed, it will have crossed the meridian just one time less than the star. A sidereal day is less than the solar day, for it is measured by 360°, whereas the mean solar day is measured by $360^\circ\ 59'\ 8''$ nearly. If an astronomical day be $=1$, then a sidereal day is $=0.997269722$; or the difference between the measures of a mean solar day, and a sidereal day, viz. $59'\ 8''$, reduced to time, at the rate of 24 hours to 360°, gives $3'\ 56''$; from which we learn that a star which was on the meridian with the sun on one noon, will return to that meridian $3'\ 56''$ previous to the next noon: therefore, a clock which measures mean days by 24 hours, will give 23 h. 56 m. 4 sec. for the length of a sidereal day.

57
Days vary in length.

Astronomical or solar days, as they are also called, are not equal. Two causes conspire to produce their inequality, namely, the unequal velocity of the sun in his orbit, and the obliquity of the ecliptic. The effect of the first cause is sensible. At the summer solstice, when the sun's motion is slowest, the astronomical day approaches nearer the sidereal, than at the winter solstice when his motion is most rapid.

To conceive the effect of the second cause, it is necessary to recollect that the excess of the astronomical day above the sidereal is owing to the motion of the sun, referred to the equator. The sun describes every day a small arch of the ecliptic. Through the extremities of this arch suppose two meridian great circles drawn, the arc of the equator, which they intercept, is the sun's motion for that day referred to the equator; and the time which that arc takes to pass the meridian is equal to the excess of the astronomical day above the sidereal. But it is obvious, that at the equinoxes, the arc of the equator is smaller than the corresponding arc of the eclptic in the proportion of the cosine of the obliquity of the ecliptic to radius: at the solstices, on the contrary, it is greater in the proportion of radius to the cosine of the same obliquity. The astronomical day is diminished in the first case, and lengthened in the second.

58
Mean astronomical day.

To have a mean astronomical day, independent of these causes of inequality, astronomers have supposed a second sun to move uniformly on the ecliptic, and to pass over the extremities of the axis of the sun's orbit, at the same instant with the real sun. This removes the inequality arising from the inequality of the sun's motion. To remove the inequality arising from the obliquity of the ecliptic, astronomers suppose a third sun passing through the equinoxes at the same instant with the second sun, and moving along the equator in such a manner that the angular distances of the two suns at the vernal equinox shall be always equal. The interval between two consecutive returns of this third sun to the meridian forms the *mean astronomical day*. *Mean time* is measured by the number of the returns of this third sun to the meridian; and true time is measured by the returns of the real sun to the meridian. The arc of the equator, intercepted between two meridian circles drawn through the centres of the true sun, and the imaginary third sun, reduced to time, is what is called the *equation of time*. This will be rendered plainer by the following diagram.

Let Z♈♋♎ (fig. 7.) be the earth; ZFR♋ its axis; *abcde*, &c. the equator; ABCDE, &c. the northern half of the ecliptic from ♈ to ♎, on the side of the globe next the eye; and MNOP, &c. the southern half on the opposite side from W to ♈. Let the points at A, B, C, D, E, F, &c. quite round from ♈ to ♈ again bound equal portions of the ecliptic, gone through in equal times by the real sun; and those at *a*, *b*, *c*, *d*, *e*, *f*, &c. equal portions of the equator described in equal times by the fictitious sun; and let Z♈♋ be the meridian.

As the real sun moves obliquely in the ecliptic, and the fictitious sun directly in the equator, with respect to the meridian; a degree, or any number of degrees, between ♈ and F on the ecliptic, must be nearer the meridian Z♈♋, than a degree, or any corresponding number of degrees, on the equator from ♈ to *f*; and the more so, as they are the more oblique: and therefore the true sun comes sooner to the meridian every day whilst he is in the quadrant ♈ F, than the fictitious sun does in the quadrant ♈ *f*; for which reason, the solar noon precedes noon by the clock, until the real sun comes to F, and the fictitious to *f*; which two points, being equidistant from the meridian, both suns will come to it precisely at noon by the clock.

Whilst the real sun describes the second quadrant of the ecliptic FGHIKL from Cancer to ♎, he comes later to the meridian every day than the fictitious sun moving through the second quadrant of the equator from *f* to ♎; for the points at G, H, I, K, and L, being farther from the meridian, their corresponding points at *g*, *h*, *i*, and *l*, must be later of coming to it;

and

Apparent Motions of the Heavenly Bodies.

and as both suns come at the same moment to the point W, they come to the meridian at the moment of noon by the clock.

In departing from Libra, through the third quadrant, the real sun going through MNOPQ towards ♑ at R, and the fictitious sun through *m n o p q* towards *r*, the former comes to the meridian every day sooner than the latter, until the real sun comes to ⊙, and the fictitious to *r*, and then they come both to the meridian at the same time.

Lastly, As the real sun moves equably through STUVW, from ⊙ towards ♈; and the fictitious sun through *s t u v w*, from *r* towards ♈, the former comes later every day to the meridian than the latter, until they both arrive at the point ♈, and then they make it noon at the same time with the clock.

Having explained one cause of the difference of time shown by a well-regulated clock and a true sun-dial, supposing the sun, not the earth, as moving in the ecliptic; we now proceed to explain the other cause of this difference, namely, the inequality of the sun's apparent motion; which is slowest in summer, when the sun is farthest from the earth, and swiftest in winter when he is nearest to it.

If the sun's motion were equable in the ecliptic, the whole difference between the equal time as shown by the clock, and the unequal time as shown by the sun, would arise from the obliquity of the ecliptic. But the sun's motion sometimes exceeds a degree in 24 hours, though generally it is less: and when his motion is slowest, any particular meridian will revolve sooner to him than when his motion is quickest; for it will overtake him in less time when he advances a less space than when he moves through a larger.

Now, if there were two suns moving in the plane of the ecliptic, so as to go round it in a year; the one describing an equal arc every 24 hours, and the other describing sometimes a less arc in 24 hours, and at other times a larger, gaining at one time of the year what it lost at the opposite; it is evident, that either of these suns would come sooner or later to the meridian than the other, as it happened to be behind or before the other; and when they were both in conjunction, they would come to the meridian at the same moment.

As the real sun moves unequably in the ecliptic, let us suppose a fictitious sun to move equably in a circle coincident with the plane of the ecliptic. Let ABCD (fig. 8.) be the ecliptic or orbit in which the real sun moves, and the dotted circle *a b c d* the imaginary orbit of the fictitious sun; each going round in a year according to the order of letters, or from west to east. Let HIKL be the earth turning round its axis the same way every 24 hours; and suppose both suns to start from A and *a*, in a right line with the plane of the meridian EH, at the same moment: the real sun at A, being then at his greatest distance from the earth, at which time his motion is slowest; and the fictitious sun at *a*, whose motion is always equable, because his distance from the earth is supposed to be always the same. In the time that the meridian revolves from H to H again, according to the order of the letters HIKL, the real sun has moved from A to F; and the fictitious with a quicker motion from *a* to *f*, through a large arc: therefore, the meridian EH will revolve sooner from H to *h* under the real sun at F, than from HE to *k* under the fictitious sun at *f*; and consequently it will then be noon by the sun-dial sooner than by the clock.

As the real sun moves from A towards C, the swiftness of his motion increases all the way to C, where it is at the quickest. But notwithstanding this, the fictitious sun gains so much upon the real, soon after his departing from A, that the increasing velocity of the real sun does not bring him up with the equally-moving fictitious sun till the former comes to C, and the latter to *c*, when each has gone half round its respective orbit; and then being in conjunction, the meridian EH, revolving to EK, comes to both suns at the same time, and therefore it is noon by them both at the same moment.

But the increased velocity of the real sun now being at the quickest, carries him before the fictitious one; and therefore, the same meridian will come to the fictitious sun sooner than to the real: for whilst the fictitious sun moves from *a* to *g*, the real sun moves through a greater arc from C to G: consequently the point K has its noon by the clock when it comes to *k*, but not its noon by the sun till it comes to *l*. And although the velocity of the real sun diminishes all the way from C to A, and the fictitious sun by an equable motion is still coming nearer to the real sun, yet they are not in conjunction till the one comes to A and the other to *a*, and then it is noon by them both at the same moment.

True time is obtained by adding or subtracting this equation to the mean time. The mean and apparent solar days are never equal, except when the sun's daily motion in right ascension is 59′ 8″; this is nearly the case about April 15th, June 15th, September 1st, and December 24th: on these days the equation is nothing, or nearly so; it is at the greatest about November 1st, when it is 16 m. 14 sec.

59 Year.

The return of the sun to the same equinox marks the years, in the same way as his return to the same meridian indicates the days. It has been ascertained, that before the sun returns again to the same equinox, an interval of 365.242222 days elapses, or 365 days, 5 hours, 48 minutes, and 47 seconds. This is called the *tropical year:* The sun takes a larger interval of time to return again to the same star. The *sidereal year* is the interval which the sun employs to return from one star to another. It is greater than the tropical year by 0.014162 days, or 20 m. 23 sec.; therefore the length of the sidereal year is 365 days, 6 h. 9 m. and 10 sec. From this it follows, that the equinoxes do not retain the same place in the ecliptic, but that they have a retrograde motion, or contrary to that of the sun, in consequence of which they describe every year an arc equal to the mean space which the sun passes over in 20′ 23″, or about 50″; so that they would make a complete revolution in 25972 years. This is called the *precession of the equinoxes.*

60 Method of computing the equation of time.

Dr Maskelyne has invented a rule for computing the equation of time, in which the precession of the equinoxes, as well as the two causes mentioned above, are included. Let APLQ, fig. 9. be the ecliptic, ALQ the equator, A the first point of Aries, P the point where the sun's apparent motion is slowest, S any place of the sun; draw S *v* perpendicular to the equator,

Apparent Motions of the Heavenly Bodies.

equator, and take $An = AP$. When the sun begins to move from P, suppose a star to begin to move from n, with the sun's mean motion in right ascension or longitude, viz. at the rate of 59′ 8″ in a day, and when n passes the meridian let the clock be adjusted to 12. Take $nm = Ps$, and when the star comes to m, if the sun moved uniformly with his mean motion, he would be found at s; but at that time let S be the place of the sun. Let the sun S, and consequently v, be on the meridian; and then as m is the place of the imaginary star at that instant, mv must be the equation of time. The sun's mean place is at s, and as $An = AP$, and $nm = Ps$, we have $Am = APs$, consequently $mv = Av - Am = Av - APs$. Let a be the mean equinox, or the point where it would have been if it had moved with its mean velocity, and draw az perpendicular to AQ; then $Am = Az + zm = Aa \times \text{cosine } zAa + zm$: or because the cosine of zAa the obliquity of the ecliptic, 23° 28′, is $= \frac{11}{12}$ very nearly, $Am = \frac{11}{12}Aa + zm$: hence $mv = Av - zm - \frac{11}{12}Aa$. Here Av is the sun's true right ascension, zm the mean right ascension or mean longitude; and $\frac{11}{12}Aa$ (viz. Ax) is the equation of the equinoxes in right ascension; therefore the equation of time is equal to the difference of the sun's true right ascension and his mean longitude, corrected by the equation of the equinoxes in right ascension.—When Am is less than Av, mean or true time precedes apparent; when it is greater, apparent time precedes mean. That is, when the sun's true right ascension is greater than his mean longitude corrected as above shewn, we must add the equation of time to the apparent to obtain the mean time; and when it is less, we must subtract. To convert mean time into apparent, we must subtract in the former case, and add in the latter.

Tables of the equation of time are computed by this rule, for the use of astronomers: they are either calculated for the noon of each day, as given in the Nautical and some other almanacks; or for every degree of the sun's place in the ecliptic. But a table of this kind will not answer accurately for many years, on account of the precession and other causes, which render a frequent revisal of the calculations necessary.

61 Smaller divisions of time.

The smaller divisions of time were anciently measured by the phases of the moon. It is well known that the moon changes once every 29 or 30 days, and that the interval from one new moon to another is called a *lunation*, or, in common language, a *month*. There are about twelve lunations in a year. Hence the year was divided into twelve months. In ancient times people were placed upon eminences on purpose to watch the first appearance of the new moon, when their month began. It was customary for these persons to proclaim the first appearance of the moon. Hence the first day of every month was called *Calendæ*; from which term the word calendar is derived. Almost all nations have divided the year into twelve months, because the seasons nearly return in that period. But they soon perceived that twelve lunar months were far from making a complete year or revolution of the sun. They were anxious, however, to be able to divide the solar year into a precise number of lunar months, because many of the feasts depended upon particular new moons. Various contrivances were fallen upon for this purpose without much success, till at last Meton, a Greek philosopher, announced that 19 years contained exactly 235 lunations: an affirmation which is within $2\frac{1}{8}$ hours of being exact. To make every year correspond as nearly as possible to the lunar, he divided the year into 12 months, consisting alternately of 30 and 29 days each; at the end of every three years an intercalary month of 30 days was added, and at the end of the 19th year there was added an intercalary month of 29 days. So that at the end of 19 years the solar and lunar years began again on the same day their cycle of 19 years. This discovery of Meton appeared so admirable to the Greeks, that they engraved it in letters of gold in their public places. Hence the number which denotes the current year of that cycle is denominated *golden number*.

As the moon changes its appearance in a very remarkable degree every seven days, almost all nations have subdivided the month into periods of seven days, called *weeks*; the ancient Greeks were almost the only people who did not employ that division.

62 Roman year.

The Roman year in the time of Romulus consisted of 10 months only, of 30 or 31 days each, so that its length was 304 days only. Numa added 50 days to that year, and thus made it 354 days; and he added two additional months of 29 and 28 days by shortening some of the ancient months. He made the year commence on the first of January. Numa's year was still more than 11 days shorter than a complete revolution of the sun. To make it correspond with the seasons, it was necessary to intercalate three days; and these intercalations being left entirely to the priests, were converted into a state engine; being omitted, inserted, altered, and varied, as it suited the purposes of those magistrates whose views they favoured. The consequence was, what might have been expected, the most complete confusion and want of correspondence between the year and the seasons.

63 Reformed by Julius Cæsar,

Julius Cæsar undertook to remedy this inconvenience. He was both dictator and high pontiff, and of course the reformation of the calendar was his peculiar province. That the undertaking might be properly executed, he invited Sosigenes, an Egyptian mathematician, to come to his assistance. It was agreed upon to abandon the motions of the moon altogether, and to make the year correspond with those of the sun.

The reformation was made in the year 47 before the Christian era. Ninety days were added to that year, which was from that circumstance called *the year of confusion*, consisting of 445 days. Instead of 354 days, the year of Numa, Sosigenes made the year to consist of 365 days, dispersing the additional days among those months which had only 29 days. As the revolution of the sun employs nearly six hours more than 365 days, an additional day was intercalated every fourth year, so that every such year was to consist of 366 days. The additional day was inserted after the 23d of February, or the 7th before the calends of March; the day before the annual feast celebrated in commemoration of the flight of Tarquin from Rome. That feast was held the 6th before the calends of March.

The

Apparent Motions of the Heavenly Bodies.

The intercalated day was also called the 6th before the calends of March. So that every fourth year there were two days denominated the 6th before the calends of March. Hence that year was called *bissextile*. In Britain it is denominated *leap year*. After the death of Julius Cæsar there was a degree of confusion respecting the intercalations, from the ignorance of the priests. Augustus corrected the mistake, and after that time the Julian period went on without any interruption.

It is obvious that the Julian year, though a great improvement upon the ancient Roman, was still imperfect. It went on the supposition that the revolution of the sun occupied precisely 365 days and 6 hours, which is about 11 minutes more than the truth. This error in the interval which elapsed between the reformation of Julius Cæsar and the year 1582, had accumulated till it amounted to 10 days; of course the year began 10 days later than it ought to have begun; and the same error had taken place respecting the seasons and the equinoctial points. Various attempts had been made to correct this error; at last it was corrected by Pope Gregory XIII. The Gregorian calendar commenced in the year 1582; the changes which he introduced were two in number. He ordered, that after the 4th of October 1582, ten days should be omitted, so that the day which succeeded the 4th was reckoned not the 5th but the 15th of the month. This corrected the error which had crept into the Julian year. To prevent any such error from accumulating again, he ordered that the secular years 1700, 1800, 1900, should not be bissextile but common years; that the secular year 2000 should be bissextile, the next three secular years common, the fourth again bissextile, and so on, as in the following table.

64 and by Gregory XIII.

1600 bissextile.	2100 common.	2600 common.
1700 common.	2200 ib.	2700 ib.
1800 ib.	2300 ib.	2800 bissextile.
1900 ib.	2400 bissextile.	2900 common.
2000 bissextile.	2500 common.	3000 ib.

In short these secular years only are bissextile whose number, omitting the cyphers, is divisible by 4.

The Gregorian calendar is sufficiently exact for the purposes of common life, though it does not correspond precisely with the revolution of the sun. The error will amount to a day in 3600 years, so that in the year 5200 it will be necessary to omit the additional day which ought to be added according to the rule laid down above.

The Gregorian calendar was immediately adopted by all the Roman Catholic kingdoms in Europe, but the Protestant states refused at first to accede to it. It was adopted by most of them on the continent about the beginning of the 18th century; but in England the change did not take place till 1752. From that year 11 days were omitted; the omission of the additional day in 1700 having made the difference between the Julian and Gregorian calendar amount to 11 days. The Julian calendar is called the *old style*, the Gregorian, the *new style*. At present the difference between them is 12 days, in consequence of the omission of the additional day in 1800.

Sect. III. *Of the Nature of the Sun.*

Apparent Motions of the Heavenly Bodies.

The smallness of the sun's parallax is a demonstration of its immense size. We are certain that at the distance at which the sun appears to us under an angle of $0^{\circ}.53424$, the earth would be seen under an angle not exceeding $0^{\circ}.009$. Now, as the sun is obviously a spherical body as well as the earth; and as spheres are to each other as the cubes of their diameters, it follows from this, that the sun is at least 200,000 times bigger than the earth. By the exactest observations it has been ascertained, that the diameter of the sun is nearly 883,000 miles.

Dark spots are very frequently observed upon the surface of the sun. These were entirely unknown before the invention of telescopes, though they are sometimes of sufficient magnitude to be discerned by the naked eye, only looking through a smoked glass to prevent the brightness of the luminary from destroying the sight. The spots are said to have been first discovered in the year 1611; and the honour of the discovery is disputed betwixt Galileo and Scheiner, a German Jesuit at Ingolstadt. But whatever merit Scheiner might have in the priority of the discovery, it is certain that Galileo far exceeded him in accuracy, though the work of Scheiner has considerable merit, as containing observations selected from above 3000, made by himself. Since his time the subject has been carefully studied by all the astronomers in Europe.

65 Solar spots when first discovered.

There is great variety in the magnitudes of the solar spots; the difference is chiefly in superficial extent of length and breadth; their depth or thickness is very small; some have been so large, as by computation to be capable of covering the continents of Asia and Africa; nay, the whole surface of the earth, or even five times its surface. The diameter of a spot, when near the middle of the disk, is measured by comparing the time it takes in passing over a cross hair in a telescope, with the time wherein the whole disk of the sun passes over the same hair; it may also be measured by the micrometer; and by either of these methods we may judge how many times the diameter of the spot is contained in the diameter of the sun. Spots are subject to increase and diminution of magnitude, and seldom continue long in the same state. They are of various shapes; most of them having a deep black nucleus surrounded by a dusky cloud, whereof the inner parts near the black are a little brighter than the outskirts. They change their shapes, something in the manner that our clouds do; though not often so suddenly; thus, what is of a certain figure to-day, shall to-morrow, or perhaps in a few hours, be of a different one; what is now but one spot, shall in a little time be broken into two or three; and sometimes two or three spots shall coalesce, and be united into one. Dr Long, many years since, while he was viewing the image of the sun through a telescope cast upon white paper, saw one roundish spot, by estimation not much less than the diameter of our earth, break into two, which receded from one another with prodigious velocity. This observation was singular at the time; for though several writers had taken notice of this after it was done, none of them had been making any observation at the time it was actually doing.

66 Dr Long's account of them.

The

Apparent Motions of the Heavenly Bodies.

The number of spots on the sun is very uncertain; sometimes there are a great many, sometimes very few; and sometimes none at all. Scheiner made observations on the sun from 1611 to 1629; and says he never found its disk quite free of spots, excepting a few days in December 1624. At other times he frequently saw 20, 30, and in the year 1625 he was able to count 50 spots on the sun at a time. In an interval afterwards of 20 years, from 1650 to 1670, scarce any spots were to be seen, and since that time some years have furnished a great number of spots, and others none at all; but since the beginning of the last century, not a year passed wherein some were not seen; and at present, says Mr Cassini, in his *Elemens d'Astronomie* published in 1740, they are so frequent, that the sun is seldom without spots, and often shows a good number of them at a time.

From these phenomena, it is evident, that the spots are not endowed with any permanency; nor are they at all regular in their shape, magnitude, number, or in the time of their appearance or continuance. Hevelius observed one that arose and vanished in 16 or 17 hours; nor has any been observed to continue longer than 70 days, which was the duration of one in the year 1676. Those spots that are formed gradually, are gradually dissolved; while those that arise suddenly, are for the most part suddenly dissolved. When a spot disappears, that part where it was generally becomes brighter than the rest of the sun, and continues so for several days: on the other hand, those bright parts (called *faculæ*, as the others are called *maculæ*) sometimes turn to spots.

67 The solar spots move from west to east.

The solar spots appear to have a motion which carries them across the sun's disk. Every spot, if it continues long enough without being dissolved, appears to enter the sun's disk on the east side, to go from thence with the velocity continually increasing till it has gone half its way; and then to move slower and slower, till it goes off at the west side; after which it disappears for about the same space of time that it spent in crossing the disk, and then enters upon the east side again, nearly in the same place, and crosses it in the same track, and with the same unequal motion as before. This apparent inequality in the motion of the spots is purely optical, and is in such proportion as demonstrates them to be carried round equably or in a circle, the plane of which continued passes through or near the eye of a spectator upon the earth.

Besides the real changes of the spots already mentioned, there is another which is purely optical, and is owing to their being seen on a globe differently turned towards us. If we imagine the globe of the sun to have a number of circles drawn upon its surface, all passing through the poles, and cutting his equator at equal distances, these circles which we may call meridians, if they were visible, would appear to us at unequal distances, as in fig. 2. Now, suppose a spot were round, and so large as to reach from one meridian to another, it would appear round only at *g*, when it was in the middle of that half of the globe which is towards our earth; for then we view the full extent of it in length and breadth: in every other place it turns away from us, and appears narrower, though of the same length, the farther it is from the middle; and on its coming on at *a*, and going off at *n*, it appears as small as a thread, the thin edge being then all that we see.

These spots have made us acquainted with a very important phenomenon, namely the *rotation* of the sun upon its axis. Amidst the changes which these spots are continually undergoing, regular motions may be detected, agreeing exactly with the motion of the surface of the sun, on the supposition that this luminary revolves round an axis almost perpendicular to the ecliptic in the same direction with its motion in its orbit round the earth. By a careful examination of the motion of these spots, it has been ascertained that the sun turns round its axis in about 25 days and a half, and that its equator is inclined to the ecliptic about 7°.5.

The spots on the sun's disk are almost always confined to a zone, extending about 30°.5 on each side of the equator. Sometimes, however, they have been observed at the distance of 39°.5 from the equator of the sun.

Bouguer demonstrated, by a number of curious experiments on the sun's light, that the intensity of the light is much greater toward the centre of the sun's disk than towards its circumference. Now, when a portion of the sun's surface is transported by the rotation of that luminary from the centre to the circumference of his disk, as it is seen under a smaller angle, the intensity of its light, instead of diminishing, ought to increase. Hence it follows, that part of the light which issues from the sun towards the circumference of his disk, must be somehow or other prevented from making its way to the earth. This cannot be accounted for, without supposing that the sun is surrounded by a dense atmosphere, which, being traversed obliquely by the rays from the circumference, intercepts more of them than of those from the centre which pass it perpendicularly.

68 Account of the phenomena by different observers.

The phenomena of the solar spots, as delivered by Scheiner and Hevelius, may be summed up in the following particulars. 1. Every spot which hath a nucleus, or considerably dark part, hath also an umbra, or fainter shade, surrounding it. 2. The boundary between the nucleus and umbra is always distinct and well defined. 3. The increase of a spot is gradual, the breadth of the nucleus and umbra dilating at the same time. 4. In like manner, the decrease of a spot is gradual, the breadth of the nucleus and umbra contracting at the same time. 5. The exterior boundary of the umbra never consists of sharp angles; but is always curvilinear, how irregular soever the outline of the nucleus may be. 6. The nucleus of a spot, whilst on the decrease, often changes its figure by the umbra encroaching irregularly upon it, insomuch that in a small space of time new encroachments are discernible, whereby the boundary between the nucleus and umbra is perpetually varying. 7. It often happens, by these encroachments, that the nucleus of a spot is divided into two or more nuclei. 8. The nuclei of the spots vanish sooner than the umbra. 9. Small umbræ are often seen without nuclei. 10. An umbra of any considerable size is seldom seen without a nucleus in the middle of it. 11. When a spot which consisted of a nucleus and umbra is about to disappear, if it is not suc-

Digitized by Google

ceeded by a *facula*, or spot brighter than the rest of the disk, the place where it was is soon after not distinguishable from the rest.

In the Philosophical Transactions, vol. lxiv. Dr Wilson, professor of astronomy at Glasgow, hath given a dissertation on the nature of the solar spots, and mentions the following appearances. 1. When the spot is about to disappear on the western edge of the sun's limb, the eastern part of the umbra first contracts, then vanishes, the nucleus and western part of the umbra remaining; then the nucleus gradually contracts and vanishes, while the western part of the umbra remains. At last this disappears also; and if the spot remains long enough to become again visible, the eastern part of the umbra first becomes visible, then the nucleus; and when the spot approaches the middle of the disk, the nucleus appears environed by the umbra on all sides, as already mentioned. 2. When two spots lie very near to one another, the umbra is deficient on that side which lies next to the other spot: and this will be the case, though a large spot should be contiguous to one much smaller; the umbra of the large spot will be totally wanting on that side next the small one. If there are little spots on each side of the large one, the umbra does not totally vanish; but appears flattened or pressed in towards the nucleus on each side. When the little spots disappear, the umbra of the large one extends itself as usual. This circumstance, he observes, may sometimes prevent the disappearance of the umbra in the manner above mentioned; so that the western umbra may disappear before the nucleus, if a small spot happens to break out on that side.

In the same volume, p. 337. Mr Wollaston observes, that the appearances mentioned by Dr Wilson are not constant. He positively affirms, that the faculæ or bright spots on the sun are often converted into dark ones. "I have many times (says he) observed, near the eastern limb, a bright facula just come on, which has the next day shown itself as a spot, though I do not recollect to have seen such a facula near the western one after a spot's disappearance. Yet, I believe, both these circumstances have been observed by others; and perhaps not only near the limbs. The circumstance of the faculæ being converted into spots, I think I may be sure of. That there is generally (perhaps always) a mottled appearance over the face of the sun, when carefully attended to, I think I may be as certain. It is most visible towards the limbs, but I have undoubtedly seen it in the centre; yet I do not recollect to have observed this appearance, or indeed any spots, towards the poles. Once I saw, with a twelve inch reflector, a spot burst to pieces while I was looking at it. I could not expect such an event, and therefore cannot be certain of the exact particulars; but the appearance, as it struck me at the time, was like that of a piece of ice when dashed on a frozen pond, which breaks to pieces and slides in various directions." He also acquaints us, that the nuclei of the spots are not always in the middle of the umbræ; and gives the figure of one

69 Mr Dunn's account.

seen in November 13th 1773, which is a remarkable instance to the contrary. Mr Dunn, however, in his new Atlas of the Mundane System, gives some particulars very different from the above. "The face of the sun (says he) has frequently many large black spots, of various forms and dimensions, which move from east to west, and round the sun, according to some observations in 25 days, according to others in 26, and according to some in 27 days. The black or central part of each spot is in the middle of a great number of very small ones, which permit the light to pass between them. The small spots are scarce ever in contact with the central ones: but, what is most remarkable, when the whole spot is near the limb of the sun, the surrounding small ones form nearly a straight line, and the central part projects a little over it, like Saturn in his ring."

70 Herschel observations.

Dr Herschel, with a view of ascertaining more accurately the nature of the sun, made frequent observations upon it from the year 1779 to the year 1794. He imagines that the dark spots on the sun are mountains on its surface, which, considering the great attraction exerted by the sun upon bodies placed at its surface, and the slow revolution it has upon its axis, he thinks may be more than 300 miles high, and yet stand very firmly. He says, that in August 1792, he examined the sun with several powers from 90 to 500; and it evidently appeared that the dark spots are the opaque ground or body of the sun; and that the luminous part is an atmosphere, which, being interrupted or broken, gives us a view of the sun itself. Hence he concludes, that the sun has a very extensive atmosphere, which consists of elastic fluids that are more or less lucid and transparent; and of which the lucid ones furnish us with light. This atmosphere, he thinks, is not less than 1843, nor more than 2765 miles in height; and, he supposes, that the density of the luminous solar clouds need not be much more than that of our aurora borealis, in order to produce the effects with which we are acquainted. The sun then, if this hypothesis be admitted, is similar to the other globes of the solar system, with regard to its solidity—its atmosphere—its surface diversified with mountains and valleys—its rotation on its axis—and the fall of heavy bodies on its surface; it therefore appears to be a very eminent, large, and lucid planet, the primary one in our system, disseminating its light and heat to all the bodies with which it is connected.

Dr Herschel has lately given up the use of the old terms such as *spots*, *nuclei*, *penumbræ*, &c. and has introduced a number of new terms, which he considers as more precise. It will be necessary, before we proceed farther, to insert his explanation of these terms.

71 Explanation of his terms.

"The expressions," says he, "which I have used are *openings*, *shallows*, *ridges*, *nodules*, *corrugations*, *indentations*, and *pores*.

"*Openings* are those places where, by the accidental removal of the luminous clouds of the sun, its own solid body may be seen; and this not being lucid, the openings through which we see it may, by a common telescope, be mistaken for mere black spots, or their nuclei.

"*Shallows* are extensive and level depressions of the luminous solar clouds, generally surrounding the openings to a considerable distance. As they are less luminous than the rest of the sun, they seem to have some distant, though very imperfect resemblance to penumbræ; which might occasion their having been called so formerly.

"*Ridges* are bright elevations of luminous matter, extended in rows of an irregular arrangement.

"*Nodules* are also bright elevations of luminous matter,

ter, but confined to a small space. These nodules, and ridges, on account of their being brighter than the general surface of the sun, and also differing a little from it in colour, have been called faculæ, and luculi.

"*Corrugations*, I call that very particular and remarkable unevenness, ruggedness, or asperity, which is peculiar to the luminous solar clouds, and extends all over the surface of the globe of the sun. As the depressed parts of the corrugations are less luminous than the elevated ones, the disk of the sun has an appearance which may be called mottled.

Indentations are the depressed or low parts of the corrugations; they also extend over the whole surface of the luminous solar clouds.

Pores are very small holes or openings, about the middle of the indentations.

From the numerous observations of this philosopher he has drawn the following conclusions:—

72 Openings.

1. Openings are places where the luminous clouds of the sun are removed: large openings have generally shallows about them; but small openings are generally without shallows. They have generally ridges and nodules about them, and they have a tendency to run into each other. New openings often break out near other openings. Hence he supposes that the openings are occasioned by an elastic but not luminous gas, which comes up through the pores and incipient openings, and spreads itself on the luminous clouds, forcing them out of its way, and widening its passage. Openings sometimes differ in colour; they divide when decayed; sometimes they increase again; but when divided they usually decrease and vanish; sometimes they become large indentations, and sometimes they turn into pores.

73 Shallows.

2. Shallows are depressed below the general surface of the sun, and are places from which the luminous solar clouds of the upper regions are removed. Their thickness is visible; sometimes they exist without openings in them. Incipient shallows come from the openings, or branch out from shallows already formed, and go forward. He supposes that the shallows are occasioned by something coming out of the openings, which, by its propelling motion, drives away the luminous clouds from the place where it meets with the least resistance; or which, by its nature, dissolves them as it comes up to them. If it be an elastic gas, its levity must be such as to make it ascend through the inferior region of the solar clouds, and diffuse itself among the superior luminous matter.

74 Ridges.

3. Ridges are elevations above the general surface of the luminous clouds of the sun. One of them, which he measured, extended over an angular space of 2′ 45″.9, which is nearly 75,000 miles.

Ridges generally accompany openings: but they often also exist in places where there are no openings. They usually disperse very soon. He supposes, that the openings permit a transparent elastic fluid to come out, which disturbs the luminous matter on the top, so as to occasion ridges, and nodules; or, more precisely, that some elastic gas, acting below the luminous clouds, lifts them up, or increases them; and at last forces itself a passage through them, by throwing them aside.

75 Nodules.

4. Nodules are small, but highly elevated luminous places. He thinks that they may be ridges fore-shortened.

5. Corrugations consist of elevations and depressions. They extend all over the surface of the sun; they change their shape and situation; they increase, diminish, divide, and vanish quickly. Dispersed ridges and nodules form corrugations.

76 Pores.

6. The dark places of corrugations are indentations. Indentations are usually without openings, though in some places they contain small ones. They change to openings, and are of the same nature as shallows. They are low places, which often contain very small openings. They are of different sizes, and are extended all over the sun. With low magnifying powers they appear like points. The low places of indentations are *pores*. Pores increase sometimes, and become openings: they vanish quickly.

"It must be sufficiently evident," says Dr Herschel, "from what we have shown of the nature of openings, shallows, ridges, nodules, corrugations, indentations, and pores, that these phenomena could not appear, if the shining matter of the sun were a liquid; since, by the laws of hydrostatics, the openings, shallows, indentations, and pores, would instantly be filled up; nor could ridges and nodules preserve their elevation for a single moment. Whereas, many openings have been known to last for a whole revolution of the sun; and extensive elevations have remained supported for several days. Much less can it be an elastic fluid of an atmospheric nature: this would be still more ready to fill up the low places, and to expand itself to a level at the top. It remains, therefore, only for us to admit this shining matter to exist in the manner of empyreal, luminous, or phosphoric clouds, residing in the higher regions of the solar atmosphere."

77 Two regions of solar clouds.

From his observations, Dr Herschel concludes, that there are two different regions of solar clouds; that the inferior clouds are opaque, and probably not unlike those of our planet; while the superior are luminous, and emit a vast quantity of light: that the opaque inferior clouds probably suffer but little of the light of the self-luminous superior clouds to come to the body of the sun. "The shallows about large openings," he observes, "are generally of such a size, as hardly to permit any direct illumination from the superior olouds to pass over them into the openings; and the great height and closeness of the sides of small ones, though not often guarded by shallows, must also have nearly the same effect. By this it appears, that the planetary clouds are indeed a most effectual curtain, to keep the brightness of the superior regions from the body of the sun.

"Another advantage arising from the planetary clouds of the sun, is of no less importance to the whole solar system. Corrugations are everywhere dispersed over the sun; and their indentations may be called shallows in miniature. From this we may conclude, that the immense curtain of the planetary solar clouds is everywhere closely drawn; and, as our photometrical experiments have proved that these clouds reflect no less than 469 rays out of 1000, it is evident that they must add a most capital support to the splendour of the sun, by throwing back so great a share of the brightness

Digitized by Google

brightness coming to them from the illumination of the whole superior regions."

These observations are sufficient to prove, that the sun has an atmosphere of great density, and extending to a great height. Like our atmosphere, it is obviously subject to agitations, similar to our winds; and it is also transparent. The following is Dr Herschel's theoretical explanation of the solar phenomena.

78 Theory of the solar phenomena.

"We have admitted," says he, "that a transparent elastic gas comes up through the openings, by forcing itself a passage through the planetary clouds. Our observations seemed naturally to lead to this supposition, or rather to prove it; for, in tracing the shallows to their origin, it has been shown, that they always begin from the openings, and go forwards. We have also seen, that in one case, a particular bias given to incipient shallows, lengthened a number of them out in one certain direction, which evidently denoted a propelling force acting the same way in them all. I am, however, well prepared to distinguish between facts observed, and the consequences that in reasoning upon them we may draw from them; and it will be easy to separate them, if that should hereafter be required.

If, however, it be now allowed, that the cause we have assigned may be the true one, it will then appear, that the operations which are carried on in the atmosphere of the sun are very simple and uniform.

"By the nature and construction of the sun, an elastic gas, which may be called empyreal, is constantly formed. This ascends everywhere, by a specific gravity less than that of the general solar atmospheric gas contained in the lower regions. When it goes up in moderate quantities, it makes itself small passages among the lower regions of clouds: these we have frequently observed, and have called them pores. We have shewn that they are liable to continual and quick changes, which must be a natural consequence of their fleeting generation.

"When this empyreal gas has reached the higher regions of the sun's atmosphere, it mixes with other gases, which, from their specific gravity, have their residence there, and occasions decompositions which produce the appearance of corrugations. It has been shown, that the elevated parts of the corrugations are small self-luminous nodules, or broken ridges; and I have used the name of self-luminous clouds, as a general expression for all phenomena of the sun, in what shape soever they may appear, that shine by their own light. These terms do not exactly convey the idea affixed to them; but those of meteors, coruscations, inflammations, luminous wisps, or others, which I might have selected, would have been liable to still greater objections. It is true, that when speaking of clouds, we generally conceive something too gross, and even too permanent, to permit us to apply that expression properly to luminous decompositions, which cannot float or swim in air, as we are used to see our planetary clouds do. But it should be remembered, that, on account of the great compression arising from the force of the gravity, all the elastic solar gases must be much condensed; and that, consequently, phenomena in the sun's atmosphere, which in ours would be mere transitory coruscations, such as those of the aurora borealis, will be so compressed as to become much more efficacious and permanent.

"The great light occasioned by the brilliant superior regions, must scatter itself on the tops of the inferior planetary clouds, and, on account of their great density, bring on a very vivid reflection. Between the interstices of the elevated parts of the corrugations, or self-luminous clouds, which, according to the observations that have been given, are not closely connected, the light reflected from the lower clouds will be plainly visible, and, being considerably less intense than the direct illumination from the upper regions, will occasion that faint appearance which we have called indentations.

"This mixture of the light reflected from the indentations, and that which is emitted directly from the higher parts of the corrugations, unless very attentively examined by a superior telescope, will only have the resemblance of a mottled surface.

"When a quantity of empyreal gas, more than what produces only pores in ascending, is formed, it will make itself small openings; or, meeting perhaps with some resistance in passing upwards, it may exert its action in the production of ridges and nodules.

"Lastly, If still further an uncommon quantity of this gas should be formed, it will burst through the planetary regions of clouds, and thus will produce great openings; then, spreading itself above them, it will occasion large shallows, and, mixing afterwards gradually with other superior gases, it will promote the increase, and assist in the maintenance, of the general luminous phenomena.

"If this account of the solar appearances should be well founded, we shall have no difficulty in ascertaining the actual state of the sun, with regard to its energy in giving light and heat to our globe; and nothing will now remain, but to decide the question which will naturally occur, whether there be actually any considerable difference in the quantity of light and heat emitted from the sun at different times." This question he decides in the affirmative, considering the great number of spots as a proof that the sun is emitting a great quantity of light and heat, and the want of spots as the contrary. The first is connected with a warm and good season; the second, on the contrary, produces a bad one *.

* Phil. Trans. 1801 part ii. p. 265.

Chap. II. *Of the Moon.*

Next to the sun, the most conspicuous of all the heavenly bodies is the moon. The changes which it undergoes are more striking and more frequent than those of the sun, and its apparent motions much more rapid. Hence they were attended to even before those of the sun were known; a fact which explains why the first inhabitants of the earth reckoned their time by the moon's motions, and of course followed the lunar instead of the solar year. In considering the moon, we shall follow the same plan that we observed with respect to the sun. We shall first give an account of her apparent motions; and, secondly, of her nature as far as it has been ascertained. These topics shall occupy the two following sections.

Apparent Motions of the Heavenly Bodies.

Sect. I. *Of the Apparent Motions of the Moon.*

79 Moon's motion in her orbit.

The moon, like the sun, has a peculiar motion from east to west. If we observe her any evening when she is situated very near any fixed star, we shall find her, in 24 hours, about 13° to the east of that star; and her distance continually increases, till at last, after a certain number of days, she returns again to the same star from the west, having performed a complete revolution in the heavens. By a continued series of observations it has been ascertained, that the moon makes a complete revolution in 27.32166118036 days, or 27 days 7 hours 43′ 11″ 31‴ 35⁗. Such at least was the duration of its revolution at the commencement of 1700. But it does not remain always the same. From a comparison between the observations of the ancients and those of the moderns, it appears, that the mean motion of the moon in her orbit is accelerating. This acceleration, but just sensible at present, will gradually become more and more obvious. It is a point of great importance to discover, whether it will always continue to increase, or whether, after arriving at a certain maximum, it will again diminish. Observations could be of no service for many ages in the resolution of this question; but the Newtonian theory has enabled astronomers to ascertain that the acceleration is periodical.

The moon's motion in her orbit is still more unequal than that of the sun. In one part of her orbit she moves faster, in another slower. By knowing the time of a complete revolution, we can easily calculate the mean motion for a day, or any given time; and this mean motion is called the mean anomaly. The true motion is called the true anomaly: the difference between the two is called the equation. Now the moon's equation sometimes amounts to 6° 18′ 32″.

Her apparent diameter varies with the velocity of her angular motion. When she moves fastest, her diameter is largest; it is smallest when her angular motion is slowest. When smallest, the apparent diameter is 0.489420°; when biggest, it is 0.558030°. Hence it follows, that the distance of the moon from the earth

80 Elliptical.

varies. By following the same mode of reasoning, which we have detailed in the last chapter, Kepler ascertained that the orbit of the moon is an ellipse, having the earth in one of its foci. Her radius vector describes equal areas in equal times; and her angular motion is inversely proportional to the square of her distance from the earth.

81 Its eccentricity.

The eccentricity of the elliptic orbit of the moon, has been ascertained to amount to 0.0550368, (the mean distance of the earth being represented by unity); or the greater axis is to the smaller, nearly as 100,000 to 99,848.

That point of the moon's orbit which is nearest the earth, is called the *perigee;* the opposite point is the *apogee*. The line which joins these opposite points, is called the line of the moon's *apsides*. It moves slowly eastward, completing a sidereal revolution in 3232.46643 days, or nearly 9 years.

82 Moon's irregularities.

The inclination of the moon's orbit is also variable: the greatest inequality is proportional to the cosine of twice the sun's angular distance from the ascending node, and amounts when a maximum to 0.14679°.

Even the elliptical orbit of the moon represents but imperfectly her real motion round the earth; for that luminary is subjected to a great number of irregularities, evidently connected with the positions of the sun, which considerably alter the figure of her orbit. The three following are the principal of these.

1. The greatest of all, and the one which was first ascertained, is called by astronomers the moon's *evection*. 83 The evection.
It is proportional to the sine of twice the mean angular distance of the moon from the sun, minus the mean angular distance of the moon from the perigee of its orbit. Its maximum amounts to 1.3410°. In the oppositions and conjunctions of the sun and moon it coincides with the equation of the centre, which it always diminishes. Hence the ancients, who determined that equation by means of the eclipses, found that equation smaller than it is in reality.

2. There is another inequality in the motion of the moon, which disappears during the conjunctions and oppositions of the sun and moon; and likewise when these bodies are 90° distant from each other. It is at its maximum when their mutual distance is about 45°, and then amounts to about 0.594°. Hence it has been concluded to be proportional to the sine of twice the mean angular distance of the moon from the sun. This inequality is called the *variation*. It disappears during the eclipses. 84 Variations.

3. The moon's motion is accelerated when that of the sun is retarded, and the contrary. This occasions an irregularity called the *annual equation*. It follows exactly the same law with that of the *equation of the centre* of the sun, only with a contrary sine. At its maximum it amounts to 0.18576°. During eclipses, it coincides with the equation of the sun. 85 Annual equation.

The moon's orbit is inclined to the ecliptic at an angle of 6.14692°. The points where it intersects the ecliptic are called the *nodes*. Their position is not fixed in the heavens. They have a *retrograde* motion, that is to say, a motion contrary to that of the sun. This motion may be easily traced by marking the successive stars which the moon passes when she crosses the ecliptic. They make a complete revolution of the heavens in 6793.3009 days. The *ascending* node is that in which the moon rises above the ecliptic towards the north pole, the *descending* node that in which she sinks below the equator towards the south pole. The motion of the nodes is subjected to several irregularities, the greatest of which is proportional to the sine of twice the angular distance of the sun from the ascending node of the lunar orbit. When at a maximum, it amounts to 1.62945°. The inclination of the orbit itself is variable. Its greatest inequality amounts to 0.14679°. It is proportional to the cosine of the same angle on which the irregularity in the motion of the nodes depends. 86 Revolution of her nodes.

The apparent diameter of the moon varies as well as that of the sun, and in a more remarkable manner. When smallest, it measures 29.5′; when largest, 34′. This must be owing to the distance of the moon from the earth being subject to variations.

The great distance of the sun from the earth renders it difficult to determine its parallax, on account of its minuteness. This is not the case with the moon. The distance of that luminary from the earth may be determined without much difficulty. 87 Moon's parallax.

Digitized by Google

Apparent Motions of the Heavenly Bodies.

Let BAG (fig. 10.) be one half of the earth, AC its semidiameter, S the sun, *m* the moon, and EKOL a quarter of the circle described by the moon in revolving from the meridian to the meridian again. Let CRS be the rational horizon of an observer at A, extended to the sun in the heavens; and HAO, his sensible horizon extended to the moon's orbit. ALC is the angle under which the earth's semidiameter AC is seen from the moon at L; which is equal to the angle OAL, because the right lines AO and CL, which include both those angles, are parallel. ASC is the angle under which the earth's semidiameter AC is seen from the sun at S: and is equal to the angle OA*f*, because the lines AO and CRS are parallel. Now, it is found by observation, that the angle OAL is much greater than the angle OA*f*; but OAL is equal to ALC, and OA*f* is equal to ASC. Now as ASC is much less than ALC, it proves that the earth's semidiameter AC appears much greater as seen from the moon at L than from the sun at S; and therefore the earth is much farther from the sun than from the moon. The quantities of these angles may be determined by observation in the following manner.

Let a graduated instrument, as DAE (the larger the better), having a moveable index with sight-holes, be fixed in such a manner, that its plane surface may be parallel to the plane of the equator, and its edge AD in the meridian: so that when the moon is in the equinoctial, and on the meridian ADE, she may be seen through the sight-holes when the edge of the moveable index cuts the beginning of the divisions at o, on the graduated limb DE; and when she is so seen, let the precise time be noted. Now as the moon revolves about the earth from the meridian to the meridian again in about 24 hours 48 minutes, she will go a fourth part round it in a fourth part of that time, viz. in 6 hours 12 minutes as seen from C, that is, from the earth's centre or pole. But as seen from A, the observer's place on the earth's surface, the moon will seem to have gone a quarter round the earth when she comes to the sensible horizon at O; for the index through the sights of which she is then viewed will be at *d*, 90 degrees from D, where it was when she was seen at E. Now let the exact moment when the moon is seen at O (which will be when she is in or near the sensible horizon) be carefully noted (G) that it may be known in what time she has gone from E to O; which time subtracted from 6 hours 12 minutes (the time of her going from E to L) leaves the time of her going from O to L, and affords an easy method for finding the angle OAL (called the *moon's horizontal parallax*, which is equal to the angle ALC) by the following analogy: As the time of the moon's describing the arc EO is to 90 degrees, so is 6 hours 12 minutes to the degrees of the arc D*d*E, which measures the angle EAL; from which subtract 90 degrees, and there remains the angle OAL, equal to the angle ALC, under which the earth's semidiameter AC is seen from the moon. Now, since all the angles of a right-lined triangle are equal to 180 degrees, or to two right angles, and the sides of a triangle are always proportional to the sines of the opposite angles, say, by the Rule of Three, As the sine of the angle ALC at the moon L, is to its opposite side AC, the earth's semidiameter, which is known to be 3985 miles; so is radius, viz. the sine of 90 degrees, or of the right angle ACL, to its opposite side AL, which is the moon's distance at L from the observer's place at A on the earth's surface; or, so is the sine of the angle CAL to its opposite side CL, which is the moon's distance from the earth's centre, and comes out at a mean rate to be 240,000 miles. The angle CAL is equal to what OAL wants of 90 degrees.

88 Another method.

Other methods have been fallen upon for determining the moon's parallax; of which the following is recommended as the best, by Mr Ferguson, though hitherto it has not been put in practice. "Let two observers be placed under the same meridian, one in the northern hemisphere, and the other in the southern, at such a distance from each other, that the arc of the celestial meridian included between their two zeniths may be at least 80 or 90 degrees. Let each observer take the distance of the moon's centre from his zenith, by means of an exceeding good instrument, at the moment of her passing the meridian: and these two zenith distances of the moon together, and their excess above the distance between the two zeniths, will be the distance between the two apparent places of the moon. Then, as the sum of the natural sines of the two zenith distances of the moon is to radius, so is the distance between her two apparent places to her horizontal parallax: which being found, her distance from the earth's centre may be found by the analogy mentioned above.

Thus, in fig. 11. let VECQ be the earth, M the moon, and *Zbaz* an arc of the celestial meridian. Let V be Vienna, whose latitude EV is 48° 20′ north; and C the Cape of Good Hope, whose latitude EC is 34° 30′ south: both which latitudes we suppose to be accurately determined beforehand by the observers. As these two places are on the same meridian *n* VEC *s*, and in different hemispheres, the sum of their latitudes 82° 50′ is their distance from each other. Z is the zenith of Vienna, and *z* the zenith of the Cape of of Good Hope; which two zeniths are also 82° 50′ distant from each other, in the common celestial meridian Z*z*. To the observer at Vienna, the moon's centre will appear at *a* in the celestial meridian; and at the same instant, to the observer at the Cape, it will appear at *b*. Now suppose the moon's distance Z*a* from the zenith of Vienna to be 38° 1′ 53″, and her distance *zb* from the zenith of the Cape of Good Hope to be 46° 4′ 41″: the sum of these two zenith distances ($Za+zb$) is 84° 6′ 34″; from which subtract 82° 50′, the distance of Z*z* between the zeniths of these two places, and there will remain 1° 16′ 34″ for the arc *b a*, or distance between the two apparent places of the moon's eentre, as seen from V and from C. Then, supposing

(G) Here proper allowance must be made for the refraction, which being about 34 minutes of a degree in the horizon, will cause the moon's centre to appear 34 minutes above the horizon when her centre is really in it.

Digitized by Google

Apparent Motions of the Heavenly Bodies.

supposing the tabular radius to be 10,000,000, the natural sine of 38° 1′ 53″ (the arc *Za*) is 6,160,816, and the natural sine of 46° 4′ 41″ (the arc *zb*) is 7,202,821: the sum of both these sines is 13,363,637. Say therefore, As 13,363,637 is to 10,000,000, so is 1° 16′ 34″ to 57′ 18″, which is the moon's horizontal parallax.

If the two places of observation be not exactly under the same meridian, their difference of longitude must be accurately taken, that proper allowance may be made for the moon's declination whilst she is passing from the meridian of the one to the meridian of the other.

89 Moon's size.

From the theory of the parallax we know, that at the distance of the moon from the earth the apparent size of the earth would be to that of the moon as 21,352 to 5823. Their respective diameters must be proportional to these numbers, or almost as 11 to 3. Hence the bulk of the moon is 49 times less than that of the earth.

90 Her phases explained.

The different appearances, or *phases*, of the moon constitute some of the most striking phenomena of the heavens. When she emerges from the rays of the sun in an evening, she appears after sunset as a small crescent just visible. The size of this crescent increases continually as she separates to a greater distance from the sun, and when she is exactly in opposition to that luminary, she appears under the form of a complete circle. This circle changes into a crescent as she approaches nearer that luminary, exactly in the same manner it had increased, till at last she disappears altogether, plunging into the sun's rays in the morning at sunrise. The crescent of the moon being always directed towards the sun, indicates obviously that she borrows her light from that luminary; while the law of the variation of her phases, almost proportional to the versed side of the angular distance of the moon from the sun, demonstrates that her figure is spherical. Hence it follows, that the moon is an opaque spherical body.

These different phases of the moon are renewed after every conjunction. They depend upon the excess of the synodical movement of the moon above that of the sun, an excess which is usually termed the synodical motion of the moon. The duration of the synodical revolution of the moon in the mean period between two conjunctions is 29.530588 days. It is to the tropical year nearly in the ratio of 19 to 235, that is to say, that 19 solar years consist of about 235 lunar months.

The points of the lunar orbit, in which the moon is either in conjunction or opposition to the sun are called *syzigies*. In the first point the moon is said to be *new*, in the second to be *full*. The *quadratures* are those points in which the moon is distant from the sun 90° or 270°. When in these points, the moon is said to be in her *first* and *third quarter*. One half only of the moon is then illuminated or seen from the earth. As a more particular account of these phases may be deemed necessary, we subjoin the following explanation, which will perhaps be better understood by the generality of readers.

91 Reflects the sun's light.

The moon is an opaque globe like the earth, and shines only by reflecting the light of the sun: therefore, whilst that half of her which is towards the sun is enlightened, the other half must be dark and invisible. Hence she disappears when she comes between us and the sun; because her dark side is then towards us. When she is gone a little way forward, we see a little of her enlightened side: which still increases to our view as she advances forward, until she comes to be opposite to the sun; and then her whole enlightened side is towards the earth, and she appears with a round illuminated orb, which we call the *full moon;* her dark side being then turned away from the earth. From the full she seems to decrease gradually as she goes through the other half of her course; showing us less and less of her enlightened side every day, till her next change or conjunction with the sun, and then she disappears as before.

The moon has scarce any difference of seasons; her axis being almost perpendicular to the ecliptic. What is very singular, one half of her has no darkness at all; the earth constantly affording it a strong light in the sun's absence; while the other half has a fortnight's darkness and a fortnight's light by turns.

92 Earth appears a moon to our moon.

Our earth is thought to be a moon to the moon; waxing and waning regularly, but appearing 13 times as big, and affording her 13 times as much light as she does us. When she changes to us, the earth appears full to her; and when she is in her first quarter to us, the earth is in its third quarter to her; and *vice versa*.

But from one half of the moon the earth is never seen at all: from the middle of the other half, it is always seen over head; turning round almost 30 times as quick as the moon does. From the circle which limits our view of the moon, only one half of the earth's side next her is seen; the other half being hid below the horizon of all places on that circle. To her the earth seems to be the biggest body in the universe; for it appears 13 times as big as she does to us.

As the earth turns round its axis, the several continents, seas, and islands, appear to the moon's inhabitants like so many spots of different forms and brightness, moving over its surface; but much fainter at some times than others, as our clouds cover them or leave them. By these spots the lunarians can determine the time of the earth's diurnal motion, just as we do the motion of the sun: and perhaps they measure their time by the motion of the earth's spots: for they cannot have a truer dial.

93 How the lunar inhabitants can measure their year.

The moon's axis is so nearly perpendicular to the ecliptic, that the sun never removes sensibly from her equator; and the obliquity of her orbit, which is next to nothing as seen from the sun, cannot cause the sun to decline sensibly from her equator. Yet her inhabitants are not destitute of means for ascertaining the length of their year, though their method and ours must differ. For we can know the length of our year by the return of our equinoxes; but the lunarians having always equal day and night, must have recourse to another method; and we may suppose, they measure their year by observing when either of the poles of our earth begins to be enlightened, and the other to disappear, which is always at our equinoxes; they being conveniently situated for observing great tracts of land about our earth's poles which are entirely unknown to us. Hence we may conclude, that the year is of the same absolute length both to the earth and moon, though

very

Digitized by Google

Apparent Motions of the Heavenly Bodies.

very different as to the number of days; we having $365\frac{1}{4}$ natural days, and the lunarians only $12\frac{1}{19}$, every day and night in the moon being as long as $29\frac{1}{2}$ on the earth.

94 Longitude easily found.

The moon's inhabitants on the side next the earth may as easily find the longitude of their places as we can find the latitude of ours. For the earth keeping constantly, or very nearly so, over one meridian of the moon, the east or west distances of places from that meridian are as easily found as we can find our distance from the equator by the altitude of our celestial poles.

As the sun can only enlighten that half of the earth which is at any moment turned towards him, and, being withdrawn from the opposite half, leaves it in darkness, so he likewise doth to the moon; only with this difference, that as the earth is surrounded by an atmosphere, we have twilight after the sun sets; but if the moon has none of her own, nor is included in that of the earth, the lunar inhabitants have an immediate transition from the brightest sunshine to the blackest darkness. For, let *t r k s w* be the earth, and A, B, C, D, E, F, G, H, the moon in eight different parts of her orbit. As the earth turns round its axis from west to east, when any place comes to *t*, the twilight begins there, and when it revolves from thence to *r* the sun S rises; when the place comes to *s* the sun sets, and when it comes to *w* the twilight ends. But as the moon turns round her axis, which is only once a-month, the moment that any part of her surface comes to *r* (see the moon at G), the sun rises there without any previous warning by twilight; and when the same point comes to *s* the sun sets, and that point goes into darkness as black as at midnight.

Fig. 12.

95 Her phases explained.

The moon being an opaque spherical body (for her hills take off no more from her roundness than the inequalities on the surface of an orange take off from its roundness), we can only see that part of the enlightened half of her which is towards the earth. And therefore, when the moon is at A, in conjunction with the sun S, her dark half is towards the earth, and she disappears, as at *a*, there being no light on that half to render it visible. When she comes to her first octant at B, or has gone an eighth part of her orbit from her conjunction, a quarter of her enlightened side is towards the earth; and she appears horned, as at *b*. When she has gone a quarter of her orbit from between the earth and sun to C, she shows us one half of her enlightened side, as at *c*, and we say she is a quarter old. At D, she is in her second octant; and by showing us more of her enlightened side she appears gibbous, as at *d*. At E, her whole enlightened side is towards the earth; and therefore she appears round, as at *e*; when we say it is full moon. In her third octant at F, part of her dark side being towards the earth, she again appears gibbous, and is on the decrease, as at *f*. At G, we see just one half of her enlightened side; and she appears half decreased, or in her third quarter, as at *g*. At H, we only see a quarter of her enlightened side, being in her fourth octant; where she appears horned, as at *h*. And at A, having completed her course from the sun to the sun again, she disappears; and we say it is new moon. Thus, in going from A to E, the moon seems continually to increase; and in going from E to A, to decrease in the same proportion; having like phases at equal distances from A to E, but as seen from the sun S she is always full.

96 Never appears perfectly round.

The moon appears not perfectly round when she is full in the highest or lowest part of her orbit, because we have not a full view of her enlightened side at that time. When full in the highest part of her orbit, a small deficiency appears on her lower edge; and the contrary when full in the lowest part of her orbit.

It is plain by the figure, that when the moon changes to the earth, the earth appears full to the moon; and *vice versa*. For when the moon is at A, new to the earth, the whole enlightened side of the earth is towards the moon; and when the moon is at E, full to the earth, its dark side is towards her. Hence a new moon answers to a full earth, and a full moon to a new earth. The quarters are also reversed to each other.

97 Agreeable representation of her phases.

Between the third quarter and change, the moon is frequently visible in the forenoon, even when the sun shines; and then she affords us an opportunity of seeing a very agreeable appearance, wherever we find a globular stone above the level of the eye, as suppose on the top of a gate. For, if the sun shines on the stone, and we place ourselves so as the upper part of the stone may just seem to touch the point of the moon's lowermost horn, we shall then see the enlightened part of the stone exactly of the same shape with the moon; horned as she is, and inclined the same way to the horizon. The reason is plain; for the sun enlightens the stone the same way as he does the moon: and both being globes, when we put ourselves into the above situation, the moon and stone have the same position to our eyes; and therefore we must see as much of the illuminated part of the one as of the other.

98 Nonagesimal degree.

The position of the moon's cusps, or a right line touching the points of her horns, is very differently inclined to the horizon at different hours of the same day of her age. Sometimes she stands, as it were, upright on her lower horn, and then such a line is perpendicular to the horizon: when this happens, she is in what the astronomers call *the nonagesimal degree;* which is the highest point of the ecliptic above the horizon at that time, and is 90° from both sides of the horizon where it is then cut by the ecliptic. But this never happens when the moon is on the meridian, except when she is at the very beginning of Cancer or Capricorn.

99 Eclipses of the moon.

The explanation of the phases of the moon leads us to that of the eclipses; those phenomena which formerly were the subjects of dread and error, but which philosophers have converted to the purposes of utility and instruction. The moon can only become eclipsed by the interposition of an opaque body, which intercepts from it the light of the sun; and it is obvious that this opaque body is the earth, because the eclipses of the moon never happen except when the moon is in opposition, and consequently when the earth is interposed between her and the sun. The globe of the earth projects behind it relatively to the motion of the sun a conical shadow, whose axis is the straight line that joins the centres of the earth and sun, and which terminates at the point when the apparent diameters of these two bodies become equal. The diameter of these bodies seen from the centre of the moon in opposition

Digitized by Google

Apparent Motions of the Heavenly Bodies.

sition, are nearly in the proportion of 3 for the sun and 11 for the earth. Therefore, the conical shadow of the earth is at least thrice as long as the distance between the earth and moon, and its breadth at the point where it is traversed by the moon more than double the diameter of that luminary.

The moon, therefore, would be eclipsed every time that it is in opposition, if the plane of its orbit coincided with the ecliptic. But in consequence of the mutual inclination of these two planes, the moon, when in opposition, is often elevated above the earth's conical shadow, or depressed below it; and never can pass through that shadow unless when it is near the nodes. If the whole of the moon's disk plunges into the shadow, the eclipse is said to be *total;* if only a part of the disk enter the shadow, the eclipse is said to be *partial.*

100 Period of the eclipses.

The mean duration of a revolution of the sun relatively to the nodes of the lunar orbit is 346.61963 days, and is to the duration of a synodical revolution of the moon nearly as 223 to 19. Consequently, after a period of 223 lunar months, the sun and moon return nearly to the same situation relatively to the order of the lunar orbit. Of course the eclipses must return in the same order after every 223 lunations. This gives us an easy method of predicting them. But the inequalities in the motions of the sun and moon occasion sensible differences; besides the return of the two luminaries to the same points relatively to the nodes not being rigorously true, the deviations occasioned by this want of exactness alter at last the order of the eclipses observed during one of these periods.

The following explanation of the lunar eclipses being more particular, may be acceptable to some of our readers.

That the moon can never be eclipsed but at the time of her being full, and the reason why she is not eclipsed at every full, has been shown already. In fig. 13. let S be the sun, E the earth, RR the earth's shadow, and B the moon in opposition to the sun: In this situation the earth intercepts the sun's light in its way to the moon; and when the moon touches the earth's shadow at *v*, she begins to be eclipsed on her eastern limb *x*, and continues eclipsed until her western limb *y* leaves the shadow at *w:* at B she is in the middle of the shadow, and consequently in the middle of the eclipse.

101 Why the moon is visible when eclipsed.

The moon, when totally eclipsed, is not invisible if she be above the horizon and the sky be clear; but appears generally of a dusky colour, like tarnished copper, which some have thought to be the moon's native light. But the true cause of her being visible is the scattered beams of the sun, bent into the earth's shadow by going through the atmosphere; which, being more or less dense near the earth than at considerable heights above it, refracts or bends the sun's rays more inward, the nearer they are passing by the earth's surface, than those rays which go through higher parts of the atmosphere, where it is less dense according to its height, until it be so thin or rare as to lose its refractive power. Let the circle *f*, *g*, *h*, *i*, concentric to the earth, include the atmosphere whose refractive power vanishes at the height *f* and *i;* so that the rays W *f w* and V *i v* go on straight without suffering the least refraction: but all those rays which enter the atmosphere between *f* and *k*, and between *i* and *l*, on opposite sides of the earth, are gradually more bent inward as they go through a greater portion of the atmosphere, until the rays W *k* and V *l* touching the earth at *m* and *n*, are bent so much as to meet at *q*, a little short of the moon; and therefore the dark shadow of the earth is contained in the space *m o p q n*, where none of the sun's rays can enter; all the rest, R, R, being mixed by the scattered rays which are refracted as above, is in some measure enlightened by them; and some of those rays falling on the moon, give her the colour of tarnished copper or of iron almost red hot. So that if the earth had no atmosphere, the moon would be as invisible in total eclipses as she is when new. If the moon were so near the earth as to go into its dark shadow, suppose about *p o*, she would be invisible during her stay in it; but visible before and after in the fainter shadow RR.

When the moon goes through the centre of the earth's shadow she is directly opposite to the sun; yet the moon has been often seen totally eclipsed in the horizon, when the sun was also visible in the opposite part of it; for the horizontal refraction being almost 34 minutes of a degree, and the diameter of the sun and moon being each at a mean state but 32 minutes, the refraction causes both luminaries to appear above the horizon when they are really below it.

When the moon is full at 12 degrees from either of her nodes, she just touches the earth's shadow, but enters not into it. In fig. 14. let GH be the ecliptic, *e f* the moon's orbit where she is 12 degrees from the node at her full, *c d* her orbit where she is 6 degrees from the node, *a b* her orbit where she is full in the node, AB the earth's shadow, and M the moon. When the moon describes the line *e f*, she just touches the shadow, but does not enter into it; when she describes the line *c d*, she is totally, though not centrally, immersed in the shadow; and when she describes the line *a b*, she passes by the node at M in the centre of the shadow, and takes the longest line possible, which is a diameter, through it: and such an eclipse being both total and central, is of the longest duration, namely, 3 h. 57 m. 6 sec. from the beginning to the end, if the moon be at her greatest distance from the earth; and 3 h. 37 m. 26. sec. if she be at her least distance. The reason of this difference is, that when the moon is farthest from the earth, she moves slowest; and when nearest to it, quickest.

The moon's diameter, as well as the sun's, is supposed to be divided into 12 equal parts, called *digits;* and so many of these parts as are darkened by the earth's shadow, so many digits is the moon eclipsed. All that the moon is eclipsed above 12 digits, shows how far the shadow of the earth is over the body of the moon, on that edge to which she is nearest at the middle of the eclipse.

102 Lunar eclipses difficultly observed.

It is difficult to observe exactly either the beginning or ending of a lunar eclipse, even with a good telescope, because the earth's shadow is so faint and ill-defined about the edges, that when the moon is either just touching or leaving it, the obscuration of her limb is scarce sensible; and therefore the nicest observers can hardly be certain to four or five seconds of time. But both

Digitized by Google

Apparent Motions of the Heavenly Bodies.

both the beginning and ending of solar eclipses are visibly instantaneous: for the moment that the edge of the moon's disk touches the sun's, his roundness seems a little broke on that part: and the moment she leaves it, he appears perfectly round again.

103 Eclipses of the sun.

The eclipses of the sun only take place during the conjunctions of the sun and moon, or when the moon is placed between the sun and the earth. They are owing to the moon concealing the sun from the earth, or to the earth being plunged in the shadow of the moon. The moon is indeed much smaller than the sun; but it is so much nearer to the earth that its apparent diameter does not differ much from the diameter of that luminary: and, in consequence of the changes which take place in the apparent diameter of these bodies, it happens that sometimes the apparent diameter of the moon is greater than that of the sun. If we suppose the centres of the sun and moon in the same straight line with the eye of a spectator placed on the earth, he will see the sun eclipsed. If the apparent diameter of the moon happens to surpass that of the sun, the eclipse will be *total*: but if the moon's diameter be smallest, the observer will see a luminous ring, formed by that part of the sun's disk which exceeds that of the moon's, and the eclipse will in that case be *annular*. If the centre of the moon is not in the same straight line which joins the observer and the centre of the sun, the eclipse can only be *partial*, as the moon can only conceal a *part* of the sun's disk. Hence there must be a great variety in the appearance of the solar eclipses. We may add also to these causes of variety the elevation of the moon above the horizon, which changes its apparent diameter considerably. For it is well known, that the moon's diameter appears larger when she is near the horizon than when she is elevated far above it. Now, as the moon's height above the horizon varies according to the longitude of the observer, it follows, that the solar eclipses will not have the same appearance to the observers situated in different longitudes. One observer may see an eclipse which does not happen relatively to another. In this respect the solar differ from the lunar eclipses, which are the same to all the inhabitants of the earth.

104 Number of eclipses in a year.

In any year, the number of eclipses of both luminaries cannot be less than two, nor more than seven; the most usual number is four, and it is very rare to have more than six. For the sun passes by both the nodes but once a-year, unless he passes by one of them in the beginning of the year; and, if he does, he will pass by the same node again a little before the year be finished; because, as these points move $19\frac{1}{3}$ degrees backwards every year, the sun will come to either of them 173 days after the other. And when either node is within 17 degrees of the sun at the time of new moon, the sun will be eclipsed. At the subsequent opposition, the moon will be eclipsed in the other node, and come round to the next conjunction again ere the former node be 17 degrees past the sun, and will therefore eclipse him again. When three eclipses fall about either node, the like number generally falls about the opposite; as the sun comes to it in 173 days afterwards; and six lunations contain but four days more. Thus, there may be two eclipses of the sun and one of the moon about each of her nodes. But when the moon changes in either of the nodes, she cannot be near enough the other node at the next full to be eclipsed; and in six lunar months afterwards she will change nearer the other node; in these cases, there can be but two eclipses in a year, and they are both of the sun.

A longer period than the above mentioned, for comparing and examining eclipses which happen at long intervals of time, is 557 years, 21 days, 18 hours, 30 minutes, 11 seconds; in which time there are 6890 mean lunations; and the sun and node meet again so nearly as to be but 11 seconds distant; but then it is not the same eclipse that returns, as in the shorter period above mentioned.

105 Why more eclipses of the moon than of the sun are observed.

Eclipses of the sun are more frequent than of the moon, because the sun's ecliptic limits are greater than the moon's; yet we have more visible eclipses of the moon than of the sun, because eclipses of the moon are seen from all parts of that hemisphere of the earth which is next her, and are equally great to each of those parts: but the sun's eclipses are visible only to that small portion of the hemisphere next him whereon the moon's shadow falls.

The moon's orbit being elliptical, and the earth in one of its focuses, she is once at her least distance from the earth, and once at her greatest in every lunation.

106 Total and annular eclipses.

When the moon changes at her least distance from the earth, and so near the node that her dark shadow falls upon the earth, she appears big enough to cover the whole disk of the sun from that part on which her shallow falls; and the sun appears totally eclipsed there for some minutes: but, when the moon changes at her greatest distance from the earth, and so near the node that her dark shadow is directed towards the earth, her diameter subtends a less angle than the sun's; and therefore she cannot hide his whole disk from any part of the earth, nor does her shadow reach it at that time; and to the place over which the point of her shadow hangs, the eclipse is annular, the sun's edge appearing like a luminous ring all round the body of the moon.

When the change happens within 17 degrees of the node, and the moon at her mean distance from the earth, the point of her shadow just touches the earth and she eclipseth the sun totally to that small spot whereon her shadow falls; but the darkness is not of a moment's continuance.

The moon's apparent diameter, when largest, exceeds the sun's, when least, only 1 minute 38 seconds of a degree; and in the greatest eclipse of the sun that can happen at any time and place, the total darkness continues no longer than whilst the moon is going 1 minute 38 seconds from the sun in her orbit, which is about 3 minutes and 13 seconds of an hour.

107 Extent of the moon's shadow and penumbra.

The moon's dark shadow covers only a spot on the earth's surface about 180 English miles broad, when the moon's diameter appears largest, and the sun's least; and the total darkness can extend no farther than the dark shadow covers. Yet the moon's partial shadow or penumbra may then cover a circular space 4900 miles in diameter, within all which the sun is more or less eclipsed, as the places are less or more distant from the centre of the penumbra. When the moon changes exactly

Digitized by Google

Apparent Motions of the Heavenly Bodies.

exactly in the node, the penumbra is circular on the earth at the middle of the general eclipse; because at that time it falls perpendicularly on the earth's surface; but at every other moment it falls obliquely, and will therefore be elliptical; and the more so, as the time is longer before or after the middle of the general eclipse; and then much greater portions of the earth's surface are involved in the penumbra.

108
Beginning, ending, &c. of a solar eclipse.

When the penumbra first touches the earth, the general eclipse begins; when it leaves the earth, the general eclipse ends: from the beginning to the end the sun appears eclipsed in some part of the earth or other. When the penumbra touches any place, the eclipse begins at that place, and ends when the penumbra leaves it. When the moon changes in the node, the penumbra goes over the centre of the earth's disk as seen from the moon; and consequently, by describing the longest line possible on the earth, continues the longest upon it; namely, at a mean rate, 5 hours, 50 minutes; more, if the moon be at her greatest distance from the earth, because she then moves slowest; less if she be at her least distance, because of her quicker motion.

Fig. 13.

To make several of the above and other phenomena plainer, let S be the sun, E the earth, M the moon, and AMP the moon's orbit. Draw the right line W *e* from the western side of the sun at W, touching the western side of the moon at *c*, and the earth at *e*: draw also the right line V *d*, from the eastern side of the sun at V, touching the eastern side of the moon at *d*, and the earth at *e*: the dark space *c e d* included between those lines is the moon's shadow, ending in a point at *e*, where it touches the earth; because in this case the moon is supposed to change at M in the middle between A the apogee, or farthest point of her orbit from the earth, and P the perigee, or nearest point to it. For, had the point P been at M, the moon had been nearer the earth: and her dark shadow at *e* would have covered a space upon it about 180 miles broad, and the sun would have been totally darkened, with some continuance: but had the point A been at M, the moon would have been farther from the earth, and her shadow would have ended in a point a little above *e*, and therefore the sun would have appeared like a luminous ring all around the moon. Draw the right lines WX *d h* and VX *c g*, touching the contrary sides of the sun and moon, and ending on the earth at *a* and *b*; draw also the right line SXM, from the centre of the sun's disk, through the moon's centre to the earth; and suppose the two former lines WX *d h* and VX *c g* to revolve on the line SXM as an axis, and their points *a* and *b* will describe the limits of the penumbra TT on the earth's surface, including the large space *a b a*; within which the sun appears more or less eclipsed, as the places are more or less distant from the verge of the penumbra *a b*.

Draw the right line *y* 12 across the sun's disk, perpendicular to SXM the axis of the penumbra; then divide the line *y* 12 into twelve equal parts, as in the figure, for the twelve digits or equal parts of the sun's diameter; and at equal distances from the centre of the penumbra at *e* (on the earth's surface YY) to its edge *a b*, draw twelve concentric circles, marked with the numeral figures 1 2 3 4, &c. and remember that the moon's motion in her orbit AMP is from west to east, as from *s* to *t*. Then,

To an observer on the earth at *b*, the eastern limb of the moon at *d* seems to touch the western limb of the sun at W, when the moon is at M; and the sun's eclipse begins at *b*, appearing as at A, fig. 15. at the left hand; but at the same moment of absolute time, to an observer at *a* in fig. 14. the western edge of the moon at *c* leaves the eastern edge of the sun at V, and the eclipse ends, as at the right hand C, fig. 15. At the very same instant, to all those who live on the circle marked 1 on the earth A, in fig. 14. the moon M cuts off or darkens a twelfth part of the sun S, and eclipses him one digit, as at 1 in fig. 15.: to those who live on the circle marked 2 in fig. 14. the moon cuts off two twelfth parts of the sun, as at 2 in fig. 15.: to those on the circle 3, three parts; and so on to the centre at 12 in fig. 14. where the sun is centrally eclipsed, as at B in the middle of fig. 15.; under which figure there is a scale of hours and minutes, to show at a mean state how long it is from the beginning to the end of a central eclipse of the sun on the parallel of London; and how many digits are eclipsed at any particular time from the beginning at A to the middle at B, or the end at C. Thus, in 16 minutes from the beginning, the sun is two digits eclipsed; in an hour and five minutes, eight digits; and in an hour and 37 minutes, 12 digits.

By fig. 14. it is plain, that the sun is totally or centrally eclipsed but to a small part of the earth at any time, because the dark conical shadow *e* of the moon M falls but on a small part of the earth; and that the partial eclipse is confined at that time to the space included by the circle *a b*, of which only one half can be projected in the figure, the other half being supposed to be hid by the convexity of the earth E; and likewise, that no part of the sun is eclipsed to the large space YY of the earth, because the moon is not between the sun and any of that part of the earth; and therefore to all that part the eclipse is invisible. The earth turns eastward on its axis, as from *g* to *h*, which is the same way that the moon's shadow moves; but the moon's motion is much swifter in her orbit from *s t*; and therefore, although eclipses of the sun are of no longer duration on account of the earth's motion on its axis than they would be if that motion was stopped, yet in four minutes of time at most, the moon's swifter motion carries her dark shadow quite over any place that its centre touches at the time of greatest obscuration. The motion of the shadow on the earth's disk is equal to the moon's motion from the sun, which is about $30\frac{1}{2}$ minutes of a degree every hour at a mean rate: but so much of the moon's orbit is equal to $30\frac{1}{2}$ degrees of a great circle on the earth; and therefore the moon's shadow goes $30\frac{1}{2}$ degrees, or 1830 geographical miles on the earth in an hour, or $30\frac{1}{2}$ miles in a minute, which is almost four times as swift as the motion of a cannon-ball.

As seen from the sun or moon, the earth's axis appears differently inclined every day of the year, on account of keeping its parallelism throughout its annual course. In fig. 16. let EDON be the earth at the two equinoxes and the two solstices, NS its axis, N the north pole, S the south pole, ÆQ the equator,

Apparent Motions of the Heavenly Bodies.

T the tropic of Cancer, *t* the tropic of Capricorn, and ABC the circumference of the earth's enlightened disk as seen from the sun or new moon at these times. The earth's axis has the position NES at the vernal equinox, lying towards the right hand, as seen from the sun or new moon; its poles N and S being then in the circumference of the disk; and the equator and all its parallels seem to be straight lines, because their planes pass through the observer's eye looking down upon the earth from the sun or moon directly over E, where the ecliptic FG intersects the equator Æ. At the summer solstice the earth's axis has the position NDS; and that part of the ecliptic FG, in which the moon is then new, touches the tropic of Cancer T at D. The north pole N, at that time inclining $23\frac{1}{2}$ degrees towards the sun, falls so many degrees within the earth's enlightened disk, because the sun is then vertical to D $23\frac{1}{2}$ degrees north of the equator or ÆQ; and the equator, with all its parallels, seem elliptic curves bending downward, or towards the south pole, as seen from the sun; which pole, together with $23\frac{1}{2}$ degrees all round it, is hid behind the disk in the dark hemisphere of the earth. At the autumnal equinox, the earth's axis has the position NOS, lying to the left hand as seen from the sun or new moon, which are then vertical to O, where the ecliptic cuts the equator ÆQ. Both poles now lie in the circumference of the disk, the north pole just going to disappear behind it, and the south pole just entering into it; and the equator with all its parallels seem to be straight lines, because their planes pass through the observer's eye, as seen from the sun, and very nearly so as seen from the moon. At the winter solstice, the earth's axis has the position NNS, when its south pole S inclining $23\frac{1}{2}$ degrees towards the sun, falls $23\frac{1}{2}$ degrees within the enlightened disk, as seen from the sun or new moon, which are then vertical to the tropic of Capricorn *t*, $23\frac{1}{2}$ degrees south of the equator ÆQ; and the equator, with all its parallels, seem elliptic curves bending upward; the north pole being as far hid behind the disk in the dark hemisphere as the south pole is come into the light. The nearer that any time of the year is to the equinoxes or solstices, the more it partakes of the phenomena relating to them.

Thus it appears, that from the vernal equinox to the autumnal, the north pole is enlightened: and the equator and all its parallels appear elliptical as seen from the sun, more or less curved as the time is nearer to, or farther from, the summer solstice; and bending downwards, or towards the south pole; the reverse of which happens from the autumnal equinox to the vernal. A little consideration will be sufficient to convince the reader, that the earth's axis inclines towards the sun at the summer solstice; from the sun at the winter solstice; and sidewise to the sun at the equinoxes: but towards the right hand, as seen from the sun at the vernal equinox; and towards the left hand at the autumnal. From the winter to the summer solstice, the earth's axis inclines more or less to the right hand, as seen from the sun; and the contrary from the summer to the winter solstice.

The different positions of the earth's axis, as seen from the sun at different times of the year, affect solar eclipses greatly with regard to particular places: yea, so far as would make central eclipses which fall at one time of the year invisible if they fell at another, even though the moon should always change in the nodes, and at the same hour of the day; of which indefinitely various affections, we shall only give examples for the times of the equinoxes and solstices.

109 Eclipses affected by the position of the earth's axis.

In the same diagram, let FG be part of the ecliptic, and IK, *ik*, *ik*, *ik*, part of the moon's orbit; both seen edgewise, and therefore projected into right lines; and let the intersections NODE be one and the same node at the above times, when the earth has the forementioned different positions; and let the spaces included by the circles P*ppp* be the penumbra at these times, as its centre is passing over the centre of the earth's disk. At the winter solstice, when the earth's axis has the position NNS, the centre of the penumbra P touches the tropic of Capricorn *t* in N at the middle of the general eclipse; but no part of the penumbra P touches the tropic of Cancer T. At the summer solstice, when the earth's axis has the position NDS (*i* D *k* being then part of the moon's orbit whose node is at D), the penumbra *p* has its centre at D, on the tropic of Cancer T, at the middle of the general eclipse, and then no part of it touches the tropic of Capricorn *t*. At the autumnal equinox, the earth's axis has the position NOS (*i* O *k* being then part of the moon's orbit), and the penumbra equally includes part of both tropics T and *t*, at the middle of the general eclipse: at the vernal equinox it does the same, because the earth's axis has the position NES; but, in the former of these two last cases, the penumbra enters the earth at A, north of the tropic of Cancer T, and leaves it at *m* south of the tropic of Capricorn *t*, having gone over the earth obliquely southward, as its centre described the line AO *m*: whereas, in the latter case, the penumbra touches the earth at *n*, south of the equator ÆQ, and describing the line *n* E *q* (similar to the former line AO*m* in open space), goes obliquely northward over the earth, and leaves it at *q*, north of the equator.

In all these circumstances the moon has been supposed to change at noon in her descending node: Had she changed in her ascending node, the phenomena would have been as various the contrary way, with respect to the penumbra's going northward or southward over the earth. But because the moon changes at all hours, as often in one node as in the other, and at all distances from them both at different times as it happens, the variety of the phases of eclipses are almost innumerable, even at the same places; considering also how variously the same places are situated on the enlightened disk of the earth, with respect to the penumbra's motion, at the different hours when eclipses happen.

When the moon changes 17 degrees short of her descending node, the penumbra P 18 just touches the northern part of the earth's disk, near the north pole N; and as seen from that place, the moon appears to touch the sun, but hides no part of him from sight. Had the change been as far short of the ascending node, the penumbra would have touched the southern part of the disk near the south pole S. When the moon changes 12 degrees short of the descending node, more than a third part of the penumbra P 12 falls on the northern parts of the earth at the middle of the general eclipse: Had she changed as far past the same node,

Apparent Motions of the Heavenly Bodies.

as much of the other side of the penumbra about P would have fallen on the southern parts of the earth; all the rest in the expansum, or open space. When the moon changes 6 degrees from the node, almost the whole penumbra P 6 falls on the earth at the middle of the general eclipse. And, lastly, when the moon changes in the node at N, the penumbra PN takes the longest course possible on the earth's disk: its centre falling on the middle thereof, at the middle of the general eclipse. The farther the moon changes from either node, within 17 degrees of it, the shorter is the penumbra's continuance on the earth, because it goes over a less portion of the disk, as is evident by the figure.

110
Duration of eclipses in different parts of the earth.

The nearer that the penumbra's centre is to the equator at the middle of the general eclipse, the longer is the duration of the eclipse at all those places where it is central; because, the nearer that any place is to the equator, the greater is the circle it describes by the earth's motion on its axis; and so, the place moving quicker, keeps longer in the penumbra, whose motion is the same way with that of the place, though faster, as has been already mentioned. Thus (see the earth at D and the penumbra at 12) whilst the point *b* in the polar circle *a b c d* is carried from *b* to *c* by the earth's diurnal motion, the point *d* on the tropic of Cancer T is carried a much greater length from *d* to D; and therefore, if the penumbra's centre goes one time over *c* and another time over D, the penumbra will be longer in passing over the moving place *d* than it was in passing over the moving place *b*. Consequently, central eclipses about the poles are of the shortest duration; and about the equator, of the longest.

In the middle of summer, the whole frigid zone, included by the polar circle *a b c d*, is enlightened: and if it then happens that the penumbra's centre goes over the north pole, the sun will be eclipsed much the same number of digits at *a* as at *c;* but whilst the penumbra moves eastward over *c*, it moves eastward over *a;* because, with respect to the penumbra, the motions of *a* and *c* are contrary: for *c* moves the same way with the penumbra towards *d*, but *a* moves the contrary way towards *b;* and therefore the eclipse will be of longer duration at *c* than at *a*. At *a* the eclipse begins on the sun's eastern limb, but at *c* on his western: at all places lying without the polar circles, the sun's eclipses begin on his western limb, or near it, and end on or near his eastern. At those places where the penumbra touches the earth, the eclipse begins with the rising sun, on the top of his western or uppermost edge; and at those places where the penumbra leaves the earth, the eclipse ends with the setting sun, on the top of his eastern edge, which is then the uppermost, just at its disappearing in the horizon.

About the new moon, that part of the lunar disk which is not illuminated by the sun is perceptible, owing to the feeble light reflected on it by the hemisphere of the earth that is illuminated.

SECT. II. *Of the Nature of the Moon.*

111
Moon's size.

WE have seen that the moon is about 39 times smaller than the earth. Her diameter is generally reckoned about 2180 miles. This is to the diameter of the earth nearly as 20 to 73; therefore, the surface of the moon is to that of the earth (being as the squares of their diameters) nearly as 1 to $14\frac{1}{3}$. And, admitting the moon's density to be to that of the earth as 5 to 4, their respective quantities of matter will be as 1 to 39 very nearly.

112
Light.

Bouguer has shown, by a set of curious experiments, that the light emitted by the full moon is 300,000 times less intense than that of the sun. Even when concentrated by the most powerful mirrors, it produces no effect on the thermometer.

113
Spots on her surface.

Many duskish spots may be seen upon the moon's disk, even with the naked eye; and through a telescope, their number is prodigiously increased: she also appears very plainly to be more protuberant in the middle than at the edges, or to have the figure of a globe and not a flat circle. When the moon is horned or gibbous, the one side appears very ragged and uneven, but the other always exactly defined and circular. The spots in the moon always keep their places exactly; never vanishing, or going from one side to the other, as those of the sun do. We sometimes see more or less of the northern and southern, and eastern and western part of the disk or face; but this is owing to what is called her libration, and will hereafter be explained. The astronomers Florentius, Langrenus, John Hevelius of Dantzic, Grimaldus, Ricciolus, Cassini, and M. de la Hire, have drawn the face of the moon as she is seen through telescopes magnifying between 200 and 300 times. Particular care has been taken to note all the shining parts in her surface; and, for the better distinguishing them, each has been marked with a proper name. Langrenus and Ricciolus have divided the lunar regions among the philosophers, astronomers, and other eminent men; but Hevelius and others, fearing lest the philosophers should quarrel about the division of their lands, have endeavoured to spoil them of their property, by giving the names belonging to different countries, islands, and seas on earth, to different parts of the moon's surface, without regard to situation or figure. The names adopted by Ricciolus, however, are those which are generally followed, as the names of *Hipparchus*, *Tycho*, *Copernicus*, &c. are more pleasing to astronomers than those of Africa, the Mediterranean sea, Sicily, and Mount Ætna. Fig. 17. is a tolerably exact representation of the full moon in her mean libration, with the numbers to the principal spots according to Ricciolus, Cassini, Mayer, &c. The asterisk refers to one of the volcanoes discovered by Dr Herschel, to be afterwards more particularly noticed. The names are as follow:

114 Great inequalities on the surface of the Moon.

That there are prodigious inequalities on her surface, is proved by looking at her through a telescope, at any other time than when she is full; for then there is no regular line bounding light and darkness: but the confines of these parts appear as it were toothed and cut with innumerable notches and breaks: and even in the dark part, near the borders of the lucid surface, there are seen some small spaces enlightened by the sun's beams. Upon the fourth day after new moon, there may be perceived some shining points like rocks or small islands within the dark body of the moon; but not far from the confines of light and darkness there are observed other little spaces which join to the enlightened surface, but run out into the dark side, which by degrees change their figure, till at last they come wholly within the illuminated face, and have no dark parts round them at all. Afterwards many more shining spaces are observed to arise by degrees, and to appear within the dark side of the moon, which before they drew near to the confines of light and darkness were invisible, being without any light, and totally immersed in the shadow. The contrary is observed in the decreasing phases, where the lucid spaces which joined the illuminated surface by degrees recede from it, and, after they are quite separated from the confines of light and darkness, remain for some time visible, till at last they also disappear. Now it is impossible that this should be the case, unless these shining points were higher than the rest of the surface, so that the light of the sun may reach them.

115 Method of measuring the lunar mountains. Fig. 20.

Not content with perceiving the bare existence of these lunar mountains, astronomers have endeavoured to measure their height in the following manner. Let EGD be the hemisphere of the moon illuminated by the sun, ECD the diameter of the circle bounding light and darkness, and A the top of a hill within the dark part when it first begins to be illuminated. Observe with a telescope the proportion of the right line AE, or the distance of the point A from the lucid surface to the diameter of the moon ED; and because in this case the ray of light ES touches the globe of the moon, AEC will be a right angle by 16th prop. of Euclid's third book; and, therefore, in the triangle AEC having the two sides AE and EC, we can find out the third side AC; from which subducting BC or EC, there will remain AB the height of the mountain. Ricciolus affirms, that upon the fourth day after new moon he has observed the top of the hill called *St Catharine's* to be illuminated, and that it was distant from the confines of the lucid surface about a sixteenth part of the moon's diameter. Therefore, if CF=8, A E will be 1, and $AC^2=CE^2+AE^2$ by prop. 47. of Euclid's first book. Now, the square of CE being 64, and the square of AE being 1, the square of AC will be 65, whose square root is 8,062, which expresses the length of AC. From which deducting BC=8, there will remain AC=0,062. So that CB or CE is therefore to AB as 8 is to 0,062, that is, as 8000 is to 62. If the diameter of the moon therefore was known, the height of this mountain would also be known. This demonstration is taken from Dr Keill, who supposes the semidiameter of the moon to be 1182 miles; according to which, the mountain must be somewhat more than nine miles of perpendicular height: but astronomers having now determined the moon's semidiameter to be only 1090 miles, the height of the mountain will be nearly 8½ miles.

116 Height of the lunar mountains overrated.

In the former edition of this work, we could not help making some remarks on the improbability that the mountains of the moon, a planet so much inferior in size to the earth, should exceed in such vast proportion the highest of our mountains, which are computed at little more than one-third of the height just mentioned. Our remark is now confirmed by the observations of Dr Herschel. After explaining the method used by Galileo, Hevelius, &c. for measuring the lunar mountains, he tells us, that the former takes the distance of the top of a lunar mountain from the line that divides the illuminated part of the disk from that which is in the shade to be equal to one-twentieth of the moon's diameter; but Hevelius makes it only one twenty-sixth. When we calculate the height of such a mountain, therefore, it will be found, according to Galileo, almost 5¼ miles; and according to Hevelius 3¼ miles, admitting the moon's diameter to be 2180 miles. Mr Ferguson, however, says (Astronomy Explained, § 252.), that some of her mountains, by comparing their height with her diameter, are found to be three times higher than the highest hills on earth: and Keill, in his Astronomical Lectures, has calculated the height of St Catharine's hill, according to the observations of Ricciolus, and finds it nine miles.

117 Dr Herschel's observations on them.

Having premised these accounts, Dr Herschel explains his method of taking the height of a lunar mountain from observations made when the moon was not in her quadrature, as the method laid down by Hevelius answers only to that particular case; for in all others the projection must appear shorter than it really is. "Let SLM, says he, or *s l m*, (fig. 96.) be a line drawn from the sun to the mountain, touching the moon at L or *l*, and the mountain at M or *m*. Then, to an observer at E, or *e*, the lines LM, *l m*, will not appear of the same length, though the mountain should be of an equal height; for LM will be projected into *o n*, and *l m* into ON. But these are the quantities that are taken by the micrometer when we observe a mountain to project from the line of illumination. From the observed quantity *o n*, when the moon is not in her quadrature, to find LM, we have the following analogy. The triangles *o* OL, *r* ML, are similar; therefore L *o* : LO : : L *r* : LM, or $\frac{LO+o\,n}{L\,o}$=LM: but LO is the radius of the moon, and L *r* or *o n* is the observed distance of the mountain's projection; and L *o* is the sine of the angle ROL = *o* LS; which we may take to be the distance of the sun from the moon without any material error, and which therefore we may find at any given time from the ephemeris."

The telescope used in these observations was a Newtonian

Digitized by Google

Apparent Motions of the Heavenly Bodies.

Newtonian reflector of six feet eight inches focal length, to which a micrometer was adapted, consisting of two parallel hairs, one of which was moveable by means of a fine screw. The value of the parts shown by the index was determined by a trigonometrical observation of a known object at a known distance, and was verified by several trials. The power was always 222, excepting where another is expressly mentioned; and this was also determined by experiment, which frequently differs from theory on account of some small errors in the data, hardly to be avoided. The moon having sufficient light, an aperture of no more than four inches was made use of; and, says Dr Herschel, "I believe, that for distinctness of vision, this instrument is perhaps equal to any that ever was made."

With this instrument he observed a prominence, which he calls a *rock*, situated near the *Lacus Niger* of Hevelius, and found that it projected 41.56″. To reduce this into miles, put R for the semidiameter of the moon in seconds, as given by the nautical almanack at the time of observation, and Q for the observed quantity, also in seconds and centesimals; then it will be in general, $R : 1090 :: Q : \frac{1090Q}{R} = on$ in miles.

Thus it is found, that 41.56″ is 46.79 miles. The distance of the sun from the moon at that time was, by the nautical almanack, about $93° 57\frac{1}{2}'$; the sine of which to the radius 1 is .9985, &c. and $\frac{on}{Lo}$ in this case is LM=46.85 miles. Then, by Hevelius's method, the perpendicular height of the rock is found to be about one mile. At the same time, a great many rocks, situated about the middle of the disk, projected from 25.92″ to 26.56″; which gives *o n* about 29.3 miles: so that these rocks are all less than half a mile high.

These observations were made on the 13th of November 1779. On the 13th of January 1780, examining the mountains of the moon, he found that there was not one of them fairly placed on level ground, which is very necessary for an exact measurement of the projection: for if there should be a declivity on the moon before the mountains, or a tract of hills placed so as to cast a shadow upon that part before them which would otherwise be illuminated, the projection would appear too large; and, on the contrary, should there be a rising ground before them, it would appear too little.

Proceeding in this cautious manner, Dr Herschel measured the height of many of the lunar prominences, and draws at last the following conclusions.—"From these observations I believe it is evident, that the height of the lunar mountains in general is greatly overrated; and that, when we have excepted a few, the generality do not exceed half a mile in their perpendicular elevation. It is not so easy to find any certain mountain exactly in the same situation it has been measured in before; therefore some little difference must be expected in these measures. Hitherto I have not had an opportunity of particularly observing the three mountains mentioned by Hevelius; nor that which Ricciolus found to project a sixteenth part of the moon's diameter. If Keill had calculated the height of this last-mentioned hill according to the theorem I had given, he would have found (supposing the observation to have been made, as he says, on the fourth day after new moon) that its perpendicular height could not well be less than between 11 and 12 miles. I shall not fail to take the first opportunity of observing these four, and every other mountain of any eminence; and if other persons, who are furnished with good telescopes and micrometers, would take the quantity of the projection of the lunar mountains, I make no doubt but that we would be nearly as well acquainted with their heights, as we are with the elevation of our own.

118 Caution to be observed in using Dollond's telescopes.

One caution I would beg leave to mention to those who may use the excellent $3\frac{1}{2}$ feet refractors of Mr Dollond. The admirable quantity of light, which on most occasions is so desirable, will probably give the measure of the projection somewhat larger than the true, if not guarded against by proper limitations placed before the object-glass. I have taken no notice of any allowance to be made for the refraction a ray of light must suffer in passing through the atmosphere of the moon, when it illuminates the top of the mountain, whereby its apparent height will be lessened, as we are too little acquainted with that atmosphere to take it into consideration. It is also to be observed, that this would equally affect the conclusions of Hevelius, and therefore the difference in our inferences would still remain the same."

In the continuation of his observations, Dr Herschel informs us that he had measured the height of one of the mountains that had been measured by Hevelius. "Antitaurus (says he), the mountain measured by Hevelius, was badly situated: because Mount Moschus and its neighbouring hills cast a deep shadow, which may be mistaken for the natural convexity of the moon. A good, full, but just measure, 25.105″; in miles, 29.27: therefore LM 31.7 miles, and the perpendicular height not quite half a mile. As great exactness was desired in this observation, it was repeated with very nearly the same result. Several other mountains were measured by the same method; and all his observations concurred in making the height of the lunar mountains much less than what former astronomers had done. Mount Lipulus was found to be near two-thirds of a mile; one of the Apennine mountains, between Lacus Thrasimenus and Pontus Euxinus, measured a mile and a quarter; Mons Armenia, near Taurus, two-thirds of a mile; Mons Leucoptera three quarters of a mile. Mons Sacer projected 45.625″; 'but (says he) I am almost certain that there are two very considerable cavities, or places where the ground descends below the level of the convexity, just before these mountains; so that these measures must of course be a good deal too large; but supposing them to be just, it follows, that *o n* is 50.193 miles, LM=64 miles, and the perpendicular height above one mile and three-fourths.'

119 Volcanoes discovered in the moon.

As the moon has on its surface mountains and valleys in common with the earth, some modern astronomers have discovered a still greater similarity, viz. that some of these are really volcanoes, emitting fire as those on earth do. An appearance of this kind was discovered some years ago by Don Ulloa in an eclipse of the sun. It was a small bright spot like a star near the margin of the moon, and which he at that time supposed to have been a hole with the sun's light shining

Apparent Motions of the Heavenly Bodies.

ing through it. Succeeding observations, however, have induced astronomers to attribute appearances of this kind to the eruption of volcanic fire; and Dr Herschel has particularly observed several eruptions of the lunar volcanoes, the last of which he gives an account of in the Phil. Trans. for 1787. "April 19. 10 h. 36 m. sidereal time. I perceive (says he) three volcanoes in different places of the dark part of the new moon. Two of them are either already nearly extinct, or otherwise in a state of going to break out; which perhaps may be decided next lunation. The third shows an actual eruption of fire or luminous matter. I measured the distance of the crater from the northern limb of the moon, and found it 3′ 57.3″; its light is much brighter than the nucleus of the comet which M. Mechain discovered at Paris the 10th of this month.

"April 20. 10 h. 2 m. sidereal time. The volcano burns with greater violence than last night. Its diameter cannot be less than 3 sec. by comparing it with that of the Georgian planet: as Jupiter was near at hand, I turned the telescope to his third satellite, and estimated the diameter of the burning part of the volcano to be equal to at least twice that of the satellite; whence we may compute that the shining or burning matter must be above three miles in diameter. It is of an irregular round figure, and very sharply defined on the edges. The other two volcanoes are much farther towards the centre of the moon, and resemble large, pretty faint nebulæ, that are gradually much brighter in the middle; but no well defined luminous spot can be discerned in them. These three spots are plainly to be distinguished from the rest of the marks upon the moon; for the reflection of the sun's rays from the earth is, in its present situation, sufficiently bright, with a ten feet reflector, to show the moon's spots, even the darkest of them; nor did I perceive any similar phenomena last lunation, though I then viewed the same places with the same instrument.

"The appearance of what I have called the *actual fire*, or eruption of a volcano, exactly resembled a small piece of burning charcoal when it is covered by a very thin coat of white ashes, which frequently adhere to it when it has been some time ignited; and it had a degree of brightness about as strong as that with which such a coal would be seen to glow in faint daylight. All the adjacent parts of the volcanic mountain seemed to be faintly illuminated by the eruption, and were gradually more obscure as they lay at a greater distance from the crater. This eruption resembled much that which I saw on the 4th of May in the year 1783, but differed considerably in magnitude and brightness; for the volcano of the year 1783, though much brighter than that which is now burning, was not nearly so large in the dimensions of its eruption: the former seen in the telescope resembled a star of the fourth magnitude as it appears to the naked eye; this, on the contrary, shows a visible disk of luminous matter very different from the sparkling brightness of star light."

120 Conjectures concerning her substance.

Concerning the nature of the moon's substance there have been many conjectures formed. Some have imagined, that, besides the light reflected from the sun, the moon hath also some obscure light of her own, by which she would be visible without being illuminated by the sunbeams. In proof of this it is urged, that during the time of even total eclipses the moon is still visible, appearing of a dull red colour, as if obscured by a great deal of smoke. In reply to this it hath been advanced, that this is not always the case; the moon sometimes disappearing totally in the time of an eclipse, so as not to be discernible by the best glasses, while little stars of the fifth and sixth magnitudes were distinctly seen as usual. This phenomenon was observed by Kepler twice, in the years 1580 and 1583; and by Hevelius in 1620. Ricciolus and other Jesuits at Bologna, and many people throughout Holland, observed the same on April 14. 1642: yet at Venice and Vienna she was all the time conspicuous. In the year 1703, Dec. 23. there was another total obscuration. At Arles, she appeared of a yellowish brown; at Avignon, ruddy and transparent, as if the sun had shone through her; at Marseilles, one part was reddish and the other very dusky; and at length, though in a clear sky, she totally disappeared. The general reason for her appearance at all during the time of eclipses shall be given afterwards: but as for these particular phenomena, they have not yet, as far as we know, been satisfactorily accounted for.

Different conjectures have also been formed concerning the spots on the moon's surface. Some philosophers have been so taken with the beauty of the brightest places observed in her disk, that they have imagined them to be rocks of diamonds; and others have compared them to pearls and precious stones. Dr Keill and the greatest part of astronomers now are of opinion, that these are only the tops of mountains, which by reason of their elevation are more capable of reflecting the sun's light than others which are lower. The duskish spots, he says, cannot be seas, nor any thing of a liquid substance; because, when examined by the telescope, they appear to consist of an infinity of caverns and empty pits, whose shadows fall within them, which can never be the case with seas, or any liquid substance: but, even within these spots, brighter places are also to be observed; which, according to his hypothesis, ought to be the points of rocks standing up within the cavities. Dr Long, however, is of opinion, that several of the dark spots on the moon are really water. May not the lunar seas and lakes (says he) have islands in them, wherein there may be pits and caverns? And if some of these dark parts be brighter than others, may not that be owing to the seas and lakes being of different depths, and to their having rocks in some places and flats in others?

It has also been urged, that if all the dark spots observed on the moon's surface were really the shadows of mountains, or of the sides of deep pits, they could not possibly be so permanent as they are found to be; but would vary according to the position of the moon with regard to the sun, as we find shadows on earth are varied according as the earth is turned towards or from the sun. Accordingly it is pretended, that variable spots are actually discovered on the moon's disk, and that the direction of these is always opposite to the sun. Hence they are found among those parts which are soonest illuminated in the increasing moon, and in the decreasing moon lose their light sooner than the intermediate ones; running round, and appearing sometimes longer, and sometimes shorter. The permanent

Digitized by Google

manent dark spots, therefore, it is said, must be some matter which is not fitted for reflecting the rays of the sun so much as the bright parts do: and this property, we know by experience, belongs to water rather than land; whence these philosophers conclude, that the moon, as well as our earth, is made up of land and seas.

121 Whether the moon has any atmosphere.

It has been a matter of dispute whether the moon has any atmosphere or not. The following arguments have been urged by those who take the negative side.

1. The moon constantly appears with the same brightness when there are no clouds in our atmosphere; which could not be the case if she were surrounded with an atmosphere like ours, so variable in its density, and so frequently obscured by clouds and vapours. 2. In an appulse of the moon to a star, when she comes so near it that part of her atmosphere is interposed between our eye and the star, refraction would cause the latter to seem to change its place, so that the moon would appear to touch it later than by her own motion she would do. 3. Some philosophers are of opinion, that because there are no seas or lakes in the moon, there is therefore no atmosphere, as there is no water to be raised up in vapours.

All these arguments, however, have been answered by other astronomers in the following manner. 1. It is denied that the moon appears always with the same brightness, even when our atmosphere appears equally clear. Hevelius relates, that he has several times found in skies perfectly clear, when even stars of the sixth and seventh magnitude were visible, that at the same altitude of the moon, and the same elongation from the earth, and with one and the same telescope, the moon and its maculæ do not appear equally lucid, clear, and conspicuous at all times; but are much brighter and more distinct at some times than at others. From the circumstances of this observation, say they, it is evident that the reason of this phenomenon is neither in our air, in the tube, in the moon, nor in the spectator's eye; but must be looked for in something existing about the moon. An additional argument is drawn from the different appearances of the moon already mentioned in total eclipses, which are supposed to be owing to the different constitutions of the lunar atmosphere.

122 Why the light is not refracted by the moon's atmosphere.

To the second argument Dr Long replies, that Sir Isaac Newton has shown (*Princip.* prop. 37. cor. 5.), that the weight of any body upon the moon is but a third part of what the weight of the same would be upon the earth; now the expansion of the air is reciprocally as the weight that compresses it: the air, therefore, surrounding the moon, being pressed together, by a weight, or being attracted towards the centre of the moon by a force equal only to one-third of that which attracts our air towards the centre of the earth, it thence follows, that the lunar atmosphere is only one-third as dense as that of the earth, which is too little to produce any sensible refraction of the stars light. Other astronomers have contended that such refraction was sometimes very apparent. M. Cassini says that he frequently observed Saturn, Jupiter, and the fixed stars, to have their circular figure changed into an elliptical one, when they approached either to the moon's dark or illuminated limb; though they own, that in other occultations no such change could be observed. With regard to the fixed stars, indeed, it has been urged, that granting the moon to have an atmosphere of the same nature and quantity as ours, no such effect as a gradual diminution of light ought to take place; at least, that we could by no means be capable of perceiving it. Our atmosphere is found to be so rare at the height of 44 miles as to be incapable of refracting the rays of light. This height is the 180th part of the earth's diameter; but since clouds are never observed higher than four miles, we must conclude that the vaporous or obscure part is only one 1980th. The mean apparent diameter of the moon is 31′ 29″, or 1889 seconds: therefore the obscure parts of her atmosphere, when viewed from the earth, must subtend an angle of less than one second; which space is passed over by the moon in less than two seconds of time. It can therefore hardly be expected that observation should generally determine whether the supposed obscuration takes place or not.

The third argument is necessarily inconclusive, because we know not whether there is any water in the moon or not; nor though this could be demonstrated, would it follow that the lunar atmosphere answers no other purpose than the raising of water into vapours There is, however, a strong argument in favour of the existence of a lunar atmosphere, taken from the appearance of a luminous ring round the moon in the time of solar eclipses. In the eclipse of May 1. 1706, Captain Stanyan, from Bern in Switzerland, writes, that "the sun was totally darkened there for the space of four minutes and a half: that a fixed star and planet appeared very bright: that his getting out of the eclipse was preceded by a blood-red streak of light from his left limb, which continued not longer than six or seven seconds of time; then part of the sun's disk appeared all on a sudden, brighter than Venus was ever seen in the night; and in that very instant gave light and shadow to things as strong as moon light uses to do." The publisher of this account observes that the red streak of light preceding the emersion of the sun's body, is a proof that the moon has an atmosphere; and its short continuance of five or six seconds shows that its height is not more than the five or six hundredth part of her diameter.

123 Luminous ring observed about the moon in total eclipses.

Fatio, who observed the same eclipse at Geneva, tells us, that "there was seen during the whole time of the total immersion, a whiteness which seemed to break out from behind the moon, and to encompass her on all sides equally: this whiteness was not well defined on its outward side, and the breadth of it was not a twelfth part of the diameter of the moon. The planet appeared very black, and her disk very well defined within the whiteness which encompassed it about, and was of the same colour as that of a white crown or halo, of about four or five degrees in diameter, which accompanied it, and had the moon for its centre. A little after the sun had begun to appear again, the whiteness, and the crown which had encompassed the moon, did entirely vanish." "I must add (says Dr Long), that this description is a little perplexed, either through the fault of the author or of the translator; for I suppose Fatio wrote in French: however, it plainly appears by it that the moon's atmosphere was visible, surrounded by a light of larger extent, which

I

Apparent Motions of the Heavenly Bodies.

I think must be that luminous appearance (the zodiacal light) mentioned from Cassini." Flamstead, who published this account, takes notice, that, according to these observations, the altitude of the moon's atmosphere cannot be well supposed less than 180 geographical miles; and that probably this atmosphere was never discovered before the eclipse, by reason of the smallness of the refraction, and the want of proper observations.

An account of the same eclipse, as it appeared at Zurich, is given by Dr Scheuchzer, in the following words: "We had an eclipse of the sun, which was both total and annular; total, because the whole sun was covered by the moon; annular, not what is properly so called, but by refraction: for there appeared round the moon a bright shining, which was owing to the rays of the sun refracted through the atmosphere of the moon."

Dom. Cassini, from a number of accounts sent him from different parts, says, that in all those places where it was total, during the time of total darkness, there was seen round the moon a crown or broad circle of pale light, the breadth whereof was about a 12th part of the moon's diameter: that at Montpelier, where the observers were particularly attentive to see if they could distinguish the zodiacal light already mentioned, they took notice of a paler light of a larger extent, which surrounded the crown of light before mentioned, and spread itself on each side of it, to the distance of four degrees. He then mentions Kepler's opinion, that the crown of light which appears round the moon during the total darkness in an eclipse of the sun is caused by some celestial matter surrounding the moon, of sufficient density to receive the rays of the sun and send them to us; and that the moon may have an atmosphere similar to that of our earth, which may refract

124 the sun's light.

Dr Halley's account of a solar eclipse in 1715.

A total eclipse of the sun was observed on the 22d of April O. S. in the year 1715, by Dr Halley at London, and by M. Louville of the Academy of Sciences at Paris. Dr Halley relates, that "when the first part of the sun remained on his east side, it grew very faint, and was easily supportable to the naked eye even through the telescope, for above a minute of time before the total darkness; whereas, on the contrary, the eye could not endure the splendour of the emerging beams through the telescope even from the first moment. To this, two causes perhaps concurred: the one, that the pupil of the eye did necessarily dilate itself during the darkness, which before had been much contracted by looking on the sun: the other that the eastern parts of the moon, having been heated with a day near as long as 30 of ours, must of necessity have that part of its atmosphere replete with vapours raised by the so long continued action of the sun; and, by consequence, it was more dense near the moon's surface, and more capable of obstructing the sun's beams; whereas at the same time the western edge of the moon had suffered as long a night, during which there might fall in dews all the vapours that were raised in the preceding long day; and for that reason, that that part of its atmosphere might be seen much more pure and transparent.

"About two minutes before the total immersion, the remaining part of the sun was reduced to a very fine horn, whose extremities seemed to lose their acuteness, and to become round like stars; and for the space of about a quarter of a minute a small piece of the southern horn of the eclipse seemed to be cut off from the rest by a good interval, and appeared like an oblong star rounded at both ends; which appearance would proceed from no other cause but the inequalities of the moon's surface; there being some elevated parts thereof near the moon's southern pole, by whose interposition part of that exceedingly fine filament of light was intercepted. A few seconds before the sun was totally hid, there discovered itself round the moon a luminous ring, about a digit, or perhaps a tenth part of the moon's diameter in breadth. It was of a pale whiteness, or rather of a pearl colour, seeming to me a little tinged with the colour of the iris, and to be concentric with the moon; whence I concluded it the moon's atmosphere. But the great height of it, far exceeding that of our earth's atmosphere, and the observations of some who found the breadth of the ring to increase on the west side of the moon as the emersion approached, together with the contrary sentiments of those whose judgments I shall always revere, make me less confident, especially in a matter to which I gave not all the attention requisite. 125

Flashes of light appear to dart from behind the moon.

"Whatever it was, the ring appeared much brighter and whiter near the body of the moon than at a distance from it; and its outward circumference, which was ill defined, seemed terminated only by the extreme rarity of the matter of which it was composed, and in all respects resembled the appearance of an enlightened atmosphere seen from far: but whether it belonged to the sun or moon, I shall not pretend to determine. During the whole time of the total eclipse, I kept my telescope constantly fixed on the moon, in order to observe what might occur in this uncommon appearance; and I saw perpetual flashes or coruscations of light, which seemed for a moment to dart out from behind the moon, now here, now there, on all sides, but more especially on the western side, a little before the emersion; and about two or three seconds before it, on the same western side, where the sun was just coming out, a long and very narrow streak of dusky but strong red light seemed to colour the dark edge of the moon, though nothing like it had been seen immediately after the immersion. But this instantly vanished after the appearance of the sun, as did also the aforesaid luminous ring." 126

Mr Louville's observations.

Mr Louville relates, that a luminous ring of a silver colour appeared round the moon as soon as the sun was entirely covered by her disk, and disappeared the moment he recovered his light; and this ring was brightest near the moon, and grew gradually fainter towards its outer circumference, where it was, however, defined; that it was not equally bright all over, but had several breaks in it: but he makes no doubt of its being occasioned by the moon's atmosphere, and thinks that the breaks in it were occasioned by the mountains of the moon; he says also, that this ring had the moon, and not the sun, for its centre, during the whole time of its appearance. Another proof brought by him of the moon having an atmosphere is, that, towards the end of the total darkness, there was seen on that side of the moon on which the sun was going to appear, a piece of a circle, of a lively red, which might be

Digitized by Google

Apparent Motions of the Heavenly Bodies.

be owing to the red rays that are least refrangible being transmitted through the moon's atmosphere in the greatest quantity: and that he might be assured this redness did not proceed from the glasses of his telescope, he took care to bring the red part into the middle of his glasses.

127 Lightning supposed to be frequent in the moon.

He lays great stress on the streaks of light which he saw dart instantaneously from different places of the moon during the time of total darkness, but chiefly near the eastern edge of the disk: these he takes to be lightning, such as a spectator would see flashing from the dark hemisphere of the earth, if he were placed upon the moon, and saw the earth come between himself and the sun. "Now (says Dr Long) it is highly probable, that if a man had, at any time, a view of that half of the earth where it is night, he would see lightning in some part of it or other." Louville farther observes, that the most mountainous countries are most liable to tempests; and that mountains being more frequent in the moon, and *higher, than on earth**, thunder and lightning must be more frequent there than with us; and that the eastern side of the moon would be most subject to thunder and lightning, those parts having been heated by the sun for half the month immediately preceding. It must here be observed, that Halley, in mentioning these flashes, says they seemed to come from behind the moon; and Louville, though he says they came sometimes from one part and sometimes from another, owns, that he himself only saw them near the eastern part of the disk; and that, not knowing at that time what it was that he saw, he did not take notice whether the same appearance was to be seen on other parts of the moon or not. He tells us, however, of an English astronomer, who presented the Royal Society with a draught of what he saw in the moon at the time of this eclipse; from which Louville seems to conclude, that lightnings had been observed by that astronomer near the centre of the moon's disk. "Now (says Mr Long) thunder and lightning would be a demonstration of the moon having an atmosphere similar to ours, wherein vapours and exhalations may be supported, and furnish materials for clouds, storms, and tempests. But the strongest proof brought by Louville of the moon having an atmosphere is this, that as soon as the eclipse began, those parts of the sun which were going to be hid by the moon grew sensibly palish as the former came near them, suffering beforehand a kind of imperfect eclipse or diminution of light; this would be owing to nothing else but the atmosphere of the moon, the eastern part whereof going before her reached the sun before the moon did.

* See N° 114. *et seq.*

128 Great height of the lunar atmosphere accounted for.

As to the great height of the lunar atmosphere, which from the breadth of the luminous ring, being about a whole digit, would upon a calculation come out 180 miles, above three times as high as the atmosphere of the earth, Louville thinks that no objection; since if the moon were surrounded with an atmosphere of the same nature with that which encompasses the earth, the gravitation thereof towards the moon would be but one third of that of our atmosphere towards the earth; and consequently its expansion would make the height of it three times as great from the moon as is the height of our atmosphere from the earth."

The same luminous ring has been observed in other total eclipses, and even in such as are annular, though without the luminous streaks or flashes of lightning above-mentioned; it is even taken notice of by Plutarch: however, some members of the academy at Paris have endeavoured to account for both these phenomena without having recourse to a lunar atmosphere; and for this purpose they made the following experiments:

129 These phenomena otherwise accounted for.

The image of the sun coming through a small hole into a darkened room, was received upon a circle of wood or metal of a diameter a good deal larger than that of the sun's image; then the shadow of this opaque circle was cast upon white paper, and there appeared round it, on the paper, a luminous circle such as that which surrounds the moon. The like experiment being made with a globe of wood and with another of stone not polished, the shadows of both these cast upon paper were surrounded with a palish light, most vivid near the shadows, and gradually more diluted at a distance from them. They observe also, that the ring round the moon was seen in the eclipse of 1706 by Wurzelbaur, who cast her shadow upon white paper. The same appearance was observed on holding an opaque globe in the sun, so as to cover his whole body from the eye; for, looking at it through a smoked glass, in order to prevent the eye from being hurt by the glare of light it would otherwise be exposed to, the globe appeared with a light resembling that round the moon in a total eclipse of the sun.

Thus they solve the phenomenon of the ring seen round the moon by the inflection, or *diffraction* as they call it, of the solar rays passing near an opaque substance. As for the small streaks of light above-mentioned, and which are supposed to be lightning, they explain these by an hypothesis concerning the cavities of the moon themselves; which they consider as concave mirrors reflecting the light of the sun nearly to the same point; and as these are continually changing their situation with great velocity by the moon's motion from the sun, the light which any one of them sends to our eye is seen but for a moment. This, however, will not account for the flashes, if any such there are, seen near the centre of the disk, though it does, in no very satisfactory manner, account for those at the edges.

130 Occultations of the fixed stars by the moon.

It has already been observed, that the occultations of the fixed stars and planets by the moon, in general happen without any kind of refraction of their light by the lunar atmosphere. The contrary, however, has sometimes been observed, and the stars have been seen manifestly to change their shape and colour on going behind the moon's disk. An instance of this happened on the 28th of June N. S. in the year 1715, when an occultation of Venus by the moon happened in the day-time. Some astronomers in France observing this with a telescope, saw Venus change colour for about a minute before she was hid by the moon; and the same change of colour was observed immediately after her emersion from behind the disk. At both times the edge of the disk of Venus that was nearest the moon appeared reddish, and that which was most distant of a bluish colour. These appearances, however, which might have been taken for proofs of a lunar atmosphere, were supposed to be owing to the observers having directed the axis of their telescopes towards the moon. This would necessarily cause any planet or star near the edge of the moon's disk to be seen through those parts of the glasses which are near their circum-

Apparent Motions of the Heavenly Bodies.

ference, and consequently to appear coloured. This was evidently the case from other observations of an occultation of Jupiter by the moon the same year, when no such appearance of refraction could be perceived while he was kept in the middle of the telescope. Maraldi also informs us, that he had observed before this two other occultations of Venus and one of Jupiter; and was always attentive to see whether those planets changed their figure or colour either upon the approach of the moon to cover them, or at their first coming again into sight; but never could perceive any such thing. Nor could he, in a great number of occultations of the fixed stars, perceive the smallest apparent change in any of them, excepting once that a fixed star seemed to increase its distance a little from the moon as it was going to be covered by her; but this, he suspected, might be owing to his telescope being directed so as to have the star seen too far from the middle of its aperture. He concludes, therefore, that the moon has no atmosphere: and he remarks, that at Montpelier, perhaps because the air is clearer there than at London, the luminous ring round the moon appeared much larger than at London; that it was very white near the moon, and gradually decreasing in brightness, formed round her a circular area of about eight degrees in diameter. If, says he, this light was caused by the atmosphere of the moon, of what a prodigious extent must that atmosphere be?

131 Moon has no sensible atmosphere.

We have related all these opinions at full length, in order to put our readers in possession of the arguments that have been advanced upon this subject; but it is now generally admitted, and indeed, scarcely can be denied, that the atmosphere of the moon, if it really has any, is almost entirely insensible.

132 Turns round her axis.

From the spots upon the moon's disk it has been ascertained, that the same hemisphere of that luminary is always directed towards the earth. Hence it follows that she turns round her axis once during every revolution round the earth.

133 Libration of the moon.

Exact observations have ascertained that slight varieties take place respecting the appearances of the moon's disk. The spots are observed alternately to approach towards and recede from the edge of the moon. Those that are very near the edge appear and disappear alternately, making periodical oscillations, which are distinguished by the name of the *libration of the moon.* To form a precise idea of the nature of this libration, we must consider that the disk of the moon, seen from the centre of the earth, is terminated by the circumference of a great circle of the moon, perpendicular to a line drawn from the earth's centre to that of the moon. The lunar hemisphere is projected upon the plane of this circle turned towards the earth, and its appearances are due to the movements of rotation of that body relative to its radius vector. If the moon did not revolve round her axis, this radius vector would describe a great circle on the moon's surface, all the points of which would present themselves successively to us. But the moon, revolving in the same time that this radius vector describes the great circle, always keeps the same point of the circle nearly upon the radius, and of course the same hemisphere turned towards the earth. The inequalities of her motion produce the slight variations in her appearance: for the rotation of the moon does not partake sensibly of these irregularities. Hence it varies somewhat relatively to the radius vector, which accordingly cuts successively different points of the surface. Of course the globe of the moon makes oscillations relatively to that radius corresponding to the inequalities of her motions, which alternately conceal from our view and discover to us some parts of her surface.

Farther: the axis of rotation of the moon is not exactly perpendicular to the plane of her orbit. If we suppose the position of this axis fixed, during a revolution of the moon it inclines more or less to the radius vector, so that the angle formed by these two lines is acute during one part of her revolution, and obtuse during another part of it. Hence the poles of rotation are alternately visible from the earth, and those parts of her surface that are near these poles.

Besides all this, the observer is not placed at the centre of the earth, but at its surface. It is the radius drawn from his eye to the centre of the moon, which determines the middle point of her visible hemisphere. But in consequence of the lunar parallax, it is obvious that this radius must cut the surface of the moon in points sensibly different according to the height of that luminary above the horizon. All these causes concur to produce the *libration* of the moon, a phenomenon which is merely optical, and not connected with her rotation, which relatively to us is perfectly equable, or at least if it be subjected to any irregularities, they are too small to be observed.

This is not the case with the variations in the plane of the moon's equator. While endeavouring to determine its position by the lunar spots, Cassini was led to this remarkable conclusion, which includes the whole astronomical theory of the real libration of that luminary. Conceive a plane passing through the centre of the moon perpendicular to her axis of rotation, and of course coinciding with the plane of her equator; conceive a second plane, parallel to the ecliptic, to pass through the same centre; and also a third plane, which is the mean plane of the lunar orbit: these three planes have a common intersection; the second, placed between the two others, forms with the first an angle of 1°.503, and with the third an angle of 5°.14692; therefore the intersections of the lunar equator with the ecliptic coincide always with the mean nodes of the lunar orbit, and like them have a retrograde motion, which is completed in the period of 6793.3009 days. During that interval the two poles of the equator and lunar orbit describe small circles parallel to the ecliptic, enclosing between them the pole of the ecliptic, so that these three poles are constantly upon a great circle of the heavenly sphere. 134 Theory of it.

Chap. III. *Of the Planets.*

Amidst the infinite variety of stars which occupy a place in the sphere of the heavens, and which occupy nearly the same relative position with respect to each other, there are eight which may be observed to move in a very complicated manner, but following certain precise laws, for they always commence the same motions again after every period. The motions of these

Digitized by Google

Apparent Motions of the Heavenly Bodies.

these stars, called planets, constitute one of the principal objects of astronomy. These planets are called

1. Mercury.
2. Venus.
3. Mars.
4. Ceres.
5. Pallas.
6. Jupiter.
7. Saturn.
8. Herschel.

Mercury and Venus never separate from the sun farther than certain limits; the rest separate to all the possible angular distances. The movements of all these bodies are included in a zone of the heavenly sphere called the *zodiac*. This zone is divided into two equal parts by the ecliptic. Its breadth was formerly considered as only about 16°; but it must be much increased if the orbits of Ceres and Pallas, the two newly discovered planets, are to be comprehended in it. It will be proper to consider the motions and appearances of each of these planets. This will be the subject of the following sections.

SECT. I. *Of Mercury.*

Mercury is a small star, but emits a very bright white light: though, by reason of his always keeping near the sun, he is seldom to be seen; and when he does make his appearance, his motion towards the sun is so swift, that he can only be discerned for a short time. He appears a little after sunset, and again a little before sunrise.

135 His apparent motion. Mercury never goes to a greater distance from the sun than about 27°.5; so that he is never longer in setting after the sun than an hour and 50 minutes; nor does he ever rise sooner than 1 hour and 50 minutes before that luminary. Very frequently, he goes so near the sun as to be lost altogether in his rays. When he begins to make his appearance in the evening after sunset, he can scarcely at first be distinguished in the rays of the twilight. But the planet disengages itself more and more, and is seen at a greater distance from the sun every successive evening; and having got to the distance of about 22°.5, it begins to return again. During this interval, the motion of Mercury referred to the stars is direct; but when it approaches within 18° of the sun it appears for some time stationary; and then its motion begins to be retrograde. The planet continues to approach the sun, and at last plunges into his rays in the evening, and disappears. Soon after, it may be perceived in the morning, before sunrise, separating farther and farther from the sun, his motion being retrograde, as before he disappeared. At the distance of 18° it becomes stationary, and assumes a direct motion, continuing, however, to separate till it comes to 22.5° of distance; then it returns again to the sun, plunges into his rays, and appears soon after in the evening, after sunset, to repeat the same career. The angular distance from the sun, which the planet reaches on both sides of that luminary, varies from 16° to nearly 28°.

The duration of a complete oscillation, or the interval of time that elapses before the planet returns again to the point from which it set out, varies also from 100 to 130 days. The mean arc of his retrogradation is about $13\frac{1}{3}$°; its mean duration 23 days. But the quantity differs greatly in different retrogradations. In general, the laws of the movements of Mercury are very complicated; he does not move exactly in the plane of the ecliptic; sometimes he deviates from it more than 5°.

Some considerable time must have elapsed before astronomers suspected that the stars which were seen approaching the sun in the evening and in the morning were one and the same. The circumstance, however, of the one never being seen at the same time with the other would gradually lead them to the right conclusion.

The apparent diameter of Mercury varies as well as that of the sun and moon, and this variation is obviously connected with his position relatively to the sun, and with the direction of his movement. The diameter is at its minimum when the planet plunges into the solar rays in the morning, or when it disengages itself from them: it is at its maximum when the planet plunges into the solar rays in the evening, or when it disengages itself from them in the evening; that is to say, when the planet passes the sun in its retrograde motion, its diameter is the greatest possible; when it passes the sun in its direct motion, it is the smallest possible;—and the mean length of the apparent diameter of Mercury is 11″. 136 Diameter.

Sometimes, when the planet disappears during its retrograde motion, that is to say, when it plunges into the sun's rays in the evening, it may be seen crossing the sun under the form of a black spot, which describes a chord along the disk of the sun. This black spot is recognised to be the planet by its position, its apparent diameter, and its retrograde motion. These *transits* of Mercury, as they are termed, are real annular eclipses of the sun: they demonstrate that the planet is an opaque body, and that it borrows its light from the sun. When examined by means of telescopes magnifying about 200 or 300 times, he appears equally luminous throughout his whole surface, without the least dark spot. But he exhibits the same difference of phases with the moon, being sometimes horned, sometimes gibbous, and sometimes shining almost with a round face, though not entirely full, because his enlightened side is never turned directly towards us; but at all times perfectly well defined without any ragged edge, and perfectly bright. Like the moon, the crescent is always turned towards the sun. These different phases throw considerable light on the orbit of Mercury. 137 Nature.

SECT. II. *Of Venus.*

Venus, the most beautiful star in the heavens, known by the names of the *morning* and *evening star*, likewise keeps near the sun, though she recedes from him almost double the distance of Mercury. She is never seen in the eastern quarter of the heavens when the sun is in the western; but always seems to attend him in the evening, or to give notice of his approach in the morning.

The planet Venus presents the same phenomena with Mercury; but her different phases are much more sensible, her oscillations wider, and of longer duration. Her greatest distance from the sun varies from 45° to nearly 48°, and the mean duration of a complete oscillation is 584 days.

Venus has been sometimes seen moving across the sun's disk in the form of a round black spot, with an apparent diameter of about 59″. A few days after this has been observed, Venus is seen in the morning, 138 Her apparent motions.

 west

Apparent Motions of the Heavenly Bodies.

west of the sun, in the form of a fine crescent, with the convexity turned toward the sun. She moves gradually westward with a retarded motion, and the crescent becomes more full. In about ten weeks she has moved 46° west of the sun, and is now a semicircle, and her diameter is 26″. She is now stationary. She then moves eastward with a motion gradually accelerated, and overtakes the sun about $9\frac{1}{7}$ months after having been seen on his disk. Some time after, she is seen in the evening, east of the sun, round, but very small. She moves eastward, and increases in diameter, but loses of her roundness, till she gets about 46° east of the sun, when she is again a semicircle. She now moves westwards, increasing in diameter, but becoming a crescent like the waning moon; and, at last, after a period of nearly 584 days, comes again into conjunction with the sun with an apparent diameter of 59″.

The mean arc of her retrogradation is about 16°, and its mean duration is 42 days. She does not move exactly in the plane of the ecliptic, but deviates from it several degrees. Like Mercury, she sometimes crosses the sun's disk. The duration of these transits, as observed from different parts of the earth's surface, are very different: this is owing to the parallax of Venus, in consequence of which different observers refer to different parts of the sun's disk, and see her describe different chords on that disk. In the transit which happened in 1769, the difference of its duration, as observed at Otaheite and at Wardhuys in Lapland, amounted to 23 m. 10 sec. This difference gives us the parallax of Venus, and of course her distance from the earth during a conjunction. The knowledge of this parallax enables us, by a method to be afterwards described, to ascertain that of the sun, and consequently to discover its distance from the earth.

The great variations of the apparent diameter of Venus demonstrates that her distance from the earth is exceedingly variable. It is largest when the planet passes over the surface of the sun. Her mean apparent diameter is 58″.

139 Revolution round her axis.

From the movement of certain spots upon the surface of Venus, it has been concluded that she revolves round her axis once in 24 hours; but this requires to be corrected by future observations. It is extremely difficult to perceive or examine these spots in our climate. The subject merits the attention of astronomers farther to the south, in more favourable circumstances. The following detail will show the uncertainty which has prevailed among astronomers respecting these spots.

140 Spots when first discovered on the disk of Venus.

Dr Long informs us, that the earliest account he had met with of any spots seen by means of the telescope on the disk of Venus was in a collection of letters printed at Paris in 1665, in one of which Mr Auzout relates his having received advice from Poland that Mr Burratini had, by means of large telescopes, seen spots upon the planet Venus similar to those upon the moon.

141 Cassini's observations.

In 1667, Cassini, in a letter to Mr Petit, mentions his having for a long time carefully observed Venus through an excellent telescope made by Campani, in order to know whether that planet revolved on its axis or not, as he had before found Jupiter and Mars to do. But though he then observed some spots upon her, he says, that even when the air was quiet and clear, they appeared faint, irregular, and not well defined; so that it was difficult to have such a distinct view of any of them as to be certain that it was the same spot which was seen again in any subsequent observation; and this difficulty was increased, in the first place, when Venus was in her inferior semicircle; because at that time she must be viewed through the thick vapours near the horizon; though otherwise it was most proper, on account of her being then nearest to us. In the second place, if we would observe her at some height above those vapours, it could only be for a short time; and thirdly, when she is low in her inferior circle, and at that time nearest the earth, the enlightened part of her is too small to discover any motion in it. He was therefore of opinion, that he should succeed better in his observations when the planet was about its mean distance from us, showing about one half of her enlightened hemisphere; at which time also he could observe her for a much longer time above the gross atmospherical vapours. His first appearance of success was October 14. 1666, at three quarters past five in the evening; when he saw a bright spot (fig. 37.), but could not then view that spot long enough to draw any inference concerning the planet's motion. He had no farther success till the 20th of April the following year; when, about a quarter of an hour before sunrise, he began again to perceive on the disk of Venus, now about half enlightened, a bright part near the section, distant from the southern horn a little more than a fourth part of the diameter of the disk, and near the eastern edge. He took notice also of a darkish oblong spot nearer to the northern than the southern horn: at sunrise the bright part was advanced farther from the southern horn than when he first observed it; 142

142 Why the spots seem to move from south to north.

but though he was pleased to find that he had now a convincing proof of the planet's motion, he was surprised that the spots moved from south to north in the lower part of the disk, and from north to south in the upper part; a kind of motion of which we have no example except in the librations of the moon. This, however, was occasioned by the situation of the planet's axis. Cassini expected to have found the rotation of Venus similar to that of Jupiter and Mars, both of which have their axis perpendicular to their respective orbits, and turn round according to the order of the signs; so that in each of them the motion of the inferior half of their respective globe, or that part next the sun, is from east to west; in the superior half from west to east; but in Venus, whose axis is inclined 75 degrees towards her orbit, the coincidence is so near, that one half of her disk appears to move from south to north, the other from north to south.

On the 21st of April, at sunrise, the bright part was a good way off the section, and about a fourth part of the diameter distant from the southern horn. 143

143 Particular account of the appearances of the spots at different times.

When the sun was eight degrees six minutes high, it seemed to be got beyond the centre, and was cut through by the section. At the time the sun was seven degrees high, the section cut it in the middle, which showed its motion to have some inclination towards the centre.

May 9. a little before sunrise, the bright spot was seen near the centre, a little to the northward, with two obscure ones situated between the section and the circumference, at a distance from each other, equal to that

that of each of them from the nearest angular point or horn of the planet. The weather being at that time clear, he observed for an hour and half a quarter the motion of the bright spot, which seemed to be exactly from south to north, without any sensible declination to east or west. A variation was at the same time perceived in the darkish spot, too great to be ascribed to any optical cause. The bright spot was also seen on the 10 and 13th days of May before sunrise between the northern horn and the centre, and the same irregular change of darkish spots was taken notice of; but as the planet removed to a greater distance from the earth, it became more difficult to observe these appearances. The above phenomena are represented as they occurred, in fig. 19. to 25.

144 Cassini's conclusions concerning the revolution of Venus on her axis.

But though, from the appearances just now related, M. Cassini was of opinion that Venus revolved on her axis, he was by no means so positive in this matter as with regard to Mars and Jupiter. "The spots on these (says he) I could attentively observe for a whole night, when the planets were in opposition to the sun: I could see them return to the same situation, and consider their motion during some hours, and judge whether they were the same spots or not, and what time they took in turning round: but it was not the same with the spots of Venus; for they can be observed only for so short a time, that it is much more difficult to know with certainty when they return into the same situation. I can, however, supposing that the bright spot which I observed on Venus, and particularly this year, was the same, say that she finishes her motion, whether of rotation or libration, in less than a day; so that, in 23 days nearly, the spot comes into the same situation on nearly the same hour of the day, though not without some irregularity. Now (supposing the bright spot observed to be always the same) whether this motion is an entire turning round, or only a libration, is what I dare not positively affirm."

145 Difficulties attending these observations.

In 1669, M. Cassini again observed Venus through a telescope, but could not then perceive any spots upon her surface; the reason of which Du Hamel conjectures to have been the fluctuation of the vapours near the horizon, which prevented them from being visible. However, we hear nothing more of any spots being seen on her disk till the year 1726; when, on the 9th of February, Bianchini, with some of Campani's telescopes of 90 and 100 Roman palms, began to observe the planet at the altitude of 40° above the horizon, and continued his observation till, by the motion of several spots, he determined the position of her axis to be inclined as above mentioned, that the north pole pointed at a circle of latitude drawn through the 20th degree of Aquarius, elevated 15° or 20° above the orbit of Venus. He delineated also the figures of several spots which he supposed to be seas, and complimented the king of Portugal and some other great men by calling them by their names. Though none of Bianchini's observations were continued long enough to know whether the spots, at the end of the period assigned for the rotation of the planet, would have been in a different situation from what they were at the beginning of it; yet, from observations of two and of four days, he concluded the motion of the spots to be at the rate of 15° per day; at which advance the planet must turn round either once in 24 days or in 23 hours; but without farther observation it could not be determined which of the two was the period of revolution: for if an observer should at a particular hour, suppose seven in the evening, mark exactly the place of a spot, and at the same hour next evening find the spot advanced 15°, he would not be able to determine whether the spot had advanced only 15°, or had gone once quite round with the addition of 15° more in part of another rotation. Mr Bianchini, however, supposes Venus to revolve in 24 days eight hours; the principal proof adduced for which is an observation of three spots, ABC, being situated as in fig. 26. when they were viewed by himself, and several persons of distinction, for about an hour, during which they could not perceive any change of place. The planet being then hid behind the Barbarini palace, they could not have another view of her till three hours after, when the spots still appeared unmoved. "Now (says Mr Bianchini) if her rotation were so swift as to go round in 23 hours, in this second view, three hours after the former, the spots must have advanced near 50 degrees; so that the spot C would have been gone off at R, the spot B would have succeeded into the place of C, the spot A into the place of B, and there would have been no more but two spots, A and B, to have been seen."

146 Bianchini's observations.

147 Doubts concerning the time she takes in revolving round her axis.

148 Dispute between Cassini and Bianchini.

Cassini, the son, in a memoir for 1732, denies the conclusion of Bianchini to be certain. He says, that during the three hours interval, the spot C might be gone off the disk, and the spot B got into the place thereof, where, being near the edge, it would appear less than in the middle. That A, succeeding into the place of B, would appear larger than it had done near the edge, and that another spot might come into the place of A; and there were other spots besides these three on the globe of the planet, as appears by the figures of Bianchini himself, particularly one which would naturally come in the place of A. That if the rotation of Venus be supposed to be in 23 hours, it will agree with Bianchini's observations, as well as with those of his father; but that, on the other supposition, the latter must be entirely rejected as erroneous: and he concludes with telling us, that Venus had frequently been observed in the most favourable times by Mr Maraldi and himself with excellent telescopes of 80 and 100 feet focus, without their being able to see any distinct spot upon her disk. "Perhaps (says Dr Long) those seen by Bianchini had disappeared, or the air in France was not clear enough; which last might be the reason why his father could never see those spots in France which he had observed in Italy, even when he made use of the longest telescopes." Neither of these astronomers take notice of any indentings in the curve which divides the illuminated part from the dark in the disk of Venus, though in some views of that planet by Fontana and Ricciolus, the curve is indented; and it has from thence been concluded, that the surface of the planet is mountainous like that of the moon. This had also been supposed by Burratini, already mentioned; and a late writer has observed, that, "when the air is in a good state for observation, mountains like those of the moon may be observed with a very powerful telescope."

149 Cassini discovers her satellite.

Cassini, besides the discovery of the spots on the disk of Venus, by which he was enabled to ascertain her revolution

Digitized by Google

Apparent Motions of the Heavenly Bodies.

volution on an axis, had also a view of her satellite or moon, of which he gives the following account.—"A. D. 1686, August 28th, at 15 minutes after four in the morning, looking at Venus with a telescope of 34 feet, I saw, at the distance of one-third of her diameter eastward, a luminous appearance, of a shape not well defined, that seemed to have the same phase with Venus, which was then gibbous on the western side. The diameter of this phenomenon was nearly equal to a fourth part of the diameter of Venus. I observed it attentively for a quarter of an hour, and having left off looking at it for four or five minutes, I saw it no more; but daylight was then advanced. I had seen a like phenomenon which resembled the phase of Venus, Jan. 25th, A. D. 1672, from 52 minutes after six in the morning to two minutes after seven, when the brightness of the twilight made it disappear. Venus was then horned; and this phenomenon, the diameter whereof was nearly a fourth part of the diameter of Venus, was of the same shape. It was distant from the southern horn of Venus, a diameter of the planet, on the western side. In these two observations, I was in doubt whether it was not a satellite of Venus of such a consistence as not to be very well fitted to reflect the light of the sun; and which, in magnitude, bore nearly the same proportion to Venus as the moon does to the earth, being at the same distance from the sun and the earth as Venus was, the phases whereof it resembled. Notwithstanding all the pains I took in looking for it after these two observations, and at divers other times, in order to complete so considerable a discovery, I was never able to see it. I therefore suspended my judgment of this phenomenon. If it should return often, there will be these two epochas, which, compared with other observations, may be of use to find out the periodical time of its return, if it can be reduced to any rule."

150 Discovered also by Mr Short.

A similar observation was made by Mr Short on the 23d of October 1740, about sunrise. He used at this time a reflecting telescope of about 16.5 inches, which magnified between 50 and 60 times, with which he perceived a small star at about 10′ distance from Venus, as measured by the micrometer; and, putting on a magnifying power of 240 times, he found the star put on the same appearance with the planet herself. Its diameter was somewhat less than a third of that of the primary, but its light was less vivid, though exceedingly sharp and well defined. The same appearance continued with a magnifying power of 140 times. A line, passing through the centre of Venus and it, made an angle of 18 or 20 degrees with the equator: he saw it several times that morning for about the space of an hour, after which he lost sight of it, and could never find it again.

From this time the satellite of Venus, though very frequently looked for by astronomers, could never be perceived, which made it generally believed that Cassini and Mr Short had been mistaken; but as the transits of the planet over the sun in 1761 and 1769 seemed to promise a greater certainty of finding it, the satellite was very carefully looked for by almost every one who had an opportunity of seeing the transit, but generally without success. Mr Baudouin at Paris had provided a telescope of 25 feet, in order to observe the passage of the planet over the sun, and to look for its satellite; but he did not succeed either at that time or in the months of April and May following. Mr Montaigne, however, one of the members of the Society of Limoges, had better success. On the 3d of May 1761, he perceived, about half an hour after nine at night, at the distance of 20′ from Venus, a small crescent, with the horns pointing the same way as those of the planet; the diameter of the former being about one-fourth of that of the latter; and a line drawn from Venus to the satellite making an angle with the vertical of about 20° towards the south. But though he repeated this observation several times, some doubt remained whether it was not a small star. Next day he saw the same star at the same hour, distant from Venus about half a minute or a minute more than before, and making with the vertical an angle of 10° below on the north side; so that the satellite seemed to have described an arc of about 30°, whereof Venus was the centre, and the radius 20′. The two following nights were hazy, so that Venus could only be seen; but on the 7th of May, at the same hour as before, he saw the satellite again above Venus, and on the north side, at the distance of 25′ or 26′ upon a line which made an angle of about 45° with the vertical towards the right hand. The light of the satellite was always very weak, but it had the same phases with its primary, whether viewed together with it in the field of his telescope or by itself. The telescope was nine feet long, and magnified an object between 40 and 50 times, but had no micrometer; so that the distances above mentioned are only from estimation.

151 Seen by Mr Montaigne at the transit in 1761.

Fig. 27. represents the three observations of Mr Montaigne. V is the planet Venus; ZN the vertical. EC, a parallel to the ecliptic, making them an angle with the vertical of 45°; the numbers, 3, 4, 7, mark the situations of the satellite on the respective days. From the figure it appears that the points 3 and 7 would have been diametrically opposite, had the satellite gone 15° more round the point V at the last observation; so that in four days it went through 155°. Then, as 155° is to four days or 96 hours, so is 360 to a fourth number, which gives 9 days 7 hours for the whole length of the synodical revolution. Hence Mr Baudouin concluded that the distance of this satellite was about 60 of the semidiameters of Venus from its surface; that its orbit cut the ecliptic nearly at right angles; had its ascending node in 22° of Virgo; and was in its greatest northern digression on the 7th at nine at night; and he supposed that at the transit of the primary the satellite would be seen accompanying it. By a subsequent observation, however, on the 11th of May, he corrected his calculation of the periodical time of the satellite, which he now enlarged to 12 days; in consequence of which he found that it would not pass over the disk of the sun along with its primary, but go at the distance of above 20′ from his southern limb; though if the time of its revolution should be 15 hours longer than 12 days, it might then pass over the sun after Venus was gone off. He imagined the reason why this satellite was so difficult to be observed might be, that one part of its globe was crusted over with spots, or otherwise unfit to reflect the light of the sun. By comparing the periodical time of this satellite with that of our moon, he computed the quantity of matter in Venus to be nearly equal

152 Why this satellite is so difficult to be seen.

equal to that in our earth; in which case it must have considerable influence in changing the obliquity of the ecliptic, the latitudes and longitudes of stars, &c.

It is now known that this supposed satellite of Cassini was merely an optical deception.

153 Observations concerning the atmosphere of Venus.

In the Philosophical Transactions for 1761, Mr Hirst gives an account of his having observed an atmosphere round the planet Venus. The observations were made at Fort St George; and looking attentively at that part of the sun's disk where he expected the planet would enter, he plainly perceived a faint shade or penumbra; on which he called out to his two assistants, "'Tis a coming!" and two or three seconds after, the first external contact took place, in the moment whereof all the three agreed; but he could not see the penumbra after the egress; and of the other two gentlemen, one had gone home, and the other had lost the planet out of the field of his telescope. Mr Dunn at Chelsea saw a penumbra, or small diminution of light, that grew darker and darker for about five seconds before the internal contact preceding the egress; from whence he determines that Venus is surrounded with an atmosphere of about 50 geographical miles high. His observations, he tells us, were made mith an excellent six-feet Newtonian reflector, with a magnifying power of 110, and of 220 times; he had a clear dark glass next his eye, and the sun's limb appeared well defined; but a very narrow waterish penumbra appeared round Venus. The darkest part of the planet's phasis was at the distance of about a sixth part of her diameter from its edge; from which an imperfect light increased to the centre, and illuminated round about.

In the northern parts of Europe this penumbra could not be seen. Mr Wargentin, who communicated several observations of the first external contact, says, that he could not mark the time exactly, because of the undulation of the limb of the sun; but thought it very remarkable that, at the egress, the limb of Venus that was gone off the sun showed itself with a faint light during almost the whole time of emersion. Mr Bergman, who was then at the observatory at Upsal, begins his account at the time when three-fourths of the disk of the planet was entered upon that of the sun; and he says, that the part which was not come upon the sun was visible though dark, and surrounded by a crescent of faint light, as in fig. 28.: but this appearance was much more remarkable at the egress; for as soon as any part of the planet was got off the sun, that part was visible with a like crescent, but brighter, fig. 29. As more of the planetary disk went off that of the sun, however, that part of the crescent which was farthest from the sun grew fainter, and vanished, until at last only the horns could be seen, as in fig. 30. The total ingress was not instantaneous; but, as two drops of water, when about to part, form a ligament between them; so there was a dark swelling stretched out between Venus and the sun, as in fig. 31.; and when this ligament broke, the planet appeared to have got about an eighth part of her diameter from the nearest limb of the sun, fig. 32.: he saw the like appearance at going off, but not so distinct. fig. 33. Mr Chappe likewise took notice, that the part of Venus which was not upon the sun was visible during part of the time of ingress and egress; that it was farther surrounded by a small luminous ring of a deep yellow near the place that appeared in the form of a crescent, which was much brighter at the going off than coming upon the sun; and that, during the whole time the disk of Venus was upon the sun, he saw nothing of it. The time of total ingress was instantaneous like a flash of lightning; but at the egress the limb of the sun began to be obscured three seconds before the interior contact. Some of the French astronomers attributed this luminous ring round Venus to the inflection of the sun's rays, as they also do the light seen round the moon in solar eclipses; but Mr Chappe supposes it to have been owing to the sun enlightening more than one half of the planetary globe, though he owns this cause not to be altogether sufficient. Mr Fouchy, who observed the transit at La Muette in France, perceived, during the whole time, a kind of ring round Venus, brighter than the rest of the sun, which became fainter the farther it went from the planet, but appeared more vivid in proportion as the sun was clearer. Mr Ferner, who observed at the same place, confirms the testimony of Mr Fouchy. "During the whole time (says he) of my observing with the telescope, and the blue and green glasses, I perceived a light round about Venus, which followed her like a luminous atmosphere, more or less lively according as the air was more or less clear. Its extent altered in the same manner; nor was it well terminated, throwing out, as it were, some feeble rays on all sides."

154 Dr Long's opinion on these observations.

"I am not clear (says Dr Long) as to the meaning of the luminous circle here mentioned; whether, when the whole planet was upon the sun, they saw a ring of light round it, distinct from the light of the sun; or whether they mean only the light which surrounded that part of Venus that was not upon the sun." Mr Chappe takes this and other accounts of the observations made in France in this latter sense; and though he sometimes called the luminous part of the crescent that surrounded the part of the planet not upon the sun a ring, he explains himself that he did so, because at the coming upon the sun he perceived it at one side of the planet, and on the opposite side on its going off: for which reason he supposed that it surrounded it on all sides. See fig. 34, 35.

Sect. III. *Of Mars.*

The two planets which we have just described, appear to accompany the sun like satellites, and their mean motion round the earth is the same with that luminary. The remaining planets go to all the possible angular distances from the sun. But their motions have obviously a connection with the sun's position.

Mars is of a red fiery colour, and always gives a much duller light than Venus, though sometimes he equals her in size. He is not subject to the same limitation in his motions as Mercury or Venus; but appears sometimes very near the sun, and sometimes at a great distance from him; sometimes rising when the sun sets, or setting when he rises. Of this planet it is remarkable, that when he approaches any of the fixed stars, which all the planets frequently do, these stars change their colour, grow dim, and often become totally invisible, though at some little distance from the body of the planet: but Dr Herschel thinks this has been exaggerated by former astronomers.

Mars

Digitized by Google

Apparent Motions of the Heavenly Bodies.

Mars appears to move from west to east round the earth. The mean duration of his sidereal revolution is 686.979579 days. His motion is very unequal. When we begin to perceive this planet in the morning when he begins to separate from the sun, his motion is direct and the most rapid possible. This rapidity diminishes gradually, and the motion ceases altogether when the planet is about 137° distant from the sun; then his motion becomes retrograde, and increases in rapidity till he comes into opposition with the sun. It then gradually diminishes again, and becomes nothing when Mars approaches within 137° of the sun. Then the motion becomes direct after having been retrograde for 73 days, during which interval the planet described an arch of about 16°. Continuing to approach the sun, the planet at last is lost in the evening in the rays of that luminary. All these different phenomena are renewed after every opposition of Mars; but there are considerable differences both in the extent and duration of his retrogradations.

Mars does not move exactly in the plane of the ecliptic, but deviates from it several degrees. His apparent diameter varies exceedingly. His mean apparent diameter is 27″, and it increases so much, that when the planet is in opposition, the apparent diameter is 81″. Then the parallax of Mars becomes sensible, and about double that of the sun.

The disk of Mars changes its form relatively to its position with regard to the sun, and becomes oval. Its phases show that it derives its light from that luminary. The spots observed on its surface have informed astronomers that it moves round its axis from west to east in 1.02733 days, and its axis is inclined to the ecliptic at an angle of about 59.7°.

155 Spots when first seen on Mars.

They were first observed in 1666 by Cassini at Bologna with a telescope of Campani about 16½ feet long; and continuing to observe them for a month, he found they came into the same situation in 24 hours and 40 minutes. The planet was observed by some astronomers at Rome with longer telescopes made by Eustachio Divini; but they assigned to it a rotation in 13 hours only. This, however, was afterwards shown by Mr Cassini to have been a mistake, and to have arisen from their not distinguishing the opposite sides of the planet, which it seems have spots pretty much alike. He made further observations on the spots of this planet in 1670; from whence he drew an additional confirmation of the time the planet took to revolve. The spots were again observed in subsequent oppositions; particularly for several days in 1704 by Maraldi, who took notice that they were not always well defined, and that they not only changed their shape frequently in the space between two oppositions, but even in the space of a month. Some of them, however, continued of the same form long enough to ascertain the time of the planet's revolution. Among these there appeared this year an oblong spot, resembling one of the belts of Jupiter when broken. It did not reach quite round the body of the planet; but had, not far from the middle of it, a small protuberance towards the north, so well defined that he was thereby enabled to settle the period of its revolution at 24 hours 39 minutes; only one minute less than what Cassini had determined it to be. See fig. 45.

The near approach of Mars to the earth in 1719, gave a much better opportunity of viewing him than had been obtained before; as he was then within 2½° of his perihelion, and at the same time in opposition to the sun. His apparent magnitude and brightness were thus so much increased, that he was by the vulgar taken for a new star. His appearance at that time, as seen by Maraldi through a telescope of 34 feet long, is represented in fig. 37. There was then a long belt that reached half way round, to the end of which another shorter belt was joined, forming an obtuse angle with the former, as in fig. 38. This angular point was observed on the 19th and 20th of August, at 11 hours 15 minutes, a little east of the middle of the disk; and 37 days after, on the 25th and 26th of September, returned to the same situation. This interval, divided by 36, the number of revolutions contained in it, gives 24 hours 40 minutes for the period of one revolution; which was verified by another spot of a triangular shape, one angle whereof was towards the north pole, and the base towards the south, which on the 5th and 6th of August appeared as in fig. 39. and after 72 revolutions returned to the same situation on the 16th and 17th of October. The appearances of Mars, as delineated by Mr Hook, when viewed through a 36 feet telescope are represented in fig. 40. He appeared through this instrument as big as the full moon. Some of the belts of this planet are said to be parallel to his equator; but that seen by Maraldi was very much inclined to it.

156 Bright spots about the poles of Mars.

Besides these dark spots former astronomers took notice that a segment of his globe about the south pole exceeded the rest of his disk so much in brightness, that it appeared beyond them as if it were the segment of a larger globe. Maraldi informs us, that this bright spot had been taken notice of for 60 years, and was more permanent than the other spots on the planet. One part of it is brighter than the rest, and the least bright part is subject to great changes, and has sometimes disappeared.

A similar brightness about the north pole of Mars was also sometimes observed; and these observations are now confirmed by Herschel, who has viewed the planet with much better instruments, and much higher magnifying powers, than any other astronomer ever was in possession of. His observations were made with a view to determine the figure of the planet, the position of his axis, &c. A very particular account of them is given in the 74th volume of the Philosophical Transactions, but which our limits will not allow us to insert. Fig. 41. to 64. show the particular appearances of Mars, as viewed on the days there marked. The magnifying powers he used were sometimes as high as 932; and with this the south polar spot was found to be in diameter 41‴. Fig. 65. shows the connection of the other figures marked 56, 57, 58, 59, 60, 61, 62, which complete the whole equatorial succession of spots on the disk of the planet. The centre of the circle marked 57 is placed on the circumference of the inner circle, by making its distance from the circle marked 59 answer to the interval of time between the two observations, properly calculated and reduced to sidereal measure. The same is done with regard to the circles marked 58, 59, &c. and it will be found by placing any one of these connected circles in such a manner as to have its contents in a similar situation with the figures

157 Dr Herschel's account of these spots.

Apparent Motions of the Heavenly Bodies.

gures in the single representation, which bears the same number, that there is a sufficient resemblance between them; though some allowance must undoubtedly be made for the distortions occasioned by this kind of projection.

158 Causes of the appearance and disappearance of these spots.

With regard to the bright spots themselves, Dr Herschel informs us, that the poles of the planets are not exactly in the middle of them, though nearly so. "From the appearance and disappearance (says he) of the bright north polar spot in the year 1781, we collect that the circle of its motion was at some considerable distance from the pole. By calculation, its latitude must have been about 76° or 77° north; for I find that, to the inhabitants of Mars, the declination of the sun, June 25th, 12h. 15m. of our time was about 9° 56′ south; and the spot must have been so far removed from the north pole as to fall a few degrees within the enlightened part of the disk to become visible to us. The south pole of Mars could not be many degrees from the centre of the large bright southern spot of the year 1781; though this spot was of such a magnitude as to cover all the polar regions farther than the 70th or 65th degree; and in that part which was on the meridian, July 3d, at 10 h. 54 minutes, perhaps a little farther.

"From the appearances of the south polar spot in 1781, we may conclude that its centre was nearly polar. We find it continued visible all the time Mars revolved on his axis; and to present us generally with a pretty equal share of the luminous appearance, a spot which covered from 45° to 60° of a great circle on the globe of the planet, could not have any considerable polar distance.

159 Of the exact position of the poles of Mars.

From the observations and calculations made concerning the poles of Mars, we may conclude that his north pole must be directed towards some point of the heavens, between $9^s\ 24^\circ\ 35'$ and $0^s\ 7^\circ\ 15'$; because the change of the situation of the pole from left to right, which happened in the time the planet passed from one place to the other, is a plain indication of its having gone through the node of its axis. Next, we may also conclude, that the node must be considerably nearer the latter point of the ecliptic than the former; for whatever be the inclination of the axis, it will be seen under equal angles at equal distances from the node. But by a trigonometrical process of solving a few triangles, we soon discovered both the inclination of the axis, and the place where it intersects the ecliptic at rectangles (which, for want of a better term, I have perhaps improperly called its *node*). Accordingly I find by calculation, that the node is in 17° 47′ of Pisces, the north pole of Mars being directed towards that part of the heavens; and that the inclination of the axis to the ecliptic is 59° 40′. By further calculations we find that the pole of Mars on the 17th of April 1777, was then actually 81° 27′ inclined to the ecliptic, and pointed towards the left as seen from the sun.

"The inclination and situation of the node of the axis of Mars, with respect to the ecliptic, being found, may be thus reduced to the orbit of the planet himself. Let EC (fig. 66.) be a part of the ecliptic, OM part of the orbit of Mars, PEO a line drawn from P, the celestial pole of Mars, through E, that point which has been determined to be the place of the node of the axis of Mars in the ecliptic, and continued to O, where it intersects his orbit. Now, if, according to M. de la Lande, we put the node of the orbit of Mars for 1783 in $1^s\ 17^\circ\ 58'$, we have from the place of the node of the axis, that is, $11^s\ 17^\circ\ 47'$ to the place of the node of the orbit, an arch EN of 60° 11′. In the triangle NEO, right-angled at E, there is also given the angle ENO, according to the same author, 1° 51′, which is the inclination of the orbit of Mars to the ecliptic. Hence we find the angle EON 89° 5′, and the side ON 60° 12′. Again, when Mars is in the node of its orbit N, we have by calculation the angle PNE=63° 7′; to which adding the angle ENO=1° 51′, we have PNO=64° 58′: from which two angles, PON and PNO, with the distance ON, we obtain the inclination of the axis of Mars, and place of its node with respect to its own orbit; the inclination being 61° 18′, and the place of the node of the axis 58° 31′ preceding the intersection of the ecliptic with the orbit of Mars, or in our 19° 28′ of Pisces."

160 Of the seasons in Mars.

Our author next proceeds to show how the seasons in this planet may be calculated, &c. Which conjectures, though they belong properly to the next section, yet are so much connected with what has gone before, that we shall insert here what he says upon the subject.

"Being thus acquainted with what the inhabitants of Mars will call the obliquity of their ecliptic, and the situation of their equinoctial and solstitial points, we are furnished with the means of calculating the seasons on that planet, and may account, in a manner which I think highly probable, for the remarkable appearance about its polar regions.

"But first, it may not be improper to give an instance how to resolve any query concerning the Martial seasons. Thus, let it be required to compute the declination of the sun on Mars, June 25. 1781, at midnight of our time. If ♈, ♉, ♊, ♋, &c. (fig. 67), represent the ecliptic of Mars, and ♈, ♋, ♎, ♑ the ecliptic of out planet, A *a*, *b* B the mutual intersection of the Martial and terrestrial ecliptics; then there is given the heliocentric longitude of Mars, ♈ $m=9^s\ 10^\circ\ 30'$; then taking away six signs, and ♎ *h* or ♈ $a=1^s\ 17^\circ\ 58'$, there remains $b\,m=1^s\ 22^\circ\ 32'$. From this arch, with the given inclination 1° 51′ of the orbits to each other, we have cosine of inclination to radius, as tangent of $b\,m$ to tangent of $BM=1^s\ 22^\circ\ 33'$. And taking away B ♈$=1^s\ 1^\circ\ 29'$, which is the complement to ♑ B (or ♋ A, already shown to be $1^s\ 28^\circ\ 31'$), there will remain ♈ $M=0^s\ 21^\circ\ 4'$, the place of Mars in its own orbit; that is, on the time above mentioned, the sun's longitude on Mars will be $6^s\ 21^\circ\ 4'$; and the obliquity of the Martial ecliptic, 28° 42′, being also given, we find, by the usual method, the sun's declination 9° 56′ south.

161 Considerable resemblance betwixt the earth and Mars.

"The analogy between Mars and the earth is perhaps by far the greatest in the whole solar system. Their diurnal motion is nearly the same; the obliquity of their respective ecliptics not very different: of all the superior planets, the distance of Mars from the sun is by far the nearest alike to that of the earth; nor will the length of the Martial year appear very different

Apparent Motions of the Heavenly Bodies.

different from what we enjoy, when compared to the surprising duration of the years of Jupiter, Saturn, and the Georgium Sidus. If we then find that the globe we inhabit has its polar region frozen and covered with mountains of ice and snow that only partly melt when alternately exposed to the sun, I may well be permitted to surmise, that the same causes may probably have the same effect on the globe of Mars; that the bright polar spots are owing to the vivid reflection of light from frozen regions; and that the reduction of those spots is to be ascribed to their being exposed to the sun. In the year 1781, the south polar spot was extremely large, which we might well expect, as that pole had but lately been involved in a whole twelvemonth's darkness and absence of the sun; but in 1783, I found it considerably smaller than before, and it decreased continually from the 20th of May till about the middle of September, when it seemed to be at a stand. During this last period the south pole had already been above eight months enjoying the benefit of summer, and still continued to receive the sun-beams, though, towards the latter end, in such an oblique direction as to be but little benefited by them. On the other hand, in the year 1781, the north polar spot, which had then been its twelvemonth in the sunshine, and was but lately returning into darkness, appeared small, though undoubtedly increasing in size. Its not being visible in the year 1783, is no objection to these phenomena, being owing to the position of the axis, by which it was removed out of sight.

162 White spots about the poles of Mars, supposed to be occasioned by snow.

163 Of the spheroidical form of Mars.

"That a planetary globe, such as Mars, turning on an axis, should be of a spheroidical form, will easily find admittance, when two familiar instances in Jupiter and the earth, as well as the known laws of gravitation and the centrifugal force of rotatory bodies, lead the way to the reception of such doctrines. So far from creating difficulties, or doubts, it will rather appear singular, that the spheroidical form of this planet has not already been noticed by former astronomers; and yet, reflecting on the general appearance of Mars, we soon find, that opportunities of making observations on its real form cannot be very frequent: for when it is near enough to view it to an advantage, we see it generally gibbous, and its appositions are so scarce, and of so short a duration, that in more than two years time, we have not above three or four weeks for such observations. Besides, astronomers being generally accustomed to see this planet distorted, the spheroidical form might easily be overlooked.

164 Difference between the equatorial and polar diameter of Mars.

"September 25. 1783. At 9 h. 50 m. the equatorial diameter of Mars measured 21″ 53‴; the polar diameter 21″ 15‴ *full measure;* that is, certainly not too small. This difference of the diameters was shown, on the 28th of the same month, to Mr Wilson of Glasgow, who saw it perfectly well, so as to be convinced that it was not owing to any defect or distortion occasioned by the lens; and because I wished him to be satisfied of the reality of the appearance, I reminded him of several precautions; such as causing the planet to pass directly through the centre of the field of view, and judging of its figure when it was most distinct and best defined, &c. Next day the difference between the two diameters was shown to Dr Blagden and Mr Aubert. The former not only saw it immediately, but thought the flattening almost as much as that of Jupiter. Mr Aubert also saw it very plainly, so as to entertain no manner of doubt about the appearance.

"September 30th, 10h. 52m. the equatorial diameter was 22″ 9‴, with a magnifying power of 278. By a second measure it was 22″ 31‴, full large; the polar diameter, very exact, was 21″ 26‴. On the first of October, at 10h. 50m. the equatorial diameter measured 103 by the micrometer; and the polar 98; the value of the divisions in seconds and thirds not being well determined, on account of some changes lately made in the focal length of the object metals of the telescope. On the 13th, the equatorial diameter was exactly 22″ 35‴: the polar diameter 21″ 35‴." In a great number of succeeding observations, the same appearance occurred; but on account of the quick changes in the appearance of this planet, Dr Herschel thought proper to settle the proportion betwixt the equatorial and polar diameters from those which were made on the very day of the apposition, and which were also to be preferred on account of their being repeated with a very high power, and in a fine clear air, with two different instruments of an excellent quality. From these he determined the proportions to be as 103 to 98, or 1355 to 1272.

165 Of the atmosphere of Mars.

It has been commonly related by astronomers, that the atmosphere of this planet is possessed of such strong refractive powers, as to render the small fixed stars near which it passes invisible. Dr Smith relates an observation of Cassini, where a star in the water of Aquarius at the distance of six minutes from the disk of Mars, became so faint before its occultation, that it could not be seen by the naked eye, nor with a three-feet telescope. This would indicate an atmosphere of a very extraordinary size and density: but the following observations of Dr Herschel seem to show that it is of much smaller dimensions. "1783, Oct. 26th. There are two small stars preceding Mars, of different sizes; with 460 they appear both dusky red, and are pretty unequal; with 218 they appear considerably unequal. The distance from Mars of the nearest, which is also the largest, with 227 measured 3′ 26″ 20‴. Some time after, the same evening, the distance was 3′ 8″ 55‴, Mars being retrograde. Both of them were seen very distinctly. They were viewed with a new 20 feet reflector, and appeared very bright. October 27th, the small star is not quite so bright in proportion to the large one as it was last night, being a good deal nearer to Mars, which is now on the side of the small star; but when the planet was drawn aside, or out of view, it appeared as plainly as usual. The distance of the small star was 2′ 5″ 25‴. The largest of the two stars (adds he), on which the above observations were made, cannot exceed the 12th, and the smallest the 13th or 14th magnitude; and I have no reason to suppose that they were any otherwise affected by the approach of Mars, than what the brightness of its superior light may account for. From other phenomena it appears, however, that this planet is not without a considerable atmosphere; for besides the permanent spots on its surface, I have often noticed occasional changes of partial bright belts, and also once a darkish one in a pretty high latitude; and these alterations we can hardly ascribe to any other cause than the variable disposition of clouds and vapours floating in the atmosphere of the planet."

Apparent Motions of the Heavenly Bodies.

Sect. IV. *Of Jupiter.*

Jupiter is the brightest of all the planets except Venus. He moves from west to east in a period of 4332.602208 days, exhibiting irregularities similar to those of Mars. Before he comes into opposition, and when distant from the sun about 115°, his motion becomes retrograde, and increases in swiftness till he comes into opposition. The motion then becomes gradually slower, and becomes direct when the planet advances within 115° of the sun. The duration of the retrograde motion is about 121 days, and the arch of retrogradation described is about 10°. But there is a considerable difference both in the amount and in the duration of this retrograde motion.

166 Belts of Jupiter when first discovered.

Jupiter has the same general appearance with Mars, only that the belts on his surface are much larger and more permanent. Their general appearance, as described by Dr Long, is represented fig. 68—71.; but they are not to be seen but by an excellent telescope. They are said to have been first discovered by Fontana and two other Italians; but Cassini was the first who gave a good account of them. Their number is very variable, as sometimes only one, and at others no fewer than eight, may be perceived. They are generally parallel to one another, but not always so; and their breadth is likewise variable, one belt having been observed to grow narrow, while another in its neighbourhood has increased in breadth, as if the one had flowed into the other: and in this case Dr Long observes, that a part of an oblique belt lay between them, as if to form a communication for this purpose. The time of their continuance is very uncertain, sometimes remaining unchanged for three months; at others, new belts

167 Spots sometimes appear in them.

have been formed in an hour or two. In some of these belts large black spots have appeared, which moved swiftly over the disk from east to west, and returned in a short time to the same place; from whence the rotation of this planet about its axis has been determined. On the 9th of May 1664, Dr Hook, with a good 12 feet telescope, observed a small spot in the biggest of the three obscure belts of Jupiter; and observing it from time to time, found that in two hours it had moved from east to west about half the visible diameter of the planet. In 1665, Cassini observed a spot near the largest belt of Jupiter which is most frequently seen. It appeared round, and moved with the greatest velocity when in the middle, but appeared narrower, and moved slower, the nearer it was to the circumference. "These circumstances (says Dr Long) showed that the spot adhered to the body of Jupiter, and was carried round upon it. It continued thereon till the year following; long enough to determine the periodical time of Jupiter's rotation upon his axis

168 Account of one of these spots.

to be 9 h. 56 m." This principal, or ancient spot as it is called, is the largest, and of the longest continuance of any hitherto known, and has appeared and vanished no fewer than eight times between the years 1665 and 1708; from the year last mentioned it was invisible till 1713. The longest time of its continuing to be visible was three years; and the longest time of its disappearing was from 1708 to 1713: it seems to have some connection with the principal southern belt; for the spot has never been seen when that disappeared, though that belt has often been visible without that spot. Besides this ancient spot, Cassini, in the year 1669, saw one of less stability that did not continue of the same shape or dimensions, but broke into several small ones, whereof the revolution was but 9 h. 51 m.; and two other spots that revolved in 9 h. 52½ m. The figure of Jupiter is evidently an oblate spheroid, the longest diameter of his disk being to the shortest as 13 to 12. His rotation is from west to east, like that of the sun, and the plane of his equator is

169 No difference of seasons in Jupiter.

very nearly coincident with that of his orbit; so that there can scarcely be any difference of seasons in that planet. His rotation has been observed to be somewhat quicker in his aphelion than his perihelion. The axis of rotation is nearly perpendicular to the plane of the ecliptic, and the planet makes one revolution in 0.41377 day, or about 9 h. 35′ and 37″. The changes in the appearance of these spots, and the difference in the time of their rotation, make it probable that they do not adhere to Jupiter, but are clouds transported by the winds with different velocities in an atmosphere subject to violent agitations.

The apparent diameter of this planet is a maximum during his opposition to the sun, it is then equal to about 46″; when in conjunction it is smaller, being only about 31″: his mean apparent diameter is equal to 36″.

170 Is attended by four moons.

Four little stars are observed around Jupiter, which constantly accompany him. Their relative situation is continually changing. They oscillate on both sides of the planet, and their relative rank is determined by the length of these oscillations. That one in which the oscillation is shortest is called the *first satellite*, and so on. These satellites are analogous to our moon. See fig. 18. and 186. They are all supposed to move in ellipses; though the eccentricities of all of them are too small to be measured, excepting that of the fourth; and even this amounts to no more than 0.007 of its mean distance from the primary. The orbits of these planets were thought by Galileo to be in the same plane with that of their primary: but Mr Cassini has found that their orbits make a small angle with it; and, as he did not find any difference in the place of their nodes, he concluded that they were all in the same place, and that their ascending nodes were in the middle of Aquarius. After observing them for more than 36 years, he found their greatest latitude, or deviation from the

171 Distances and periodical times of Jupiter's moons.

plane of Jupiter's orbit, to be 2° 55′. The first of these satellites revolves at the distance of 5.697 of Jupiter's semidiameters, or 1′ 51″ as measured by proper instruments; its periodical time is 1 d. 18 h. 27′ 34″. The next satellite revolves at the distance of 9.017 semidiameters, or 2′ 56″, in 3 d. 13 h. 13′ 43″; the third at the distance of 14.384 semidiameters, or 4′ 42″, in 7 d. 3 h. 42′ 36″; and the fourth at the distance of 25.266, or 8′ 16″, in 16 d. 16 h. 32′ 09″.

Since the time of Cassini it has been found that the nodes of Jupiter's satellites are not in the same place; and from the different points of view in which we have an opportunity of observing them from the earth, we see them sometimes apparently moving in straight lines, and at other times in elliptic curves. All of them, by reason of their immense distance, seem to keep near their primary, and their apparent motion is a kind of oscillation like that of a pendulum, going alternately

Digitized by Google

Apparent Motions of the Heavenly Bodies.

ly from their greatest distance on one side to the greatest distance on the other, sometimes in a straight line, and sometimes in an elliptic curve. When a satellite is in its superior semicircle, or that half of its orbit which is more distant from the earth than Jupiter is, its motion appears to us direct, according to the order of the signs; but in its inferior semicircle, when it is nearer to us than Jupiter, its motion appears retrograde; and both these motions seem quicker the nearer the satellites are to the centre of the primary, slower the more distant they are, and at the greatest distance of all they appear for a short time to be stationary.

172 Occultations and eclipses of Jupiter's satellites.

From this account of the system of Jupiter and his satellites, it is evident, that occultations of them must frequently happen by their going behind their primary, or by coming in betwixt us and it. The former takes place when they proceed towards the middle of their upper semicircle; the latter, when they pass through the same part of their inferior semicircle. Occultations of the former kind happen to the first and second satellite; at every revolution, the third very rarely escapes an occultation, but the fourth more frequently by reason of its greater distance. It is seldom that a satellite can be discovered upon the disk of Jupiter, even by the best telescopes, excepting at its first entrance, when by reason of its being more directly illuminated by the rays of the sun than the planet itself, it appears like a lucid spot upon it.

173 The satellites sometimes appear as dark spots.

Sometimes, however, a satellite in passing over the disk, appears like a dark spot, and is easily to be distinguished. This is supposed to be owing to spots on the body of these secondary planets; and it is remarkable, that the same satellite has been known to pass over the disk at one time as a dark spot, and at another so luminous that it could not be distinguished from Jupiter himself, except at its coming on and going off. To account for this, we must say, that either the spots are subject to change; or if they be permanent like those of our moon, that the satellites at different times turn different parts of their globes towards us.

174 Why they vary in their light and apparent magnitude.

Possibly both these causes may contribute to produce the phenomena just mentioned. For these reasons also both the light and apparent magnitude of the satellites are variable; for the fewer spots there are upon that side which is turned towards us, the brighter it will appear; and as the bright side only can be seen, a satellite must appear larger the more of its bright side it turns towards the earth, and the less so the more it happens to be covered with spots. The fourth satellite, though generally the smallest, sometimes appears bigger than any of the rest: the third sometimes seems least, though usually the largest; nay, a satellite may be so covered with spots as to appear less than its shadow passing over the disk of the primary, though we are certain that the shadow must be smaller than the body which casts it. To a spectator placed on the surface of Jupiter, each of these satellites would put on the phases of the moon; but as the distance of any of them from Jupiter is but small when compared with the distance of that planet from the sun, the satellites are therefore illuminated by the sun very nearly in the same manner with the primary itself; hence they appear to us always round, having constantly the greatest part of their enlightened half turned towards the earth: and indeed they are so small, that were they to put on the phases of the moon, these phases could scarce be discerned through the best telescopes.

175 Their shadows sometimes visible on the disk of Jupiter.

When the satellites pass through their inferior semicircles, they may cast a shadow upon their primary, and thus cause an eclipse of the sun to his inhabitants if there are any; and in some situations this shadow may be observed going before or following the satellite.

176 Three of Jupiter's moons eclipsed in every revolution.

On the other hand, in passing through their superior semicircles, the satellites may be eclipsed in the same manner as our moon by passing through the shadow of Jupiter: and this is actually the case with the first, second, and third of these bodies; but the fourth, by reason of the largeness of its orbit, passes sometimes above or below the shadow, as is the case with our moon.

177 At what time the eclipses, occultations, &c. of Jupiter's satellites are visible.

The beginnings and endings of these eclipses are easily seen by a telescope when the earth is in a proper situation with regard to Jupiter and the sun; but when this or any other planet is in conjunction with the sun, the superior brightness of that luminary renders both it and the satellites invisible. From the time of its first appearing after a conjunction until near the apposition, only the immersions of the satellites into his shadow, or the beginnings of the eclipses, are visible; at the apposition, only the occultations of the satellites, by going behind or coming before their primary, are observable; and from the apposition to the conjunction, only the emersions, or end of the eclipses, are to be seen. This is exactly true in the first satellite, of which we can never see an immersion with its immediately subsequent emersion: and it is but rarely that they can be both seen in the second; as in order to their being so, that satellite must be near one of its limits, at the same time that the planet is near his perihelion and quadrature with the sun. With regard to the third, when Jupiter is more than 46 degrees from conjunction with, or apposition to, the sun, both its immersions and immediately subsequent emersions are visible; as they likewise are in the fourth, when the distance of Jupiter from conjunction or apposition is 24 degrees.

When Jupiter is in quadrature with the sun, the earth is farthest out of the line that passes through the centres of the sun and Jupiter, and therefore the shadow of the planet is then most exposed to our view: but even then the body of the planet will hide from us one side of that part of the shadow which is nearest to it, through which the first satellite passes; which is the reason that though we see the entrance of that satellite into the shadow, or its coming out from thence, as the earth is situated on the east or west side thereof, we cannot see them both; whereas the other satellites going through the shadow at a greater distance from Jupiter, their ingress and egress are both visible.

Sect. V. *Of Saturn.*

Saturn is likewise a very conspicuous planet, though not so brilliant as Jupiter. The period of his sidereal revolution round the earth, is 10759.077213 days. He moves from west to east nearly in the plane of the ecliptic, and exhibits irregularities similar to those of Jupiter and Mars. He becomes retrograde both before and after his opposition, when at the distance of about 109° from the sun. His retrograde motion continues about 139 days, and during its continuance he describes an

Apparent Motions of the Heavenly Bodies.

an arc of about 6°. His diameter is a maximum at his opposition, and his mean apparent diameter is 18″.

178 Telescopic appearance of Saturn.

Saturn, when viewed through a good telescope, makes a more remarkable appearance than any of the other planets. Galileo first discovered his uncommon shape, which he thought to be like two small globes, one on each side of a large one; and he published his discovery in a Latin sentence: the meaning of which was, that he had seen him appear with three bodies; though, in order to keep the discovery a secret, the letters were transposed. Having viewed him for two years, he was surprised to see him become quite round without these appendages, and then after some time to

179 His ring first discovered by Huygens.

assume them as before. These adjoining globes were what are now called the *ansæ* of his ring, the true shape of which was first discovered by Huygens about 40 years after Galileo, first with a telescope of 12 feet, and then with one of 23 feet, which magnified objects 100 times. From the discoveries made by him and other astronomers, it appears that this planet is surrounded by a broad thin ring, the edge of which reflects little or none of the sun's light to us, but the planes of the ring reflect the light in the same manner that the planet itself does; and if we suppose the diameter of Saturn to be divided into three equal parts, the diameter of the ring is about seven of these parts. The ring is detached from the body of Saturn in such a manner, that the distance between the innermost part of the ring and the body is equal to its breadth. If we had a view of the planet and his ring, with our eyes, perpendicular to one of the planes of the latter, we should see them as in fig. 72.: but our eye is never so much elevated above either plane as to have the visual ray stand at right angles to it, nor indeed is it ever elevated more than about 30 degrees above it; so that the ring, being commonly viewed at an oblique angle, appears of an oval form, and through very good telescopes double, as represented fig. 73. and 74. Both the outward and inward rim is projected into an ellipsis, more or less oblong according to the different degrees of obliquity with which it is viewed. Sometimes our eye is in the plane of the ring, and then it becomes invisible; either because the outward edge is not fitted to reflect the sun's light, or more probably because it is too thin to be seen at such a distance. As the plane of this ring keeps always parallel to itself, that is, its situation in one part of the orbit is always parallel to that in any other part, it disappears twice in every revolution of the planet, that is, about once in 15 years; and he sometimes appears quite round for nine months together. At other times, the distance betwixt the body of the planet and the ring is very perceptible; insomuch that Mr Whiston tells us of Dr Clarke's father having seen a star through the opening, and supposed him to have been the only person who ever saw a sight so rare, as the opening, though certainly very large, appears very small to us. When Saturn appears round, if our eye be in the plane of the ring, it will appear as a dark line across the middle of the planet's disk; and if our eye be elevated above the plane of the ring, a shadowy belt will be visible, caused by the shadow of the ring as well as by the interposition of part of it betwixt the eye and the planet. The shadow of the ring is broadest when the sun is most elevated, but its obscure parts appear broadest when our eye is most elevated above the plane of it. When it appears double, the ring next the body of the planet appears brightest; when the ring appears of an elliptical form, the parts about the ends of the largest axis are called the *ansæ*, as has been already mentioned. These, a little before and after the disappearing of the ring, are of unequal magnitude: the largest ansa is longer visible before the planet's round phase, and appears again sooner, than the

180 Ring of Saturn probably has a revolution on its axis.

other. On the first of October 1714, the largest ansa was on the east side, and on the 12th on the west side of the disk of the planet, which makes it probable that the ring has a rotation round an axis. Herschel has demonstrated, that it revolves in its own plane in 10 hours 32′ 15.4″. The observations of this philosopher have added greatly to our knowledge of Saturn's ring. According to him there is one single, dark, considerably broad line, belt, or zone, which he has constantly found on the north side of the ring. As this dark belt is subject to no change whatever, it is probably owing to some permanent construction of the surface of the ring: this construction cannot be owing to the shadow of a chain of mountains, since it is visible all round on the ring; for there could be no shade at the ends of the ring: a similar argument will apply against the opinion of very extended caverns. It is pretty evident that this dark zone is contained between two concentric circles; for all the phenomena correspond with the projection of such a zone. The nature of the ring Dr Herschel thinks no less solid than that of Saturn itself, and it is observed to cast a strong shadow upon the planet. The light of the ring is also generally brighter than that of the planet; for the ring appears sufficiently bright when the telescope affords scarcely light enough for Saturn. The doctor concludes that the edge of the ring is not flat, but spherical or speroidical. The dimensions of the ring, or of the two rings with the space between them, Dr Herschel gives as below:

	Miles.
Inner diameter of smaller ring	146345
Outside diam. of ditto	184393
Inner diam. of larger ring	190248

Breadth of the outer ring	7200
Breadth of the vacant space, or dark zone	2839

There have been various conjectures relative to the nature of this ring. Some persons have imagined that the diameter of the planet Saturn was once equal to the present diameter of the outer ring, and that it was hollow; the present body being contained within the former surface, in like manner as a kernel is contained within its shell: they suppose that, in consequence of some concussion, or other cause, the outer shell all fell down to the inner body, and left only the ring at the greater distance from the centre, as we now perceive it. This conjecture is in some measure corroborated by the consideration, that both the planet and its ring perform their rotations about the same common axis, and in very nearly the same time. But from the observations of Dr Herschel, he thus concludes: "It does not appear to me that there is sufficient ground for admitting the ring of Saturn to be of a very changeable nature, and I guess that its phenomena will hereafter be so fully explained, as to reconcile

Digitized by Google

Apparent Motions of the Heavenly Bodies.

reconcile all observations. In the meanwhile we must withhold a final judgment of its construction, till we can have more observations. Its division, however, into two very unequal parts, can admit of no doubt."

The diameters of Saturn are not equal: that which is perpendicular to the plane of his ring appears less by one-eleventh than the diameter situated in that plane. If we compare this form with that of Jupiter, we have reason to conclude that Saturn turns rapidly round his shorter axis, and that the ring moves in the plane of his equator. Herschel has confirmed this opinion by actual observation. He has ascertained the duration of a revolution of Saturn round his axis to amount to 0.428 day. Huygens observed five belts upon this planet nearly parallel to the equator.

181 His seven satellites.

Saturn is still better attended than Jupiter (see fig. 18. and 186.); having, besides the ring above-mentioned, no fewer than seven moons continually circulating round him. The first, at the distance of 2.097 semidiameters of his ring, and 4.893 of the planet itself, performs its revolution in 1 d. 21 h. 18′ 57″; the second, at 2.686 semidiameters of the ring, and 6.268 of Saturn, revolves in 2 d. 17 h. 41′ 22″; the third, at the distance of 8.754 semidiameters of Saturn, and 3.752 of the ring, in 4 d. 12 h. 25′ 12″; the fourth, called the *Huygenian satellite*, at 8.698 semidiameters of the ring, and 20.295 of Saturn, revolves in 15 d. 22 h. 41′ 12″; while the fifth, placed at the vast distance of 59.154 semidiameters of Saturn, or 25.348 of his ring, does not perform its revolution in less than 79 d. 7 h. 47′ 00″. The orbits of all these satellites, except the fifth, are nearly in the same plane, which makes an angle with the plane of Saturn's orbit of about 31°; and by reason of their being inclined at such large angles, they cannot pass either across their primary or behind it with respect to the earth, except when very near their nodes; so that eclipses of them happen much more seldom than of the satellites of Jupiter. There is, however, an account in the Philos. Transact. of an occultation of the fourth satellite behind the body of Saturn; and there is a curious account by Cassini in the Memoirs of the Royal Academy for 1692, of a fixed star being covered by the fourth satellite, so that

182 Fifth satellite sometimes disappears, and why.

for 13 minutes they appeared both as one star. By reason of their extreme smallness, these satellites cannot be seen unless the air be very clear; and Dom. Cassini for several years observed the fifth satellite to grow less and less as it went through the eastern part of its orbit until it became quite invisible; while in the western part it gradually became more and more bright until it arrived at its greatest splendour.—"This phenomenon (says Dr Long) cannot be better accounted for than by supposing one half of the surface of this satellite to be unfit to reflect the light of the sun in sufficient quantity to make it visible, and that it turns round its axis nearly in the same time as it revolves round its primary; and that, by means of this rotation, and keeping always the same face toward Saturn, we upon the earth may, during one half of its periodical time, be able to see successively more and more of its bright side, and during the other half of its period have more and more of the spotted or dark side turned towards us. In the year 1705, this satellite unexpectedly became visible in all parts of its orbit through the very same telescopes that were before often made use of to view it in the eastern part without success: this shows the spots upon this satellite, like those upon Jupiter and some other of the primary planets, are not permanent, but subject to change."

The two other satellites were discovered by Dr Herschel in 1787 and 1788. They are nearer to Saturn than any of the other five. But in order to prevent confusion, they have been called the 6th and 7th satellites. The fifth satellite has been observed by Dr Herschel to turn once round its axis, exactly in the time in which it revolves round Saturn. In this respect it resembles our moon.

Sect. VI. *Of Herschel.*

The planets hitherto described have been known from the remotest antiquity; but the planet Herschel, called also the Georgium Sidus, and Uranus, escaped the attention of the ancient astronomers. Flamstead, Mayer, and Le Mounier had observed it as a small star; but in 1781 Dr Herschel discovered its motion, and ascertained it to be a planet. Like Mars, Jupiter, and Saturn, it moves from west to east round the sun. The duration of its sidereal revolution is 30689 days. Its motion, which is nearly in the plane of the ecliptic, begins to be retrograde before and after the opposition, when the planet is 103.5° from the sun; its retrograde motion continues for about 151 days; and the arc of retrogradation amounts to 3.6°. If we judge of the distance of this planet by the slowness of its motions, it ought to be at the very confines of the planetary system.

183 Its satellites.

The apparent magnitude of this planet is so small that it can seldom be seen with the naked eye. It is accompanied by six satellites: two of them, which were discovered by Dr Herschel in 1787, revolve about that planet in periods of 8 d. 17 h. 1 m. 19. sec. and 13 d. 11 h. 5 m. 1½ sec. respectively, the angular distances from the primary being 33″ and 44⅔″: their orbits are nearly perpendicular to the plane of the ecliptic. The history of the discovery of the other four, with such elements as could then be ascertained, are given in the Philosophical Transactions for 1798, Part I. The precise periods of these additional satellites cannot be ascertained without a greater number of observations than had been made when Dr Herschel sent the account of their discovery to the Royal Society; but he gave the following estimates as the most probable which could be formed by means of the data then determined. Admitting the distance of the anterior satellite to be 25″.5, its periodical revolution will be 5 d. 21 h. 25 m. If the intermediate satellite be placed at an equal distance between the two old satellites, or at 38″.57, its period will be 10 d. 23 h. 4 m. The nearest exterior satellite is about double the distance of the farthest old one; its periodical time will therefore be about 38 d. 1 h. 49 m. The most distant satellite is full four times as far from the planet as the old second satellite: it will therefore take at least 107 d. 16 h. 40 m. to complete one revolution. All these satellites perform their revolutions in their orbits contrary to the order of the signs; that is, their real motion is retrograde.

Apparent Motions of the Heavenly Bodies.

Sect. VII. *Of Ceres and Pallas.*

These two planets, lately discovered by Piazzi and Olbers, two foreign astronomers, ought to have followed Mars in the order of description, as their orbits are placed between those of Mars and Jupiter; but as they have been observed only for a very short time, we judged it more proper to reserve the account of them till we came to the words Ceres and Pallas, when the elements of their orbits will in all probability be determined with more precision than at present. They are invisible to the naked eye; and Dr Herschel has ascertained that their size is extremely small. For that reason, together with the great obliquity of their orbits, he has proposed to distinguish them from the planets, and to call them *asteroids*.

Chap. IV. *Of the Comets.*

The planets are not the only moving bodies visible in the heavens. There are others which appear at uncertain intervals, and with a very different aspect from the planets. These are very numerous, and no fewer than 450 are supposed to belong to our solar system. They are called *Comets*, from their having a long tail, somewhat resembling the appearance of hair. This, however, is not always the case; for some comets have appeared which were as well defined, and as round as planets: but in general they have a luminous matter diffused around them, or projecting out from them, which to appearance very much resembles the Aurora Borealis. When these appear, they come in a direct line towards the sun, as if they were going to fall into his body; and after having disappeared for some time in consequence of their proximity to that luminary, they fly off again on the other side as fast as they came, projecting a tail much greater and brighter in their recess from him than when they advanced towards him; but, getting daily at a farther distance from us in the heavens, they continually lose of their splendour, and at last totally disappear. Their apparent magnitude is very different; sometimes they appear only of the bigness of the fixed stars; at other times they will equal the diameter of Venus, and sometimes even of the sun or moon. So, in 1652, Hevelius observed a comet which seemed not inferior to the moon in size, though it had not so bright a splendour, but appeared with a pale and dim light, and had a dismal aspect. These bodies will also sometimes lose their splendour suddenly, while their apparent bulk remains unaltered. With respect to their apparent motions, they have all the inequalities of the planets; sometimes seeming to go forwards, sometimes backwards, and sometimes to be stationary.

The comets, viewed through a telescope, have a very different appearance from any of the planets. The nucleus, or star, seems much more dim. Sturmius tells us, that observing the comet of 1680 with a telescope, it appeared like a coal dimly glowing; or a rude mass of matter illuminated with a dusky fumid light, less sensible at the extremes than in the middle; and not at all like a star, which appears with a round disk and a vivid light.

Hevelius observed of the comet in 1661, that its body was of a yellowish colour, bright and conspicuous, but without any glittering light. In the middle was a dense ruddy nucleus, almost equal to Jupiter, encompassed with a much fainter thinner matter.—February 5th. The nucleus was somewhat bigger and brighter, of a gold colour, but its light more dusky than the rest of the stars; it appeared also divided into a number of parts.—Feb. 6th. The nuclei still appeared, though less than before. One of them on the left side of the lower part of the disk appeared to be much denser and brighter than the rest; its body round, and representing a little lucid star; the nuclei still encompassed with another kind of matter.—Feb. 10th. The nuclei more obscure and confused, but brighter at top than at bottom.—Feb. 13th. The head diminished much both in brightness and in magnitude.—March 2d. Its roundness a little impaired, and the edges lacerated.—March 28th. Its matter much dispersed; and no distinct nucleus at all appearing.

Wiegelius, who saw through a telescope the comet of 1664, the moon, and a little cloud illuminated by the sun, at the same time, observed that the moon appeared of a continued luminous surface, but the comet very different, being perfectly like the little cloud enlightened by the sun's beams.

184

Atmospheres and phases of comets.

The comets, too, are to appearance surrounded with atmospheres of a prodigious size, often rising ten times higher than the nucleus. They have often likewise different phases, like the moon.

185

Dr Long's account of them.

"The head of a comet (says Dr Long) to the eye, unassisted by glasses, appears sometimes like a cloudy star; sometimes shines with a dull light like that of the planet Saturn: some comets have been said to equal, some to exceed, stars of the first magnitude; some to have surpassed Jupiter, and even Venus; and to have cast a shadow as Venus sometimes does.

"The head of a comet, seen through a good telescope, appears to consist of a solid globe, and an atmosphere that surrounds it. The solid part is frequently called the *nucleus;* which through a telescope is easily distinguished from the atmosphere or hairy appearance.

"A comet is generally attended with a blaze or tail, whereby it is distinguished from a star or planet; as it is also by its motion. Sometimes the tail only of a comet has been visible at a place where the head has been all the while under the horizon; such an appearance is called a *beam*.

186

Appearances of the comet of 1618.

"The nucleus of the comet of 1618 is said, a few days after coming into view, to have broken into three or four parts of irregular figures. One observer compares them to so many burning coals; and says they changed their situation while he was looking at them, as when a person stirs a fire; and a few days after were broken into a great number of smaller pieces. Another account of the same is, that on the 1st and 4th of December, the nucleus appeared to be a round, solid, and luminous body, of a dusky lead colour, larger than any star of the first magnitude. On the 8th of the same month it was broken into three or four parts of irregular figures; and on the 20th was changed into a cluster of small stars.

187

Phenomena of their tails.

"As the tail of a comet is owing to the heat of the sun, it grows larger as the comet approaches near to, and

Apparent Motions of the Heavenly Bodies.

and shortens as it recedes from, that luminary. If the tail of a comet were to continue of the same length, it would appear longer or shorter according to the different views of the spectator; for if his eye be in a line drawn through the middle of the tail lengthwise, or nearly so, the tail will not be distinguished from the rest of the atmosphere, but the whole will appear round; if the eye be a little out of that line, the tail will appear short as in fig. 75.; and it is called a *bearded comet*, when the tail hangs down towards the horizon, as in that figure. If the tail of a comet be viewed sidewise, the whole length of it is seen. It is obvious to remark, that the nearer the eye is to the tail, the greater will be the apparent length thereof.

"The tails of comets often appear bent, as in fig. 76. and 77. owing to the resistance of the æther; which, though extremely small, may have a sensible effect on so thin a vapour as the tails consist of. This bending is seen only when the earth is not in the plane of the orbit of the comet continued. When that plane passes through the eye of the spectator, the tail appears straight, as in fig. 78, 79.

"Longomontanus mentions a comet, that, in 1618, Dec. 10th, had a tail above 100 degrees in length; which shows that it must then have been very near the earth. The tail of a comet will at the same time appear of different lengths in different places, according as the air in one place is clearer than in another. It need not be mentioned, that in the same place, the difference in the eyes of the spectators will be the cause of their disagreeing in their estimate of the length of the tail of a comet.

188 Difference between the observations of Hevelius and Hooke.

"Hevelius is very particular in telling us, that he observed the comet of 1665 to cast a shadow upon the tail; for in the middle thereof there appeared a dark line. It is somewhat surprising, that Hooke should be positive in affirming, on the contrary, that the place where the shadow of the comet should have been, if there had been any shadow, was brighter than any other part of the tail. He was of opinion that comets have some light of their own: His observations were made in a hurry; he owns they were short and transitory. Hevelius's were made with so much care, that there is more reason to depend upon them. Dom. Cassini observed, in the tail of the comet of 1680, a darkness in the middle; and the like was taken notice of by a curious observer in that of 1744.

189 Account of the comet of 1680.

"There are three comets, viz. of 1680, 1744, and 1759, that deserve to have a farther account given of them. The comet of 1680 was remarkable for its near approach to the sun; so near, that in its perihelion it was not above a sixth part of the diameter of that luminary from the surface thereof. Fig. 77. taken from Newton's Principia, represents so much of the trajectory of this comet as it passed through while it was visible to the inhabitants of our earth, in going from and returning to its perihelion. It shows also the tail, as it appeared on the days mentioned in the figure. The tail, like that of other comets, increased in length and brightness as it came nearer to the sun; and grew shorter and fainter as it went farther from him and from the earth, till that and the comet were too far off to be any longer visible.

190 Of that of 1744.

"The comet of 1744 was first seen at Lausanne in Switzerland, Dec. 13. 1743, N. S. From that time it increased in brightness and magnitude as it was coming nearer to the sun. The diameter of it, when at the distance of the sun from us, measured about one minute; which brings it out equal to three times the diameter of the earth. It came so near Mercury, that, if its attraction had been proportionable to its magnitude, it was thought probable it would have disturbed the motion of that planet. Mr Betts of Oxford, however, from some observations made there, and at Lord Macclesfield's observatory at Sherburn, found, that when the comet was at its least distance from Mercury, and almost twice as near the sun as that planet was, it was still distant from him a fifth part of the distance of the sun from the earth; and could therefore have no effect upon the planet's motions. He judged the comet to be at least equal in magnitude to the earth. He says, that in the evening of Jan. 23d, this comet appeared exceedingly distinct and bright, and the diameter of its nucleus nearly equal to that of Jupiter. Its tail extended above 26 degrees from its body; and was in length, supposing the sun's parallax 10″, no less than 23 millions of miles. Dr Bevis, in the month of May 1744, made four observations of Mercury, and found the places of that planet, calculated from correct tables, differed so little from the places observed, as to show that the comet had no influence upon Mercury's motion.

"The nucleus, which had before been always round, on the 10th of February appeared oblong in the direction of the tail, and seemed divided into two parts, by a black stroke in the middle. One of the parts had a sort of beard brighter than the tail; this beard was surrounded by two unequal dark strokes, that separated the beard from the hair of the comet. The odd phenomena disappeared the next day, and nothing was seen but irregular obscure spaces like smoke in the middle of the tail; and the head resumed its natural form. February 15th, the tail was divided into two branches; the eastern part about seven or eight degrees long, the western 24. On the 23d, the tail began to be bent; it shewed no tail till it was as near to the sun as the orbit of Mars; the tail grew longer as it approached nearer the sun; and at its greatest length was computed to equal a third part of the distance of the earth from the sun. Fig. 76. is a view of this comet, taken by an observer at Cambridge. I remember that, in viewing it, I thought the tail seemed to sparkle, or vibrate luminous particles. Hevelius mentions the like in other comets; and that their tails lengthen and shorten while we are viewing. This is probably owing to the motion of our air.

191 Of the comet of 1759.

"The comet of 1759 did not make any considerable appearance by reason of the unfavourable situation of the earth all the time its tail might otherwise have been conspicuous; the comet being then too near the sun to be seen by us; but deserves our particular consideration, as it was the first that ever had its return foretold."

Hevelius gives pictures of comets of various shapes; as they are described by historians to have been like a sword, a buckler, a tun, &c. These are drawn by fancy only, from the description in words. He gives, however, also pictures of some comets, engraved by his

Digitized by Google

his own hand from the views he had of them through a very long and excellent telescope. In these we find changes in the nucleus and the atmosphere of the same comet. The nucleus of the comet of 1661, which in one observation appeared as one round body, as it is represented in fig. 87. in subsequent views seemed to consist of several smaller ones separated from one another, as in fig. 86. The atmosphere surrounding the nucleus, at different times, varied in the extent thereof; as did also the tail in length and breadth. The nuclei of other comets, as has already been observed, have sometimes phases like the moon. Those of 1744 and 1769 had both this kind of appearance.

Chap. V. *Of the Fixed Stars.*

192 Number of fixed stars increased by telescopes. The parallax of the stars is insensible. When viewed through the best telescopes, they appear not at all magnified, but rather diminished in bulk; by reason as is thought by some, that the telescope takes off that twinkling appearance they make to the naked eye; but by others, more probably, that the telescope tube excludes a quantity of the rays of light, which are not only emitted from the particular stars themselves, but by many thousands more, which falling upon our eyelids and the aerial particles about us, are reflected into our eyes so strongly as to excite vibrations, not only on those points of the retina where the images of the stars are formed, but also in other points at the same distance round about. This, without the telescope, makes us imagine the stars to be much bigger than when we see them only by a few rays coming directly from them, so as to enter our eyes without being intermixed with others. The smallness of their apparent diameter is proved by the suddenness with which they disappear on their occultations by the moon. The time which they take does not amount to one second, which shows their apparent diameter not to exceed 4″. The vivacity of their light, compared with their small diameter, leads us to suppose them at a much greater distance than the planets, and to consider them as luminous bodies like our sun, instead of borrowing their light from that luminary like the planets.

193 Different magnitudes of the stars. The stars, on account of their apparently various magnitudes, have been distributed into several classes or orders. Those which appear largest are called *stars of the first magnitude*; the next to them in lustre, *stars of the second magnitude*; and so on to the *sixth*, which are the smallest that are visible to the naked eye. This distribution having been made long before the invention of telescopes, the stars which cannot be seen without the assistance of these instruments are distinguished by the name of *telescopic stars*.

194 Telescopic stars. The ancients divided the starry sphere into particular constellations, or systems of stars, according as they lay near one another, so as to occupy those spaces which the figures of different sorts of animals or things would take up, if they were there delineated. **195 Unformed stars.** And those stars which could not be brought into any particular constellation were called *unformed stars*.

196 Uses of their division into constellations. This division of the stars into different constellations, or asterisms, serves to distinguish them from one another, so that any particular star may be readily found in the heavens by means of a celestial globe; on which the constellations are so delineated, as to put the most remarkable stars into such parts of the figures as are most easily distinguished. The number of the ancient constellations is 48, and upon our present globes about 70. On Senex's globes are inserted Bayer's letters; the first in the Greek alphabet being put to the biggest star in each constellation, the second to the next, and so on: by which means, every star is as easily found as if a name were given to it. Thus, if the star γ in the constellation of the Ram be mentioned, every astronomer knows as well what star is meant as if it were pointed out to him in the heavens. See fig. 205, 206, where the stars are represented with the figures of the animals fiom whence the constellations are marked.

197 Division of the heavens. These is also a division of the heavens into three parts. 1. The zodiac (ζωδιακος), from ζωδιον, *zodion*, "an animal," because most of the constellations in it, which are 12 in number, have the names of animals: Fig. 26, 29.
As *Aries* the ram, *Taurus* the bull, *Gemini* the twins, *Cancer* the crab, *Leo* the lion, *Virgo* the virgin, *Libra* the balance, *Scorpio* the scorpion, *Sagittarius* the archer, *Capricornus* the goat, *Aquarius* the water-bearer, and *Pisces* the fishes. The zodiac goes quite round the heavens: it is about 16 degrees broad, so that it takes in the orbits of all the planets, and likewise the orbit of the moon. Along the middle of this zone or belt is the ecliptic, or circle which the earth describes annually as seen from the sun, and which the sun appears to describe as seen from the earth. 2. All that region of the heavens which is on the north side of the zodiac, containing 21 constellations. And, 3. That on the south side, containing 15.

198 Zodiac how divided. The ancients divided the zodiac into the above 12 constellations or signs in the following manner: They took a vessel with a small hole in the bottom, and, having filled it with water, suffered the same to distil drop by drop into another vessel set beneath to receive it; beginning at the moment when some star arose, and continuing till it rose the next following night. The water falling down into the receiver they divided into 12 equal parts; and having two other small vessels in readiness, each of them fit to contain one part, they again poured all the water into the upper vessel; and, observing the rising of some star in the zodiac, they at the same time suffered the water to drop into one of the small vessels; and as soon as it was full, they shifted it, and set an empty one in its place. When each vessel was full, they took notice what star of the zodiac rose; and though this could not be done in one night, yet in many they observed the rising of 12 stars or points, by which they divided the zodiac into 12 parts.

The names of the constellations, and the number of stars observed in each of them by different astronomers, are as follows.

Several stars observed by the ancients are now no more to be seen, but are destroyed; and new ones have appeared which were unknown to the ancients. Some of them have also disappeared for some time, and again become visible.

We are also assured from the observations of astronomers, that some stars have been observed which never were seen before, and for a certain time they have distinguished themselves by their superlative lustre; but afterwards decreasing, they vanished by degrees, and were no more to be seen. One of these stars being first seen and observed by Hipparchus, the chief of the ancient astronomers, set him upon composing a catalogue of the fixed stars, that by it posterity might learn whether any of the stars perish, and others are produced afresh.

After several ages, another new star appeared to Tycho Brahe and the astronomers who were cotemporary with him: which put him on the same design with Hipparchus, namely, the making a catalogue of the fixed stars. Of this, and other stars which have appeared since that time, we have the following history by Dr Halley: "The first new star in the chair of Cassiopeia, was not seen by Cornelius Gemma on the 8th of November 1572, who says, he that night considered that part of the heaven in a very serene sky, and saw it not: but that the next night, November 9. it appeared with a splendour surpassing all the fixed stars, and scarce less bright than Venus. This was not seen by Tycho Brahe before the 11th of the same month: but from thence he assures us that it gradually decreased and died away, so as in March 1574, after sixteen months, to be no longer visible; and at this day no signs of it remain. The place thereof in the sphere of fixed stars, by the accurate observations of the same Tycho, was $0^s\ 9^\circ\ 17'$ *a* 1ma * ♈is, with $53^\circ\ 45'$ north latitude.

200 Dr Halley's history of new stars.

"Such another star was seen and observed by the scholars of Kepler, to begin to appear on Sept. 30. *st. vet.* anno 1604, which was not to be seen the day before: but it broke out at once with a lustre surpassing that of Jupiter; and like the former, it died away gradually, and in much about the same time disappeared totally, there remaining no footsteps thereof in January $160\frac{5}{6}$. This was near the ecliptic, following the right leg of Serpentarius; and by the observations of Kepler and others, was in $7^s\ 20^\circ\ 00'$ *a* 1ma * ♈, with north latitude $1^\circ\ 56'$. These two seem to be of a distinct species from the rest, and nothing like them has appeared since.

"But between them, viz. in the year 1596, we have the first account of the wonderful star in Collo Ceti, seen by David Fabricius on the third of August *st. vet.* as bright as a star of the 3d magnitude, which has been since found to appear and disappear periodically; its period being precisely enough seven revolutions in six years, though it returns not always with the same lustre. Nor is it ever totally extinguished, but may at all times be seen with a six feet tube. This was singular in its kind, till that in Collo Cygni was discovered. It precedes the first star of Aries $1^\circ\ 40'$, with $15^\circ\ 57'$ south latitude.

"Another new star was first discovered by William Jansonius in the year 1600, *in pectore*, or rather *in eductione*, Colli Cygni, which exceeded not the third magnitude. This having continued some years, became at length so small, as to be thought by some to have disappeared entirely; but in the years 1657, 1658, and 1659, it again rose to the third magnitude; though soon after it decayed by degrees to the fifth or sixth magnitude, and at this day is to be seen as such in $9^s\ 18^\circ\ 38'$ *a* 1ma * ♈, with $55^\circ\ 29'$ north latitude.

"A fifth new star was first seen by Hevelius in the year 1670, on July 15. *st. vet.* as a star of the third magnitude, but by the beginning of October was scarce to be perceived by the naked eye. In April following it was again as bright as before, or rather greater than of the third magnitude, yet wholly disappeared about the middle of August. The next year, in March 1672, it was seen again, but not exceeding the sixth magnitude: since when, it has been no further visible, though we have frequently sought for its return; its place is $9^s\ 3^\circ\ 17'$ *a* 1ma * ♈, and has lat. north $47^\circ\ 28'$.

"The sixth and last is that discovered by Mr G. Kirch in the year 1686, and its period determined to be of $404\frac{1}{2}$ days; and though it rarely exceeds the fifth magnitude, yet it is very regular in its returns, as we found in the year 1714. Since then we have watched, as the absence of the moon and clearness of the weather would permit, to catch the first beginning of its appearance in a six feet tube, that, bearing a very great aperture, discovers most minute stars. And on June 15. last, it was first perceived like one of the very least telescopical stars; but in the rest of that month and July, it gradually increased, so as to become in August visible to the naked eye: and so continued till the month of September. After that, it again died away by degrees: and on the 8th of December, at night, was scarcely discernible by the tube; and, as near as could be guessed, equal to what it was at its first appearance on June 25th: so that this year it has been seen in all near six months, which is but little less than half its period; and the middle, and consequently the greatest brightness, falls about the 10th of September."

201 Mr Montanere's account of changes amongst the fixed stars.

Concerning the changes which happen among the fixed stars, Mr Montanere, professor of mathematics at Bononia, gave the following account, in a letter to the Royal Society, dated April 30th 1670. "There are now wanting in the heavens two stars of the second magnitude in the stern of the ship Argo, and its yard; Bayerus marked them with the letters β and χ. I and others observed them in the year 1664, upon the occasion of the comet that appeared that year: when they disappeared first, I know not: only I am sure that in the year 1668, upon the 10th of April, there was not the least glimpse of them to be seen; and yet the rest

Digitized by Google

Apparent Motions of the Heavenly Bodies.

rest about them, even of the third and fourth magnitudes, remained the same. I have observed many more changes among the fixed stars, even to the number of a hundred, though none of them are so great as those I have showed."

The late improvements in astronomy, and particularly those in the construction of telescopes, have now given astronomers an opportunity of observing the changes which take place among the stars with much greater accuracy than could be formerly done. In a paper in the 76th volume of the Philosophical Transactions, Mr Edward Pigot gives a dissertation on the stars suspected by the astronomers of last century to be changeable. For the greater accuracy in the investigation of his subject, he divides them into two classes; one containing those which are undoubtedly changeable, and the other those which are only suspected to be so. The former contains a list of 12 stars, from the first to the fourth magnitude; including the new one which appeared in Cassiopeia in 1572, and that in Serpentarius in 1604: the other contains the names of 38 stars of all magnitudes, from the first to the seventh. He is of opinion, that the celebrated new star in Cassiopeia is a periodical one, and that it returns once in 150 years. Mr Keill is of the same opinion: and Mr Pigot thinks, that its not being observed at the expiration of each period is no argument against the truth of that opinion; "since (says he), perhaps, as with most of the variables, it may at different periods have different degrees of lustre, so as sometimes only to increase to the ninth magnitude; and if this should be the case, its period is probably much shorter." For this reason, in September 1782, he took a plan of the small stars near the place where it formerly appeared, but in four years had observed no alteration.

202 Mr Pigot's remarks on the accounts of variable stars.

203 Star in Collo Ceti.

The star in the neck of the Whale had also been examined by Mr Pigot from the end of 1782 to 1786; but he never found it exceed the sixth magnitude; though Mr Goodricke had observed it on the 9th of August to be of the second magnitude, and on the 3d of September the same year it was of the third magnitude. Mr Pigot deduced its period from its apparent equality with a small star in the neighbourhood, and thence found it to be 320, 328, and 337 days.

204 Algol.

The most remarkable of these changeable stars is that called *Algol*, in the head of Medusa. It had long been known to be variable; but its period was first ascertained by Mr Goodricke of York, who began to observe it in the beginning of 1783. It changes continually from the first to the fourth magnitude; and the time taken up from its greatest diminution to its least is found, at a mean, to be 2 d. 20 h. 49 m. and 3 sec. During four hours it gradually diminishes in lustre, which it recovers during the succeeding four hours; and in the remaining part of the period it invariably preserves its greatest lustre, and after the expiration of the term its diminution again commences. According to Mr Pigot, the degree of brightness of this star when at its *minimum* is variable in different periods, and he is of the same opinion with regard to its brightness when at its full; but whether these differences return regularly or not, has not been determined.

The 420th of Mayer's catalogue, in Leo, has lately been shown to be variable by Mr Koch. Some years before 1782, that gentleman perceived it undoubtedly smaller than the 419th of the same catalogue. In February that year, it was of the same brightness with the 419th, that is, of the seventh magnitude. In April 1783, it was of the ninth magnitude; and in the same month 1784, it was of the tenth. Mr Pigot could never observe this star, though he frequently looked for it with a night-glass, and on the fifth of April 1785 with a three feet achromatic transit instrument.

205 Variable star in Hydra.

In 1704, Maraldi observed a variable star in Hydra, whose period he settled at about two years, though with considerable variations: but from the observations even of Maraldi, Mr Pigot concludes, that its period was then only 494 days; and from some others made by himself, he thinks that now it is only 487 days; so that since the time of Maraldi it has shortened seven days. The particulars relating to this star are as follow. 1. When at its full brightness it is of the fourth magnitude, and does not perceptibly change for a fortnight. 2. It is about six months in increasing from the tenth magnitude and returning to the same: so that it may be considered as invisible during that time. 3. It is considerably more quick, perhaps one half more so, in its increase than in its decrease. 4. Though when at its full it may always be styled a star of the fourth magnitude, it does not constantly attain the same degree of brightness, but the differences are very small. This star is the 30th of Hydra in Hevelius's catalogue, and is marked by him of the sixth magnitude.

The new star in Serpentarius, observed by Kepler, seems to have been of the same nature with that of Cassiopeia; and Mr Pigot therefore looks upon it also to be a periodical one, though, after taking a plan of the nearest stars in that part of the heavens, in the year 1782, he could, in four years time, perceive no alteration.

206 Swan's Head.

The variation of the star β Lyræ was discovered by Mr Goodricke above-mentioned, who suspects its period to be six days nine hours; which coincides with the opinion of Mr Pigot.

The new star near the Swan's Head, observed by Don Anthelme in December 1669, soon became of the third magnitude, and disappeared in 1672. Mr Pigot has constantly looked for it since November 1781, but without success. He is of opinion, that had it only increased to the 10th or 11th magnitude, he would have seen it, having taken a plan of all the neighbouring small stars.

The next variable star in Mr Pigot's catalogue is the η Antinoi, whose variation and period he discovered in 1785. From his corrected observations, he concludes that it continues at its greatest brightness 40 hours without decreasing; it is 66 hours after it begins to decrease before it comes to its full diminution; after which it continues stationary for 30 hours more, and then increases for 36 hours. In every period it seems to acquire its full brightness, and to be equally decreased.

207 Swan's Neck.

The variable star in the Swan's Neck was observed for three years. The period of this star had been settled by Maraldi and Cassini at 405, and by M. le Gentil at 405.3 days; but from a mean of the observations of Mr Pigot, it appears to be only 392.

Digitized by Google

"Perhaps (says he) its period is irregular; to determine which several intervals of 15 years ought to be taken; and I am much inclined to believe that it will be found only 396 days 21 hours." The particulars relating to this star are, 1. When at its full brightness it undergoes no perceptible change for a fortnight. 2. It is about three months and a half in increasing from the 11th magnitude to its full brightness, and the same in decreasing; for which reason it may be considered as invisible during six months. 3. It does not always attain the same degree of lustre, being sometimes of the fifth and sometimes of the seventh magnitude.

208 Swan's Breast.

In 1600, G. Jansonius discovered a variable star in the breast of the Swan, which was afterwards observed by different astronomers, and supposed to have a period of about 10 years. The results of Mr Pigot's calculations from the observations of former astronomers are, 1. That it continues in full lustre for five years. 2. It decreases rapidly for two years. 3. It is invisible to the naked eye for four years. 4. It increases slowly during seven years. 5. All these changes are completed in 18 years. 6. It was at its *minimum* at the end of the year 1663. 7. It does not always increase to the same degree of brightness, being sometimes of the third, and at others only of the sixth, magnitude. "I am entirely ignorant (says Mr Pigot) whether it is subject to the same changes in this century, having not met with any series of observations on it; but if the above conjectures are right, it will be at its minimum in a very few years. Since November 1781 I have constantly seen it of the sixth magnitude. Sometimes I have suspected that it has decreased within these two last years, though in a very small degree."

The last star in Mr Pigot's first class is the δ Cephei, whose variation was discovered by Mr Goodricke. Its changes are very difficult to be seen, unless it is observed at the times of its greatest and least brightness. The result of the observations hitherto made upon it are, that its period consists of 5 days 8 hours 37′ on a mean. The following observations relate to some stars of the second class.

209 Stars, variation of which is less certain.

1. Hevelius's 6th Cassiopeiæ was missing in 1782, nor could Mr Pigot find it in 1783 and 1784.

2. ξ or 46 Andromedæ, said to be variable, but the evidence is not convincing to Mr Pigot.

3. Flamstead's 50, 52, υ Andromedæ, and Hevelius's 41 Andromedæ. The position and characters of these stars differ considerably in different catalogues, and some of them are said by Cassini to have disappeared and reappeared. Mr Pigot therefore gives their comparative brightness as observed in the years 1783, 1784, and 1785, during which time he does not mention any particular change.

4. Tycho's 20th Ceti. "This (says Mr Pigot) must be the star which Hevelius said had disappeared, being Tycho's second in the Whale's Belly. There can hardly be any doubt that it is the χ, misplaced by Tycho. This χ is of the fourth or fifth magnitude.

5. ε, or the 17th Eridani of Ptolemy and Ulug Beigh. Flamstead says he could not see this star in 1691 and 1692; but in 1782, 1783, and 1784, Mr Pigot observed in that place one of the seventh magnitude, which appeared always of the same lustre.

6. Flamstead's 41 Tauri was supposed by Cassini to be either a new or variable star; but Mr Pigot thinks there is no reason to be of that opinion. "That it is not new (says he) is evident, since it is Ulug Beigh's 26th and Tycho's 43d.

7. A star about 2½° north of 53 Eridani, and 47 Eridani. Cassini supposed the first of these stars to be a new one, and that it was not visible in 1664. He mentions another star thereabouts, which he also esteemed a new one.

8. γ Canis Majoris. Maraldi could not see this star in 1670; but in 1692 and 1693 it appeared of the fourth magnitude. Mr Pigot made frequent observations upon it from 1782 to 1786, but could perceive no variation.

9. α β Geminorum. "If any of these stars (says our author) have changed in brightness, it is probably the β. In 1783, 1784, and 1785, the β was undoubtedly brighter than α."

10. ξ Leonis. According to Montanari, this star was hardly visible in 1693. In 1783, 1784, and 1785, it was of the fifth magnitude. By Tycho, Flamstead, Mayer, Bradley, &c. it is marked of the fourth.

11. ψ Leonis. This star is said to have disappeared before the year 1667; but according to Mr Pigot's observations, was constantly of the fifth or sixth magnitude since 1783.

12. 25th Leonis. In 1783, our author first perceived that this star was missing, and could not perceive it in 1784 and 1785, even with a transit instrument.

13. Bayer's ι Leonis, or Tycho's 16 Leonis was not visible in 1709, nor could it be seen in 1785. It is a different star from the ι Leonis of the other catalogues, though Tycho's description of its place is the same.

14. δ Ursæ Majoris. This star is suspected to change in brightness, on account of its being marked by Tycho, the prince of Hesse, &c. of the second magnitude, while Hevelius, Bradley, and others, have marked it of the third. In 1786, and for three years before, it appeared as a bright star of the fourth magnitude.

15. ν Virginis. This is supposed to be variable, because Flamstead, on the 27th of January 1680, could not see it; but he observed it in 1677, and some years afterwards. Mr Pigot observed it frequently in 1784 and 1785, and found it a star of the sixth magnitude without any perceptible change.

16. Bayer's star of the sixth magnitude 1° south of *g* Virginis. "This star (says Mr Pigot) is not in any of the nine catalogues that I have. Maraldi looked for it in vain; and in May 1785 I could not see the least appearance of it." It certainly was not of the eighth magnitude.

17. A star in the northern thigh of Virgo, marked by Ricciolus of the sixth magnitude, could not be seen by Maraldi in 1709; nor was it of the ninth magnitude, if at all visible in 1785.

18. The 91 and 92 Virginis. In 1685, one of these stars, probably the 91, was missing: the remaining one is of the sixth or seventh magnitude.

19. α Draconis. Mr Pigot coincides in opinion with Dr Herschel, that this star is variable. Bradley, Flamstead, &c. mark it of the second magnitude, but in 1786 it was only a bright fourth. It was frequently examined

Apparent Motions of the Heavenly Bodies.

examined by Mr Pigot from the fourth of October 1782, but without any alteration being perceived.

20. Bayer's star in the west scale of Libra. Maraldi could not see this star, and it was likewise invisible to Mr Pigot in 1784 and 1785.

21. N° 6 of Ptolemy and Ulug Beigh's unformed in Libra. This star is not mentioned in any other catalogues than the above. Mr Pigot frequently observed a little star of the seventh magnitude very near its place

22. κ Libræ. This star is thought to be variable, but Mr Pigot is not of that opinion, though "certainly (says he) it is rather singular, that Hevelius, whose attention was directed to that part of the heavens to find Tycho's 11th, did not find the κ; and the more so, as he has noticed two much smaller stars not far from it. During these three years I have found the κ constantly of the fifth magnitude."

23. Tycho's 11th Libræ. Mr Pigot is of opinion that no such star as this ever existed; and that it is no other than the κ with an error of 2 degrees of longitude.

24. 33 Serpentis. This star was missing in 1784; nor could it be perceived with a night-glass in 1785.

25. A star marked by Bayer near ι Ursæ majoris. This star could not be seen by Cassini; nor was Mr Pigot able to discover it with a night-glass in 1782.

26. The ρ, or Ptolemy and Ulug Beigh's 14th Ophiuchi, or Flamstead's 36th. Mr Pigot has no doubt that this is the star which is said to have disappeared before the year 1695; and it is evident that it was not seen by Hevelius. In 1784 and 1785 Mr Pigot found it of the fourth or fifth magnitude; but he is far from being certain of its having undergone any change, especially as it has a southern declination of 26 degrees; for which reason great attention must be paid to the state of the atmosphere.

27. Ptolemy's 13th and 18th Ophiuchi, fourth magnitude. Mr Pigot is of opinion that these stars are misplaced in the catalogues. The 18th of Ptolemy he thinks ought to be marked with a north latitude instead of a south, which would make it agree nearly with Flamstead's 58th; and he is also of opinion that the 13th of Ptolemy is the 40th of Flamstead.

28. σ Sagittarii. Dr Herschel, as well as Mr Pigot, is of opinion, that this star has probably changed its magnitude, though the reason seems only to be the great disagreement concerning it among the different catalogues of stars.

29. θ Serpentis. This star, according to Mr Montanari, is of variable magnitude; but Mr Pigot never could perceive any alteration.

30. Tycho's 27th Capricorni was missing in Hevelius's time, and Mr Pigot could not find it with a transit instrument.

31. Tycho's 22d Andromedæ, and ι Andromedæ. Mr Cassini informs us, that in his time the former had grown so small that it could scarcely be seen; and Mr Pigot, that no star was to be seen in its place in 1784 and 1785: but he is of opinion that Cassini may have mistaken the ι Andromedæ for the 22d; for which reason he observed this star three years, but without any alteration in its brightness.

32. Tycho's 19th Aquarii. Hevelius says that this star was missing, and that Flamstead could not see it with his naked eye in 1679. Mr Pigot could not see it in 1782; but is persuaded that it is the same with Flamstead's 56th, marked *f* by Bayer, from which it is only a degree and a half distant. The 53d of Flamstead, marked *f* in Ptolemy's catalogue, is a different star.

33. La Caille's 483 Aquarii was first discovered to be missing in 1778, and was not visible in 1783 and 1784.

Besides these there are several others certainly variable, but which cannot be seen in this country. There are some also suspected to be variable, but for which Mr Pigot thinks there is no reason. Dr Herschel also gives strong reasons for not laying great stress on all the observations by which new stars have been said to be discovered. Mr Pigot assures us from repeated experience, that even more than a single observation, if not particularised and compared with neighbouring stars, is very little to be depended upon; different streaks of the clouds, the state of the weather, &c. having often caused him to err a whole magnitude in the brightness of a star.

210 Wollaston's method of discovering variations among the fixed stars.

As these changes to which the fixed stars are liable do not seem to be subject to any certain rule, Mr Wollaston has given an easy method of observing whether they do take place in any part of the heavens or not, and that without much expence of instruments or waste of time, which are great objections to astronomical observations in general. His first idea was, that the work should be undertaken by astronomers in general; each taking a particular district of the heavens, and from time to time observing the right ascension and declination of every star in that space allotted to him, framing an exact map of it, and communicating their observations to one common place of information.—This method, however, being too laborious, he next proposes the noting down at the time, or making a drawing of what one sees while they are observing. A drawing of this kind once made, would remain, and could be consulted on any future occasion; and if done at first with care, a transient review would discover whether any sensible change had taken place since it was last examined, which could not so well be done by catalogues or verbal description. For this purpose he recommends the following method: "To a night glass, but of Dollond's construction, which magnifies about six times, and takes in about as many degrees of a great circle, I have added cross wires intersecting one another at an angle of 45 degrees. More wires may be crossed in other directions; but I apprehend these will be sufficient. This telescope I mount on a polar axis. One coarsely made, and without any divisions on its circle of declination, will answer the purpose, as there is no great occasion for accuracy in that respect; but as the heavenly bodies are more readily followed by an equatorial motion of the telescope, so their relative positions are much more easily discerned when they are looked at constantly as in the same direction. A horizontal motion, except in the meridian, would be apt to mislead the judgment. It is scarcely necessary to add, that the wires must stand so as for one to describe a parallel of the equator nearly; another will then be a horary circle, and the whole area will be divided into eight equal sectors.

"Thus prepared, the telescope is to be pointed to a known

Digitized by Google

Apparent Motions of the Heavenly Bodies.

known star, which is to be brought into the centre or common intersection of all the wires. The relative positions of such other stars as appear within the field are to be judged of by the eye; whether at $\frac{1}{4}$, $\frac{1}{3}$, or $\frac{1}{2}$, from the centre towards the circumference, or *vice versa;* and so with regard to the nearest wire respectively. These, as one sees them, are to be noted down with a black-lead pencil upon a large message-card held in the hand, upon which a circle similarly divided is ready drawn. One of three inches diameter seems most convenient. The motion of the heavenly bodies in such a telescope is so slow, and the noting down of the stars so quickly done, that there is commonly full time for it without moving the telescope. When that is wanted, the principal star is easily brought back again into the centre of the field at pleasure, and the work resumed. After a little practice, it is astonishing how near one can come to the truth in this way: and though neither the right ascensions nor the declinations are laid down by it, nor the distances between the stars measured; yet their apparent situations being preserved in black and white, with the day and year, and hour, if thought necessary, written underneath, each card then becomes a register of the then appearance of the heavens; which is easily re-examined at any time with little more than a transient view; and which will yet show, on the first glance, if there should have happened in it any alteration of consequence."

Fig. 80. shows part of the Corona Borealis delineated in this manner, and which was afterwards fully taken down by making the stars α, β, γ, δ, ϵ, ζ, θ, ι, κ, π, ρ, σ, and τ, successively central; and these were joined with some of the stars of Bootes, for the sake of connecting the whole, and united into one map, as represented in fig. 81.

In observing in this way, it is evident, that the places of such stars as happen to be under or very near any of the wires, are more to be depended upon than those which are in the intermediate spaces, especially if towards the edges of the fields; so also those which are nearest to the centre, because better defined, and more within the reach of one wire or another. For this reason, different stars of the same set must successively be made central, or brought towards one of the wires, where any suspicion arises of a mistake, in order to approach nearer to a certainty; but if the stand of the telescope be tolerably well adjusted and fixed, this is soon done.

In such a glass it is seldom that light sufficient for discerning the wires is wanting. When an illuminator is required, a piece of card or white pasteboard projecting on one side beyond the tube, and which may be brought forward occasionally, is better than any other. By cutting across a small segment of the object-glass, it throws a sufficient light down the tube though the candle be at a great distance, and one may lose sight of the false glare by drawing back the head, and moving the eye a little to one side, when the small stars will be seen as if no illuminator was there. See a delineation of the principal fixed stars, with the apparent path of the sun among them, in figures 82 and 83.

211 Galaxy, or milky-way.

A very remarkable appearance in the heavens is that called the *galaxy*, or *milky-way*. This is a broad circle, sometimes double, but for the most part single, surrounding the whole celestial concave. We perceive also in different parts of the heavens small white spots, which appear to be of the same nature with the milky-way. These spots are called *nebulæ*.

We shall subjoin in this place, for the entertainment of the reader, the theories of Mr Michell and Dr Herschel, concerning the nature and position of the fixed stars.

212 Mr Michell's conjectures concerning the nature of the fixed stars.

"The very great number of stars (says Mr Michell) that have been discovered to be double, triple, &c. particularly by Mr Herschel, if we apply the doctrine of chances, as I have heretofore done in my inquiry into the probable parallax, &c. of the fixed stars, published in the Philosophical Transactions for the year 1767, cannot leave a doubt with any one who is properly acquainted with the force of those arguments, that by far the greatest part, if not all of them, are systems of stars so near each other, as probably to be liable to be affected sensibly by their mutual gravitation; and it is therefore not unlikely, that the periods of the revolutions of some of these about their principals (the smaller ones being, upon this hypothesis, to be considered as satellites to the other) may some time or other be discovered." Having then shown in what manner the magnitude of a fixed star, if its density were known, would affect the velocity of its light, he

213 In what cases light may be supposed to return to the body that emits it.

concludes at last, that "if the semidiameter of a sphere of the same density with the sun were to exceed his in the proportion of 500 to 1, a body falling from an infinite height towards it (or moving in a parabolic curve at its surface) would have acquired a greater velocity than that of light; and consequently, supposing light to be attracted by the same force in proportion to its *vis inertiæ* with other bodies, all light emitted from such a body would be made to return towards it by its own proper gravity. But if the semidiameter of a sphere, of the same density with the sun, was of any other size less than 497 times that of the sun, though the velocity of light emitted by such a body would never be wholly destroyed, yet it would always suffer some diminution, more or less according to the magnitude of the sphere. The same effects would likewise take place if the semidiameters were different from those already mentioned, provided the density was greater or less in the duplicate ratio of these semidiameters inversely.

214 Comparative brightness of the sun and fixed stars.

After proceeding in his calculations, in order to find the diameter and distance of any star, he proceeds thus: "According to Mr Bouguer the brightness of the sun exceeds that of a wax-candle in no less a proportion than that of 8000 to 1. If therefore the brightness of any of the fixed stars should not exceed that of our common candles, which, as being something less luminous than wax, we will suppose in round numbers to be only one ten thousandth part as bright as the sun, such a star would not be visible at more than one hundredth part of the distance at which it would be seen if it were as bright as the sun. Now, because the sun would still, I apprehend, appear as bright and luminous as the star Sirius, if removed to 400,000 times his present distance, such a body, if no brighter than our common candles, would only appear equally luminous with that star at 4000 times the distance of the sun; and we might then be able, with the best telescopes, to distinguish some sensible apparent

Digitized by Google

Apparent Motions of the Heavenly Bodies.

parent diameter of it: but the apparent diameters of the stars of lesser magnitudes would still be too small to be distinguishable even with our best telescopes, unless they were yet a good deal less luminous; which may possibly, however, be the case with some of them: for though we have indeed very slight grounds to go upon with regard to the specific brightness of the fixed stars, compared with that of the sun at present, and can therefore form only very uncertain and random conjectures concerning it; yet from the infinite variety which we find in the works of the creation, it is not unreasonable to suspect, that very possibly some of the fixed stars may have so little natural brightness in proportion to their magnitude, as to admit of their diameters having some sensible apparent size when they shall come to be more carefully examined, and with larger and better telescopes than have been hitherto in common use.

215 Luminous appearance of the sun supposed to proceed from an atmosphere.

"With respect to the sun, we know that his whole surface is extremely luminous, a very small and temporary interruption sometimes, from a few spots, excepted. This universal and excessive brightness of the whole surface is probably owing to an atmosphere, which being luminous throughout, and in some measure also transparent, the light proceeding from a considerable depth of it, all arrives at the eye, in the same manner as the light of a great number of candles would do if they were placed one behind another, and their flames were sufficiently transparent to permit the light of the more distant ones to pass through those that were nearer without interruption.

"How far the same constitution may take place in the fixed stars we do not know: probably, however, it may still do so in many; but there are some appearances, with regard to a few of them, which seem to make it probable that it does not do so universally. Now, if I am right in supposing the light of the sun to proceed from a luminous atmosphere which must necessarily diffuse itself equally over the whole surface, and I think there can be very little doubt that this is really the case, this constitution cannot well take place in those stars which are in some degree periodically more and less luminous, such as that in Collo Ceti, &c. It is also not very improbable, that there is some difference from that of the sun in the constitution of those stars which have sometimes appeared and disappeared, of which that in the constellation of Cassiopeia is a notable instance. And if these conjectures are well founded which have been formed by some philosophers concerning stars of this kind, that they are not wholly luminous, or at least not constantly so, but that all, or by far the greatest part of their surfaces, is subject to considerable changes, sometimes becoming luminous, at other times extinguished; it is amongst stars of this sort that we are most likely to meet with instances of a sensible apparent diameter, their light being much more likely not to be so great in proportion as that of the sun, which if removed to 400,000 times his present distance, would still appear, I apprehend, as bright as Sirius, as I have observed above; whereas it is hardly to be expected, with any telescope whatsoever, that we should ever be able to distinguish a well-defined disk of any body of the same size with the sun at much more than 10,000 times his present distance.

216 Of the variable stars.

"Hence the greatest distance at which it would be possible to distinguish any sensible apparent diameter of a body as dense as the sun, cannot well greatly exceed five hundred times ten thousand; that is, five million times the distance of the sun; for if the diameter of such a body was not less than 500 times that of the sun, its light, as has been shown above, could never arrive at us."

217 Dr Herschel's opinion concerning the construction of the universe.

Dr Herschel, improving on Mr Michell's idea of the fixed stars being collected into groups, and assisted by his own observations with the extraordinary telescopic powers already mentioned, has suggested a theory concerning the construction of the universe entirely new and singular. It had been the opinion of former astronomers, that our sun, besides occupying the centre of the system which properly belongs to him, occupied also the centre of the universe: but Dr Herschel is of a very different opinion. "Hitherto (says he) the sidereal heavens have, not inadequately for the purpose designed, been represented by the concave surface of a sphere, in the centre of which the eye of the observer might be supposed to be placed. It is true, the various magnitudes of the fixed stars even then plainly suggested to us, and would have better suited, the idea of an expanded firmament of three dimensions; but the observations upon which I am now going to enter, still farther illustrate and enforce the necessity of considering the heavens in this point of view. In future therefore we shall look upon those regions into which we may now penetrate by means of such large telescopes (A), as a naturalist regards a rich extent of ground or chain of mountains containing strata variously inclined and directed, as well as consisting of very different materials. A surface of a globe or map therefore will but ill delineate the interior parts of the heavens."

218 His observations on the Via Lactea.

With the powerful telescope mentioned in the note, Dr Herschel first began to survey the Via Lactea, and found that it completely resolved the whitish appearance into stars, which the telescopes he formerly used had not light enough to do. The portion he first observed was that about the hand and club of Orion; and found therein an astonishing multitude of stars, whose number he endeavoured to estimate by counting many *fields* (B), and computing from a mean of these how many might be contained in a given portion of the milky-way. In the most vacant place to be met with in that neighbourhood he found 63 stars; other six fields contained 110, 60, 70, 90, 70, and 74 stars; a mean of all which gave 79 for the number of stars to each field; and thus he found, that by allowing 15 minutes

(A) Dr Herschel's observations, on which this theory is founded, were made with a Newtonian reflector of 20 feet focal length, and an aperture of 18 inches.

(B) By this word we are to understand the apparent space in the heavens he could see at once through his telescope.

Apparent Motions of the Heavenly Bodies.

minutes for the diameter of his field of view, a belt of 15 degrees long and two broad, which he had often seen pass before his telescope in an hour's time, could not contain less than 50,000 stars, large enough to be distinctly numbered; besides which, he suspected twice as many more, which could be seen only now and then by faint glimpses for want of sufficient light.

219
On the nebulæ.

The success he had within the milky-way soon induced him to turn his telescope to the nebulous parts of the heavens, of which an accurate list had been published in the *Connoisance des Temps* for 1783 and 1784. Most of these yielded to a Newtonian reflector of 20 feet focal distance and 12 inches aperture; which plainly discovered them to be composed of stars, or at least to contain stars, and to show every other indication of consisting of them entirely. "The nebulæ (says he) are arranged into strata, and run on to a great length; and some of them I have been able to pursue, and to guess pretty well at their form and direction. It is probable enough that they may surround the whole starry sphere of the heavens, not unlike the milky-way, which undoubtedly is nothing but a stratum of fixed stars: And as this latter immense starry bed is not of equal breadth or lustre in every part, nor runs on in one straight direction, but is curved, and even divided into two streams along a very considerable portion of it; we may likewise expect the greatest variety in the strata of the clusters of stars and nebulæ. One of these nebulous beds is so rich, that, in passing through a section of it in the time of only 36 minutes, I have detected no less than 31 nebulæ, all distinctly visible upon a fine blue sky. Their situation and shape, as well as condition, seem to denote the greatest variety imaginable. In another stratum, or perhaps a different branch of the former, I have often seen double and treble nebulæ variously arranged; large ones with small seeming attendants; narrow, but much extended lucid nebulæ or bright dashes; some of the shape of a fan, resembling an electric brush issuing from a lucid point; others of the cometic shape, with a seeming nucleus in the centre, or like cloudy stars, surrounded with a nebulous atmosphere: a different sort again contain a nebulosity of the milky kind, like that wonderful inexplicable phenomenon about θ Orionis; while others shine with a fainter mottled kind of light, which denotes their being resolvable into stars.

220
They are arranged into strata.

221
Variety of shapes assumed by them.

222
Why the milky-way appears to surround the heavens.

"It is very probable that the great stratum called the *milky-way*, is that in which the sun is placed, though perhaps not in the very centre of its thickness. We gather this from the appearance of the galaxy, which seems to encompass the whole heavens, as it certainly must do if the sun is within the same. For suppose a number of stars arranged between two parallel planes, indefinitely extended every way, but at a given considerable distance from one another, and calling this a sidereal stratum, an eye placed somewhere within it will see all the stars in the direction of the planes of the stratum projected into a great circle, which will appear lucid on account of the accumulation of the stars, while the rest of the heavens at the sides will only seem to be scattered over with constellations, more or less crowded according to the distance of the planes or number of stars contained in the thickness or sides of the stratum.

"Thus in fig. 83. an eye at S within the stratum *a b*, will see the stars in the direction of its length *a b*, or height *e d*, with all those in the intermediate situation, projected into the lucid circle ABCD; while those in the sides *m e*, *n w*, will be seen scattered over the remaining part of the heavens at MVNW.

223
Celestial appearances solved on Dr Herschel's hypothesis.

"If the eye were placed somewhere without the stratum, at no very great distance, the appearance of the stars within it would assume the form of one of the lesser circles of the sphere, which would be more or less contracted to the distance of the eye; and if this distance were exceedingly increased, the whole stratum might at last be drawn together into a lucid spot of any shape, according to the position, length, and height of the stratum.

"Let us now suppose, that a branch or smaller stratum should run out from the former in a certain direction, and let it also be contained between two parallel planes extended indefinitely onwards, but so that the eye may be placed in the great stratum somewhere before the separation, and not far from the place where the strata are still united; then will this second stratum not be projected into a bright circle like the former, but will be seen as a lucid branch proceeding from the first, and returning to it again at a certain distance less than a semicircle. Thus, in the same figure, the stars in the small stratum *p g* will be projected into a bright arch at PRRP, which after its separation from the circle CBD, unites with it again at P.

"What has been instanced in parallel planes may easily be applied to strata irregularly bounded, and running in various directions; for their projection will of consequence vary according to the quantities of the variations in the strata and the distance of the eye from the same. And thus any kind of curvatures, as well as various degrees of brightness, may be produced in the projections.

224
Of the sun's place in the universe.

"From appearances, then, as I observed before, we may infer, that the sun is most likely placed in one of the great strata of the fixed stars, and very probably not far from the place where some smaller stratum branches out from it. Such a supposition will satisfactorily, and with great simplicity, account for all the phenomena of the milky-way; which according to this hypothesis, is no other than the appearance of the projection of the stars contained in this stratum and its secondary branch. As a farther inducement to look on the galaxy in this point of view, let it be considered, that we can no longer doubt of its whitish appearance arising from the mixed lustre of the numberless stars that compose it. Now, should we suppose it to be an irregular ring of stars, in the centre nearly of which we must then suppose the sun to be placed, it will appear not a little extraordinary, that the sun, being a fixed star, like those which compose this imagined ring, should just be in the centre of such a multitude of celestial bodies, without any apparent reason for this singular distinction; whereas, on our supposition, every star in this stratum, not very near the termination of its length or height, will be so placed as also to have its own galaxy, with only such variations in the form and lustre of it as may arise from the particular situation of each star.

225
Herschel's method of gauging the heavens.

"Various methods may be taken to come to a knowledge of the sun's place in the sidereal stratum, one

one of which I have already begun to put in practice: I call it *gauging the heavens*; or the *star-gauge*. It consists in repeatedly taking the number of stars in ten fields of view of my reflector very near each other; and by adding their sums, and cutting off one decimal on the right, a mean of the contents of the heavens in all the parts which are thus gauged are obtained. Thus it appears that the number of stars increases very much as we approach the milky-way; for in the parallel from 92 to 94 degrees north polar distance, and right ascension 15 h. 10′, the star-gauge runs up from 9.4 stars in the field to 18.6 in about an hour and a half; whereas in the parallel from 78 to 80 degrees north polar distance, and R. A. 11, 12, 13, and 14 hours, it very seldom rises above 4. We are, however, to remember, that, with different instruments, the account of the gauges will be very different, especially on our supposition of the sun in a stratum of stars. For let *ab* fig. 84. be the stratum, and suppose the small circle *ghlk* to represent the space into which, by the light and power of a given telescope, we are enabled to penetrate, and let GHLK be the extent of another portion which we are enabled to visit by means of a larger aperture and power, it is evident, that the gauges with the latter instrument will differ very much in their account of stars contained at MN and at KG or LH, when with the former they will hardly be affected with the change from *mn* to *kg* or *lk*.

226 How to find the place of the sun in the sidereal stratum.

"The situation of the sun in the sidereal stratum will be found by considering in what manner the star-gauge agrees with the length of a ray revolving in several directions about an assumed point, and cut off by the bounds of the stratum. Thus, in fig. 85. let S be the place of an observer: S r r r, *S r r r*, lines in the plane r S r, *r S r*, drawn from S within the stratum to one of the boundaries here represented by the plane AB. Then, since neither the situation of S nor the form of the limiting surface AB is known, we are to assume a point, and apply to it lines proportional to the several gauges that have been obtained, and at such angles from each other as they may point out: then will the termination of these lines delineate the boundary of the stratum, and consequently manifest the situation of the sun within the same.

227 Observations on nebulæ.

"In my late observations on nebulæ, I soon found, that I generally detected them in certain directions rather than in others: that the spaces preceding them were generally quite deprived of their stars, so as often to afford many fields without a single star in it: that the nebulæ generally appeared some time after among stars of a certain considerable size, and but seldom among very small stars: that when I came to one nebula, I generally found several more in the neighbourhood: that afterwards a considerable time passed before I came to another parcel. These events being often repeated in different altitudes of my instrument, and some of them at considerable distances from each other, it occurred to me that the intermediate spaces between the sweeps might also contain nebulæ; and finding this to hold good more than once, I ventured to give notice to my assistant at the clock, that I 'found myself on nebulous ground.' But how far these circumstances of vacant places preceding and following the nebulous strata, and their being as it were contained in a bed of stars sparingly scattered between them, may hold good in more distant portions of the heavens, and which I have not been yet able to visit in any regular manner, I ought by no means to hazard a conjecture. I may venture, however, to add a few particulars about the direction of some of the capital strata or their branches. The well-known nebula of Cancer, visible to the naked eye, is probably one belonging to a certain stratum, in which I suppose it to be so placed as to lie nearest to us. This stratum I shall call that of Cancer. It runs from ι Cancri towards the south, over the 67th nebula of the *Connoissance des Temps*, which is a very beautiful and pretty much compressed cluster of stars, easily to be seen by any good telescope; and in which I have observed above 200 stars at once in the field of view of my great reflector with a power of 157. This cluster appearing so plainly with any good common telescope, and being so near to the one which may be seen with the naked eye, denotes it to be probably the next in distance to that within the quartile formed by γ, δ, η, θ. From the 67th nebula the stratum of Cancer proceeds towards the head of Hydra; but I have not yet had time to trace it farther than the equator.

228 Direction of some of the principal strata of stars.

"Another stratum, which perhaps approaches nearer to the solar system than any of the rest, and whose situation is nearly at rectangles with the great sidereal stratum in which the sun is placed, is that of Coma Berenices, as I shall call it. I suppose the Coma itself to be one of the clusters in it, and that on account of its nearness it appears to be so scattered. It has many capital nebulæ very near it: and in all probability this stratum runs out a very considerable way. It may perhaps even make the circuit of the heavens, though very likely not in one of the great circles of the sphere; for unless it should chance to intersect the great sidereal stratum of the milky-way before mentioned, in the very place in which the sun is stationed, such an appearance would hardly be produced. However, if the stratum of Coma Berenices should extend so far as I apprehend it may, the direction of it towards the north lies probably, with some windings, through the Great Bear onwards to Cassiopeia, thence through the girdle of Andromeda and the Northern Fish, proceeding towards Cetus; while towards the south it passes through the Virgin, probably on to the tail of Hydra and Centaurus."

229 Of the interior construction of the heavens.

By a continued series of observations, Dr Herschel became confirmed in his notions; and in a succeeding paper * has given a sketch of his opinions concerning the interior construction of the heavens. "That the milky-way (says he) is a most extensive stratum of stars of various sizes, admits no longer of the least doubt; and that our sun is one of the heavenly bodies belonging to it is as evident. I have now viewed and gauged this shining zone in almost every direction, and find it composed of shining stars, whose number, by the account of those gauges, constantly increases and decreases in proportion to its apparent brightness to the naked eye. But in order to develope the ideas of the universe that have been suggested by my late observations, it will be best to take the subject from a point of view at a considerable distance both of space and time.

* Phil. Trans. vol. lxxv.

"Let us then suppose numberless stars of various sizes scattered over an indefinite portion of space, in such

Digitized by Google

Apparent Motions of the Heavenly Bodies.

such a manner as to be almost equally distributed through the whole. The laws of attraction, which no doubt extend to the remotest regions of the fixed stars, will operate in such a manner as most probably to produce the following remarkable effects.

230 Consequences of the laws of attraction acting among the stars.

"I. It will frequently happen, that a star, being considerably larger than its neighbouring ones, will attract them more than they will be attracted by others that are immediately around them; by which means they will be in time, as it were, condensed about a centre: or, in other words, form themselves into a cluster of stars of almost a globular figure, more or less regularly so according to the size and original distance of the surrounding stars. The perturbations of these mutual attractions must undoubtedly be very intricate, as we may easily comprehend, by considering what Sir Isaac Newton has said, *Princip.* lib. 1. prop. 38. *et seq.*: but in order to apply this great author's reasoning of bodies moving in ellipses to such as are here for a while supposed to have no other motion than what their mutual gravity has imparted to them, we must suppose the conjugate axes of these ellipses indefinitely diminished, whereby the ellipses will become straight lines.

231 Nebulæ, how formed.

"II. The next case, which will happen almost as frequently as the former, is where a few stars, though not superior in size to the rest, may change to be rather nearer each other than the surrounding ones; for here also will be formed a prevailing attraction in the combined centre of gravity of them all, which will occasion the neighbouring stars to draw together; not, indeed, so as to form a regular globular figure, but, however, in such a manner as to be condensed towards the common centre of gravity of the whole irregular cluster. And this construction admits of the utmost variety of shapes, according to the number and situation of the stars which first gave rise to the condensation of the rest.

"III. From the composition and repeated conjunction of both the foregoing forms, a third may be derived, when many large stars, or combined small ones, are situated in long extended regular or crooked rows, hooks, or branches; for they will also draw the surrounding ones so as to produce figures of condensed stars coarsely similar to the former, which gave rise to these condensations.

"IV. We may likewise admit of still more extensive combinations; when, at the same time that a cluster of stars is forming in one part of space, there may be another collecting in a different, but perhaps not far distant quarter, which may occasion a mutual approach towards their common centre of gravity.

232 Vacancies, how they are occasioned in the heavens.

"V. In the last place, as a natural consequence of the former cases, there will be great cavities or vacancies formed by the retreat of the stars towards the various centres which attract them; so that, upon the whole, there is evidently a field of the greatest variety for the mutual and combined attractions of the heavenly bodies to exert themselves in.

"From this theoretical view of the heavens, which has been taken from a point not less distant in time than in space, we will now retreat to our own retired station, in one of the planets attending a star in its great combination with numberless others: and in order to investigate what will be the appearances from this contracted situation, let us begin with the naked eye. The stars of the first magnitude, being in all probability the nearest, will furnish us with a step to begin our scale. Setting off, therefore, with the distance of Sirius or Arcturus, for instance, as unity, we will at present suppose, that those of the second magnitude are at double, those of the third at treble, the distance, &c. Taking it for granted, then, that a star of the seventh magnitude (the smallest supposed visible with the naked eye) is about seven times as far as one of the first, it follows, that an observer who is enclosed in a globular cluster of stars, and not far from the centre, will never be able with the naked eye to see to the end of it; for since, according to the above estimations, he can only extend his view to above seven times the distance of Sirius, it cannot be expected that his eyes should reach the borders of a cluster which has perhaps not less than 50 stars in depth everywhere around him. The whole universe to him, therefore, will be comprised in a set of constellations richly ornamented with scattered stars of all sizes: Or, if the united brightness of a neighbouring cluster of stars should, in a remarkable clear night, reach his sight, it will put on the appearance of a small, faint, whitish, nebulous cloud, not to be perceived without the greatest attention. Let us suppose him placed in a much extended stratum or branching cluster of millions of stars, such as may fall under the third form of nebulæ already considered. Here also the heavens will not only be richly scattered over with brilliant constellations, but a shining zone or milky-way will be perceived to surround the whole sphere of the heavens, owing to the combined light of these stars which are too small, that is, too remote, to be seen. Our observer's sight will be so confined, that he will imagine this single collection of stars, though he does not even perceive the thousandth part of them, to be the whole contents of the heavens. Allowing him now the use of a common telescope, he begins to suspect that all the milkiness of the bright path which surrounds the sphere may be owing to stars. He perceives a few clusters of them in various parts of the heavens, and finds also that there are a kind of nebulous patches: but still his views are not extended to reach so far as to the end of the stratum in which he is situated; so that he looks upon these patches as belonging to that system which to him seems to comprehend every celestial object. He now increases his power of vision; and, applying himself to a close observation, finds that the milky-way is indeed no other than a collection of very small stars. He perceives, that those objects which had been called *nebulæ*, are evidently nothing but clusters of stars. Their number increases upon him; and when he resolves one nebula into stars, he discovers ten new ones which he cannot resolve. He then forms the idea of immense strata of fixed stars, of clusters of stars, and of nebulæ; till, going on with such interesting observations, he now perceives, that all these appearances must naturally arise from the confined situation in which we are placed. *Confined* it may justly be called, though in no less a space than what appeared before to be the whole region of the fixed stars, but which now has assumed the shape of a crookedly branching nebula; not indeed one of the least, but perhaps very far from being the most considerable, of those numberless

Apparent Motions of the Heavenly Bodies.

233 How the stars must appear to us according to this hypothesis.

Digitized by Google

Apparent Motions of the Heavenly Bodies.

numberless clusters that enter into the construction of the heavens."

Our author now proceeds to show that this theoretical view of the heavens is perfectly consistent with facts, and seems to be confirmed by a series of observations.

234 Arguments in favour of the foregoing theory from observations on nebulæ.

Many hundreds of nebulæ of the first and second forms are to be seen in the heavens; and their places, he says, will hereafter be pointed out; many of the third form described, and instances of the fourth related; a few of the cavities mentioned in the fifth particularized, though many more have been already observed: so that, "upon the whole (says he), I believe it will be found, that the foregoing theoretical view, with all its consequential appearances, as seen by an eye enclosed in one of the nebulæ, is no other than a drawing from nature, wherein the features of the original have been closely copied: and I hope the resemblance will not be called a bad one, when it shall be considered how very limited must be the pencil of an inhabitant of so small and retired a portion of an indefinite system in attempting the picture of so unbounded an extent."

235 Method of measuring the dimensions of the heavens.

Dr Herschel next presents us with a long table of star-gauges, or accounts of the number of stars at once in the field of his telescope, which go as high as 588; after which he proposes the following

Problem.

"The stars being supposed nearly equally scattered, and their number, in a field of view of a known angular diameter, being given; to determine the length of the visual ray.

"Here, the arrangement of the stars not being fixed upon, we must endeavour to find which way they may be placed so as to fill a given space most equally. Suppose a rectangular cone cut into frustula by many equidistant planes perpendicular to the axis; then, if one star be placed at the vertex and another in the axis at the first intersection, six stars may be set around it so as to be equally distant from one another and from the central star. These positions being carried on in the same manner, we shall have every star within the cone surrounded by eight others at an equal distance from that star taken as a centre. Fig. 100. contains four sections of such a cone distinguished by alternate shades; which will be sufficient to explain what sort of arrangement I would point out.

"The series of the number of stars contained in the several sections will be 1, 7, 19, 37, 61, 91, &c. which continued to n terms, the sum of it, by the differential method, will be $na+n.\frac{n-1}{2}d+n.\frac{n-1}{2}.\frac{n-2}{3}d''$, &c. where a is the first term, d', d'', d''', &c. the first, second, and third differences. Then, since $a=1$, $d'=6$, $d''=6$, $d'''=0$, the sum of the series will be n^3. Let S be the given number of stars; 1 the diameter of the base of the field of view; and B the diameter of the great rectangular cone; and by trigonometry we shall have $B=\frac{\text{Radius}}{\text{Tang. } \frac{1}{2} \text{ field}}$. Now, since the field of view of a telescope is a cone, we shall have its solidity to that of the great cone of the stars formed by the above construction, as the square of the diameter of the base of the field of view, to the square of the diameter of the great cone, the height of both being the same; and the stars in each cone being in the ratio of the solidity, as being equally scattered, we have $n=\sqrt[3]{B^2S}$; and the length of the visual ray $=n-1$, which was to be determined." Another solution of this problem, on the supposition of another arrangement of stars, is given; but Dr Herschel prefers the former.

236 Proof of our sidereal system being a nebula.

From the data now laid down, Dr Herschel next endeavours to prove that the earth is 'the planet of a star belonging to a compound nebula of the third form.' "I shall now (says he) proceed to show, that the stupendous sidereal system we inhabit, this extensive stratum, and its secondary branch, consisting of many millions of stars, is in all probability *a detached nebula*. In order to go upon grounds that seem to me to be capable of great certainty, they being no less than an actual survey of the boundaries of our sidereal system, which I have plainly perceived as far as I have yet gone round it, everywhere terminated, and in most places very narrowly too, it will be proper to show the length of my sounding line, if I may so call it, that it may appear whether it was sufficiently long for the purpose.

237 Length of the line by which Dr Herschel measures the heavens.

"In the most crowded parts of the milky-way, I have had fields of view that contained no fewer than 588 stars, and these were continued for many minutes: so that in one quarter of an hour's time there passed no less than 116,000 stars through the field of view of my telescope. Now, if we compute the length of the visual ray, by putting $S=588$, and the diameter of the field of view 15 minutes, we shall find $n=\sqrt[3]{B^2S}=498$; so that it appears the length of what I have called my Sounding Line, or $n-1$, was not probably less than 497 times the distance of Sirius from the sun.

"It may seem inaccurate that we should found an argument on the stars being equally scattered, when, in all probability, there may not be any two of them in the heavens whose mutual distance shall be equal to that of any other two given stars: but it should be considered, that when we take all the stars collectively, there will be a mean distance which may be assumed as the general one; and an argument founded on such a supposition will have in its favour the greatest probability of not being far short of truth. And here I must observe, that the difference between a crowded place and a cluster (none of the latter being put into the gauge table), may easily be perceived by the arrangement as well as the size and mutual distance of the stars; for in a cluster they are generally not only resembling each other pretty nearly in size, but a certain uniformity of distance also takes place: they are more and more accumulated towards the centre, and put on all the appearances which we should naturally expect from a number of them collected into a group at a certain distance from us. On the other hand, the rich parts of the milky-way, as well as those in the distant broad parts of the stratum, consist of a mixture of stars of all possible sizes, that are seemingly placed without any particular apparent order. Perhaps, we might recollect, that a greater condensation towards the centre of our system than towards the borders of it should be taken into consideration; but with a nebula of the third form containing such various and extensive combinations

238 Cluster of stars defined.

binations

binations as I have found to take place in ours, this circumstance, which in one of the first form would be of considerable moment, may, I think, be safely neglected.

"If some other high gauge be selected from the table, such as 472 or 344, the length of the visual ray will be found 461 and 415. And although, in consequence of what has been said, a certain degree of doubt may be left about the arrangement and scattering of the stars, yet when it is recollected, that in those parts of the milky-way, where these high gauges were taken, the stars were neither so small nor so crowded as they must have been, on a suppostion of a much farther continuance of them, when certainly a milky or nebulous appearance must have come on, I need not fear to have overrated the extent of my visual ray; and indeed every thing that can be said to shorten it will only contract the limits of our nebula, as it has in most places been of sufficient length to go far beyond the bounds of it. Thus in the sides of our stratum, opposite to our situation in it, where the gauges often

239 Extent of our nebula.

run below 5, our nebula cannot extend to 100 times the distance of Sirius; and the same telescope which could show 588 stars in a field of view of 15 minutes, must certainly have presented me also with the stars in these situations, had they been there. If we should answer this by observing, that they might be at too great a distance to be perceived, it will be allowing that there must at least be a vacancy amounting to the length of a visual ray, not short of 400 times the distance of Sirius; and this is amply sufficient to make our nebula a detached one. It is true, that it would not be consistent confidently to affirm that we were on an island, unless we had found ourselves everywhere bounded by the ocean; and therefore I shall go no farther than the gauges will authorize; but considering the little depth of the stratum in all those places which have been actually gauged, to which must be added all the intermediate parts that have been viewed and found to be much like the rest, there is but little room to expect a connection between our nebula and any of the neighbouring ones. A telescope, with a much larger aperture than my present one, grasping together a greater quantity of light, and thereby enabling us to see farther into space, will be the surest means of completing and establishing the arguments that have been used: for if our nebula is not absolutely a detached one, I am firmly persuaded that an instrument may be made large enough to discover the places where the stars continue onwards. A very bright milky nebulosity must there undoubtedly come on, since the stars in a field of view will increase in the ratio of n^3 greater than that of the cube of the visual ray. Thus, if 588 stars in a given field of view are to be seen by a ray of 497 times the distance of Sirius, when this is lengthened to 1000, which is but little more than double the former, the number of stars in the same field of view will be no less than 4774; for when the visual ray r is given, the number of stars S will be $=\frac{n^3}{B^2}$; where $n=r+$; and a telescope with a threefold power of extending into space, or with a ray of 1500, which I think may easily be constructed, will give us 16,096 stars. Nor would these be so close, but that a good power applied to such an instrument might easily distinguish them; for they need not, if arranged in regular squares, approach nearer to each other than 6″.27; but the milky nebulosity I have mentioned, would be produced by the numberless stars beyond them, which, in one respect, the visual ray might also be said to reach. To make this appear, we must return to the naked eye: which, as we have before estimated, can only see the stars of the seventh magnitude so as to distinguish them: but it is nevertheless very evident, that the united lustre of millions of stars, such as I suppose the nebula in Andromeda to be, will reach our sight in the shape of a very small faint nebulosity; since the nebula of which I speak may easily be seen in a fine evening. In the same manner, my present telescope, as I have argued, has not only a visual ray that will reach the stars at 497 times the distance of Sirius, so as to distinguish them, and probably much farther, but also a power of showing the united lustre of the accumulated stars that compose a milky nebulosity at a distance far exceeding the former limits: so that from these considerations it appears again highly probable, that my present telescope not showing such a nebulosity in the milky-way, goes already far beyond its extent; and consequently much more would an instrument, such as I have mentioned, remove all doubt on the subject, both by showing the stars in the continuation of the stratum, and by exposing a very strong milky nebulosity beyond them, that could no longer be mistaken for the dark ground of the heavens.

240 Analogical arguments in favour of his doctrine.

"To these arguments, which rest on the firm basis of a series of observation, we may add the following considerations drawn from analogy. Among the great number of nebulæ which I have now already seen, amounting to more than 900, there are many which in all probability are equally extensive with that which we inhabit; and yet they are all separated from each other by very considerable intervals. Some, indeed, there are that seem to be double and treble; and though with most of these it may be that they are at a very great distance from each other, yet we allow that some such conjunctions really are to be found; nor is this what we mean to exclude: But then these compound or double nebulæ, which are those of the third and fourth forms, still make a detached link in the great chain. It is also to be supposed, that there may be some thinly scattered solitary stars between the large interstices of nebulæ; which being situated so as to be nearly equally attracted by the several clusters when they were forming, remain unassociated: and though we cannot expect to see those stars on account of their vast distance, yet we may well presume that their number cannot be very considerable in comparison to those that are already drawn into systems; which conjecture is also abundantly confirmed in situations where the nebulæ are near enough to have their stars visible; for they are all insulated, and generally to be seen upon a very clear and pure ground, without any star near them that might be thought to belong to them. And though I have often seen them in beds of stars, yet from the size of these latter we may be certain, that they were much nearer to us than those nebulæ, and belong undoubtedly to our own system."

Having thus determined that the visible system of nature, by us called the *universe*, consisting of all the

celestial

Apparent Motions of the Heavenly Bodies.

celestial bodies, and many more than can be seen by the naked eye, is only a group of stars or suns with their planets, constituting one of those patches called a *nebula*, and perhaps not one ten-thousandth part of what is really the universe, Dr Herschel goes on to delineate the figure of this vast nebula, which he is of opinion may now be done; and for this purpose he gives a table, calculating the distances of the stars which form its extreme boundaries, or the length of the visual ray in different parts, by the number of stars contained in the field of his telescope at different times, according to the principles already laid down. He does not, however, as yet attempt the whole nebula, but of a particular section, represented fig. 160. "I have taken one (says he) which passes through the poles of our system, and is at rectangles to the conjunction of the branches, which I have called its *length*. The name of *poles* seems to me not improperly applied to those points which are 90 degrees distant from a circle passing along the milky-way; and the north pole is here supposed to be situated in right ascension 186°, and polar distance (that is from the pole commonly so called) 58°. The section is one which makes an angle of 35° with our equator, crossing it in $124\frac{1}{2}°$ and $304\frac{1}{2}°$. A celestial globe, adjusted to the latitude of 55° north, and having σ Ceti near the meridian, will have the plane of this section pointed out by the horizon. The visual rays are to be projected on the plane of the horizon of the latitude just mentioned, which may be done accurately enough by a globe adjusted in the manner directed. The stars in the border, which are marked larger than the rest, are those pointed out by the gauges. The intermediate parts are filled up by smaller stars, arranged in straight lines between the gauged ones. From this figure, which I hope is not a very inaccurate one, we may see that our nebula, as we observed before, is of the third form; that is, a very extensive, branching, compound congeries of many millions of stars, which most probably owes its origin to many remarkably large, as well as pretty closely scattered, small stars, that may have drawn together the rest. Now, to have some idea of the wonderful extent of this system, I must observe, that this section of it is drawn upon a scale where the distance of Sirius is no more than the 80th part of an inch; so that probably all the stars, which in the finest nights we are able to distinguish with the naked eye, may be comprehended within a sphere drawn round the large star near the middle, representing our situation in the nebula, of less than half a quarter of an inch radius."

241 How the figure of our nebula may be delineated.

Dr Herschel now proceeds to offer some further thoughts on the origin of the nebulous strata of the heavens: in doing which he gives some hints concerning the antiquity of them. "If it were possible (says he) to distinguish between the parts of an indefinitely extended whole, the nebula we inhabit might be said to be one that has fewer marks of antiquity than any of the rest. To explain this idea perhaps more clearly, we should recollect, that the condensation of clusters of stars has been ascribed to a gradual approach; and whoever reflects on the number of ages that must have passed before some of the clusters that are to be found in my intended catalogue of them could be so far condensed as we find them at present, will not wonder if I ascribe a certain air of youth and vigour to many very regularly scattered regions of our sidereal stratum. There are, moreover, many places in it in which, if we may judge from appearances, there is the greatest reason to believe that the stars are drawing towards secondary centres, and will in time separate into clusters, so as to occasion many subdivisions. Hence me may surmise, that when a nebulous stratum consists chiefly of nebulæ of the first and second forms, it probably owes its origin to what may be called the decay of a great compound nebula of the third form; and that the subdivisions which happened to it in length of time, occasioned all the small nebulæ which sprung from it to lie in a certain range, according as they were detached from the primary one. In like manner, our system, after numbers of ages, may very possibly become divided, so as to give rise to a stratum of two or three hundred nebulæ; for it would not be difficult to point out so many beginning or gathering clusters in it. This throws a considerable light upon that remarkable collection of many hundreds of nebulæ which are to be seen in what I have called the *nebulous stratum* in Coma Berenices. It appears, from the extended and branching figure of our nebula, that there is room for the decomposed small nebulæ of a large reduced former great one to approach nearer to us in the sides than in any other parts. Nay, possibly there might originally be another very large joining branch, which in time became separated by the condensation of the stars: and this may be the reason of the little remaining breadth of our system in that very place; for the nebulæ of the stratum of the Coma are brightest and most crowded just opposite to our situation, or in the pole of our system. As soon as this idea was suggested, I tried also the opposite pole; where accordingly I have met with a great number of nebulæ, though under a much more scattered form.

Apparent Motions of the Heavenly Bodies.

242 Of the decay and recomposition of nebulæ.

"Some parts of our system indeed seem already to have sustained greater ravages of time than others; for instance, in the body of the Scorpion is an opening or hole, which is probably owing to this cause. It is at least four degrees broad; but its height I have not yet ascertained. It is remarkable, that the 80th *Nebuleuse sans Etoiles* of the *Connoissance des Temps*, which is one of the richest and most compressed clusters of small stars I remember to have seen, is situated just on the west border of it, and would almost authorize a suspicion that the stars of which it is composed were collected from that place, and had left the vacancy. What adds not a little to this surmise, is, that the same phenomenon is once more repeated with the fourth cluster of the *Connoissance des Temps;* which is also on the western border of another vacancy, and has moreover a small miniature cluster, or easily resolvable nebula, of about $2\frac{1}{2}$ minutes in diameter north, following it at no very great distance.

"There is a remarkable purity or clearness in the heavens when we look out of our stratum at the sides; that is, towards Leo, Virgo, and Coma Berenices on one hand, and towards Cetus on the other; whereas the ground of the heavens becomes troubled as we approach towards the length or height of it. These troubled appearances are easily to be explained by ascribing them to some of the distant straggling stars that yield hardly light enough to be distinguished. And

Apparent Motions of the Heavenly Bodies.

And I have indeed often experienced this to be the cause, by examining these troubled spots for a long while together, when at last I generally perceived the stars which occasioned them. But when we look towards the poles of our system, where the visual ray does not graze along the side, the straggling stars will of course be very few in number: and therefore the ground of the heavens will assume that purity which I have always observed to take place in those regions."

243 Universe composed of nebulæ.

Thus, then, according to Dr Herschel, the universe consists of *nebulæ*, or innumerable collections of innumerable stars, each individual of which is a sun not only equal, but much superior to ours: at least if the words of Mr Nicholson have any weight; for he tells us, that "each individual sun is destined to give light to *hundreds* of worlds that revolve about it, but which can no more be seen by us, on account of their great distance, than the solar planets can be seen from the fixed stars." "Yet (continues he), as in this unexplored, and perhaps unexplorable, abyss of space, it is no necessary condition that the planets should be of the same magnitudes as those belonging to our system, it is not impossible but that planetary bodies may be discovered among the double and triple stars."

Nat. Phil. i. 195, 196.

Though in the above extracts from Dr Herschel's papers, the words *condensations*, *clusters*, &c. of stars frequently occur, we are by no means from thence to imagine that any of the celestial bodies in our nebula are nearer to one another than we are to Sirius, whose distance is supposed not to be less than 400,000 times that of the sun from us, or 38 millions of millions of miles. The whole extent of the nebula being in some places near 500 times as great, must be such, that the light of a star placed at its extreme boundary, supposing it to fly with the velocity of 12 millions of miles every minute, must have taken near 3000 years to reach us. Dr Herschel, however, is by no means of opinion, that our nebula is the most considerable in the universe. "As we are used (says he) to call the appearance of the heavens, where it is surrounded with a bright zone, the *milky-way*, it may not be amiss to point out some other very remarkable nebulæ, which cannot well be less, but are probably much larger, than our own system; and being also extended, the inhabitants of the planets that attend the stars which compose them, must likewise perceive the same phenomena: for which reason they may also be called *milky-ways*, by way of distinction.

244 Of the size and distance of nebulæ.

"My opinion of their size is grounded on the following observations: There are many round nebulæ of the first form, of about five or six minutes in diameter, the stars of which I can see very distinctly; and on comparing them with the visual ray calculated from some of my long gauges, I suppose by the appearance of the small stars in those gauges, that the centres of these round nebulæ may be 600 times the distance of Sirius from us."—He then goes on to tell us, that the stars in such nebulæ are probably twice as much condensed as those of our system; otherwise the centre of it would not be less than 6000 times the distance of Sirius from us; and that it is possibly much underrated by supposing it only 600 times the distance of that star.

"Some of these round nebulæ (says Dr Herschel) have others near them, perfectly similar in form, colour, and the distribution of stars, but of only half the diameter: and the stars in them seem to be doubly crowded, and only at about half the distance from each other. They are indeed so small, as not to be visible without the utmost attention. I suppose these miniature nebulæ to be at double the distance of the first. An instance equally remarkable and instructive is a case where, in the neighbourhood of two such nebulæ as have been mentioned, I met with a third similar, resolvable, but much smaller and fainter nebula. The stars of it are no longer to be perceived; but a resemblance of colour with the former two, and its diminished size and light, may well permit us to place it at full twice the distance of the second, or about four or five times the distance of the first. And yet the nebulosity is not of the milky kind; nor is it so much as difficultly resolvable or colourless. Now in a few of the extended nebulæ, the light changes gradually, so as from the resolvable to approach to the milky kind; which appears to me an indication, that the milky light of nebulæ is owing to their much greater distance. A nebula, therefore, whose light is perfectly milky, cannot well be supposed to be at less than six or eight thousand times the distance of Sirius; and though the numbers here assumed are not to be taken otherwise than as very coarse estimates, yet an extended nebula, which an oblique situation, where it is possibly foreshortened by one-half, two-thirds, or three-fourths of its length, subtends a degree or more in diameter, cannot be otherwise than of a wonderful magnitude, and may well outvie our milky-way in grandeur."

245 Vast length of time requisite to form the nebulæ.

Dr Herschel next proceeds to give an account of several remarkable nebulæ, and then concludes thus: "Now, what great length of time must be required to produce these effects (the formation of nebulæ) may easily be conceived, when, in all probability, our whole system of about 800 stars in diameter, if it were seen at such a distance that one end of it might assume the resolvable nebulosity, would not, at the other end, present us with the irresolvable, much less with the colourless and milky, sort of nebulosities." Great indeed must be the length of time requisite for such distant bodies to form combinations by the laws of attraction, since, according to the distances he has assumed, the light of some of his nebulæ must be thirty-six or forty-eight thousand years in arriving from them to us. It would be worth while then to inquire, whether *attraction* is a virtue propagated in time or not; or whether it moves quicker or slower than light?

246 Why the stars do not fall upon one another.

In the course of Dr Herschel's observations and inquiries concerning the structure of the heavens, an objection occurred, that if the different systems were formed by the mutual attractions of the stars, the whole would be in danger of destruction by the falling of them one upon another. A sufficient answer to this, he thinks, is, that if we can really prove the system of the universe to be what he has said, there is no doubt but that the great Author of it has amply provided for the preservation of the whole, though it should not appear to us in what manner this is effected. Several circumstances, however, he is of opinion, manifestly tend to a general preservation: as, in the first place, the indefinite extent of the sidereal heavens; which must produce a balance that will effectually secure all the parts of the great whole from approaching to each other.

Digitized by Google

Apparent Motions of the Heavenly Bodies.

other. There remains then (says he) only to see how the particular stars belonging to separate clusters are prevented from rushing on to their centres of attraction." This he supposes may be done by projectile forces; "the admission of which will prove such a barrier against the seeming destructive power of attraction, as to secure from it all the stars belonging to a cluster, if not for ever, at least for millions of ages. Besides, we ought perhaps to look upon such clusters, and the destruction of a star now and then in some thousands of ages as the very means by which the whole is preserved and renewed. These clusters may be the *laboratories* of the universe, wherein the most salutary remedies for the decay of the whole are prepared."

247 Of the planetary nebulæ.

In speaking of the planetary nebulæ, by which name he distinguishes those spots that are all over equally luminous, he says, "if we should suppose them to be single stars, with large diameters, we shall find it difficult to account for their not being brighter, unless we should admit that the intrinsic light of some stars may be very much inferior to that of the generality; which, however, can hardly be imagined to extend to such a degree. We might suppose them to be comets about their aphelion, if the brightness, as well as magnitude of their diameters did not oppose this idea; so that, after all, we can hardly find any hypothesis so probable as that of their being nebulæ; but then they must consist of stars that are compressed and accumulated in the highest degree. If it were not perhaps too hazardous to pursue a former surmise of a renewal in what I figuratively called the *Laboratories of the Universe*, the stars forming these extraordinary nebulæ, by some decay or waste of nature being no longer fit for their former purposes, and having their projectile forces, if any such they had, retarded in each other's atmosphere, may rush at last together; and, either in succession or by one general tremendous shock, unite into a new body. Perhaps the extraordinary and sudden blaze of a new star in Cassiopeia's chair, in 1572, might possibly be of such a nature. If a little attention to these bodies should prove that, having no annual parallax, they belong most probably to the class of nebulæ, they may then be expected to keep their station better than any one of the stars belonging to our system, on account of their being probably at a very great distance."

248 Method of ascertaining the situation of the stars.

As the fixed stars constantly keep nearly the same situation relative to each other, astronomers have agreed to refer to them, as to so many fixed points, the different motions of the other heavenly bodies. Hence the reason of dividing them into constellations. But it was necessary besides, for the sake of perfect precision, to mark exactly the relative situation of every star in the celestial sphere. This is accomplished in the following manner.

"A great circle is supposed to pass through the two poles, and through the centre of every star. This circle is called a circle of *declination*. The arc of this circle included between the star and the equator measures the *declination* of the star. The declination of a star then is its perpendicular distance from the equator. It is north or south, according as the star is situated on the north or south side of the equator. All the stars situated in the same parallel of the equator have of course the same declination.

The declination then marks the situation of a star north or south from the equator. Precision requires still another circle from which their distance east or west may be marked, in order to give the real place. The *circle of declination* which passes through that point of the equator, called the *vernal equinoctial point*, has been chosen for that purpose. The distance of the circle of declination of a given star from that point measured on the equator, or the arc of the equator included between the vernal equinox and the circle of declination of the star, is called its *right ascension*. If we know the declination and the right ascension of a star, we know its precise situation in the heavens.

The declination of any star may be easily found by observing the following rule: Take the meridian altitude of the star, at any place where the latitude is known, the complement of this is the *zenith distance*, and is called north or south, as the star is north or south at the time of observation. Then, 1. When the latitude of the place and zenith distance of the star are of different kinds, namely, one north and the other south, their difference will be the declination; and it is of the same kind with the latitude, when that is the greatest of the two, otherwise it is of the contrary kind. 2. If the latitude and the zenith distance are of the same kind, i. e. both north or both south, their sum is the declination; and it is of the same kind with the latitude.

249 Rules for finding the declination.

To prove the truth of this rule, turn to fig. 86. where Z is the zenith of the place, EQ the equinoctial, and EZ the latitude. 1. Let r represent the place of a star on the meridian, and Zr the zenith distance, the latitude being greater: then Er (the declination) will be equal to EZ—Zr (the zenith distance); again, let c be the place of a star in the meridian, when the zenith distance exceeds the latitude; then Ec (the declination)=Zc (the zenith distance)—EZ (the latitude). And it is manifest, that in the former instance Z and r are on the same side of the equinoctial; and that in the latter case Z and c are on contrary sides. 2dly, Let y be the place of a star on the meridian, having its zenith distance Zy of the same kind with EZ the latitude of the place: then Ey (the declination)= EZ +Zy; and the declination is of the same kind as the latitude, because Z and y are on the same side of the equinoctial. Q. E. D.

For an example, suppose that in north latitude 52° 15′, the meridian altitude of a star is 51° 28′ on the south; then 38° 32′ the zenith distance, being taken from 52° 15′ the latitude, leaves 13° 43′ for declination of the star *north*.

250 and right ascension.

Having, by means of the above, found the declination of a star, it becomes requisite, in the next place, to know *the right ascension*, as its situation with regard to the equator will then be known. Now the right ascension being estimated from the point where the equator and ecliptic intersect each other in the spring, a point which is marked out by nothing that comes under the cognizance of our senses; some phenomenon, therefore, must be chosen, whose right ascension is either given, or may be readily known at any time, that the right ascensions of other objects may be discovered by comparison with *it*. For this purpose nothing appears to

Digitized by Google

so proper as the sun; because its motion is the most simple, and its right ascension quickly found.

For if, in fig. 87. we have given QS the declination of the sun (which may be easily taken every day at noon by observation), and the angle SEQ the obliquity of the ecliptic—i. e. one leg of a right-angled spherical triangle, and its opposite angle, to find the adjacent leg EQ, the right ascension—it may be done by this proportion; as the tangent of the obliquity of the ecliptic: the tangent of the declination :: radius : the sine of the right ascension reckoned from the nearer equinoctial point.

For example: suppose on the 13th of February the sun's south declination is found to be 13° 24′, and the obliquity of the ecliptic is 23° 28′; we shall thus find the sun's right ascension:

As tangt. 23° 28′	9.6376106
To tangt. 13° 24′	9.3770030
So is radius	10.0000000
To sine 33° 16′ 58″	9.7393924

Here 33° 16′ 58″ is the sun's distance from ♈; but as the declination is at that time decreasing, and the sun approaching ♈, this must be taken from 360°, and the remainder 326° 43′ 2″ is the right ascension.

In a similar manner may the sun's right ascension be calculated for every day at noon, and arranged in tables for use: for any intermediate time between one day at noon and the following, the right ascension may be determined by proportion.

The longitude ES of the sun, when required, may be readily found by the rules to ascertain the hypothenuse of the same triangle.

The apparent diurnal motion of the heavenly bodies being uniform, and performed in circles parallel to the equator, the interval of the times in which two stars pass over any meridian must bear the same proportion to the period of the diurnal motion, as that arc of the equator intercepted between the two secondaries passing through the stars, does to 360°, as is evident from the nature of the sphere: we may therefore find the right ascension of a star thus: Let an accurate pendulum clock be so regulated that the index may pass over the twenty-four hours during the time in which any fixed star after departing from the meridian will return to it again, which is rather less than twenty-four hours. Then let the index of a clock thus regulated be set to twelve o'clock when the sun is on the meridian; and observe the time the index points to, when the fixed star whose right ascension is sought comes to the meridian; which may be most accurately known by means of a transit telescope. Let these hours and parts, as marked by the clock, be converted into degrees, &c. of the equator, by allowing 15° to an hour; and the difference between the right ascensions of the fixed star and the sun will be known; this difference added to the sun's right ascension for that day at noon, gives the right ascension of the fixed star sought.

Or, if a clock whose dial plate is divided into 360°, instead of twelve hours, be ordered in such a manner, that the index may pass round the whole circle in the interval which a star requires to come to the same meridian again, and another index be so managed as to point out the sexagesimal parts: then, when the sun is on the meridian, let the indices of the clock be put to his right ascension at noon that day; and when the star comes to the meridian, its right ascension will be shown by the clock, without any kind of reduction.

The stars are referred likewise to the ecliptic as well as to the equator. In that case the terms *longitude* and *latitude* are used.

The longitude of any of the heavenly bodies is an arc of the ecliptic contained between the first point of Aries, and a secondary to the ecliptic or circle of latitude, passing through the body; it is always measured according to the order of the signs. If the body be supposed seen from the centre of the earth, it is called *geocentric* longitude; but if it be supposed seen from the centre of the sun, then is the longitude *heliocentric*. 251 Longitude of the heavenly bodies.

The latitude of a heavenly body is its distance from the ecliptic, measured upon a secondary to the ecliptic drawn through the body. If the latitude be such as is seen from the earth's centre, it is called *geocentric* latitude; but if it be supposed seen from the centre of the sun, it is *heliocentric*. 252 Latitudes.

The equator being the principal circle which respects the earth, the latitudes and longitudes of terrestrial objects are referred to it; and, for a similar reason (the sun's motion in the ecliptic rendering that the principal of the celestial circles), the situations of heavenly objects are generally ascertained by their latitudes and longitudes referred to the ecliptic: it has therefore become a useful problem to find the latitudes and longitudes of the stars, &c. having their declinations, and right ascensions, with the obliquity of the ecliptic, given. One of the best methods of performing this problem has been thus investigated: Let 253 How found. S be the place of the body (fig. 88.), EC the ecliptic, EQ the equator: and SL and SR being respectively perpendicular to EC and EQ, ER will represent the right ascension, SR the declination, EL the longitude, and SL the latitude; then, by spherics, rad. : sine ER :: co-tang. SR : co-tang. SER; and SER∓CEQ=SEL. Also, co-sine SER : rad :: tang. ER : tang. ES; and rad. : co-sine SEL :: tang. ES : tang. EL; therefore, co-sine SER : co-sine SEL :: tang. ER : tang. EL; whence we readily get $\frac{\text{co-sine SEL} \times \text{tang. ER}}{\text{co-sine SER}}$ = the tangent of EL, the longitude. Then, rad. : sine of EL :: tang. SEL : tang. SL, the latitude.

But the same thing may be performed very expeditiously by means of the following excellent rule, given by Dr Maskelyne, the present worthy astronomer royal:

1. The sine of the right ascension + co-tang. declination —10 = co-tang. of arc A, which call *north*, or *south*, according as the declination is north or south. 2. Call the obliquity of the ecliptic south in the six first signs of right ascension, and north in the six last. Let the sum of arc A, and obliquity of ecliptic, according to their titles, = arc B with its proper title. [If one be north and the other south, the proper title is that which belongs to the greater; and in this case, arc B is their difference.] 3, The arithmetical complement of co-sine arc A + co-sine arc B × tang. right ascension = tangent of the longitude: this is of the same kind as the right ascension, unless arc B be more than 90°, when the quantity found of the same kind as the

Digitized by Google

Apparent Motions of the Heavenly Bodies.

the right ascension must be subtracted from 12 signs, or 360°. 4. The sine of longitude + tang. arc B — 10 = tang. of the required latitude, of the same title as arc B. Note, If the longitude be found near 0° or near 180°, for the sine of longitude, in the last operation, substitute tang. longitude + co-sine longitude — 10; and then the last operation will be tang. longitude + co-sine longitude + tang. arc B — 20 = tang. latitude. By sine, tang. &c. are meant logarithm sine, log. tang. &c.

This rule may be exemplified by inquiring what are the latitude and longitude of a star whose declination is $12^\circ\ 59'$ north, and right ascension $4^s\ 29^\circ\ 38'$, the obliquity of the ecliptic being $29^\circ\ 28'$?

Here, sine of right ascension	$4^s\ 29^\circ$	$38'$	9·7037486
Co-tang. of declination	12	59	10·6372126
Co-tang. of arc A, north	24	31	10·34069612
Obliquity of ecliptic south	23	28	
Arc B, north -	1	3	cos. 9·9999271
Arith. comp. of co-sine arc A			0·0410347
Tangent of right ascension			9·7678344
Tangent of longitude $147^\circ\ 13'\ 26''$			9·8087962
Or $4^s\ 27^\circ\ 13'\ 26''$, answering to $27^\circ\ 13'\ 26''$ of Leo.			
Then, sine of longitude - -			9·7334843
Tangent of arc B - -			8·2631153
Tang. of latitude, north, $34'\ 6''$			7·9965996

254 Stars vary in right ascension and declination.

Astronomers have observed that the stars vary in right ascension and in declination, but keep the same latitude: hence it was concluded that their variations in declination and right ascension were owing to the revolution of the celestial sphere round the poles of the ecliptic. Or they may be accounted for by supposing that the poles of the equator revolve slowly round those of the ecliptic. This revolution is called the precession of the equinoxes. A more particular account of it will be necessary.

255 Observations of the Asiatic shepherds.

By a long series of observations, the shepherds of Asia were able to mark out the sun's path in the heavens; he being always in the opposite point to that which comes to the meridian at midnight, with equal but opposite declination. Thus they could tell the stars among which the sun then was, although they could not see them. They discovered that this path was a great circle of the heavens, afterwards called the ECLIPTIC; which cuts the equator in two opposite points, dividing it, and being divided by it, into two equal parts. They farther observed, that when the sun was in either of those points of intersection, his circle of diurnal revolution coincided with the equator, and therefore the days and nights were equal. Hence the equator came to be called the EQUINOCTIAL LINE, and the points in which it cuts the ecliptic were called the EQUINOCTIAL POINTS, and the sun was then said to be in the equinoxes. One of these was called the VERNAL and the other the AUTUMNAL EQUINOX.

256 To determine the time of the sun's occupying the equinoctial points.

It was evidently an important problem in practical astronomy to determine the exact moment of the sun's occupying these stations; for it was natural to compute the course of the year from that moment. Accordingly this has been the leading problem in the astronomy of all nations. It is susceptible of considerable precision, without any apparatus of instruments. It is only necessary to observe the sun's declination on the noon of two or three days before and after the equinoctial day. On two consecutive days of this number, his declination must have changed from north to south, or from south to north. If his declination on one day was observed to be $11'$ north, and on the next $5'$ south, it follows that his declination was nothing, or that he was in the equinoctial point about 23 minutes after 7 in the morning of the second day. Knowing the precise moments, and knowing the rate of the sun's motion in the ecliptic, it is easy to ascertain the precise point of the ecliptic in which the equator intersected it.

257 Hipparchus's discoveries.

By a series of such observations made at Alexandria between the years 161 and 127 before Christ, Hipparchus, the father of our astronomy, found that the point of the autumnal equinox was about six degrees to the eastward of the star called SPICA VIRGINIS. Eager to determine every thing by multiplied observations, he ransacked all the Chaldean, Egyptian, and other records, to which his travels could procure him access, for observations of the same kind; but he does not mention his having found any. He found, however, some observations of Aristillus and Timochares made about 150 years before. From these it appeared evident that the point of the autumnal equinox was then about eight degrees east of the same star. He discusses these observations with great sagacity and rigour; and, on their authority, he asserts that the equinoctial points are not fixed in the heavens, but move to the westward about a degree in 75 years or somewhat less.

258 Why called the precession of the equinoxes.

This motion is called the PRECESSION OF THE EQUINOXES, because by it the time and place of the sun's equinoctial station precedes the usual calculations: it is fully confirmed by all subsequent observations. In 1750 the autumnal equinox was observed to be $20^\circ\ 21'$ westward of Spica Virginis. Supposing the motion to have been uniform during this period of ages, it follows that the annual precession is about $50''\frac{1}{3}$; that is, if the celestial equator cuts the ecliptic in a particular point on any day of this year, it will on the same day of the following year cut it in a point $50''\frac{1}{3}$ to the west of it, and the sun will come to the equinox $20'\ 23''$ before he has completed his round of the heavens. Thus the equinoctial or tropical year, or true year of seasons, is so much shorter than the revolution of the sun or the sidereal year.

259 Importance of the discovery.

It is this discovery that has chiefly immortalized the name of Hipparchus, though it must be acknowledged that all his astronomical researches have been conducted with the same sagacity and intelligence. It was natural therefore for him to value himself highly for the discovery. It must be acknowledged to be one of the most singular that has been made, that the revolution of the whole heavens should not be stable, but its axis continually changing. For it must be observed, that since the equator changes its position, and the equator is only an imaginary circle, equidistant from the two poles or extremities of the axis; these poles and this axis must equally change their positions. The equinoctial points make a complete revolution in about 25,745 years, the equator being all the while inclined to the ecliptic in nearly the same angle. Therefore the poles of this diurnal revolution must describe a circle

Digitized by Google

Apparent Motions of the Heavenly Bodies.

circle round the poles of the ecliptic at the distance of about $23\frac{1}{2}$ degrees in 25,745 years; and in the time of Timochares the north pole of the heavens must have been 30 degrees eastward of where it now is.

260
Hipparchus has been accused of plagiarism,

Hipparchus has been accused of plagiarism and insincerity in this matter. It is now very certain that the precession of the equinoxes was known to the astronomers of India many ages before the time of Hipparchus. It appears also that the Chaldeans had a pretty accurate knowledge of the year of seasons. From their saros we deduce their measure of this year to be 365 days 5 hours 49 minutes and 11 seconds, exceeding the truth only by 26″, and much more exact than the year of Hipparchus. They had also a sidereal year of 365 days 6 hours 11 minutes. Now what could occasion an attention to two years, if they did not suppose the equinoxes moveable? The Egyptians also had a knowledge of something equivalent to this: for they had discovered that the dog-star was no longer the faithful forewarner of the overflowing of the Nile: and they combined him with the star Fomalhaset * in their mystic calendar. This knowledge is also involved in the precepts of the Chinese astronomy, of much older date than the time of Hipparchus.

* See *Dupins sur le zodiaque des Egyptiens, Mem. de l'Acad. des Inscrip.*

261
but falsely.

But all these acknowledged facts are not sufficient for depriving Hipparchus of the honour of the discovery, or fixing on him the charge of plagiarism. This motion was a thing unknown to the astronomers of the Alexandrian school, and it was pointed out to them by Hipparchus in the way in which he ascertained every other position in astronomy, namely, as the mathematical result of actual observations, and not as a thing deducible from any opinions on other subjects related to it. We see him, on all other occasions, eager to confirm his own observations, and his deductions from them, by every thing he could pick up from other astronomers; and he even adduced the above-mentioned practice of the Egyptians in corroboration of his doctrine. It is more than probable then that he did not know any thing more. Had he known the Indian precession of 54″ annually, he had no temptation whatever to withhold him from using it in preference to one which he acknowledges to be inaccurate, because deduced from the very short period of 150 years, and from the observations of Timochares, in which he had no great confidence.

Small periodical irregularities in the inclination of the equator to the ecliptic, and in the precession of the equinoxes, were discovered and examined by Bradley with great sagacity. He found that the pole described an epicycle, whose diameter was about 18″, having for its centre that point of the circle round the pole of the ecliptic in which the pole would have been found independent of this new motion. He also observed, that the period of this epicyclical motion was 18 years and seven months. It struck him, that this was precisely the period of the revolution of the nodes of the moon's orbit. He gave a brief account of these results to Lord Macclesfield, then president of the Royal Society, in 1747. Mr Machin, to whom he also communicated the observations, gave him in return a very neat mathematical hypothesis, by which the motion might be calculated.

Let E (fig. 89.) be the pole of the ecliptic, and SPQ a circle distant from it 23° 28′, representing the circle described by the pole of the equator during one revolution of the equinoctial points. Let P be the place of this last-mentioned pole at some given time. Round P describe a circle ABCD, whose diameter AC is 18″. The real situation of the pole will be in the circumference of this circle; and its place, in this circumference,

262
Mathematical theory if the poles of the equator be supposed to describe a circle.

depends on the place of the moon's ascending node. Draw EPF and GPL perpendicular to it; let GL be the colure of the equinoxes, and EF the colure of the solstices. Dr Bradley's observations showed that the pole was in A when the node was in L, the vernal equinox. If the node recede to H, the winter solstice, the pole is in B. When the node is in the autumnal equinox at G, the pole is at C; and when the node is in F, the summer solstice, the pole is in D. In intermediate situations of the moon's ascending node, the pole is in a point of the circumference ABCD, three signs or 90° more advanced.

263
More exact if an ellipse be substituted for the circle.

Dr Bradley, by comparing together a great number of observations, found that the mathematical theory, and the calculation depending on it, would correspond much better with the observations, if an ellipse were substituted for the circle ABCD, making the longer axis AC 18″, and the shorter, BD, 16″. M. d'Alembert determined, by the physical theory of gravitation, the axis to be 18″ and 13″.4.

264
These observations and this theory are facts in astronomy.

These observations, and this mathematical theory, must be considered as so many facts in astronomy, and we must deduce from them the methods of computing the places of all celestial phenomena, agreeable to the universal practice of determining every point of the heavens by its longitude, latitude, right ascension, and declination.

265
Obliquity of the ecliptic.

It is evident, in the first place, that the equation of the pole's motion makes a change in the obliquity of the ecliptic. The inclination of the equator to the ecliptic is measured by the arch of a great circle intercepted between their poles. Now, if the pole be in O instead of P, it is plain that the obliquity is measured by EO instead of EP. If EP be considered as the mean obliquity of the ecliptic, it is augmented by 9″ when the moon's ascending node is in the vernal equinox, and consequently the pole in A. It is, on the contrary, diminished 9″ when the node is in the autumnal equinox, and the pole in C; and it is equal to the mean when the node is in the colure of the solstices. This change of the inclination of the earth's axis to the plane of the ecliptic was called the nutation of the axis by Sir Isaac Newton.

Dr Bradley also discovered a general and periodical motion in all the stars, which alter a little their relative situations. To form an idea of this motion, let us suppose that each star describes annually a small circumference parallel to the ecliptic, whose centre is the mean position of the star, and whose diameter, as seen from the earth, subtends an angle of about 40″; and that it was in that circumference as the sun in its orbit, but so that the sun always precedes it by 60°. This circumference, projected upon the surface of the celestial sphere, appears under the form of an ellipse, more or less flattened according to the height of the star above the equator, the smaller axis of the ellipse being to the greater axis as the sine of that height to radius. These periodical movements of the stars have received the name of *aberrations of the fixed stars*.

Digitized by Google

Besides these general motions, particular motions have been detected in several stars, excessively slow indeed, but which a long succession of ages has rendered sensible. These motions have been chiefly observed in Sirius and Arcturus. But astronomers suppose that all the stars have similar motions, which may become evident in process of time.

266 Distance of the fixed stars immeasurable.

No method of ascertaining the distance of fixed stars hath hitherto been found out. Those who have formed conjectures concerning them, have thought that they were at least 400,000 times farther from us than we are from the sun.

They are said to be fixed, because they have been generally observed to keep at the same distances from each other; their apparent diurnal revolutions being caused solely by the earth's turning on its axis. They appear of a sensible magnitude to the bare eye, because the retina is affected not only by the rays of light which are emitted directly from them, but by many thousands more, which falling upon our eyelids, and upon the aerial particles about us, are reflected into our eyes so strongly as to excite vibrations not only in those points of the retina where the real images of the stars are formed, but also in other points at some distance round about. This makes us imagine the stars to be much bigger than they would appear, if we saw them only by the few rays which come directly from them, so as to enter our eyes without being intermixed with others. Any one may be sensible of this, by looking at a star of the first magnitude through a long narrow tube; which, though it takes in as much of the sky as would hold 1000 such stars, yet scarcely renders that one visible.

267 Why they seem so big to our naked eye.

The more a telescope magnifies, the less is the aperture through which the star is seen; and consequently, the fewer rays it admits into the eye. Now, since the stars appear less in a telescope which magnifies 200 times, than they do to the bare eye, insomuch that they seem to be only indivisible points, it proves at once that the stars are at immense distances from us, and that they shine by their own proper light. If they shone by borrowed light, they would be as invisible without telescopes as the satellites of Jupiter are; for these satellites appear bigger when viewed with a good telescope than the largest fixed stars do.

268 Parallax of the fixed stars.

Dr Herschel has proposed a method of ascertaining the parallax of the fixed stars, something similar, but more complete, than that mentioned by Galileo and others; for it is by the parallax of the fixed stars that we should be best able to determine their distance. The method pointed out by Galileo, and first attempted by Hooke, Flamstead, Molineux, and Bradley, of taking distances of stars from the zenith that pass very near it, has given us a much juster idea of the immense distance of the stars, and furnished us with an approximation to the knowledge of their parallax, that is much nearer the truth than we ever had before. But Dr Herschel mentions the insufficiency of their instruments, which were similar to the present zenith sectors, the method of zenith distances being liable to considerable errors on account of refraction, the change of position of the earth's axis arising from nutation, precession of the equinoxes, and other causes, and the aberration of the light. The method of his own is by means of double stars; which is exempted from these errors, and of such a nature, that the annual parallax, even if it should not exceed the tenth part of a second, may still become more visible, and be ascertained, at least to a much greater degree of approximation than it has ever been done. This method is capable of every improvement which the telescope and mechanism of micrometers can furnish. The method and its theory will be seen by the following investigation, extracted from his paper on the subject. Let O, E, (fig. 90.) be two opposite points in the annual orbit, taken in the same plane with two stars, a, b, of unequal magnitudes. Let the angle a O b be observed, when the earth is at O, and a E b be observed when the earth is at E. From the difference of these angles, if there should be any, we may calculate the parallax of the stars, according to the theory subjoined. These two stars ought to be as near each other as possible, and also to differ as much in magnitude as we can find them.

Phil. Trans. vol. lxxii. p. 82.

Dr Herschel's theory of the annual parallax of double stars, with the method of computing from thence what is generally called the parallax of the fixed stars, or of single stars of the first magnitude, such as are nearest to us, supposes, *first*, that the stars, one with another, are about the size of the sun; and, *secondly*, that the difference of their apparent magnitudes is owing to their different distances; so that the star of the second, third, or fourth magnitude, is two, three, or four times as far off as one of the first. These principles which he premises as postulata, have so great a probability in their favour, that they will hardly be objected to by those who are in the least acquainted with the doctrine of chances. Accordingly, let OE (fig. 91.) be the whole diameter of the earth's annual orbit, and let a, b, c, be three stars situated in the ecliptic, in such a manner that they may be seen all in one line O $a\,b\,c$, when the earth is at O. Let the line O $a\,b\,c$ be perpendicular to OE, and draw PE parallel to c O; then, if Oa, $a\,b$, $b\,c$, are equal to each other, a will be a star of the first magnitude, b of the second, and c of the third. Let us now suppose the angle O a E, or parallax of the whole orbit of the earth to be 1″ of a degree; then we have PE a=O a E=1″: and because very small angles, having the same subtense OE, may be taken to be in the inverse ratio of the lines O a, O b, O c, &c. we shall have O b E$=\frac{1}{2}''$, O c E$=\frac{1}{3}''$, &c. Now when the earth is removed to E, we shall have PE b=E b $o=\frac{1}{2}''$, and PE a—PE b=a E $b=\frac{1}{2}''$, i. e. the stars a, b, will appear to be $\frac{1}{2}''$ distant. We also have PE c=E c O$=\frac{1}{3}''$, and PE a—PE c=a E $c=\frac{2}{3}''$; i. e. the stars a, c, will appear to be $\frac{2}{3}''$ distant when the earth is at E. Now, since we have b EP$=\frac{1}{2}''$, and c EP$=\frac{1}{3}''$, therefore b EP—c EP=b E $c=\frac{1}{2}''-\frac{1}{3}''=\frac{1}{6}''$; i. e. the stars b, c, will appear to be only $\frac{1}{6}''$ removed from each other when the earth is at E. Whence we may deduce the following expression, to denote the parallax that will become visible in the change of distance between the two stars, by the removal of the earth from one extreme of its orbit to the other. Let P express the total parallax of a fixed star of the first magnitude, M the magnitude of the largest of the two stars, m the magnitude of the smallest, and p the partial parallax to to be observed by the change in the distance of a double star; then will $p = \frac{m-M}{mM}P$; and p, being found by observation, will give us $P = \frac{PMm}{m-M}$. *E. G.* Suppose a star of the first magnitude should have a small star of the twelfth magnitude near it; then will the partial parallax we are to expect to see be $\frac{12 \times 1 P}{12-1}$, or $\frac{11}{12}$ of the total parallax of a fixed star of the first magnitude; and if we should, by observation, find the partial parallax between two such stars to amount to $1''$, we shall have the total parallax $P = \frac{1 \times 1 \times 12}{12-1} = 1''.0909$. If the stars are of the third and twenty-fourth magnitude, the partial parallax will be $\frac{24-3}{3 \times 24} = \frac{21}{72}P$; and if, by observation, p is found to be a tenth of a second, the whole parallax will come out $\frac{.1 \times 3 \times 24}{24-3} = 0''.3428$.

Farther, suppose the stars, being still in the ecliptic, to appear in one line, when the earth is in any other part of its orbit between O and E; then will the parallax still be expressed by the same algebraic formula, and one of the maxima will still lie at O, the other at E; but the whole effect will be divided into two parts, which will be in proportion to each other as radius — sine to radius + sine of the stars distance from the nearest conjunction or opposition.

When the stars are anywhere out of the ecliptic, situated so as to appear in one line O $a\,b\,c$ perpendicular to OE, the maximum of parallax will still be expressed by $\frac{m-M}{Mm}P$; but there will arise another additional parallax in the conjunction and opposition, which will be to that which is found 90° before or after the sun, as the sine (S) of the latitude of the stars seen at O is to the radius (R); and the effect of this parallax will be divided into two parts; half of it lying on one side of the large star, the other half on the other side of it. This latter parallax, moreover, will be compounded with the former, so that the distance of the stars in the conjunction and opposition will then be represented by the diagonal of a parallelogram, whereof the two semiparallaxes are the sides; a general expression for which will be $\sqrt{\overline{\frac{m-M}{2MP}P}\Big|^2 \times \frac{SS}{BR} + 1}$; for the stars will apparently describe two ellipses in the heavens, whose transverse axes will be to each other in the ratio of M to m (fig. 93.), and A a, B b, C c, D d, will be the cotemporary situations. Now, if b Q be drawn parallel to AC, and the parallelogram $b\,q$ BQ be completed, we shall have $b\text{Q} = \frac{1}{2}\text{CA} - \frac{1}{2}ca = \frac{1}{2}\text{C}c = \frac{1}{2}p$, or semiparallax 90° before or after the sun, and B b may be resolved into, or is compounded of, b Q and $b\,q$; but $bq = \frac{1}{2}\text{BD} - \frac{1}{2}bd =$ the semiparallax in the conjunction or opposition. We also have R : S :: bQ : $bq = \frac{pS}{2R}$; therefore the distance B b (or D d) $= \sqrt{\frac{p}{2}\Big|^2 \times \frac{pS}{2R}\Big|^2}$; and by substituting the value of p in this expression, we obtain $\sqrt{\frac{m-M}{2Mm}P\Big|^2 \times \frac{SS}{RR} + 1}$, as above. When the stars are in the pole of the ecliptic, $b\,q$ will become equal to b Q, and B b will be $7071\,P\frac{m-M}{Mm}$. Again, let the stars be at some distance, *e. g.* 5″ from each other, and let them both be in the ecliptic. This case is resolvable into the first; for imagine the star a (fig. 92.) to stand at x, and in that situation the stars x, b, c, will be in one line, and their parallax expressed by $\frac{m-M}{Mm}P$. But the angle aEx may be taken to be equal to aOx; and as the foregoing formula gives us the angles xEb xEc, we are to add aEx or 5″ to xEb, and we shall have aEb. In general, let the distance of the stars be d, and let the observed distance at E be D, then will $D = d + p$, and therefore the whole parallax of the annual orbit will be expressed by $\frac{DMm - dMm}{m-M} = P$.

Suppose the two stars now to differ only in latitude, one being in the ecliptic, the other, *e. g.* 5″ north when seen at O. This case may also be resolved by the former; for imagine the stars b, c, (fig. 91.) to be elevated at right angles above the plane of the figure, so that aOb, or aOc, may make an angle of 5″ at O; then, instead of the line O $a\,b\,c$, E a, E b, E c, EP, imagine them all to be planes at right angles to the figure; and it will appear that the parallax of the stars in longitude must be the same as if the small star had been without latitude. And since the stars b, c, by the motion of the earth from O to E, will not change their latitude, we shall have the following construction for finding the distance of the stars $a\,b$, $a\,c$, at E, and from thence the parallax B. Let the triangle $a\,b\,\beta$ (fig. 94.) represent the situation of the stars; $a\,b$ is the subtense of 5″, the angle under which they are supposed to be seen at O. The quantity b, by the former theorem, is found $\frac{m-M}{mM}P$, which is the partial parallax that would have been seen by the earth's moving from O to E, if both stars had been in the ecliptic, but on account of the difference in latitude, it will be now represented by $a\,\beta$, the hypothenuse of the triangle $a\,b\,\beta$: therefore, in general, putting $a\,b = d$, and $a\,\beta = D$, we have $\sqrt{\frac{DD - d.d \times Mm}{m-M}} = P$. Hence D being taken by observation, and d, M, and m, given, we obtain the total parallax.

If the stuation of the stars differs in longitude as well as latitude, we may resolve this case by the following method. Let the triangle $a\,b\,\beta$ (fig. 169.) represent the situation of the stars, $a\,b = d$ being their distance seen at O, $a\,\beta = D$ their distance seen at E. That the change $b\,\beta$, which is produced by the earth's motion will be truly expressed by $\frac{m-M}{Mm}P$ may be proved as before, by supposing the star a to have been placed at

Digitized by Google

α. Now let the angle of position $b\,a\,\alpha$ be taken by a micrometer, or by any other method sufficiently exact; then, by solving the triangle $a\,b\,\alpha$, we shall have the longitudinal and latitudinal differences $a\,\alpha$ and $b\,\alpha$ of the two stars. Put $a\,\alpha = x$, $b\,\alpha = y$, and it will be $x + b\beta = a\,q$, whence $D = \sqrt{\overline{x + \frac{m-MP}{M\,m}}\Big| + y\,y}$; and $\dfrac{\sqrt{D^2 - y^2} \times \overline{M^2 m - M\,m}}{m - M} = P$.

If neither of the stars should be in the ecliptic, nor have the same longitude or latitude, the last theorem will still serve to calculate the total parallax whose maximum will lie in E. There will, moreover, arise another parallax, whose maximum will be in the conjunction and opposition, which will be divided, and lie on different sides of the large star; but as we know the whole parallax to be exceedingly small; it will not be necessary to investigate every particular case of this kind; for by reason of the division of the parallax, which renders observations taken at any other time, except where it is greatest, very unfavourable, the formulæ would be of little use. Dr Herschel closes his account of this theory with a general observation on the time and place where the maxima of parallax will happen.

When two unequal stars are both in the ecliptic, or, not being in the ecliptic, have equal latitudes, north or south, and the largest star has most longitude; the maximum of the apparent distance will be when the sun's longitude is 90 degrees more than the stars, or when observed in the morning; and the minimum when the longitude of the sun is 90 degrees less than that of the stars, or when observed in the evening. When the small star has most longitude, the maximum and minimum, as well as the time of observation, will be the reverse of the former. When the stars differ in latitudes, this makes no alteration in the place of the maximum or minimum, nor in the time of observation; i. e. it is immaterial whether the largest star has the least or the greatest distance of the two stars.

Chap. VI. *Of the Figure of the Earth.*

Having now described the apparent motions of the heavenly bodies, let us return to the earth, in order to examine the information which has been collected concerning its figure.

269 Earth spherical.

We have seen already, that the earth is spherical. The force of *gravity* constantly directed towards its centre retains bodies on its surface, though situated on places diametrically opposite, or though *antipodes* to each other. The sun and stars appear always *above* the earth; for *above* and *below* are merely relative to the direction of *gravity*.

270 Dimensions how ascertained.

As soon as the spherical figure of the earth was discovered, curiosity naturally led men to endeavour to measure its dimensions. Hence it is probable, that attempts of that nature were made in very ancient times. The reference which several of the ancient measures have to the size of the globe is a confirmation of this. But among the moderns, Picard was the first who executed the task with any degree of success. He measured a degree of the meridian in France about the middle of the 17th century.

Apparent Motions of the Heavenly Bodies.

Since a meridian, or any other circle on a sphere, may be conceived to be divided into 360 equal parts, called degrees, and these into minutes and seconds, as explained by the writers on trigonometry, the circumference of the earth, and thence its diameter, may be determined by measuring the length of a degree on the meridian or any other great circle. To perform this important problem, there have been various methods invented by different philosophers of early and later times; one of these methods, which unites considerable accuracy with great facility, will be readily understood from fig. 95. where PB and ST represent two mountains or very high buildings, the distance PS between which must be very nicely determined by longimetry: then, by measuring the angles RBT and RTB with an accurate instrument, their sum taken from 180° leaves the angle BRT, which is measured also by the arc PS; whence PS is known in parts of the whole circle. Thus, if the angle BTR be 89° 45′ 32″, the angle TBR 89° 54′ 28″, and the distance PS $23\frac{1}{15}$ English miles; then the angle R or arc PS being equal to $180^\circ - \overline{89^\circ\,45'\,32'' + 89^\circ\,54'\,28''} = 20'$ it will be, as $20' : 60'$ or $1^\circ :: 23\frac{1}{15} : 69\frac{1}{5}$ English miles, length of a degree. Hence the circumference of the earth is (according to this example) 24912 miles, and its diameter nearly 7930 miles.—A material advantage attending this method is, that there is no occasion to measure the altitudes of the mountains, an object which can seldom be attained without considerable difficulty.

The method which is given above is, it must be confessed, as well as all the other methods which aim at the measurement of a degree without having recourse to the heavenly bodies, liable to some inaccuracy; for, by reason of the changes in the state of the atmosphere, distant terrestrial objects never appear in their true places; they always seem more or less elevated or distant, according to the nature of the season, and the time of the day. On this account—and because it could not escape observation, that as persons changed their situation on the earth by moving towards the north or the south, the stars and other heavenly bodies either increased or decreased their apparent altitudes proportionally—the measurement of a degree was attempted even by the earliest philosophers, by means of known fixed stars. Every person who is acquainted with plane trigonometry will admit, that the distance of two places, north and south of each other, may be accurately measured by a series of triangles; for if we measure the distance of any two objects, and take the angles which each of them make with a third, the triangle formed by the three objects will become known; so that the other two sides may be as truly determined by calculation, as if they had been actually measured. And by making either of these sides the base of a new triangle, the distances of other objects may be found in the same manner; and thus by a series of triangles, properly connected at their bases, we might measure any part of the circumference of the earth. And if these distances were reduced to the north and south, or meridian line, and the altitude of some star was measured at the extremities of the distance,

Digitized by Google

Apparent Motions of the Heavenly Bodies.

distance, the difference of the altitudes would be equal to the length of the grand lines in degrees, minutes, &c. whence the length of a degree would be known. This method was, we believe, first practised by Eratosthenes in Egypt; and has been frequently used since with greater and greater accuracy, in proportion as the instruments for taking angles became, by gradual improvements, more exact and minute.

By this method, or some others not widely different, and which it is needless here to explain, the length of a degree has been measured in different parts of the earth; the results of the most noted of these admeasurements it may be proper to give.

271 Different measurements.

Snell found the length of a degree by two different methods: by one method he made it 57064 Paris toises, or 342384 feet; and by the other 57057 toises, or 342342 feet.

M. Picard, in 1669, found by mensuration from Amiens to Malvoisin, the quantity of a degree to be 57060 toises, or 342360 feet; being nearly an arithmetical mean between the numbers of Snell.

Our countryman Norwood, about the year 1635, by measuring between London and York, determined a degree at 367196 English feet, or 57300 Paris toises, or 69 miles 288 yards.

Muschenbroek, in 1700, with a view of correcting the errors of Snell, found by particular observations that the degree between Alcmaer and Bergen-op-zoom contained 57033 toises.

Messrs Maupertuis, Clairaut, Monnier, and others from France, were sent on a northern expedition, and began their operations in July 1736; they found the length of a degree in Sweden to be 57439 toises, when reduced to the level of the sea. About the same time Messrs Godin, Bouguer, and Condamine, from France, with some philosophers from Spain, were sent to South America, and measured a degree in the province of Quito in Peru; the medium of their results gives about 56750 toises for a degree.

M. de la Caille, being at the Cape of Good Hope in 1752, found the length of a degree on the meridian there to be 57037 toises. In 1755 Father Boscovich found the length of a degree between Rome and Rimini in Italy to be 56972 toises.

In 1764, F. Beccaria measured a degree near Turin; from his measurement he deduced the length of a degree there 57024 toises. At Vienna the length of a degree was found 57091 toises.

And in 1766 Messrs Mason and Dixon measured a degree in Maryland and Pennsylvania, North America, which they determined to be 363763 English feet, or $56904\frac{1}{2}$ Paris toises.

The difference of these measures leads us to conclude that the earth is not exactly spherical, but that its axis which passes through the poles, is shorter than that which passes through the equator. But the observations which have been made to determine the magnitude and figure of the earth, have not hitherto led to results completely satisfactory. They have indeed demonstrated the compression or oblateness of the terrestrial spheroid, but they have left an uncertainty as to the quantity of that compression, extending from about the 170th, to the 330th part of the radius of the equator. Between these two quantities, the former of which is nearly double of the latter, most of the results are placed, but in such a manner that those best entitled to credit are much nearer to the least extreme than to the greatest. Sir Isaac Newton, as is well known, supposing the earth to be of uniform density, assigned for the compression at the poles $\frac{1}{230}$, nearly a mean between the two limits just mentioned; and it is probable, that, if the compression is less than this, it is owing to the increase of the density toward the centre. Boscovich, taking a mean from all the measures of degrees, so as to make the positive and negative errors equal, found the difference of the axis of the meridian $= \frac{1}{248}$. By comparing the degrees measured by Father Leisganic in Germany, with eight others that have been measured in different latitudes, La Lande finds $\frac{1}{311}$, and, suppressing the degree in Lapland, which appears to err in excess, $\frac{1}{331}$ for the compression. La Place makes it $\frac{1}{321}$; Sejour $\frac{1}{307}$, and lastly, Carouge and La Lande $\frac{1}{300}$.

272 Supposed figure of the earth.

These anomalies have induced some astronomers, especially M. de la Place, to give up the spheroidal figure of the earth altogether, to suppose that it is not a solid of revolution, and that its surface is a curve of double curvature. Mr Playfair, on the other hand, in an excellent dissertation on the subject, published in the fifth volume of the Edinburgh Transactions, supposes, that the anomalies may be owing to the different densities of the strata near the surface where the degrees were measured, occasioning errors in the measurement.

273 Latitudes and longitudes how found.

The position of the different places on the earth's surface is determined by their distance from the equator, called their *latitude*, and from a first meridian called their *longitude*. The latitude is easily ascertained by observing the height of the pole: The longitude is calculated by observing some celestial phenomenon, as an eclipse of Jupiter's satellites at the same instant in two places situated in different meridians. The difference in point of apparent time in the two places, gives their distance east or west from each other, and consequently the difference of their longitude; for it is not noon at the same time in all the different parts of the earth's surface. When it is noon at London, it is only eleven o'clock in all the places 15° west from London, while it is one o'clock in all places 15° east from London. Every 15° east or west causes the difference of an hour. Hence the difference in time, when any celestial phenomenon is observed, gives us the distance east and west, or in longitude, between the places where it is observed.

The eclipses of Jupiter's satellites are of the greatest service in determining the longitude of places on this earth, astronomers therefore have been at great pains to calculate tables for the eclipses of these satellites by their primary, for the satellites themselves have never been observed to eclipse one another. The construction

tion of such tables is indeed much easier for these satellites than of any other celestial bodies, as their motions are much more regular.

The English tables are calculated for the meridian of Greenwich, and by these it is very easy to find how many degrees of longitude any place is distant either east or west from Greenwich; for, let an observer, who has these tables, with a good telescope and a well-regulated clock at any other place of the earth, observe the beginning or ending of an eclipse of one of Jupiter's satellites, and note the precise moment of time that he saw the satellite either immerge into, or emerge out of, the shadow, and compare that time with the time shown by the tables for Greenwich: then 15 degrees difference of longitude being allowed for every hour's difference of time, will give the longitude of that place from Greenwich; and if there be any odd minutes of time, for every minute a quarter of a degree, east or west, must be allowed, as the time of observation is later or earlier than the time shown by the tables. Such eclipses are very convenient for this purpose at land, because they happen almost every day; but are of no use at sea, because the rolling of the ship hinders all nice telescopical observations.

Fig. 95.

To explain this by a figure, let J be Jupiter, K, L, M, N, his four satellites in the respective orbits, 1, 2, 3, 4; and let the earth be at F (suppose in November, although that month is no otherwise material than to find the earth readily in this scheme, where it is shown in eight different parts of the orbit). Let Q be a place on the meridian of Greenwich, R a place on some other meridian eastward from Greenwich. Let a person at R observe the instantaneous vanishing of the first satellite K into Jupiter's shadow, suppose at three o'clock in the morning; but by the tables he finds the immersion of that satellite to be at midnight at Greenwich; he then can immediately determine, that as there are three hours difference of time between Q and K, and that R is three hours forwarder in reckoning than Q, it must be 45 degrees of east longitude from the meridian of Q. Were this method as practicable at sea as at land, any sailor might almost as easily, and with equal certainty, find the longitude as the latitude.

From its impracticability, the seaman is obliged to have recourse to other celestial phenomena, and the most useful are the motions of the moon. On this subject we shall satisfy ourselves with inserting the following observations of Mr Lowe, who has pointed out a very simple method of ascertaining the longitude on land.

Philosophical Magazine, vol. xv. p. 97.

174
Mr Lowe's method of finding the longitude.

Although the method of determining the difference of longitude at sea from the lunar observations has been accurately laid down by Dr Maskelyne and other able nautical astronomers, it has, however, happened that several writers on longitude and astronomy have, in the course of the last twenty years, given rules for finding the difference of longitude at land from the moon's transits, either so erroneous or imperfect, that the adoption thereof might do a serious injury both to navigation and geography: they have given examples, but no demonstrations; or at least such obscure and imperfect ones, as prove that they had not a clear conception of the matter.

It is for these reasons that the following demonstration of a rule both easy and accurate for finding the difference of longitude is now proposed. The data are the observed increase of the moon's right ascension in passing from the first to the second meridian, and the increase of the sun's and moon's right ascension in twelve hours apparent time, which may be had from the Nautical Almanack.

Fig. 97.

Demonstration.—Let the circle ABC represent the equator, P its pole, and APD the first meridian, as that of Greenwich. Suppose that the centres of the sun, the moon, and a fixed star, are on that meridian at the same moment of time as represented at A, and that they move from thence to the westward with their respective velocities, the earth being considered as at rest. Then, after twelve hours apparent time, the sun will be at D, the opposite point to A, or 180° distant from it; but the fixed star, moving in appearance over a greater space than 180° in twelve hours apparent time, will be at E; while the moon, with a motion apparently slower than the sun and the star, will appear after twelve hours at the point B, or on a meridian BP. But ED is the distance of the sun from the star after an interval of twelve hours apparent time, and EB the distance of the moon, or, in other words, the increase of their respective right ascensions: and since ED and EB are known from the Nautical Almanack, if we subtract the first from the last, we have DB, equal to the difference between the increase of the sun's and moon's right ascension in twelve hours apparent time. Now the difference of longitude between the two meridians AP and BP is the arc A β B, equal to A β D less the arc DB; that is, equal to 180° less the difference between the increase of the sun's and moon's right ascension in twelve hours; and, since the increase of the moon's right ascension from the time of its passing the meridian AP to the time of its passing BP is known from observation, and equal to EB, we can make the following proportion for finding the difference of longitude between any other two meridians, AP and β P, from the observed increase of the moon's right ascension ι β.

As EB : A β D—DB :: ι β : A β the difference of longitude; or, in more familiar language, as the increase of the moon's right ascension in twelve hours apparent time is to 180° or 12 h. less the difference between the increase of the sun's and moon's right ascension in that time :: so is any other observed increase of the moon's right ascension between two meridians : to their difference of longitude.

If the increase of the moon's right ascension in 12 hours were uniform, or such that equal parts of it would be produced in equal times, the above rule would be strictly accurate; but as that increase arises from a motion continually accelerated or retarded, and seldom uniform but for a short space of time, it will therefore be necessary to find the mean increase of the moon's right ascension when it is at the intermediate point between A and β, in order to determine their difference of longitude with the greatest precision; and for that purpose, Taylor's Tables of Second Difference are very useful.

Example.—April the 8th, 1800, the transit of the moon's first limb was observed at the royal observatory

Digitized by Google

Apparent Motions of the Heavenly Bodies.

ry (A); and, allowance being made for the error of the clock, its right ascension was

	H.	M.	Sec.
	12	35	18.22
Add the time that the moon's semidiameter took to pass the meridian	0	1	8.38
Right ascension of the moon's centre	12	36	26.6
On a meridian (β) far to the westward, the transit of the moon's first limb was observed the same day, and being reduced to the centre, its right ascension was - - - - -	12	47	56.7
Increase of right ascension between A and β. - - - - -	0	11	30.1
The increase of the moon's right ascension in 12 hours apparent time per The Nautical Almanack was -	0	26	3
The increase of the sun's in the same time - - - - - -	0	1	49.65
Difference - - - -	0	24	13.35

And 12 hours minus this difference is = 11 h. 35 m. 46.65 sec.; therefore, as 26 m. 3 sec. : 11 h. 35 m. 46.65 sec. :: 11 m. 30.1 sec. : to 5 h. 7 m. 12 sec. the correct difference of longitude between A and β.

By reducing the three terms to seconds, and using logarithms, the operation is much shortened.

In a book published by Mr Mackay on longitude about 15 or 16 years ago, there is a rule given, and also an example, for finding the difference of longitude at land from the transits of the moon, but no demonstration. The rule, when divested of its high-sounding enunciation, runs thus:

As the increase of the moon's right ascension in 12 hours apparent time : is to 180° :: so is any other observed increase between two meridians : to their difference of longitude. It follows from this, that the moon as well as the sun would, in 12 hours apparent time, pass over an arc of 180°, although the apparent motion of the moon to the westward in 12 hours, or 180° of space, be less than that of the sun by six or seven degrees; and so much error would this method produce, if the two places differed about 180° in longitude.

The above example, wrought according to Mackay's rule, would come out thus:

	H.	M.	Sec.
As 26 m. 3 sec. : 12 h. :: 11 m. 30.1 sec. to	5	17	53.7
But the correct difference as above is	5	7	12
Error - - - - - -	0	10	41.7

which amounts to more than $2\frac{1}{2}^{\circ}$, or 150 miles, in a difference of longitude little exceeding five hours.

Mr Edward Pigot adopts the very same rule for determining the difference of longitude between Greenwich and York, and states the result in the Philosophical Transactions for 1785, p. 417.

Mr Vince has inserted this rule and example in his Treatise of Practical Astronomy; but we have to regret that they were not accompanied with a strict demonstration.

The Rev. Mr Wollaston, in the appendix to his *Fasciculus Astronomicus*, published two or three years ago, has given a rule, without demonstration or example, for finding the difference of longitude from the moon's transits, which produces the same error as Mackay's and Pigot's, although worded differently from theirs. Mr Wollaston makes the first term of his proportion apparent, and the third mean time; this renders the result erroneous. Since the motions of the sun, moon, and planets are computed for apparent time, and given so in the Nautical Almanack, mean time is not at all requisite for resolving the difference of longitude either at sea or at land. We shall therefore endeavour to apply Mr Wollaston's rule, according to its literal meaning, for finding the difference of longitude from the above observations.

The right ascension of the moon's centre on the meridian of Greenwich being known, we can easily deduce the mean and apparent time corresponding to it; and in like manner the mean and apparent time at the distant meridian β. The apparent and mean time of the transits of the moon's centre over the meridians of A and β, when strictly computed, were as follows:

	Apparent Time.			*Mean Time.*		
	H.	M.	Sec.	H.	M.	Sec.
At A - -	11	26	47.81	11	28	33.5
At β - -	11	37	29.5	11	39	11.4
Time later at β than at A	0	10	41.69	0	10	37.9
From the increase of the moon's right ascension in 12 hours -		26	3			
Subtract the increase of the sun's right ascension in that time -		1	49.65			
The moon's retardation in 12 hours -		24	13.35			

Then, "As twice the moon's retardation in 12 hours : is to 24 hours ::

"So is the mean time later at β than at A : to the difference of longitude west from A."

After doubling 24 m. 13.25 sec. and also 12, which is totally unnecessary, as the result would be the same if they stood single, we state the following proportion:

As 48 m. 26.7 sec. : 34 h. :: 10 m. 37.9 sec. to 5 h. 15 m. 1.3 sec. the difference of longitude between A and β.

But as the third term is improperly reduced to mean time, we shall take the apparent time above found, and then 48 m. 26.7 sec. : 24 h. :: 10 m. 41.69 sec. to 5 h. 17 m. 53.7 sec.; the same as results from Mackay's and Pigot's rules.

We shall only remark, that 5 h. 17 m. 53.7 sec. is the apparent time that the moon took in passing from the meridian of A to the meridian of β; but from what has been demonstrated, the apparent time at β will be equal to the difference between the increase of the sun's and moon's right ascension in that interval of apparent time; for DB, or 24 m. 13.35 sec. is the difference for 12 hours, and therefore by proportion ϡβ, or 10 m. 41.69 sec. will be the difference for 5 h. 17 m. 53.7 sec.; subtracting the former from the latter, we have 5 h. 7 m. 12 sec. the difference of longitude as before, and

Apparent Motions of the Heavenly Bodies.

a clear proof that the authors above mentioned have omitted to deduct the apparent time at the distant place or station β, from the apparent time at Greenwich.

A very important fact relative to the earth has been ascertained by astronomers, namely, that the weight of bodies does not continue the same when carried to different parts of it. It is impossible to ascertain this variation by the balance, because it affects equally the bodies weighed and the weight by which we estimate its gravity. But the pendulum affords a certain method of detecting every such change; because the number of oscillations made by a given pendulum in a given time depends upon the force of gravity. The smaller that force, the fewer vibrations will it make. Therefore, if the force of gravity diminish, the pendulum will move slower; if it decreases, it will oscillate with more celerity. In different pendulums the slowness of vibration is proportional to the length of the pendulum: If a pendulum be lengthened it moves slower, if it be shortened it moves swifter than before. Mr Richer in a voyage made to Cayenne, found that the pendulum of his clock did not vibrate so frequently there, as it did when at Paris; but that it was necessary to shorten it by about the eleventh part of an inch to make it vibrate in exact seconds. The nearer the equator a pendulum is placed it vibrates the slower, the nearer the pole it is placed it vibrates the faster. Hence it follows that the force of gravity is greatest at the poles, and that it gradually diminishes as we approach the equator, where it is smallest.

PART III. OF THE REAL MOTIONS OF THE HEAVENLY BODIES.

WE have now enumerated and explained the apparent motions of the heavenly bodies. Nothing can appear more intricate and perplexed, or more remote from what we are accustomed to consider as the simplicity of nature. Hence mankind have in all ages been tempted to consider them as merely apparent, and not real; and the object of astronomers has always been to detect the real motions of the heavenly bodies from those which they exhibit to the eye of a spectator on the earth. Neither industry nor address was spared to gain this desirable end. Hypothesis was formed after hypothesis; every new supposition was a step towards the truth; and at last the real motions have not only been ascertained but demonstrated in the most satisfactory manner. It shall be our object in this part of our treatise to lay before our readers the result of these discoveries.

Chap. I. *Of the Rotation of the Earth.*

WE find that the sun, and those planets on which there are visible spots, turn round their axis: for the spots move regularly over their disks (B). From hence we may reasonably conclude, that the other planets on which we see no spots, and the earth, which is likewise a planet, have such rotations. But being incapable of leaving the earth, and viewing it at a distance, and its rotation being smooth and uniform, we can neither see it move on its axis as we do the planets, nor feel ourselves affected by its motion. Yet there is one effect of such a motion, which will enable us to judge with certainty whether the earth revolves on its axis or not. All globes which do not turn round their axis will be perfect spheres, on account of the equality of the weight of bodies on their surfaces; especially of the fluid parts. But all globes which turn on their axis will be oblate spheroids; that is, their surfaces will be higher or farther from the centre in the equatorial than in the polar regions: for as the equatorial parts move quickest, they will recede farthest from the axis of motion, and enlarge the equatorial diameter. That our earth is really of this figure, is demonstrable from the unequal vibrations of a pendulum, and the unequal lengths of degrees in different latitudes. Since then the earth is higher at the equator than at the poles, the sea, which naturally runs downward, or towards the places which are nearest the centre, would run towards the polar regions, and leave the equatorial parts dry, if the centrifugal force of these parts, by which the waters were carried thither, did not keep them from returning. The earth's equatorial diameter is 36 miles longer than its axis.

275 Argument for the earth's motion from its spheroidal figure.

276 Weight of bodies increases towards the poles.

Bodies near the poles are heavier than those towards the equator, because they are nearer the earth's centre, where the whole force of the earth's attraction is accumulated. They are also heavier, because their centrifugal force is less, on account of their diurnal motion being slower. For both these reasons, bodies carried from the poles towards the equator gradually lose their weight. Experiments prove, that a pendulum which vibrates seconds near the poles vibrates slower near the equator, which shows that it is lighter or less attracted there. To make it oscillate in the same time it is found necessary to diminish its length. By comparing the different lengths of pendulums swinging seconds at the equator and at London, it is found that a pendulum must be $2\frac{169}{1000}$ lines shorter at the equator than at the poles. A line is a twelfth part of an inch.

If the earth turned round its axis in 84 minutes 43 seconds, the centrifugal force would be equal to the power of gravity at the equator; and all bodies there would entirely lose their weight. If the earth revolved quicker, they would all fly off and leave it.

A person on the earth can no more be sensible of its undisturbed motion on its axis, than one in the cabin of

(B) This, however, must be understood with some degree of limitation, as will evidently appear from what has been already said concerning the variable motion both of the spots of the sun and planets.

Digitized by Google

Real Motions of the Heavenly Bodies.

of a ship on smooth water can be sensible of the ship's motion, when it turns gently and uniformly round. It is therefore no argument against the earth's diurnal motion that we do not feel it; nor is the apparent revolutions of the celestial bodies every day a proof of the reality of these motions; for whether we or they revolve, the appearance is the very same. A person looking through the cabin windows of a ship, as strongly fancies the objects on land to go round when the ship turns as if they were actually in motion.

277 Earth's motion proved from the celestial appearances from different planets.

If we could translate ourselves from planet to planet, we should still find that the stars would appear of the same magnitudes, and at the same distances from each other, as they do to us here; because the width of the remotest planet's orbit bears no sensible proportion to the distance of the stars. But then the heavens would seem to revolve about very different axes; and consequently, those quiescent points, which are our poles in the heavens, would seem to revolve about other points, which, though apparently in motion as seen from the earth, would be at rest as seen from any other planet. Thus the axis of Venus, which lies at right angles to the axis of the earth, would have its motionless poles in two opposite points of the heavens lying almost in our equinoctial, where the motion appears quickest, because it is seemingly performed in the greatest circle: and the very poles, which are at rest to us, have the quickest motion of all as seen from Venus. To Mars and Jupiter the heavens appear to turn round with very different velocities on the same axis, whose poles are about $23\frac{1}{2}$ degrees from ours. Were we on Jupiter, we should be at first amazed at the rapid motion of the heavens; the sun and stars going round in 9 hours 56 minutes. Could we go from thence to Venus, we should be as much surprised at the slowness of the heavenly motions; the sun going but once round in 584 hours, and the stars in 540. And could we go from Venus to the moon, we should see the heavens turn round with a yet slower motion; the sun in 708 hours, the stars in 655. As it is impossible these various circumvolutions in such different times, and on such different axes, can be real, so it is unreasonable to suppose the heavens to revolve about our earth more than it does about any other planet. When we reflect on the vast distance of the fixed stars, to which 190,000,000 of miles, the diameter of the earth's orbit, is but a point, we are filled with amazement at the immensity of the distance. But if we try to frame an idea of the extreme rapidity with which the stars must move, if they move round the earth in 24 hours, the thought becomes so much too big for our imagination, that we can no more conceive it than we do infinity or eternity. If the sun was to go round the earth in 24 hours, he must travel upwards of 300,000 miles in a minute: but the stars being at least 400,000 times as far from the sun as the sun is from us, those about the equator must move 400,000 times as quick. And all this to serve no other purpose than what can be as fully and much more simply obtained by the earth's turning round eastward as on an axis, every 24 hours, causing thereby an apparent diurnal motion of the sun westward, and bringing about the alternate returns of day and night.

278 Another objection answered.

As to the common objections against the earth's motion on its axis, they are all easily answered and set aside. That it may turn without being seen or felt by us to do so, has been already shown. But some are apt to imagine, that if the earth turns eastward (as it certainly does if it turns at all), a ball fired perpendicularly upward in the air must fall considerably westward of the place it was projected from. The objection which at first seems to have some weight, will be found to have none at all, when we consider that the gun and ball partake of the earth's motion; and therefore the ball being carried forward with the air as quick as the earth and air turn, must fall down on the same place. A stone let fall from the top of a mainmast, if it meets with no obstacle, falls on the deck as near the foot of the mast when the ship sails as when it does not. If an inverted bottle full of liquor be hung up to the ceiling of the cabin, and a small hole be made in the cork, to let the liquor through on the floor, the drops will fall just as far forward on the floor when the ship sails as when it is at rest. And gnats or flies can as easily dance among one another in a moving cabin as in a fixed chamber. As for those Scripture expressions which seem to contradict the earth's motion, this general answer may be made to them all, viz. it is plain from many instances, that the Scriptures were never intended to instruct us in philosophy or astronomy; and therefore on those subjects expressions are not always to be taken in the literal sense, but for the most part as accommodated to the common apprehensions of mankind. Men of sense in all ages, when not treating of the sciences purposely, have followed this method: and it would be in vain to follow any other in addressing ourselves to the vulgar, or bulk of any community.

Chap. II. *Of the Revolution of the Planets round the Sun.*

The apparent motions of the planets lead us to conclude that they all move in orbits nearly circular round the sun, while the sun moves round the earth: that the orbits of Venus and Mercury are nearer the sun than the earth; but the orbits of the other planets include the earth within them. All the apparent motions are reconcilable to this opinion, and lead us to form it. It removes all the inexplicable intricacy of their apparent motions.

But the earth itself is a planet, and bears a very exact resemblance to the rest. Shall we suppose all the other planets to revolve round the sun while it alone remains stationary? Or shall we suppose that the earth, like the other planets, revolves round the sun in the course of a year? The phenomena in both cases will be exactly the same, but the motion of the earth will reduce the whole system to the greatest simplicity, whereas the motion of the sun carrying with it the revolving planets would leave the whole complicated and involved. Various opinions on this subject have been maintained by astronomers.

Concerning the opinion of the very first astronomers about the system of nature, we are necessarily as ignorant as we are of those astronomers themselves. Whatever opinions are handed down to us, must be of a vastly later date than the introduction of astronomy among mankind. If we may hazard a conjecture, however, we are inclined to think that the first opinions on

Digitized by Google

on this subject were much more just than those that were held afterwards for many ages. We are told that Pythagoras maintained the motion of the earth, which is now universally believed, but at that time appears to have been the opinion of only a few detached individuals of Greece.

279 Pythagorean system.

As the Greeks borrowed many things from the Egyptians, and Pythagoras had travelled into Egypt and Phenice, it is probable he might receive an account of this hypothesis from thence: but whether he did so or not, we have now no means of knowing, neither is it of any importance whether he did or not. Certain it is, however, that this opinion did not prevail in his days, nor for many ages after. In the second century after Christ, the very name of the Pythagorean hypothesis was suppressed by a system erected by the famous geographer and astronomer Claudius Ptolemæus.

280 Suppressed by the Ptolemaic.

This system, which commonly goes by the name of the *Ptolemaic*, he seems not to have originally invented, but adopted as the prevailing one of that age; and perhaps made it somewhat more consistent than it was before. He supposed the earth at rest in the centre of the universe. Round the earth, and the nearest to it of all the heavenly bodies, the moon performed its monthly revolutions. Next to the moon was placed the planet Mercury; then Venus; and above that the sun, Mars, Jupiter, and Saturn, in their proper orbits; then the sphere of the fixed stars; above these, two spheres of what he called *crystalline* heavens; above these was the primum mobile, which, by turning round once in 24 hours, by some unaccountable means or other, carried all the rest along with it. This primum mobile was encompassed by the empyrean heaven, which was of a cubic form, and the seat of angels and blessed spirits. Besides the motions of all the heavens round the earth once in 24 hours, each planet was supposed to have a particular motion of its own; the moon, for instance, once in a month, performed an additional revolution, the sun in a year, &c. See fig. 98.

281 Ptolemy's system insufficient.

It is easy to see, that, on this supposition, the confused motions of the planets already described could never be accounted for. Had they circulated uniformly round the earth, their apparent motion ought always to have been equal and uniform, without appearing either stationary or retrograde in any part of their courses. In consequence of this objection, Ptolemy was obliged to invent a great number of circles, interfering with each other, which he called *epicycles* and *eccentrics*. These proved a ready and effectual salvo for all the defects of his system; as, whenever a planet was deviating from the course it ought on his plan to have followed, it was then only moving in an epicycle or an eccentric, and would in due time fall into its proper path. As to the natural causes by which the planets were directed to move in these epicycles and eccentrics, it is no wonder that he found himself much at a loss, and was obliged to have recourse to divine power for an explanation, or, in other words, to own that his system was unintelligible.

282 Pythagorean system revived by Copernicus.

This system continued to be in vogue till the beginning of the 16th century, when Nicolaus Copernicus, a native of Thorn (a city of Regal Prussia), and a man of great abilities, began to try whether a more satisfactory manner of accounting for the apparent motions of the heavenly bodies could not be obtained than was afforded by the Ptolemaic hypothesis. He had recourse to every author upon the subject, to see whether any had been more consistent in explaining the irregular motions of the stars than the mathematical schools: but he received no satisfaction, till he found first from Cicero, that Nicetas the Syracusan had maintained the motion of the earth; and next from Plutarch, that others of the ancients had been of the same opinion. From the small hints he could obtain from the ancients, Copernicus then deduced a most complete system, capable of solving every phenomenon in a satisfactory manner. From him his system hath ever afterwards been called the *Copernican*, and is represented fig. 99. Here the sun is supposed to be in the centre; next him revolves the planet Mercury; then Venus; next, the Earth, with the Moon: beyond these, Mars, Jupiter, and Saturn; and far beyond the orbit of Saturn, he supposed the fixed stars to be placed, which formed the boundaries of the visible creation.

283 Tychonic system.

Though this hypothesis afforded the only natural and satisfactory solution of the phenomena which so much perplexed Ptolemy's system, it met with great opposition at first; which is not to be wondered at, considering the age in which he lived. Even the famous astronomer Tycho Brahe could never assent to the earth's motion, which was the foundation of Copernicus's scheme. He therefore invented another system, whereby he avoided the ascribing of motion to the earth, and at the same time got clear of the difficulties with which Ptolemy was embarrassed. In this system, the earth was supposed the centre of the orbits of the sun and moon; but the sun was supposed to be the centre of the orbits of the five planets; so that the sun with all the planets were by Tycho Brahe supposed to turn round the earth, in order to save the motion of the earth round its axis once in 24 hours. This system was never much followed, the superiority of the Copernican scheme being evident at first sight.

Fig. 100.

The sun is so immensely bigger and heavier than the earth, that, if he was moved out of his place, not only the earth, but all the other planets, if they were united into one mass, would be carried along with the sun as the pebble would be with the mill-stone.

284 From the proportional decrease of gravity, &c.

By considering the law of gravitation, which takes place throughout the solar system, in another light, it will be evident that the earth moves round the sun in a year, and not the sun round the earth. It has been observed, that the power of gravity decreases as the square of the distance increases; and from this it follows with mathematical certainty, that when two or more bodies move round another as their centre of motion, the squares of their periodic times will be to one another in the same proportion as the cubes of their distances from the central body. This holds precisely with regard to the planets round the sun, and the satellites round the planets; the relative distances of all which are well known. But, if we suppose the sun to move round the earth, and compare its period with the moon's by the above rule, it will be found that the sun would take no less than 173.510 days to move round the earth; in which case our year would be 475 times as long as it now is. To this we may add, that the aspects of increase and decrease of the planets, the times of their seeming to stand still, and to move direct and retrograde, answer precisely to the earth's motion; but

Digitized by Google

Real Motions of the Heavenly Bodies.

but not at all to the sun's without introducing the most absurd and monstrous suppositions, which would destroy all harmony, order, and simplicity, in the system. Moreover, if the earth be supposed to stand still, and the stars to revolve in free spaces about the earth in 24 hours, it is certain that the forces by which the stars revolve in their orbits are not directed to the earth, but to the centres of the several orbits; that is, of the several parallel circles which the stars on different sides of the equator describe every day; and the like inferences may be drawn from the supposed diurnal motion of the planets, since they are never in the equinoctial but twice in their courses with regard to the starry heavens. But, that forces should be directed to no central body, on which they physically depend, but to innumerable imaginary points in the axis of the earth produced to the poles of the heavens, is an hypothesis too absurd to be allowed of by any rational creature. And it is still more absurd to imagine that these forces should increase exactly in proportion to the distances from this axis; for this is an indication of an increase to infinity; whereas the force of attraction is found to decrease in receding from the fountain from whence it flows. But the farther any star is from the quiescent pole, the greater must be the orbit which it describes; and yet it appears to go round in the same time as the nearest star to the pole does. And if we take into consideration the twofold motion observed in the stars, one diurnal round the axis of the earth in 24 hours, and the other round the axis of the ecliptic in 25,920 years, it would require an explication of such a perplexed composition of forces, as could by no means be reconciled with any physical theory.

285 Objections against the earth's motion answered.

The strongest objections that can be made against the earth's motion round the sun is, that in opposite points of the earth's orbit, its axis, which always keeps a parallel direction, would point to different fixed stars; which is not found to be fact. But this objection is easily removed, by considering the immense distance of the stars in respect of the diameter of the earth's orbit; the latter being no more than a point when compared to the former. If we lay a ruler on the side of a table, and along the edge of the ruler view the top of a spire at ten miles distance; then lay the ruler on the opposite side of the table in a parallel situation to what it had before, and the spire will still appear along the edge of the ruler; because our eyes, even when assisted by the best instruments, are incapable of distinguishing so small a change at so great a distance.

286 Earth's motion demonstrated from the aberration of light.

Dr Bradley, our late astronomer-royal, found by a long series of the most accurate observations, that there is a small apparent motion of the fixed stars, occasioned by the aberration of their light; and so exactly answering to an annual motion of the earth, as evinces the same, even to a mathematical demonstration. He considered this matter in the following manner: he imagined CA, fig. 101. to be a ray of light falling perpendicularly upon the line BD; that, if the eye is at rest at A, the object must appear in the direction AC, whether light be propagated in time or in an instant. But if the eye is moving from B towards A, and light is propagated in time, with a velocity that is to the velocity of the eye as CA to BA; then light moving from C to A, whilst the eye moves from B to A, that particle of it by which the object will be discerned when the eye comes to A, is at C when the eye is at B. Joining the points BC, he supposed the line CB to be a tube, inclined to the line BD in the angle DBC, of such diameter as to admit but one particle of light. Then it was easy to conceive, that the particle of light at C, by which the object must be seen, when the eye, as it moves along, arrives at A, would pass through the tube BC, if it is inclined to BD, in the angle DBC, and accompanies the eye in its motion from B to A; and that it could not come to the eye placed behind such a tube, if it had any other inclination to the line BD. If, instead of supposing CB so small a tube, we imagine it to be the axis of a larger; then, for the same reason, the particle of light at C would not pass through the axis, unless it is inclined to BD in the angle CBD. In like manner, if the eye moved the contrary way, from D towards A, with the same velocity, then the tube must be inclined in the angle BCD. Although, therefore, the true or real place of an object is perpendicular to the line in which the eye is moving, yet the visible place will not be so; since that, no doubt, must be in the direction of the tube; but the difference between the true and apparent place will be *cæteris paribus* greater or less, according to the different proportion between the velocity of light and that of the eye. So that, if we could suppose that light was propagated in an instant, then there would be no difference between the real and visible place of an object, although the eye was in motion; for in that case, AC being infinite with respect to AB, the angle ACB, the difference between the true and visible place, vanishes. But if light be propagated in time, it is evident, from the foregoing considerations, that there will be always a difference between the real and visible place of an object, unless the eye is moving either directly towards or from the object. And in all cases the sine of the difference between the real and visible place of the object will be to the sine of the visible inclination of the object to the line in which the eye is moving, as the velocity of the eye is to the velocity of light.

He then shows, that if the earth revolve round the sun annually, and the velocity of light be to the velocity of the earth's motion in its orbit, as 1000 to 1, that a star really placed in the very pole of the ecliptic would, to an eye carried along with the earth, seem to change its place continually; and, neglecting the small difference on the account of the earth's diurnal revolution on its axis, would seem to describe a circle round that pole every way distant from it $3\frac{1}{2}'$; so that its longitude would be varied through all the points of the ecliptic every year, but its latitude would always remain the same. Its right ascension would also change; and its declination, according to the different situation of the sun with respect to the equinoctial points, and its apparent distance from the north pole of the equator, would be 7′ less at the autumnal than at the vernal equinox.

287 Velocity of light.

By calculating exactly the quantity of aberration of the fixed stars from their place, he found that light came from the sun to us in 8′ 13″; so that its velocity is to the velocity of the earth in its orbit as 10.201 to 1.

288 Errors in the observation of small angles.

It must here be taken notice of, however, that Mr Nevil Maskelyne, in attempting to find the parallax of Sirius,

Digitized by Google

Sirius, with a ten-feet sector, observed, that by the friction of the plummet-line on the pin which suspended it, an error of 10″, 20″, and sometimes 30″, was committed. The pin was $\frac{1}{40}$ of an inch diameter; and though he reduced it to $\frac{1}{70}$ of an inch, the error still amounted to 3″. All observations, therefore, that have hitherto been made in order to discover the parallax of the fixed stars are to be disregarded.

289 Another objection against the earth's motion answered.

It is also objected, that the sun seems to change his place daily, so as to make a tour round the starry heavens in a year. But whether the sun or earth moves, this appearance will be the same; for when the earth is in any part of the heavens, the sun will appear in the opposite. And, therefore, this appearance can be no objection against the motion of the earth.

It is well known to every person who has sailed on smooth water, or been carried by a stream in a calm, that, however fast the vessel goes he does not feel its progressive motion. The motion of the earth is incomparably more smooth and uniform than that of a ship, or any machine made and moved by human art; and therefore it is not to be imagined that we can feel its motion.

290 Diurnal motion of the earth, and different changes of the seasons illustrated by experiment.

The following experiment will give a plain idea of the diurnal or annual motions of the earth, together with the different length of days and nights, and all the beautiful variety of seasons, depending on those motions.

Fig. 102.

Take about seven feet of strong wire, and bend it into a circular form, as a b *c* d, which being viewed obliquely appears elliptical, as in the figure. Place a lighted candle on a table; and having fixed one end of a silk thread K to the north pole of a small terrestrial globe H, about three inches diameter, cause another person to hold the wire circle, so that it may be parallel to the table, and as high as the flame of the candle I, which should be in or near the centre. Then having twisted the thread as towards the left hand, that by untwisting it may turn the globe round eastward, or contrary to the way that the hands of a watch move, hang the globe by the thread within this circle, almost contiguous to it; and as the thread untwists, the globe (which is enlightened half round by the candle as the earth is by the sun) will turn round its axis, and the different places upon it will be carried through the light and dark hemispheres, and have the appearance of a regular succession of days and nights, as our earth has in reality by such a motion. As the globe turns, move your hand slowly, so as to carry the globe round the candle according to the order of the letters a b *c* d, keeping its centre even with the wire circle; and you will perceive, that the candle, being still perpendicular to the equator, will enlighten the globe from pole to pole in its whole motion round the circle; and that every place on the globe goes equally through the light and the dark, as it turns round by the untwisting of the thread, and therefore has a perpetual equinox. The globe thus turning round, represents the earth turning round its axis: and the motion of the globe round the candle represents the earth's annual motion round the sun; and shows, that if the earth's orbit had no inclination to its axis, all the days and nights of the year would be equally long, and there would be no different seasons. Hence also it appears why the planets Mars and Jupiter have a perpetual equinox, namely, because the axis is perpendicular to the plane of their orbit, as the thread round which the globe turns in this experiment is perpendicular to the plane of the area enclosed by the wire.—But now desire the person who holds the wire to hold it obliquely in the position ABCD, raising the side ♋ just as much as he depresses the side ♑, that the flame may be still in the plane of the circle; and twisting the thread as before, that the globe may turn round its axis the same way as you carry it round the candle, that is, from west to east; let the globe down into the lowermost part of the wire circle at ♑: and, if the circle be properly inclined, the candle will shine perpendicularly on the tropic of Cancer; and the frigid zone, lying within the arctic or north polar circle, will be all in the light, as in the figure; and will keep in the light, let the globe turn round its axis ever so often. From the equator to the north polar circle, all the places have longer days and shorter nights; but from the equator to the south polar circle, just the reverse. The sun does not set to any part of the north frigid zone, as shown by the candle's shining on it, so that the motion of the globe can carry no place of that zone into the dark; and at the same time the south frigid zone is involved in darkness, and the turning of the globe brings none of its places into the light. If the earth were to continue in the like part of its orbit, the sun would never set to the inhabitants of the north frigid zone, nor rise to those of the south. At the equator it would be always equal day and night; and as places are gradually more and more distant from the equator towards the arctic circle, they would have longer days and shorter nights; while those on the south side of the equator would have their nights longer than their days. In this case, there would be continual summer on the north side of the equator, and continual winter on the south side of it.

But as the globe turns round its axis, move your hand slowly forward, so as to carry the globe from H towards E, and the boundary of light and darkness will approach towards the north pole, and recede from the south pole; the northern places will go through less and less of the light, and the southern places through more and more of it; showing how the northern days decrease in length and the southern days increase, whilst the globe proceeds from H to E. When the globe is at E, it is at a mean state between the lowest and highest parts of its orbit; the candle is directly over the equator, the boundary of light and darkness just reaches to both the poles, and all places on the globe go equally through the light and dark hemispheres, showing that the days and nights are then equal at all places of the earth, the poles only excepted; for the sun is then setting to the north pole and rising to the south pole.

Continue moving the globe forward, and as it goes through the quarter A, the north pole recedes still farther into the dark hemisphere, and the south pole advances more into the light, as the globe comes nearer to ♋: and when it comes there at F, the candle is directly over the tropic of Capricorn; the days are at the shortest and nights at the longest, in the northern hemisphere, all the way from the equator to the arctic circle; and the reverse in the southern hemisphere from the equator to the antarctic circle; within which circles

Digitized by Google

Real Motions of the Heavenly Bodies.

circles it is dark to the north frigid zone, and light to the south.

Continue both motions; and as the globe moves through the quarter B, the north pole advances towards the light, and the south pole recedes towards the dark; the days lengthen in the northern hemisphere and shorten in the southern; and when the globe comes to G, the candle will be again over the equator (as when the globe was at E), and the days and nights will again be equal as formerly; and the north pole will be just coming into the light, the south pole going out of it.

Thus we see the reason why the days lengthen and shorten from the equator to the polar circles every year; why there is sometimes no day or night for many turnings of the earth, within the polar circles; why there is but one day and one night in the whole year at the poles; and why the days and nights are equally long all the year round at the equator, which is always equally cut by the circle bounding light and darkness.

The inclination of an axis or orbit is merely relative, because we compare it with some other axis or orbit which we consider as not inclined at all. Thus, our horizon being level to us, whatever place of the earth we are upon, we consider it as having no inclination; and yet, if we travel 90 degrees from that place, we shall then have a horizon perpendicular to the former; but it will still be level to us.

291 Different seasons particularly explained.

Let us now take a view of the earth in its annual course round the sun, considering its orbit as having no inclination; and its axis as inclining $23\frac{1}{2}$ degrees from a line perpendicular to the plane of its orbit, and keeping the same oblique direction in all parts of its annual course; or, as commonly termed, keeping always parallel to itself.

Fig. 102.

Let *a*, *b*, *c*, *d*, *e*, *f*, *g*, *h*, be the earth in eight different parts of its orbit, equidistant from one another; N *s* its axis, N its north pole, *s* its south pole, and S the sun nearly in the centre of the earth's orbit. As the earth goes round the sun according to the order of the letters *a b c d*, &c. its axis N *s* keeps the same obliquity, and is still parallel to the line MN *s*. When the earth is at *a*, its north pole inclines towards the sun S, and brings all the northern places more into the light, than at any other time of the year. But when the earth is at *e* in the opposite time of the year, the north pole declines from the sun, which occasions the northern places to be more in the dark than in the light, and the reverse at the southern places; as is evident by the figure which is taken from Dr Long's astronomy. When the earth is either at *c* or *g*, its axis inclines not either to or from the sun, but lies sidewise to him, and then the poles are in the boundary of light and darkness; and the sun, being directly over the equator, makes equal day and night at all places. When the earth is at *b*, it is half-way between the summer solstice and harvest equinox; when it is at *d* it is half-way from the harvest equinox to the winter solstice; at *f*, half-way from the winter solstice to the spring equinox; and at *h*, half-way from the spring equinox to the summer solstice.

From this oblique view of the earth's orbit, let us suppose ourselves to be raised far above it, and placed just over its centre S, looking down upon it from its north pole; and as the earth's orbit differs but very little from a circle, we shall have its figure in such a view represented by the circle ABCDEFG. Let us suppose this circle to be divided into 12 equal parts, called *signs*, having their names affixed to them; and each sign into 30 equal parts, called *degrees*, numbered 10, 20, 30, as in the outermost circle of the figure, which represents the great ecliptic in the heavens. The earth is shown in eight different positions in this circle; and in each position Æ is the equator, T the tropic of Cancer, the dotted circle the parallel of London, U the artic or north polar circle, and P the north pole, where all the meridians or hour-circles meet. As the earth goes round the sun, the north pole keeps constantly towards one part of the heavens, as it keeps in the figure towards the right-hand side of the place.

Fig. 103.

When the earth is at the beginning of Libra, namely on the 20th of March, in this figure the sun S as seen from the earth, appears at the beginning of Aries in the opposite part of the heavens, the north pole is just coming into the light, and the sun is vertical to the equator; which, together with the tropic of Cancer, parallel of London, and arctic circle, are all equally cut by the circle bounding light and darkness, coinciding with the six-o'clock hour-circle, and therefore the days and nights are equally long at all places: for every part of the meridian ÆTL *a* comes into the light at six in the morning, and, revolving with the earth according to the order of the hour-letters, goes into the dark at six in the evening. There are 24 meridians or hour-circles drawn on the earth in this figure, to show the time of sun-rising and setting at different seasons of the year.

As the earth moves in the ecliptic according to the order of the letters ABCD, &c. through the signs Libra, Scorpio, and Sagittarius, the north pole P comes more and more into the light; the days increase as the nights decrease in length, at all places north of the equator Æ; which is plain by viewing the earth at *b* on the 5th of May, when it is in the 15th degree of Scorpio, and the sun as seen from the earth appears in the 15th degree of Taurus. For then the tropic of Cancer T is in the light from a little after five in the morning till almost seven in the evening; the parallel of London, from half an hour past four till half an hour past seven; the polar circle U, from three till nine; and a large tract round the north pole P has day all the 24 hours, for many rotations of the earth on its axis.

When the earth comes to *c* (fig. 104.) at the beginning of Capricorn, and the sun as seen from the earth appears at the beginning of Cancer, on the 21st of June, as in this figure, it is in the position C in fig. 103.; and its north pole inclines towards the sun, so as to bring all the north frigid zone into the light, and the northern parallels of latitude more into the light than the dark from the equator to the polar circle: and the more so as they are farther from the equator. The tropic of Cancer is in the light from five in the morning till seven at night, the parallel of London from a quarter before four till a quarter after eight; and the polar circle just touches the dark, so that the sun has only the lower half of his disk hid from the inhabitants on that circle for a few minutes about midnight,

Digitized by Google

Real Motions of the Heavenly Bodies.

night, supposing no inequalities in the horizon, and no refractions.

A bare view of the figure is enough to show, that as the earth advances from Capricorn towards Aries, and the sun appears to move from Cancer towards Libra, the north pole recedes from the light, which causes the days to decrease and the nights to increase in length, till the earth comes to the beginning of Aries, and then they are equal as before; for the boundary of light and darkness cuts the equator and all its parallels equally or in halves. The north pole then goes into the dark, and continues therein until the earth goes half-way round its orbit; or, from the 23d of September till the 20th of March. In the middle between these times, viz. on the 22d of December, the north pole is as far as it can be in the dark, which is $23\frac{1}{2}$ degrees, equal to the inclination of the earth's axis from a perpendicular to its orbit: and then the northern parallels are as much in the dark as they were in the light on the 21st of June; the winter nights being as long as the summer days, and the winter days as short as the summer nights. Here it must be noted, that of all that has been said of the northern hemisphere, the contrary must be understood of the southern: for on different sides of the equator the seasons are contrary, because, when the northern hemisphere inclines towards the sun, the southern declines from him.

292 Effects of the earth's motion on the appearances of the planets.

Taking it for granted, then, that the earth revolves round the sun, let us see what effect that motion has upon the apparent motions of the other planets. For the better comprehending of these motions, however, we have hitherto supposed the earth to stand still in some part of its orbit, while they go round the sun in theirs: but as this is not the case, it now remains to consider the changes which take place in consequence of the earth's motion. Were the earth to stand still in any part of its orbit, as at A, the places of conjunction both in the superior and inferior semicircle, as also of the greatest elongation, and consequently the places of direct and retrograde motion, and of the stations of an inferior planet, would always be in the same part of the heavens. Thus, in fig. 105. upon this supposition, the places of Mercury's stations would always be the points P and R, the arc of his motion PR, and of his retrograde motion RP; whereas, on account of the earth's motion, the places where these appearances happen are continually advancing forward in the ecliptic according to the order of the signs. In fig. 106. let ABCD be the orbit of the earth; *efgh* that of Mercury; ☉ the sun; GKI an arch of the ecliptic extended to the fixed stars. When the earth is at A, the sun's geocentric place is at F: and Mercury, in order to a conjunction, must be in the line AF; that is, in his orbit he must be at *f* or *h*. Suppose him to be at *f* in his inferior semicircle: if the earth stood still at A, his next conjunction would be when he is in his superior semicircle at *h*; the places of his greatest elongation also would be at *e* and *g*, and in the ecliptic at E and G: but supposing the earth to go on in its orbit from A to B; the sun's geocentric place is now at K; and Mercury, in order to be in conjunction, ought to be in the line BK at *m*. As by the motion of the earth, the places of Mercury's conjunctions with the sun are thus continually carried round in the ecliptic in consequence, so the places of his utmost elongations must be carried in consequence also. Thus, when the earth is at A, the places of his longest elongation from the sun are in the ecliptic E and G; the motion of the earth from A to B advances them forward from G to L and from E to I. But the geocentric motion of Mercury will best be seen in fig. 107. Here we have part of the extended ecliptic marked ♈, ♉, ♊, &c. in the centre of which S represents the sun, and round him are the orbits of Mercury and the earth. The orbit of Mercury is divided into 11 equal parts, such as he goes through once in eight days; and the divisions are marked by numeral figures 1, 2, 3, &c. Part of the orbit of the earth is likewise divided into 22 equal arcs, each arc being as much as the earth goes through in eight days. The points of division are marked with the letters *a*, *b*, *c*, *d*, *e*, *f*, &c. and show as many several stations from whence Mercury may be viewed from the earth. Suppose then the planet to be at 1 and the earth at *a*; draw a line from *a* to 1, and it shows Mercury's geocentric place at A. In eight days he will be got to 2, and the earth to *b*; draw a line from 2 to *b*, and it shows his geocentric place at B. In other eight days he will have proceeded to 3, and the earth to *c*; a line drawn from 3 to *c* will show his geocentric place at C. In this manner, going through the figure, and drawing lines from the earth at *d*, *e*, *f*, *g*, &c. through 4, 5, 6, 7, &c. we shall find his geocentric places successively at the points D, E, F, G, &c. where we may observe, that from A to B, and from B to C, the motion is direct; from C to D, and from D to E, retrograde. In this figure 22 stations are marked in the earth's orbit, from whence the planet may be viewed; corresponding to which there ought to be as many in the orbit of Mercury: and for this purpose the place of that planet is marked at the end of every eight days for two of his periodical revolutions; and to denote this, two numeral figures are placed at each division.

The geocentric motion of Venus may be explained in a similar manner; only as the motion of Venus is much slower than that of Mercury, his conjunctions, oppositions, elongations, and stations, all return much more frequently than those of Venus.

To explain the stationary appearances of the planets, it must be remembered, that the diameter of the earth's orbit, and even of that of Saturn, are but mere points in comparison of the distance of the fixed stars; and therefore, any two lines, absolutely parallel, though drawn at the distance of the diameter of Saturn's orbit from each other, would, if continued to the fixed stars, appear to us to terminate in the same point. Let, then, the two circles, fig. 108. represent the orbits of Venus and of the Earth; let the lines AE, BF, CG, DH, be parallel to SP, we may nevertheless affirm, that if continued to the distance of the fixed stars, they would all terminate in the same point with the line SP. Suppose, then, Venus at E while the earth is at A, the visual ray by which she is seen is the line AE. Suppose again, that while Venus goes from E to F, the Earth goes from A to B, the visual ray by which Venus is now seen is BF parallel to AE; and therefore Venus will be all that time stationary appearing in that point of the heaven where SP extended would terminate: this station is at her changing from direct to retrograde. Again, suppose, when the Earth is at C,

Digitized by Google

Real Motions of the Heavenly Bodies.

C, Venus is at G, and the visual line CG; if, while the earth goes from C to D, Venus goes from G to H, so that she is seen in the line GH parallel to CG, she will be all that time stationary, appearing in the point where a line drawn from S through P would terminate. This station is at her changing from retrograde to direct; and both are in her inferior semicircle.

293 Perigee and apogee of the planets explained.

An inferior planet, when in conjunction with the sun in its inferior semicircle, is said to be in *perigee*, and in the other in *apogee*, on account of its different distances from the earth. Their real distances from the earth when in perigee are variable, partly owing to the eccentricities of their orbits, as well as that of the earth; and partly owing to the motions of the different bodies, by which it happens that they are in perigee in different parts of their orbits. The least possible distance is when the perigee happens when the earth is in its perihelion, and the planet in its aphelion.

294 Differences in the apparent diameters of the planets.

The difference of distance between the earth and inferior planets at different times, makes a considerable variation in their apparent diameters, which indeed is very observable in all the planets; and thus they sometimes look very considerably larger than at others. This difference in magnitude in Mercury is nearly as $5\frac{1}{2}$ to 1; and in Venus, no less than 32 to 1. A common spectator, unassisted by any instrument, may observe an inferior planet alternately approach nearer and nearer the sun, until at last it comes into conjunction with him, and then to recede farther and farther till it is at its greatest elongation, which will be first on one side and then on the other: but if we observe the apparent change of place of an inferior planet in the sphere of the heavens, its direct motions, stations, and retrogradations, measuring its diameter frequently with the micrometer, we shall find by its decrease at some times and increase at others, that its distance from us is very considerably varied; so that, taking the whole of its course into consideration, it appears to move in a very complicated curve. See fig. 109.

295 Appearances of the superior planets explained.

As the superior planets move in a larger orbit than the earth, they can only be in conjunction with the sun when they are on that side opposite to the earth; as, on the other hand, they are in opposition to him when the earth is between the sun and them. They are in quadrature with them when their geocentric places are 90° distant from that of the sun. In order to understand their apparent motions, we shall suppose them to stand still in some part of their orbit while the earth makes a complete revolution in hers; in which case, any superior planet would then have the following appearances: 1. While the earth is in her most distant semicircle, the motion of the planet will be direct. 2. While the earth is in her nearest semicircle, the planet will be retrograde. 3. While the earth is near those places of its orbit where a line drawn from the planet would be a tangent, it would appear to be stationary. Thus, in fig. 147. let *a b c d* represent the orbit of the earth; S the Sun; EFG an arc of the orbit of Jupiter; ABC an arc of the ecliptic projected on the sphere of the fixed stars. Suppose Jupiter to continue at F, while the earth goes round in her orbit according to the order of the letters *a b c d*. While the earth is in the semicircle most distant from Jupiter, going from *a* to *b* and from *b* to *c*, his motion in the heaven would appear direct, or from A to B and from B to C: but while the earth is in its nearest semicircle *c d e*, the motion of Jupiter would appear retrograde from C to B and from B to A; for *a*, *b*, *c*, *d*, may be considered as so many different stations from whence an inhabitant of the earth would view Jupiter at different seasons of the year, and a straight line drawn from each of these stations, through F the place of Jupiter, and continued to the ecliptic, would show his apparent place there to be successively at A, B, C, B, A. While the earth is near the points of contact *a* and *c*, Jupiter would appear stationary, because the visual ray drawn through both planets does not sensibly differ from the tangent F *a* or F *c*. When the earth is at *b*, a line drawn from *b* through S and F to the ecliptic, shows Jupiter to be in conjunction with the sun at B. When the earth is at *d*, a line drawn from *d* through S, continued to the ecliptic, would terminate in a point opposite to B; which shows Jupiter then to be in opposition to the sun: and thus it appears that his motion is direct in the conjunction, but retrograde when in opposition with the sun.

The direct motion of a superior planet is swifter the nearer it is to a conjunction, and slower as it approaches to a quadrature with the sun. Thus, in fig. 111. let ☉ be the sun; the little circle round it, the orbit of the earth, whereof *a b c d e f g* is the most distant semicircle; OPQ, an arc of the orbit of Jupiter; and ABCDEFG, an arc of the ecliptic in the sphere of the fixed stars. If we suppose Jupiter to stand still at P, by the earth's motion from *a* to *g*, he would appear to move direct from A to G, describing the unequal arcs AB, BC, CD, DE, EF, FG, in equal times. When the earth is at *d*, Jupiter is in conjunction with the sun at D, and there his direct motion is swiftest. When the earth is in that part of her orbit where a line drawn from Jupiter would touch it, as in the points *e* or *g*, Jupiter is nearly in quadrature with the sun; and the nearer the earth is to any of those points, the slower is the geocentric motion of Jupiter; for the arcs CD and DE are greater than BC or EF, and the arcs BC and EF are greater than AB or FG.

The retrograde motion of a superior planet is swifter the nearer it is to an opposition, and slower as it approaches to a quadrature with the sun. Thus, let ☉, fig. 112. be the sun; the little circle round it the orbit of the earth, whereof *g h i k l m n* is the nearest semicircle; OPQ, an arc of the orbit of Jupiter; NKG an arc of the ecliptic: If we suppose Jupiter to stand still at P, by the earth's motion from *g* to *n*, he would appear to move retrograde from G to N, describing the unequal arcs GH, HI, IK, KL, LM, MN, in equal times. When the earth is at *k*, Jupiter appears at K, in opposition to the sun, and there his retrograde motion is swiftest. When the earth is either at *g* or *n*, the points of contact of the tangents P *g* and P *n*, Jupiter is nearly in quadrature with the sun: and the nearer he is to either of these points, the slower is his retrogradation; for the arcs IK and KL are greater than HI or LM; and the arcs HI and LM are greater than GH or MN. Since the direct motion is swiftest

Real Motions of the Heavenly Bodies.

swiftest when the earth is at *d*, and continues diminishing till it changes to retrograde, it must be insensible near the time of change: and, in like manner, the retrograde motion being swiftest when the earth is in *k*, and diminishing gradually till it changes to direct, must also at the time of that change be insensible; for any motion gradually decreasing till it changes into a contrary one gradually increasing, must at the time of the change be altogether insensible.

The same changes in the apparent motions of this planet will also take place if we suppose him to go on slowly in his orbit; only they will happen every year when the earth is in different parts of her orbit, and consequently at different times of the year. Thus, (fig. 110.) let us suppose, that while the earth goes round her orbit, Jupiter goes from F to G; the points of the earth's orbit from which Jupiter will now appear to be stationary will be *a* and *y*; and consequently his stations must be at a time of the year different from the former. Moreover, the conjunction of Jupiter with the sun will now be when the earth is at *f*, and his opposition when it is at *e*; for which reason these also will happen at times of the year different from those of the preceding opposition and conjunction. The motion of Saturn is so slow, that it makes but little alteration either in the times or places of his conjunction or opposition; and no doubt the same will take place in a more eminent degree in the Georgium Sidus; but the motion of Mars is so much swifter than even that of Jupiter, that both the times and places of his conjunctions and oppositions are thereby very much altered.

Fig. 113. exemplifies the geocentric motion of Jupiter in a very intelligible manner; where ☉ represents the sun; the circle 1, 2, 3, 4, the orbit of the earth, divided into twelve equal arcs for the twelve months of the year; PQ an arc of the orbit of Jupiter, containing as much as he goes through in a year, and divided in like manner into twelve equal parts, each as much as he goes through in a month. Now, suppose the earth to be at 1 when Jupiter is at *a*, a line drawn through 1 and *a* shows Jupiter's place in the celestial ecliptic to be at A. In a month's time the earth will have moved from 1 to 2, Jupiter from *a* to *b*; and a line drawn from 2 to *b* will show his geocentric place to be in B. In another month, the earth will be in 3, and Jupiter at *c*, and consequently his geocentric place will be at C; and in like manner his place may be found for the other months at D, E, F, &c. It is likewise easy to observe, that his geocentric motion is direct in the arcs AB, BC, CD, DE; retrograde in EF, FG, GH, HI; and direct again in IK, KL, LM, MN. The inequality of his geocentric motion is likewise apparent from the figure.

A superior planet is in apogee when in conjunction with the sun, and in perigee when in opposition; and every one of the superior planets is at its least possible distance from the earth where it is in perigee and perihelion at the same time. Their apparent diameters are variable, according to their distances, like those of the inferior planets; and this, as might naturally be expected, is most remarkable in the planet Mars, who is nearest us. In his nearest approach, this planet is 25 times larger than when farthest off, Jupiter twice and a half, and Saturn once and a half.

Chap. III. *Of the Orbits of the Planets, and the Laws of their Motions.*

It would be exceedingly easy to ascertain the position of the planets for any given time, if their orbits were circular and uniform. But they exhibit very sensible inequalities in this respect, the laws of which are exceedingly important in astronomy, as furnishing the only clue which can lead us to the theory of the celestial motions. To ascertain these irregularities, and detect their laws, it is necessary to abstract from their apparent motions the effects produced by the motion of the earth. In the first place then, we must determine the nature and dimensions of the earth's orbit.

We have seen formerly that the sun apparently moves round the earth in an ellipse, having the earth in the focus. We have only to reverse the position to obtain the orbit of the earth. It moves round the sun in an ellipse, having that luminary in the focus; so that its radius vector describes areas proportional to the times. In general, all the remarks made formerly on the supposed orbit of the sun relative to its eccentricity, &c. apply accurately to the real orbit of the earth.

The figure of the earth's orbit being thus ascertained, let us see how astronomers have been able to determine that of the other planets. Let us take the planet Mars as an example, which, from the great eccentricity of its orbit, and its nearness to the earth, furnishes an excellent medium for discovering the laws of the planetary motions.

The motion of Mars round the sun and his orbit would be known, if we had at any given time, the angle formed by its radius vector, and a fixed straight line passing through the centre of the sun, together with the length of that radius vector. To simplify the problem, a time is chosen when one of these quantities may be had separately from the other. This happens at the oppositions, when we see the planet in the same point of the ecliptic to which it would be referred by a spectator in the sun. The difference in the velocity and periodic times of the earth and Mars causes the planet to appear when in opposition in different points of the ecliptic successively. By comparing together a great number of such oppositions, the relation which subsists between the time and the angular motion of Mars round the sun, (called *heliocentric*), may be discovered. Different methods present themselves for that purpose. But in the present case the problem is simplified by considering that the principal inequalities of Mars returning in the same manner at every sidereal revolution, the whole of them may be expressed by a rapidly converging series of the sines of the angles multiplied by its mean motion. The relative changes in the length of the radius vector, may be determined by comparing together observations made about the quadrature when the planet being about 90° from the sun, that radius presents itself under the greatest angle possible. In the triangle formed by the straight lines which join the centres of the earth, the sun, and Mars, the angle at the earth is obtained by observation, that at the sun is ascertained by the law of Mars's heliocentric motion. Hence the radius vector is deduced in parts of the earth's radius vector. By comparing together a number

Real Motions of the Heavenly Bodies.

ber of such radii vectores determined in this manner, the law of their variations, corresponding to the angles which they make with a straight line fixed in position, may be determined. In this manner Kepler determined the orbit of Mars, and found it to be an ellipse with the sun in the focus. He inferred that the other planets moved likewise in ellipses round the sun, and this inference has been confirmed by actual examination.

296
Heliocentric circles of the planets.

To a spectator placed in the sun, all the planets would appear to describe circles annually in the heavens; for though their motions are really elliptical, the eccentricity is so small, that the difference between them and true circles is not easily perceived even on earth; and at the sun, whether great or small, it would entirely vanish. These circles, which in such a situation would appear to be annually described among the fixed stars, are called the *heliocentric circles* of the planets; and if we suppose the orbits of the planets to be extended to the extreme bounds of the creation, they would describe among the fixed stars those circles just mentioned. To a spectator in the sun, the comets, though moving in the most eccentric orbits, would also appear to describe circles in the heavens: for though their orbits are in reality very long ellipses, the planes of them extended to the heavens would mark a great circle thereon, whereof the eye would be the centre; only, as the real motion is in an ellipsis, the body would appear to move much more slowly in some part of the circle than another, and to differ excessively in magnitude. To an inhabitant of any planet, however, the sun appears to go round in its own heliocentric circle, or to describe in the heavens that same curve which the planet would appear to do if seen from the sun. Thus (fig. 114.), when the earth is at *a*, if we draw a line from *a* through the sun at S, the point G, in the sphere of the heavens where the line terminates, is the place where the sun then appears to an inhabitant of the earth. In a month's time the earth will be got from *a* to *b*; draw a line then through the sun, and its extremity at H will point out his apparent place at that time. In like manner, if we draw lines from the earth in the twelve several situations in which it is represented for the twelve months of the year, the sun's apparent place will be found as above, and so it would be found by a spectator placed in Venus or any other planet.

The geocentric latitude of a superior planet may be understood from fig. 115. Let AB be the orbit of the earth, CD that of Mars, both viewed with the eye in their common section continued, by which they appear in straight lines. Let E and F be opposite points of the ecliptic, and suppose Mars to be in the south limit at C. If he were at that time viewed from S, the centre of the sun, he would appear in the sphere of the heavens at the point H; in which case his heliocentric latitude would be FH: But when viewed in C from the earth, or from its centre, which in this case is supposed to be the station of the spectator, he will appear to be in different places of the heavens according to the position of the earth. When the earth, for instance, is at B, the place of Mars will appear to be at *g*, and his geocentric latitude will be F *g*. When the earth is at A, his apparent place will be in G, and his geocentric latitude FG: and in like manner, supposing the earth to be in any other part of its orbit, as in I or K, it is easy to see, that his apparent places, as well as geocentric latitudes at those times, will be different.

297
Nodes of a planet.

The two points where the heliocentric circle of any planet cuts the ecliptic, are called its *nodes;* and that which the planet passes through as it goes into north latitude, is called the *ascending* node, and is marked thus ☊; and the opposite to this is called the *descending* node, and is marked ☋. A line drawn from one node to the other is called the *line of the nodes of the planet*, which is the common section of the plane of the ecliptic, and that of the planet produced on each side to the fixed stars. The deviation of the orbit from a circle is called the *eccentricity* of the orbit; the point where it is farthest distant from the sun is called its *aphelion;* and where nearest, the *perihelion*.

The motion of the planets is swiftest at the perihelion when the radius vector is shortest: it diminishes as the radius vector increases, and is at its minimum at the aphelion. When Kepler compared these two quantities in the planet Mars, he observed that the velocity of the planet was always proportional to the square of the radius vector, so that the product of that velocity multiplied into the square of the radius vector is a constant quantity. This product is double the area described by the radius vector in the given time. Hence that area, supposing the radius vector to set out from a fixed line, increases as the time. This Kepler announced by saying, that the areas described by the radius vector are proportional to the times. These laws are precisely those followed by the earth in her motion round the sun. Hence Kepler established as the fundamental laws of the motions of the planets the two following:

1. The orbits of the planets are ellipses, having the sun in their focus.

2. The areas described by the radius vector of each planet are proportional to the times of describing them.

These laws suffice for determining the motions of the planets round the sun: But it is necessary to know for each of the planets seven quantities, called the elements of their elliptical motion. Five of these elements relative to the motion of the ellipse are, 1. The duration of the sidereal revolution. 2. Half the greater axis or the mean distance of the planet from the sun. 3. The eccentricity of the orbit. 4. The mean longitude of the planet at a given time. 5. The longitude of its perihelion at the same epoch. The other two elements relate to the position of the orbits. They are, 6. The longitude of the nodes of the orbit at a given epoch, or the points where the orbit intersects the ecliptic. 7. The inclination of the orbit to the plane of the ecliptic. The following table exhibits a view of these elements.

From the above tables it appears that this time of the revolution of the planets increases with their distance from the sun. This induced Kepler to suspect that some relation existed between them. After many attempts continued for 17 years, he at last discovered that the squares of the periodic times of the planets are proportional to the cubes of the greater axis of their orbits.

Chap. IV. *Of the Orbits of the Comets.*

Of all the celestial bodies, comets have given rise to the greatest number of speculations and conjectures. Their strange appearance has in all ages been a matter of terror to the vulgar, who uniformly have looked upon them to be evil omens and forerunners of war, pestilence, &c. Others, less superstitious, supposed them to be meteors raised in the higher regions of the air. But we find that some part of the modern doctrine concerning them had been received into the ancient Italic

298 Supposed by the ancients to be planets.

and Pythagorean schools: for they held them to be so far of the nature of planets, that they had their periodical times of appearing; that they were out of sight for a long time, while they were carried aloft at an immense distance from the earth, but became visible when they descended into the lower regions of the air, when they were nearer to us.

These opinions were probably brought from Egypt, from whence the Greeks borrowed great part of their

299 Aristotle's opinion concerning them.

learning. However, it seems not to have been generally received; for Aristotle, who mentions it, asserted that the heavens were unchangeable, and not liable to generation or corruption. Comets, therefore, which he believed to be generated when they first made their appearance, and destroyed when they vanished from our sight, he maintained could not be heavenly bodies, but rather meteors or exhalations raised into the upper regions of the atmosphere, where they blazed out for a while, and disappeared when the matter of which they were formed was consumed. Seneca, who lived in the first century, mentions Apollonius of Myndus, a very careful observer of natural causes, to have been of the same sentiments with the most ancient Greek philosophers with regard to comets. He himself had seen two; one in the reign of Claudius, the other in that of Nero; besides another which he saw while a boy, before the death of Augustus. He plainly intimates, that he thought them above the moon; and argues strongly against those who supposed them to be meteors, or held other absurd opinions concerning them: declaring his belief that they were not fires suddenly kindled, but the eternal productions of nature. He points out also the only way to come at a certainty on this subject, viz. by collecting a number of observations concerning their appearance, in order to discover whether they return periodically or not. "For this purpose (says he) one age is not sufficient; but the time will come when the nature of comets and their magnitudes will be demonstrated, and the routes they take, so different from the planets, explained. Posterity will then wonder that the preceding ages should be ignorant of matters so plain and easy to be known."

For a long time this prediction of Seneca seemed very unlikely to be fulfilled. The great authority which Aristotle maintained for many ages, determined them to be nothing but meteors casually lighted up in the air; though they were manifestly at a great height, not only above the clouds, but subject to the diurnal revolution of the earth. In the dark and superstitious ages, they were held to be the forerunners of every kind of calamity, and were supposed to have different degrees of malignity according to the shape they assumed; from whence also they were differently denominated. Thus, some were said to be bearded, some hairy; some to represent a beam, sword or spear; others

Real Motions of the Heavenly Bodies.

others a target, &c.; whereas modern astronomers acknowledge only one species of comets, and account for their different appearances from their different situations from the sun and earth.

300 Only one species of them exists.

It was not till some time after people began to throw off the fetters of superstition and ignorance which had so long held them, that any rational hypothesis was formed concerning comets. Kepler, in other respects a very great genius, indulged the most extravagant conjectures, not only concerning comets, but the whole system of nature in general. The planets he imagined to be huge animals who swam round the sun by means of certain fins acting upon the ethereal fluid, as those of fishes do on the water: and agreeably to this notion, he imagined the comets to be monstrous and uncommon animals generated in the celestial spaces; and he explained how the air engendered them by an animal faculty. A yet more ridiculous opinion, if possible, was that of John Bodin, a learned man of France in the 17th century. He maintained that comets "are spirits, which have lived on the earth innumerable ages, and being at last arrived on the confines of death, celebrate their last triumph, or are recalled to the firmament like shining stars! This is followed by famine, plague, &c. because the cities and people destroy the governors and chiefs who appease the wrath of God." This opinion (he says) he borrowed from the philosopher Democritus, who imagined them to be the souls of famous heroes: but that being irreconcileable with Bodin's Christian sentiments, he was obliged to suppose them to be a kind of genii, or spirits subject to death, like those so much mentioned in the Mahometan fables. Others, again, have denied even the existence of comets, and maintained that they were only false appearances occasioned by the refraction or reflection of light.

301 Kepler and Bodin's opinion of them.

302 Bernoulli's opinion.

The first rational conjecture we meet with is that of James Bernoulli, an Italian astronomer, who imagined them to be the satellites of some very distant planet, which was invisible to us on account of its distance, as were also the satellites, unless when in a certain part of their course.

303 True doctrine concerning them revived by Tycho Brahe.

Tycho Brahe was the first who restored the comets to their true rank in the creation. Before his time, several comets had been observed with tolerable exactness by Regiomontanus, Appian, Fabricius, and others; yet they all thought them below the moon. But Tycho, being provided with much better instruments, set himself with great diligence to observe the famous comet of 1577; and, from many careful observations, deduced that it had no sensible diurnal parallax; and therefore was not only far above the regions of our atmosphere, but much higher than the moon. But though few have come so near the earth as to have any diurnal parallax, all of them have what may be called an annual parallax; that is, the revolution of the earth in her orbit causes their apparent motion to be very different from what it would be if viewed from the sun; and this shows them to be much nearer than the fixed stars, which have no such parallax. Kepler, the disciple of Tycho, notwithstanding his ridiculous conjecture already mentioned, was very attentive to the motions of the comets, and found that they did not move in straight lines, as had been supposed. He showed that their paths were concave towards the sun, and supposed them to move in parabolic trajectories.

304 Their motion exactly determined by Sir Isaac Newton.

Their true motion, however, was only discovered from the observations made by Sir Isaac Newton on the great comet of 1680. This descended almost perpendicularly towards the sun with a prodigious velocity; ascending again with the same velocity retarded, as it had been before accelerated. It was seen in the morning by a great number of astronomers in different parts of Europe, from the 4th to the 25th of November, in its way toward the sun; and in the evening from the 12th of December to the 9th of March following. The many exact observations made on this comet enabled Sir Isaac Newton to determine that they are a kind of planets which move in very eccentric ellipses; and this opinion is now looked upon to be certainly established. It was opposed, however, by M. de la Hire, and some other French philosophers; and it is evident that the whole dispute now turned on mere practical observations. If the return of any comet could be predicted, and its periodical time calculated like that of a planet, then the doctrine might be concluded certainly true, but not otherwise. Dr Halley therefore set himself to collect all the observations he could on comets; and afterwards calculated the periodical times of 24 of them, on a supposition of their being paraboles; but afterwards found that they agreed better with the supposition of their motion being performed in very eccentric elliptical orbits. On this he calculated a table of their elements; from which it was manifest that they were not comprehended in the zodiac, some of them making an angle of upwards of 80° with the ecliptic.

305 Dr Halley predicts a comet's return.

306 Periodical times of different comets determined.

By computations founded on these elements, the Doctor concluded that the comet of 1682 was the same which had appeared in 1607 and 1531; that it had a period of 75 or 76 years; and he ventured to foretel that it would return about the year 1758. The comet which appeared in 1661 was supposed to be the same with that of 1532, and to have a period of 129 years; and from the equality of periods, and similitude of appearances, it was concluded that the great comet of 1680 was the same which had appeared in 1106 in the time of Henry I. in the consulate of Lampadius and Orestes about the year 531, and in the year 44 B. C. before Julius Cæsar was murdered; and hence concluded that its period was 575 years. Mr Dunthorne, however, has endeavoured to show from a MS. in Pembroke-hall library, that the comet of 1106 could not be the same with that of 1680: but M. de la Lande thinks the four appearances related by Dr Halley stronger proofs than a single observation, which might be very faulty.

Since the time of Dr Halley other astronomers have calculated the elements of 25 other comets; all of which, excepting one of three which appeared in 1759, and which differs but little from that of 1531, 1607, and 1682, and is therefore accounted the same, differ very much from each other; so that we cannot help concluding them all to be different, and that the number of these bodies is very great. "It is not, however, unlikely (says Dr Long), from the immense interval between the orbit of Saturn and the nearest fixed stars, that many of them have not descended into the planetary

307 Why comets may sometimes be invisible even in their perihelion.

Real Motions of the Heavenly Bodies.

planetary regions since they have been looked upon as celestial bodies, and observed accordingly: besides, it may often happen, that a body may finish its whole period without being observed by us, on account of the unfavourable situation of the earth in her orbit when the comet is in its perihelion. Thus, if the comet be either behind or before the sun, or nearly so, it must be above our horizon in the day time, and consequently invisible, except the sun should at that time be in a total eclipse; for then the comet might be seen near the sun, as well as the stars and planets are: and this case is said to have happened; for Seneca relates from Possidonius, that a comet was seen when the sun was eclipsed, which had before been invisible by being near that luminary."

308 Why more are seen in the hemisphere towards the sun than in the opposite.

A greater number of comets are seen in the hemisphere towards the sun than in the opposite; the reason of which will easily appear from fig. 116. wherein S represents the sun, E the earth, ABCD the sphere of the fixed stars: and because comets either do not reflect light enough to be visible, or emit tails conspicuous enough to attract our notice, till they come within the planetary regions, commonly a good way within the sphere of Jupiter, let KLMN be a sphere concentric to the sun, at such a distance from him, that no comet can be seen by us till it come within that distance; though E draw the plane BD perpendicular to SE, which will divide the sphere CLMN into two hemispheres, one of which, BCD, is toward the sun, the other, DAB, opposite. Now it is manifest, that the spherical portion LMN, which is in the hemisphere BCD towards the sun, is larger than the portion NKL in the hemisphere opposite to him: and consequently a greater number of comets will appear in the hemisphere BCD than in that marked DAB.

309 Great differences in the eccentricities of the orbits of comets.

Though the orbits of all comets are very eccentric ellipses, there are vast differences amongst them; excepting Mercury, there are no great differences among the planets, either as to the eccentricity of their orbits, or the inclination of their planes; but the planes of some comets are almost perpendicular to others, and some of their ellipses are much wider than others. The narrowest ellipsis of any comet hitherto observed was that of 1680. There is also a much greater inequality in the motion of the comets than of the planets; the velocity of the former being incomparably greater in their perihelion than in their aphelion: but the planets are but very little accelerated.

310 Opinions concerning their substance.

Astronomers are now generally agreed, that comets are opaque bodies, enlightened by the sun. Hevelius, in a large work, wherein he gives the opinion of various authors on the subject, mentions some who were of the same sentiments with himself, that comets were so far transparent as to let the light of the sun pass through them, which formed their tails. Sir Isaac Newton was of opinion, that they are quite opaque; and in confirmation of this, he observes, that if a comet be seen in two parts of its orbit, at equal distances from the earth, but at unequal distances from the sun, it always shines brightest in that nearest the sun. They are of very different magnitudes, which may be conjectured from their apparent diameter and brightness. Thus the head of a comet, when of the same brightness and apparent diameter with Saturn, may be supposed to be nearly about the same magnitude with that planet; though this must be attended with some uncertainty, as we know not whether the heads of comets reflect the sun's light in the same manner the planets do. Their distance may be known from their parallax, in the manner related in a subsequent section.

311 Distances, diameters, &c. of some comets computed.

In this manner he found the distance of the comet of 1577 to be about 210 semidiameters of the earth, or about 840,000 miles distant from us, its apparent diameter being seven minutes; whence he concluded, that the true diameter of the comet was to that of the earth as 3 to 14. "But (says Dr Long) it was the hemisphere of the comet which was then measured." Hevelius, from the parallax and apparent diameter of the head of the comet in 1652, computed its diameter to be to that of the earth as 52 to 100. By the same method he found the diameter of the head of the comet of 1664 to be at one time 12 semidiameters of the earth, and at another not much more than 5. "That the head of the comet must appear less the farther it is from the earth (says Dr Long) is obvious; but besides this apparent change, there is also a real one in the dimensions of the head of the same comet; for, when near the sun, the atmosphere is diminished by the heat raising more of it into the tail; whereas, at a greater distance, the tail is diminished and the head enlarged." Hevelius computed the diameter of the nucleus of the comets of 1661 and 1665 to be only about a tenth part of that of the earth; and Cysatus makes the true diameter of the comet of 1618 to be about the same size. Some comets, however, from their apparent magnitude and distance, have been supposed much larger than the moon, or even equal in magnitude to some of the primary planets; and some

312 Eclipses occasioned by comets.

have imagined, that by an interposition of these bodies betwixt the earth and sun, we might account for those darknesses which cannot be derived from any interposition of the moon. Such are those mentioned by Herodotus, lib. vii. cap. 37. and lib. ix. cap. 70.; likewise the eclipse mentioned by Dion, which happened a little before the death of Augustus; and it is observable that Seneca saw a comet that year. Some have even attempted to account in this manner for the darkness which happened at our Saviour's crucifixion; and indeed it is certain, that were a comet in its perigee to come between the earth and sun, and to be moving the same way with the earth, it must cause a darkness much more intense, as well as of more considerable duration, than what would take place in any lunar eclipse.

313 Conjectures concerning their tails.

Various conjectures have been formed respecting the tails of comets; though it is acknowledged by all, that they depend on the sun somehow or other; and for this plain reason, that they are always turned from him; but in what manner this is accomplished, we cannot easily determine. Appian, Tycho Brahe, and others, thought the tail was formed by the sun's rays transmitted through the nucleus of the comet, which they fancied transparent, and was there refracted as in a lens of glass, so as to form a beam of light behind the comet: but this cannot be the case, as well because the figure of a comet's tail does not answer to such a refraction, as that such refracted light would not be seen by a spectator placed sideways to it, unless it fell upon some substance sufficiently dense to cause a

314 Opinion of Descartes.

reflection. Descartes and his followers were of opinion, that the tail of a comet was owing to the refraction

Real Motions of the Heavenly Bodies.

tion of its head: but if this were the case, the planets and principal fixed stars must have tails also; for the rays from them pass through the same medium as the light from the comets. Sir Isaac Newton was of opinion, that the tail of a comet is a very thin vapour which the head sends out by reason of its heat: that it ascends from the sun just as smoke does from the earth: that as the ascent of smoke is caused by the rarefaction of the air wherein it is entangled, causing such air to ascend and carry the smoke up with it; so the sun's rays acting upon the coma or atmosphere of the comet, do by rarefaction and refraction heat the same: that this heated atmosphere heats, and by heating rarefies, the ether that is involved therein; and that the specific gravity with which such ether tends to the sun, is so diminished by its rarefaction, that it will now ascend from him by its relative lightness, and carry with it the reflecting particles whereof the tail is composed. Though the immensely large tails of some comets seem to require a great quantity of matter to produce them, this is no objection to the foregoing solution: for every day's experience shows what a great quantity of smoke is produced from a very little wood or coal; and Newton has demonstrated, that a cubic inch of air equally rarefied with that at the distance of a semidiameter from the earth's surface, would fill all the planetary regions to the orbit of Saturn and beyond. Mairan entertained a very different opinion. He supposed the tails of the comets to be formed out of the luminous matter whereof the sun's atmosphere consists. This he supposes to extend as far as the orbit of the earth, and to furnish matter for the aurora borealis. M. de la Lande is for joining the two last opinions together. Part of the matter which forms the tails of comets he supposes to arise from their own atmosphere rarefied by heat and pushed forward by the force of the light streaming from the sun; and also that a comet passing through the sun's atmosphere is drenched therein, and carries away some of it. Mr Rowning objects to Newton's account, that it can hardly be supposed the thin vapour of the tail should go before the more solid body of the comet, when the motion thereof is sometimes so extremely swift, as that of some of the comets is said to be, after the rate, as Sir Isaac Newton calculated the motion of the comet of 1680 to be, of no less than 880,000 miles an hour. He therefore supposes the atmosphere of the comet to extend every way round it as far as the tail reaches; and that the part of it which makes the tail is distinguished from the rest, so as to fall thick upon that part of the atmosphere which goes before the comet in its progress along its elliptic orbit. The greatest objection to this is the immense magnitude of the atmospheres; as it must now be supposed to account for the vast lengths of the tails of some comets, which have been said to measure above 80 millions of miles.

The many discoveries which, since the time of Newton, Halley, and other celebrated mathematicians, have been made in electricity, having brought in a new element unknown to former ages, and which shows a vast power through every part of the creation with which we are acquainted, it became natural to imagine that it must extend also into those higher regions which are altogether inaccessible to man. The similarity of the tails of comets to the Aurora Borealis, which is commonly looked upon to be an electrical phenomenon, therefore suggested an opinion, at present far from being generally disbelieved, that the tails of comets are streams of electric matter. An hypothesis of this kind was published by Dr Hamilton of Dublin in a small treatise, entitled, *Conjectures on the Nature of the Aurora Borealis, and on the Tails of Comets*. His hypothesis is, that the comets are of use to bring back the electric fluid to the planets, which is continually discharged from the higher regions of their atmospheres. Having given at length the above-mentioned opinion of Sir Isaac, "We find (says he) in this account, that Sir Isaac ascribes the ascent of comets tails to their being rarer and lighter, and moving round the sun more swiftly than the solar atmosphere, with which he supposes them to be surrounded whilst in the neighbourhood of the sun; he says also, that whatever position (in respect to each other) the head and tail of a comet then receive, they will keep the same afterwards most freely; and in another place he observes, 'That the celestial spaces must be entirely void of any power of resisting, since not only the solid bodies of the planets and comets, but even the exceeding thin vapours of which comets tails are formed, move through those spaces with immense velocity, and yet with the greatest freedom.' I cannot help thinking that this account is liable to many difficulties and objections, and that it seems not very consistent with itself or with the phenomena.

315 Dr Hamilton of Dublin's opinion.

"I do not know that we have any proof of the existence of a solar atmosphere of any considerable extent, nor are we anywhere taught how to guess at the limits of it. It is evident that the existence of such an atmosphere cannot be proved merely by the ascent of comets tails from the sun, as that phenomenon may possibly arise from some other cause. However, let us suppose, for the present, that the ascent of comets tails is owing to an atmosphere surrounding the sun; and see how the effects arising from thence will agree with the phenomena. When a comet comes into the solar atmosphere, and is then descending almost directly to the sun, if the vapours which compose the tail are raised up from it by the superior density and weight of that atmosphere, they must rise into those parts that the comet has left, and therefore at that time they may appear in a direction opposite to the sun. But as soon as the comet comes near the sun, and moves in a direction nearly at right angles with the direction of its tail, the vapours which then arise, partaking of the great velocity of the comet, and being specifically lighter than the medium in which they move, and being vastly expanded through it, must necessarily suffer a resistance immensely greater than what the small and dense body of the comet meets with, and consequently cannot possibly keep up with it, but must be left behind, or, as it were, driven backwards by the resistance of that medium into a line directed towards the parts which the comet has left, and therefore can no longer appear in a direction opposite to the sun. And, in like manner, when a comet passes its perihelion, and begins to ascend from the sun, it certainly ought to appear ever after with its tail behind it, or in a direction pointed towards the sun; for if the tail of the comet be specifically lighter than the medium in which it moves with so great velocity, it must be just as impossible

Real Motions of the Heavenly Bodies.

possible it should move foremost, as it is that a torch moved swiftly through the air should project its flame and smoke before it. Since therefore we find that the tail of a comet, even when it is ascending from the sun, moves foremost, and appears in a direction nearly opposite to the sun, I think we must conclude that the comet and its tail do not move in a medium heavier and denser than the matter of which the tail consists, and consequently that the constant ascent of the tail from the sun must be owing to some other cause. For that the solar atmosphere should have density and weight sufficient to raise up the vapours of a comet from the sun, and yet not be able to give any sensible resistance to these vapours in their rapid progress through it, are two things inconsistent with each other: And therefore, since the tail of a comet is found to move as freely as the body does, we ought rather to conclude, that the celestial spaces are void of all resisting matter, than that they are filled with a solar atmosphere, be it ever so rare.

"But there is, I think, a further consideration, which will show that the received opinion, as to the ascent of comets tails, is not agreeable to the phenomena, and may at the same time lead us to some knowledge of the matter of which these tails consist; which I suspect is of a very different nature from what it has been hitherto supposed to be. Sir Isaac says, the vapours of which the tail of a comet consists, grow hot by reflecting the rays of the sun, and thereby warm and rarefy the medium which surrounds them; which must therefore ascend from the sun, and carry with it the reflecting particles of which the tail is formed; for he always speaks of the tail as shining by reflected light. But one would rather imagine, from the phenomena, that the matter which forms a comet's tail has not the least sensible power of reflecting the rays of light. For it appears from Sir Isaac's observation, which I have quoted already, that the light of the smallest stars, coming to us through the immense thickness of a comet's tail, does not suffer the least diminution. And yet, if the tail can reflect the light of the sun so copiously as it must do if its great splendour be owing to such reflection, it must undoubtedly have the same effect on the light of the stars; that is, it must reflect back the light which comes from the stars behind it, and by so doing must intercept them from our sight, considering its vast thickness, and how exceedingly slender a ray is that comes from a small star; or if it did not intercept their whole light, it must at least increase their twinkling. But we do not find that it has even this small effect; for those stars that appear through the tail are not observed to twinkle more than others in their neighbourhood. Since therefore this fact is supported by observations, what can be a plainer proof that the matter of a comet's tail has no power of reflecting the rays of light? and consequently, that it must be a self-shining substance. But the same thing will further appear, from considering that bodies reflect and refract light by one and the same power; and therefore if comets tails want the power of refracting the rays of light, they must also want the power of reflecting them. Now, that they want this refracting power appears from hence: If that great column of transparent matter which forms a comet's tail, and moves either in a vacuum or in some medium of a different density from its own, had any power of refracting a ray of light coming through it from a star to us, that ray must be turned far out of its way in passing over the great distance between the comet and the earth; and therefore we should very sensibly perceive the smallest refraction that the light of the stars might suffer in passing through a comet's tail. The consequence of such a refraction must be very remarkable: the stars that lie near the tail would, in some cases, appear double; for they would appear in their proper places by their direct rays, and we should see their images behind the tail, by means of their rays which it might refract to our eyes; and those stars that were really behind the tail would disappear in some situations, their rays being turned aside from us by refraction. In short, it is easy to imagine what strange alterations would be made in the apparent places of the fixed stars by the tails of comets, if they had a power of refracting their light, which could not fail to be taken notice of if any such ever happened. But since astronomers have not mentioned any such apparent changes of place among the stars, I take it for granted that the stars seen through all parts of a comet's tail appear in their proper places, and with their usual colours; and consequently I infer, that the rays of light suffer no refraction in passing through a comet's tail. And thence I conclude (as before), that the matter of a comet's tail has not the power of refracting or reflecting the rays of light, and must therefore be a lucid or self-shining substance."

316 Sir Isaac's account defended.

But whatever probability the Doctor's conjecture concerning the materials whereof the tails are formed may have in it, his criticism on Sir Isaac Newton's account of them seems not to be just: for that great philosopher supposes the comets to have an atmosphere peculiar to themselves; and consequently in their nearest approaches to the sun, both comet and atmosphere are immersed in the atmosphere of that luminary. In this case, the atmosphere of the comet being prodigiously heated on the side next to the sun, and consequently the equilibrium in it broken, the denser parts will continually pour in from the regions farthest from the sun; for the same reason, the more rarefied part which is before will continually fly off opposite to the sun, being displaced by that which comes from behind; for though we must suppose the comet and its atmosphere to be heated on all sides to an extreme degree, yet still that part which is farthest from the sun will be less hot, and consequently more dense, than what is nearest to his body. The consequence of this is, that there must be a constant stream of dense atmosphere descending towards the sun, and another stream of rarefied vapours and atmosphere ascending on the contrary side; just as in a common fire there is a constant stream of dense air ascending, which pushes up another of rarefied air, flame, and smoke. The resistance of a solar atmosphere may indeed be very well supposed to occasion the curvature observable in the tails of comets, and their being better defined in the fore part than behind; and this appearance we think Dr Hamilton's hypothesis is incapable of solving. We grant, that there is the utmost probability that the tails of comets are streams of electric matter; but they who advance a theory of any kind ought to solve every phenomenon, otherwise their theory is insufficient. It was incumbent

317 Dr Hamilton's hypothesis insufficient.

Digitized by Google

cumbent on Dr Hamilton, therefore to have explained how this stream of electric matter comes to be bent into a curve; and also why it is better defined and brighter on the outer side of the arch than on the inner. This indeed he attempts in the following manner: "But that this curvature was not owing to any resisting matter appears from hence, that the tail must be bent into a curve, though it met with no resistance; for it could not be a right line, unless all its particles were projected in parallel directions, and with the same velocity, and unless the comet moved uniformly in a right line. But the comet moves in a curve, and each part of the tail is projected in a direction opposite to the sun, and at the same time partakes of the motion of the comet; so that the different parts of the tail must move on in lines which diverge from each other; and a line drawn from the head of a comet to the extremity of the tail, will be parallel to a line drawn from the sun to the place where the comet was when that part of the tail began to ascend, as Sir Isaac observes: and so all the chords or lines drawn from the head of the comet to the intermediate parts of the tail, will be respectively parallel to lines drawn from the sun to the places where the comet was when these parts of the tail began to ascend. And, therefore, since these chords of the tail will be of different lengths, and parallel to different lines, they must make different angles with a great circle passing through the sun and comet; and consequently a line passing through their extremities will be a curve.

"It is observed, that the convex side of the tail which is turned from the sun is better defined, and shines a little brighter, than the concave side. Sir Isaac accounts for this, by saying, that the vapour on the convex side is fresher (that is, has ascended later) than that on the concave side; and yet I cannot see how the particles on the convex side can be thought to have ascended later than those on the concave side which may be nearer to the head of the comet. I think it rather looks as if the tail, in its rapid motion, met with some slight resistance just sufficient to cause a small condensation in that side of it which moves foremost, and which would occasion it to appear a little brighter and better defined than the other side; which slight resistance may arise from that subtile ether which is supposed to be dispersed through the celestial regions, or from this very electric matter dispersed in the same manner, if it be different from the ether."

On the last part of this observation we must remark, that though a slight resistance in the ethereal medium would have served Sir Isaac Newton's turn, it will by no means serve Dr Hamilton's; for though a stream of water or air may be easily destroyed or broken by resistance, yet a stream of electric matter seems to set every obstacle at defiance. If a sharp needle is placed on the conductor of an electric machine, and the machine set in motion, we will perceive a small stream of electric matter issuing from the point; but though we blow against this stream of fire with the utmost violence, it is impossible either to move it, or to brighten it on the side against which we blow. If the celestial spaces then are full of a subtile ether capable of thus affecting a stream of electric matter, we may be sure that it also will resist very violently: and we are then as much difficulted to account for the projectile motion continuing amidst such violent resistance; for if the ether resists the tail of the comet, it is impossible to prove that it doth not resist the head also.

Real Motions of the Heavenly Bodies.

318 Electric matter not always passive.

This objection may appear to some to be but weakly founded, as we perceive the electric fluid to be endowed with such extreme subtility, and to yield to the impression of solid bodies with such facility, that we easily imagine it to be of a very passive nature in all cases. But it is certain, that this fluid only shows itself passive where it passes from one body into another, which it seems very much inclined to do of itself. It will also be found, on proper examination of all the phenomena, that the only way we can manage the electric fluid at all is by allowing it to direct its own motions. In all cases where we ourselves attempt to assume the government of it, it shows itself the most untractable and stubborn being in nature. But these things come more properly under the article ELECTRICITY, where they are fully considered. Here it is sufficient to observe, that a stream of electric matter resists air, and from the phenomena of electric repulsion we are sure that one stream of electric matter resists another: from which we may be also certain, that if a stream of electric matter moves in an aerial fluid, such fluid will resist it; and we can only judge of the degree of resistance it meets with in the heavens from what we observe on earth. Here we see the most violent blast of air has no effect upon a stream of electric fluid: in the celestial regions, either air or some other fluid has an effect upon it according to Dr Hamilton. The resistance of that fluid, therefore, must be greater than that of the most violent blast of air we can imagine.

As to the Doctor's method of accounting for the curvature of the comet's tail, it might do very well on Sir Isaac Newton's principles, but cannot do so on his. There is no comparison between the celerity with which rarefied vapour ascends in our atmosphere, and that whereby the electric fluid is discharged. The velocity of the latter seems to equal that of light; of consequence, supposing the velocity of the comet to be equal to that of the earth in its annual course, and its tail equal in length to the distance of the sun from the earth, the curvature of the tail could only be to a straight line as the velocity of the comet in its orbit is to the velocity of light, which according to the calculations of Dr Bradley, is as 10,201 to 1. The apparent curvature of such a comet's tail, therefore, would at this rate only be $\frac{1}{10201}$ part of its visible length, and this would always be imperceptible to us. The velocity of comets is indeed sometimes inconceivably great. 319 Prodigious velocity of a comet observed by Mr Brydone.
Mr Brydone observed one at Palermo, in July 1770, which in 24 hours described an arch in the heavens upwards of 50 degrees in length; according to which he supposes, that if it was as far distant as the sun, it must have moved at the rate of upwards of 60 millions of miles in a day. But this comet was attended with no tail, so that we cannot be certain whether the curvature of the tails of these bodies corresponds with their velocity or not.

320 Vehement heat of the comet of 1680.

The near approach of some comets to the sun subjects them to intense and inconceivable degrees of heat. Newton calculated that the heat of the comet of 1680 must have been near 2000 times as great as that of red-hot iron. The calculation is founded upon this principle,

Digitized by Google

Real Motions of the Heavenly Bodies.

principle, that the heat of the sun falling upon any body at different distances is reciprocally as the squares of those distances; but it may be observed, that the effect of the heat of the sun upon all bodies near our earth depends very much on the constitution of those bodies, and of the air that surrounds them. "The comet in question (says Dr Long) certainly acquired a prodigious heat: but I cannot think it came up to what the calculation makes it: the effect of the strongest burning-glass that has ever been made use of was the vitrification of most bodies placed in its focus. What would be the effect of a still greater heat we can only conjecture; it would perhaps so disunite the parts as to make them fly off every way in atoms. This comet, according to Halley, in passing through its southern node, came within the length of the sun's semidiameter of the orbit of the earth. Had the earth then been in the part of her orbit nearest to that node, their mutual gravitation must have caused a change in the plane of the orbit of the earth, and in the length of our year: he adds, that if so large a body, with so rapid a motion as that of this comet, were to strike against the earth, a thing by no means impossible, the shock might reduce this beautiful frame to its original chaos."

We must not conclude this account without observing that Whiston, who, from Flamstead's measure of its apparent diameter, concluded the nucleus of the comet to be about ten times as big as the moon, or equal to a fourth part of the earth, attributes the universal deluge in the time of Noah to the near approach thereof. His opinion was, that the earth passing through the atmosphere of the comet, attracted therefrom great part of the water of the flood; that the nearness of the comet raised a great tide in the subterraneous waters, so that the outer crust of the earth was changed from a spherical to an oval figure; that this could not be done without making fissures and cracks in it, through which the waters forced themselves, by the hollow of the earth being changed into a less capacious form; that along with the water thus squeezed up on the surface of the earth, much slime or mud would rise; which, together with the grosser part of the comet's atmosphere, would, after the subsiding of the water, partly into the fissures and partly into the lower parts of the earth to form the sea, cover all over, to a considerable depth, the antediluvian earth. Thus he accounts for trees and bones of animals being found at a very great depth in the earth. He also held that, before the fall, the earth revolved round the sun in the plane of the ecliptic, keeping always the same points of its surface towards the same fixed stars. By this means, as every meridian would come to the sun but once in every revolution, a day and a year were then the same: but that a comet striking obliquely upon some part of the earth gave it the diurnal rotation: that the antediluvian year consisted of 360 days: but that the additional matter deposited upon the earth from the atmosphere of the comet at the flood, so retarded the revolution thereof round the sun, that it is not now performed in less than 365 days and about a quarter. The same comet he thought would probably, coming near the earth when heated in an intense degree in its perihelion, be the instrumental cause of that great catastrophe, the general conflagration, foretold in the sacred writings and from ancient tradition.

These conjectures lead us to speak somewhat more particularly concerning the nature of comets, and the purposes they may possibly answer in the creation. Hevelius, in order to account for the various appearances of the nucleus already related, supposed that they were composed of several masses compacted together, with a transparent fluid interspersed, but the apparent changes in the nucleus may be only on the surface: comets may be subject to spots as the planets are; and the vastly different degrees of heat they go through may occasion great and sudden changes, not only in their surfaces, but even in their internal frame and texture. Newton places all these apparent changes to the atmosphere that environs them; which must be very dense near their surfaces, and have clouds floating therein. It was his opinion, that the changes mentioned may all be in the clouds, not in the nucleus. This last indeed he looked upon to be a body of extreme solidity, in order to sustain such an intense heat as the comets are sometimes destined to undergo; and that, notwithstanding their running out into the immense regions of space, where they were exposed to the most intense degrees of cold, they would hardly be cooled again on their return to the sun. Indeed, according to his calculation, the comet of 1680 must be for ever in a state of violent ignition. He hath computed that a globe of red-hot iron of the same dimensions with the earth, would scarce be cool in 50,000 years. If then the comet be supposed to cool 100 times faster than red-hot iron, as its heat was 2000 times greater, it must require upwards of a million of years to cool it. In the short period of 575 years, therefore, its heat will be in a manner scarce diminished; and, of consequence, in its next and every succeeding revolution, it must acquire an increase of heat: so that, since the creation, having received a proportional addition in every succeeding revolution, it must now be in a state of ignition very little inferior to that of the sun itself. Sir Isaac Newton hath farther concluded, that this comet must be considerably retarded in every succeeding revolution by the atmosphere of the sun within which it enters; and thus must continually come nearer and nearer his body, till at last it falls into it. This, he thinks, may be one use of the comets, to furnish fuel for the sun, which otherwise would be in danger of wasting from the continual emission of its light.

221 Conjectures of Hevelius, &c. concerning the nature of comets.

He adds, that for the conservation of the water and moisture of the planets, comets seem absolutely requisite; from whose condensed vapours and exhalation all the moisture which is spent in vegetation and putrefaction, and turned into dry earth, &c. may be resupplied and recruited; for all vegetables grow and increase wholly from fluids; and again, as to their greatest part, turn by putrefaction into earth; an earthy slime being perpetually precipitated to the bottom of putrefying liquors. Hence the quantity of dry earth must continually increase, and the moisture of the globe decrease, and be quite evaporated, if it have not a continual supply from some part or other of the universe. "And I suspect (adds our great author), that the spirit which makes the finest, subtilest, and best

Digitized by Google

Real Motions of the Heavenly Bodies.

part of our air, and which is absolutely requisite for the life and being of all things, comes principally from the comets."

322 Mr Brydone's conjectures concerning comets without tails.

Mr Brydone observes, that the comets without tails seem to be of a very different species from those which have tails: To the latter, he says, they appear to bear a much less resemblance than they do even to planets. He tells us, that comets with tails have seldom been visible but on their recess from the sun: that they are kindled up, and receive their alarming appearance, in their near approach to this glorious luminary; but that those without tails are seldom or ever seen but on their way to the sun; and he does not recollect any whose return has been tolerably well ascertained. "I remember indeed (says he), a few years ago, a small one, that was said to have been discovered by a telescope after it had passed the sun, but never more became visible to the naked eye. This assertion is easily made, and nobody can contradict it; but it does not at all appear probable that it should have been so much less luminous after it had passed the sun than before it approached him: and I will own to you, when I have heard that the return of these comets had escaped the eyes of the most acute astronomers, I have been tempted to think that they did not return at all, but were absorbed in the body of the sun, which their violent motion towards him seemed to indicate." He then attempts to account for the continual emission of the sun's light without waste, by supposing that there are numberless bodies throughout the universe that are attracted into the body of the sun, which serve to supply the waste of light, and which for some time remain obscure and occasion spots on his surface, till at last they are perfectly dissolved and become bright like the rest. This hypothesis may account for the dark spots becoming as bright, or even brighter than the rest of the disk, but will by no means account for the brighter spots becoming dark. Of this comet, too, Mr Brydone remarks, that it was evidently surrounded by an atmosphere which refracted the light of the fixed stars, and seemed to cause them to change their places as the comet came near them.

323 Mr Cole's hypothesis.

A very strange opinion we find set forth in a book entitled "Observations and Conjectures on the Nature and Properties of Light, and on the Theory of Comets, by William Cole." This gentleman supposes that the comets belong to no particular system; but were originally projected in such directions, as would successively expose them to the attraction of different centres, and thus they would describe various curves of the parabolic and the hyperbolic kind. This treatise is written in answer to some objections thrown out in Mr Brydone's Tour, against the motions of the comets by means of the two forces of gravitation and projection, which were thought sufficient for that purpose by Sir Isaac Newton: of which we shall treat as fully as our limits will allow in the next section.

324 Of the periodical times, &c. of the comets.

The analogy between the periodical times of the planets and their distances from the sun, discovered by Kepler, takes place also in the comets. In consequence of this, the mean distance of a comet from the sun may be found by comparing its period with the time of the earth's revolution round the sun. Thus the period of the comet that appeared in 1531, 1607, 1682, and 1759, being about 76 years, its mean distance from the sun may be found by this proportion: As 1, the square of one year, the earth's periodical time, is to 5776 the square of 76, the comet's periodical time; so is 1,000,000 the cube of 100 the earth's mean distance from the sun, to 5,776,000,000 the cube of the comet's mean distance. The cube root of this last number is 1794; the mean distance itself in such parts as the mean distance of the earth from the sun contains 100. If the perihelion distance of this comet, 58 be taken from 3588 double the mean distance, we shall have the aphelion distance, 3530 of such parts as the distance of the earth contains 100; which is a little more than 35 times the distance of the earth from the sun. By a like method, the aphelion distance of the comet of 1680 comes out 138 times the mean distance of the earth from the sun, supposing its period to be 575 years: so that this comet, in its aphelion, goes more than 14 times the distance from the sun that Saturn does. Euler computes the orbit of this comet from three of Flamstead's observations taken near together, compared with a fourth taken at some distance from the other three, and from thence concludes the period to be a little more than 170 years. "It seems something surprising (says Dr Long), that, from the same observations which were used by Newton and Halley, he should bring out a period so very different from what these great men have determined: but it is the less to be wondered at, if we consider how small a portion of the comet's orbit lay between the most distant places used in this computation, or indeed that could be had for that purpose; so small, that the form of the ellipsis cannot be found with precision by this method, except the comet's places were more exactly verified than is possible to be done: and that he does not pretend to confirm his determination of the period by pointing out and comparing together any former appearances of this comet; a method which Newton recommended as the only one whereby the periodical times and transverse diameters of the orbits of the comets can be determined with accuracy."

The period of the comet in 1744 is much longer than even that of 1680. Mr Betts, in attempting to compute the transverse axis of its orbit, found it come out so near infinite, that, though the orbit showed itself in this manner to be a very long one, he found it impossible to calculate it without some observations made after its perihelion. Halley, after he had finished his 325 Dr Halley calculates the return of comets.
tables of comets, found such a similitude in the elements of those of 1531, 1607, and 1682, that he was induced to believe them to be returns of the same comet in an elliptic orbit: but as there was such a difference in their periodical times and inclinations of their orbits as seemed to make against this opinion; and as the observations of the first of them in 1531 by Appian, and the second in 1607 by Kepler, were not exact enough to determine so nice a point when he first published his synopsis in 1705; he only mentioned this as a thing probable, and recommended it to posterity to watch for an appearance of the same in 1758. Afterwards, looking over the catalogue of ancient comets, and finding three others at equal instruments with those now mentioned, he grew more positive in his opinion; and knowing a method of calculating with ease a motion in an elliptic orbit, how eccentric soever it might be, instead of the parabolic orbit which he had given

2

Real Motions of the Heavenly Bodies.

given for the comet of 1682, he set about adapting the plan of that orbit to an ellipsis of a given space and magnitude, having the sun in one of its foci, so as to tally with the observations of that comet made by Flamstead with great accuracy, by the help of a very large sextant. He likewise corrected the places of the comet of 1531 from Appian, and those of the comet 1607 from Kepler and Longomontanus, by rectifying the places of the stars they had made use of, and found those places agree as well with the motion in such an ellipsis as could be expected from the manner of observing of these astronomers, and the imperfections of their instruments. The greatest objection to this theory was some difference in the inclination of the orbits, and that there was above a year's difference between the two periods. The comet of 1531 was in its perihelion August 24.; that of 1607, October 16, and that of 1682, September 4.: so that the first of these periods was more than 76, the latter not quite 75 years. To obviate this, he reminds his readers of an observation made by him of the periodical revolution of Saturn having at one time been about 13 days longer than at another time; occasioned, as he supposed, by the near approach of Saturn and Jupiter, and the mutual attraction and gravitation of these two planets: and observes, that in the summer of the year 1681, the comet in its descent was for some time so near Jupiter, that its gravitation towards that planet was one-fiftieth part of its gravitation towards the sun. This, he concluded, would cause a change in the inclination of its orbit, and also in the velocity of its motion: for by continuing longer near the planet Jupiter on the side most remote from the sun, its velocity would be more increased by the joint forces of both those bodies, than it would be diminished by them acting contrarywise, when on the side next the sun where its motion was swiftest. The projectile motion being thus increased, its orbit would be enlarged, and its period lengthened; so that he thought it probable it would not return till after a longer period than 76 years, about the end of the year 1758, or beginning of 1759.

316 Why the periodical return of comets may happen at unequal intervals.

As Halley expressed his opinion modestly, though clearly enough, that this comet would appear again about the end of 1758, or the beginning of the following year, M. de la Lande pretends he must have been at a loss to know whether the period he foretold would have been of 75 or of 76 years; that he did not give a decisive prediction, as if it had been the result of calculation; and that, by considering the affair in so loose a manner as Halley did, there was a good deal of room for objecting to his reasoning. After these reflections, he is very large in his commendation of the performance of Clairault; who, he says, not only calculated strictly the effect of the attraction of Jupiter in 1681 and 1683, when the comet was again near Jupiter, but did not neglect the attraction of that planet when the comet was most distant; that he considered the uninterrupted attractions of Jupiter and Saturn upon the sun and upon the comet, but chiefly the attractions of Jupiter upon the sun, whereby that luminary was a little displaced, and gave different elements to the orbit of the comet. By this method he found the comet would be in its perihelion about the middle of April; but that, on account of some small quantities necessarily neglected in the method of approximation made use of by him, Mr Clairault desired to be indulged one month; and that the comet came just 30 days before the time he had fixed for its appearance.

That comets may have their motion disturbed by the planets, especially by the two largest, Jupiter and Saturn, appears by an instance just now mentioned. They may also affect one another by their mutual gravitation when out of the planetary regions; but of this we can take no account, nor can we estimate the resistance of the ether through which they pass; and yet both these causes may have some influence on the inclination of their orbits and the length of their periods.

Chap. V. *Of the Motions of the Satellites.*

THE moon is the satellite which moves round the earth, and as her apparent and real motions are the same, we have already given an account of her elliptical orbit and irregularities.

Jupiter is attended by four satellites. If we represent the semidiameters of Jupiter's equator by unity, then the mean distances of the satellites from Jupiter, will be represented by the following numbers.

327 Orbits and distances of Jupiter's satellites.

First satellite	5.697300 semidiameters.
Second satellite	9.065898
Third satellite	14.461628
Fourth satellite	25.436000

The durations of their revolutions are respectively,

First satellite	1.769137787069931 days.
Second satellite	3.551181016734509
Third satellite	7.154552807541524
Fourth satellite	16.689019396008634

If we compare the distances of these satellites with their periodic times, we observe the same relation pointed out by Kepler between the distances of the planets from the sun and the duration of their revolutions: for the squares of the periodic times of the satellites are proportional to the cubes of their distance from Jupiter's centre.

The frequent eclipses of these satellites have enabled astronomers to ascertain their motion, with much more precision than could have been attained merely by observing their distances from Jupiter. The following points have been ascertained.

The orbit of the first satellite is circular, at least its eccentricity is insensible; it coincides nearly with Jupiter's equator, which is inclined to the orbit of the planet at an angle of 3.9999°.

The ellipticity of the orbit of the second satellite is also insensible; its inclination to Jupiter's orbit varies, as does also the position of its nodes. These irregularities are represented pretty well, by supposing the inclination of the orbit to the equator of Jupiter 1750.968", and that its nodes move retrograde in that plane in a period of 30 years. 328 Irregularities in their motions.

A small eccentricity is observed in the orbit of the third satellite. The extremity of its longer axis next Jupiter, called the *perijove*, has a direct motion. The eccentricity of the orbit has been observed to vary considerably. The equation of the centre was at its maximum about the end of the 17th century; it then amounted

mounted to about 862″; it gradually diminished, and in the year 1775 it was at its minimum, and amounted only to about 229.7″. The inclination of the orbit of this satellite to that of Jupiter, and the position of its nodes, are variable. These different variations are represented pretty nearly, by supposing the orbit inclined to that of Jupiter, at an angle of about 726″, and giving to the nodes a retrograde motion in the plane of the equator, completed in the period of 137 years.

The orbit of the fourth satellite is very sensibly elliptical. Its perijove has a direct motion, amounting to about 2112″. This orbit is inclined to that of Jupiter, at an angle of about 147′. It is in consequence of this inclination, that the fourth satellite often passes behind the planet relatively to the sun without being eclipsed. From the first discovery of this planet, till the year 1760, the inclination of its orbit appeared constant: but it has sensibly increased since that period.

Besides all these variations, the satellites of Jupiter are subjected to several irregularities, which disturb their elliptical motion, and render their theory very complicated. These irregularities are most conspicuous in the three first satellites.

Their mean motions are such, that the mean motion of the first satellite, together with twice the mean motion of the third, is nearly equal to thrice the mean motion of the second. The same relation holds in their synodical motions. The mean longitude both synodical and sidereal of the first three satellites, seen from the centre of Jupiter, is such that the longitude of the first, minus thrice that of the second, plus twice that of the third, is nearly equal to the semicircumference. This relation is so very near the truth, that one is tempted to consider it as rigorous, and to ascribe the supposed errors to the imperfection of observations. It will hold at least for a long time to come, and shews us that the three satellites cannot be eclipsed at once.

The periods and laws of the principal irregularities of these satellites are the same in all. The irregularity of the first advances or retards its eclipses 20″ of time at its maximum. If we compare the changes on this inequality, with the relative positions of the two first satellites, we find that it disappears when these two satellites, seen from the centre of Jupiter, are in opposition at the same time; that it increases gradually, and acquires its maximum when the first satellite, at the instant of opposition, is 45° more advanced than the second; that it vanishes when the first is 90° before the second. Beyond that point it becomes negative and retards the eclipses, and increases till the two satellites are 135 degrees from each other, when it acquires its negative maximum. Then it diminishes and disappears when they are 180° distant. In the second half of the circumference the very same laws are observed as in the first. From these phenomena it has been concluded, that there exists in the motion of the first satellite round Jupiter, an inequality amounting to 1733.6″ at its maximum, and proportional to the sine of twice the excess of the mean longitude of the first satellite above that of the second; which excess is equal to the difference between the mean synodical longitudes of the two satellites. The period of this inequality does not amount to 4 days. How comes it then, it will be asked, to change into a period of 437.75 days, with respect to the eclipses of the first satellite? Let us suppose, that the first and second satellites set out together from their mean opposition to the sun. During every revolution of the first satellite, in consequence of its mean synodical motion, it will be in mean opposition. Suppose a fictitious star, whose angular motion is owing to the excess of the mean synodical motion of the first satellite, over that of the second, then twice the difference of the mean synodical motions of the two satellites will in the eclipses of the first be equal to a multiple of the circumference together with the motion of the fictitious star. Of course the sine of this last motion will be proportional to the inequality of the first satellite in its eclipses, and may represent that inequality. Its period is equal to the duration of the revolution of the fictitious star, which according to the mean motion of the two satellites is 437.75 days. Thus it is determined with more precision than by direct observation.

The irregularity of the second satellite follows a law similar to that of the first; but its sign is always contrary. It accelerates or retards the eclipses 932″ in time when at its maximum. When compared with the position of the two satellites, we perceive that it disappears when they are in opposition to the sun at the same time: that it retards the time of the eclipses more and more, till the two satellites are distant from each other 90° at the time when they take place; then the retardation diminishes and vanishes altogether, when the two satellites are 180° from each other at the time of the eclipses. It then accelerates the eclipses in the other half of the circumference precisely as it had retarded them before. From these observations it has been concluded that there exists in the motion of the second satellite an irregularity of 3647″ at its maximum proportional, (*but with a contrary sign*) to the sign of the excess of the mean longitude of the first satellite above that of the second, which excess is equal to the difference of the mean synodical motions of the two satellites.

If the two satellites set out together from their mean opposition to the sun; the second satellite will be in mean opposition every time that it completes a synodical revolution. If we suppose, as before, a star whose angular motion is equal to the excess of the mean synodical movement of the first satellite, or twice that of the second, then the difference of the two synodical movements of the two satellites will, at the eclipses of the second, equal a multiple of the circumference together with the motion of the fictitious star. Of course the inequality of the second during its eclipse will be proportional to the sine of the angular motion of that fictitious star. Hence the reason that the period and law of that irregularity are the same as in the irregularity of the first satellite.

If the third satellite produces in the motion of the second an inequality resembling that which the second seems to produce in the motion of the first, that is to say, proportional to the sine of twice the difference of the mean longitudes of the second and third satellite; that new inequality will coincide with that which is due to the first satellite. For in consequence of the relation which the mean longitude of the three first satellites have to each other, the difference of the mean longitudes of the two first satellites is equal to the semicircumference

Digitized by Google

cumference together with twice the difference of the mean longitudes of the second and third satellites, so that the sine of the first difference is the same as the sine of double the second difference, but with a contrary sign. The inequality produced by the third satellite in the motion of the second, will therefore have the same sign, and will follow the same law as the inequality observed in that motion. It is, therefore, very probable that this inequality is the result of two inequalities depending on the first and third satellite. If in the course of ages, the preceding relation between the mean longitudes of these three satellites should cease to exist, these two inequalities, at present compounded, would separate, and their respective values might be discovered.

The inequality relative to the third satellite in its eclipses, compared with the respective positions of the second and third, offers the same relations with the inequality of the second compared with the respective situations of the two first. There exists then in the motion of the third satellite, an inequality which at its maximum amounts to 268″. If we suppose a star whose angular motion is equal to the excess of the mean synodical motion of the second satellite, above twice the mean synodical motion of the third, the inequality of the third satellite will in its eclipses be proportional to the motion of this fictitious star. But in consequence of the relation which exists between the mean longitude of the three satellites, the sine of this motion is the same (except its sign), with that of the motion of the first fictitious star which we formerly considered. Therefore the inequality of the third satellite in its eclipses has the same period, and follows the same laws, with the inequalities of the two first satellites: such are the laws of the principal irregularities of the three first satellites of Jupiter.

329 **Satellites of Saturn.**

Let us now consider the satellites of Saturn, which are seven in number. The satellites of Saturn have not as yet proved so useful to astronomy or geography as those of Jupiter; principally because they cannot be seen unless very powerful telescopes be used. Five of those satellites were discovered in the year 1685, by Cassini and Huygens, who used telescopes consisting of two simple lenses, but upwards of 100 feet in length; and those were called 1st, 2d, 3d, &c. reckoning from the planet. Two others were discovered by Dr Herschel in the years 1787 and 1788, and these are smaller and nearer to the planet, on which account they ought to have been called the first and second, at the same time that the other five ought to have been called 3d, 4th, 5th, 6th, and 7th; but, imagining that this might create some confusion in the reading of old astronomical books, the five old satellites have been suffered to retain their numerical names, and the two new satellites are now called the 6th and the 7th; so that the 7th is the nearest to the planet, then comes the 6th, then the 1st; and this is followed by the 2d, 3d, 4th, and 5th.

The inclinations of the orbits of the 1st, 2d, 3d, and 4th satellites, to the ecliptic, are from 30° to 31°. That of the 5th is from 17° to 18°. Of all the satellites of the solar system, none, except the 5th of Saturn, has been observed to have any spots, from the motion of which the rotation of the satellite round its own axis might be determined. Then the 5th satellite of Saturn, as Dr Herschel has discovered, turns round its own axis; and it is remarkable, that, like our moon, it revolves round its axis exactly in the same time that it revolves round its primary.

The following table states the particulars which have been ascertained with respect to the satellites of Saturn.

The SATELLITES of SATURN.

Satellites.	Periods.				Dist. in semi-dia. of Saturn.	Dist. in miles.	App. diam. of orbits.	
	d.	h.	m.	s.			′	″
Seventh	0	22	40	46	$2\frac{5}{6}$	107,000	0	57
Sixth	1	8	53	9	$3\frac{5}{9}$	135,000	1	14
First	1	21	18	27	$4\frac{3}{8}$	170,000	1	27
Second	2	17	41	22	$5\frac{1}{8}$	217,000	1	52
Third	4	12	25	12	8	303,000	2	36
Fourth	15	22	41	13	18	704,000	6	18
Fifth	79	7	48	0	54	2,050,000	17	4

330 **Satellites of Herschel.**

The planet Herschel, with its six satellites, have been entirely discovered by Dr Herschel. The planet itself may be seen with almost any telescope; but its satellites cannot be perceived without the most powerful instruments, and the concurrence of all other favourable circumstances. One of these satellites Dr Herschel found to revolve round its primary in 8d. 17h. 1m. 19 sec.; the period of another he found to be 13d. 11h. 5m. 1.5 sec. The apparent distance of the former from the planet is 33″; that of the second 44″$\frac{2}{9}$. Their orbits are nearly perpendicular to the plane of the ecliptic.

The other four satellites were discovered a considerable time after, and of course Dr Herschel has had less time to make observations upon them. They are altogether very minute objects; so that the following particulars must be considered as being not accurate but probable. "Admitting the distance of the interior satellite to be 25″.5, its periodical revolution will be 5d. 21h. 25m.

"If the intermediate satellite be placed at an equal distance between the two old satellites, or at 38″.57, its period will be 10d. 23h. 4m. The nearest exterior satellite is about double the distance of the farthest old one; its periodical time will therefore be about 38d. 1h. 49m. The most distant satellite is full four times as far from the planet as the old second satellite; it will therefore take at least 107d. 16h. 14m. to complete one revolution. All these satellites perform their revolutions in their orbits contrary to the order of the signs; that is, their real motion is retrograde."

Theory of Universal Gravitation.

PART IV. OF THE THEORY OF UNIVERSAL GRAVITATION.

HAVING in the last two parts of this treatise given an account of the apparent and real motions of the heavenly bodies, it only remains for us to compare these motions with the laws established by mathematicians, in order to ascertain the forces that animate the solar system, and to acquire notions of the general principle of gravitation on which they depend. To develope this part of the subject properly, three particulars claim our attention. We must in the first place lay down the laws of motion as established by mathematicians; in the second place, we must apply these laws to the heavenly bodies, which will furnish us with the theory of gravitation; and, in the third place, we must apply this theory to the planetary system, and demonstrate that the whole motions of the heavenly bodies are explicable by that theory, and merely cases of it. These particulars shall be the subject of the three following chapters.

CHAP. I. *Of the Laws of Motion.*

THE laws of motion, by which all matter is regulated, and to which it is subject notwithstanding the variety of phenomena which it continually exhibits, constitute the first principles of mechanical philosophy. They will claim a separate place hereafter in this work, under the title of DYNAMICS; but some notions of them are requisite in order to understand the theory of gravitation. We shall satisfy ourselves in this place with the following short sketch.

331 Motion. A body appears to us to *move* when it changes its situation with respect to other bodies which we consider as at rest. Thus in a vessel sailing down a river, bodies are said to be in motion when they correspond successively to different parts of the vessel. But this motion is merely relative. The vessel itself is moving along the surface of the river, which turns round the axis of the earth, while the centre of the earth itself is carried round the sun, and the sun with all its attendant planets is moving through space. This renders it necessary to refer the motion of a body to the parts of *space*, which is considered as boundless, immoveable, and penetrable. A body then is said to be in motion when it corresponds successively to different parts of space.

332 Moving forces. Matter, as far as we know, is equally indifferent to motion or rest. When in motion it moves for ever unless stopt by some cause, and when at rest it remains so, unless put in motion by some cause. The cause which puts matter in motion is called a *force*. The *nature* of *moving forces* is altogether unknown, but we can measure their effects.

333 Composition of forces. Whenever a force acts upon matter it puts it in motion, if no other force prevent this effect; the straight line which the body describes, is called the *direction* of the force. Two forces may act upon matter at the same time. If their direction be the same, they increase the motion; if their direction be opposite they destroy each other; and the motion is nothing if the two forces be equal; it is merely the excess of the one force above the other if the motions be unequal. If the directions of the two forces make with each other any angle whatever, the resulting motion will be in a direction between the two. And it has been demonstrated, that if lines be taken to represent the direction and amount of the forces, if these lines be converted into a parallelogram by drawing parallels to them; the diagonal of that parallelogram will represent the direction and quantity of the resulting motion. This is called the composition of forces.

For two forces thus acting together, we may substitute their result, and *vice versa*. Hence we may decompose a force into two others, parallel to two axes situated in the same plane, and perpendicular to each other.

Thus finding that a body A, fig. 117. has moved from A to C, we may imagine either that the body has been impelled by a single force in the direction of AC, and proportionate to the length of AC, or that it has been impelled by two forces at once, viz. by one in the direction of AD, and proportionate to the length of AD; and by another force in the direction of AB or DC, and proportionate to AB or DC. Therefore, if two sides of any triangle (as AD and DC) represent both the quantities and the directions of two forces acting from a given point, then the third side (as AC) of the triangle will represent both the quantity and the direction of a third force, which acting from the same point, will be equivalent to the other two, and *vice versa*.

Thus also in fig. 118. finding that the body A has moved along the line AF from A to F in a certain time; we may imagine, 1st, that the body has been impelled by a single force in the direction and quantity represented by AF; or 2dly, that it has been impelled by two forces, viz. the one represented by AD, and the other represented by AE; or thirdly, that it has been impelled by three forces, viz. those represented by AD, AB, and AC; or lastly, that it has been impelled by any other number of forces in any directions; provided all these forces be equivalent to the single force which is represented by AF.

This supposition of a body having been impelled by two or more forces to perform a certain course; or, on the contrary, the supposition that a body has been impelled by a single force, when the body is actually known to have been impelled by several forces, which are, however, equivalent to that single force; has been called the composition and resolution of forces.

The knowledge of these principles gives mathematicians an easy method of obtaining the result of any number of forces whatever acting on a body. For every particular force may be resolved into three others, parallel to three axes given in position, and perpendicular to each other. It is obvious, that all the forces parallel to the same axis are equivalent to a single force, equal to the sum of all those which act in one direction, diminished by the sum of those which act 334 Resolution of forces.

Theory of Universal Gravitation.

act in the opposite direction. Thus the body will be acted on by three forces perpendicular to each other: if the direction of these forces be represented by the sides of a parallelopiped, the resulting force will be represented by the diagonal of that parallelopiped.

The indifference of a material body to motion or rest, and its perseverance in either state when put into it, is called the *vis inertiæ* of matter. This property is considered as the first law of motion. Hence, whenever the state of a body changes, we ascribe the change to the action of some cause: hence the motion of a body when not altered by the action of some new force, must be uniform and in a straight line.

335 Velocity.

In such uniform motions the space passed over is proportional to the time: but the time employed to describe a given space will be longer or shorter according to the greatness of the moving force. This difference in the time of traversing the same space gives us the notion of *velocity*, which in uniform motions is the ratio between the space and the time employed in traversing it. As space and time are heterogeneous quantities, they cannot indeed be compared together; it is the ratio between the numbers representing each that constitutes velocity. A unity of time, a second for instance, is chosen, and in like manner a unity of space, as a foot. Thus, if one body move over 20 feet in one second, and another only 10, then the velocity of the first is double that of the second; for the ratio between 20 and 1 is twice as great as the ratio of 10 to 1. When the space, time, and velocity, are represented by numbers, we have the space equal to the velocity multiplied by the time, and the time equal to the space divided by the time.

The force by which a body is moved is proportional to the velocity, and therefore is measured by the velocity. This has been disputed by some philosophers, but has been sufficiently established. We shall consider it, therefore, as a matter of fact, referring the reader for a discussion of the subject to the article DYNAMICS.

336 Accelerating forces.

When a body is put in motion by forces which not only act at first, but which continue to act uniformly, it will describe a curve line, the nature of which depends upon the forces which occasion the motion. *Gravitation* is an instance of a force which acts in this manner. Let us consider it a little. It appears to act in the same manner in a body at rest and in motion. A body abandoned to its action acquires a very small velocity the first instant; the second instant it acquires a new velocity equal to what it had the first instant; and thus its velocity increases every instant in proportion to the time. Suppose a right-angled triangle, one of the sides of which represents the time, and the other the velocity. The fluxion of the surface of the triangle being equal to the fluxion of the time multiplied by that of the velocity, will represent the fluxion of the space. Hence the whole triangle will represent the space described in a given time. But the triangle increasing as the square of either of its sides, it is obvious, that in the accelerated motion produced by gravitation, the velocities increase with the times, and the heights from which a body falls from rest increase as the squares of the times or of the velocities. Hence, if we denote by 1 the space through which a body falls the first second, it will fall 4 in 2″, 9 in 3″, and so on; so that every second it will describe spaces increasing as the odd numbers 1, 3, 5, 7, &c. This important point will perhaps be rendered more intelligible by the following diagram.

Let AB, fig. 119. represent the time during which a body is descending, and let BC represent the velocity acquired at the end of that time. Complete the triangle ABC, and the parallelogram ABCD. Also suppose the time to be divided into innumerable particles *ei*, *im*, *mp*, *po*, &c. and draw *ef*, *ik*, *mn*, &c. all parallel to the base BC. Then, since the velocity of the descending body has been gradually increasing from the commencement of the motion, and BC represents the ultimate velocity; therefore the parallel lines *ef*, *ik*, *mn*, &c. will represent the velocities at the ends of the respective times A*e*, A*i*, A*m*, &c. Moreover, since the velocity during an indefinitely small particle of time may be considered as uniform; therefore the right line *ef* will be as the velocity of the body in the indefinitely small particle of time *ei*; *ik* will be as the velocity in the particle of time *im*, and so forth. Now the space passed over in any time with any velocity is as the velocity multiplied by the time; viz. as the rectangle under that time and velocity; hence the space passed over in the time *ei* with the velocity *ef*, will be as the rectangle *if*; the space passed over in the time *im* with the velocity *ik*, will be as the rectangle *mk*; the space passed over in the time *mp* with the velocity *mn*, will be as the rectangle *pn*, and so on. Therefore the space passed over in the sum of all those times, will be as the sum of all those rectangles. But since the particles of time are infinitely small, the sum of all the rectangles will be equal to the triangle ABC. Now since the space passed over by a moving body in the time AB with a uniform velocity BC, is as the rectangle ABCD, (viz. as the time multiplied by the velocity) and this rectangle is equal to twice the triangle ABC (Eucl. p. 31. B. I.) therefore the space passed over in a given time by a body falling from rest, is equal to half the space passed over in the same time with an uniform velocity, equal to that which is acquired by the descending body at the end of its fall.

Since the space run over by a falling body in the time represented by AB, fig. 120. with the velocity BC is as the triangle ABC, and the space run over in any other time AD, and velocity DE, is represented by the triangle ADE; those spaces must be as the squares of the times AB AD; for the similar triangles ABC, and ADE, are as the squares of their homologous sides, viz. ABC is to ADE as the square of AB is to the square of AD, (Eucl. p. 29. B. VI.).

When a body is placed upon an inclined plane, the force of gravity which urges that body downwards, acts with a power so much less, than if the body descended freely and perpendicularly downwards, as the elevation of the plane is less than its length.

The space which is described by a body descending freely from rest towards the earth, is to the space which it will describe upon the surface of an inclined plane in the same time as the length of the plane is to its elevation, or as radius is to the sine of the plane's inclination to the horizon.

If upon the elevation BC, fig. 121. of the plane BD, as as a diameter, the semicircle BEGC be described, the part BE of the inclined plane, which is cut off by the semicircle, is that part of the plane over which a body will descend, in the same time that another body will descend freely and perpendicularly along the diameter of the circle, viz. from B to C, which is the altitude of the plane, or sine of its inclination to the horizon.

The time of a body's descending along the whole length of an inclined plane, is to the time of its descending freely and perpendicularly along the altitude of the plane, as the length of the plane is to its altitude; or as the whole force of gravity is to that part of it which acts upon the plane.

A body by descending from a certain height to the same horizontal line, will acquire the same velocity whether the descent be made perpendicularly or obliquely, over an inclined plane, or over many successive inclined planes, or lastly over a curve surface.

From these propositions, which have been sufficiently established by mathematicians, it follows, that in the circle ABC (fig. 122), a body will fall along the diameter from A to B, or along the chords CB, DB, in exactly the same line by the action of gravity.

When a body is projected in any line whatever not perpendicular to the earth's surface, it does not continue in that line, but continually deviates from it, describing a curve, of which the primary line of direction is a tangent. The motion of the body relative to this line is uniform. But if vertical lines be drawn from this tangent to the curve, it will be perceived that its velocity is uniformly accelerated in the direction of these verticals. They are proportional to the squares of the corresponding parts of the tangent. This property shows us that the curve in which the body projected moves is a parabola.

337 Of the pendulum.

The oscillations of the pendulum are regulated likewise by the same law of gravitation. The fundamental proportions respecting pendulums are the following:

If a pendulum be moved to any distance from its natural and perpendicular direction, and there be let go, it will descend towards the perpendicular; then it will ascend on the opposite side nearly as far from the perpendicular, as the place whence it began to descend; after which it will again descend towards the perpendicular, and thus it will keep moving backwards and forwards for a considerable time; and it would continue to move in that manner for ever, were it not for the resistance of the air, and the friction at the point of suspension, which always prevent its ascending to the same height as that from which it lastly began to descend.

The velocity of a pendulum in its lowest point is as the chord of the arch which it has described in its descent.

The very small vibrations of the same pendulum are performed in times nearly equal; but the vibrations through longer and unequal arches are performed in times sensibly different.

As the diameter of a circle is to its circumference, so is the time of a heavy body's descent from rest through half the length of a pendulum to the time of one of the smallest vibrations of that pendulum.

It is from these propositions, and the experiments made with pendulums, that the space described by a body falling from rest by the action of gravity has been ascertained.

The late Mr John Whitehurst, an ingenious member of the Royal Society, seems to have contrived and performed the least exceptionable experiments relatively on this subject. The result of his experiments shews, that the length of the pendulum which vibrates seconds in London, at 113 feet above the level of the sea, in the temperature of 60° of Fahrenheit's thermometer, and when the barometer is at 30 inches, is 39,1196 inches; whence it follows that the space which is passed over by bodies descending perpendicularly, in the first second of time, is 16,087 feet. This length of a second pendulum is certainly not mathematically exact, yet it may be considered as such for all common purposes; for it is not likely to differ from the truth by more than $\frac{1}{1000}$th part of an inch.

By these propositions, also, the variations of gravity in different parts of the earth's surface and on the tops of mountains has been ascertained. Newton also has shown, by means of the pendulum, that gravity does not depend upon the surface nor figure of a body.

338 Of central forces.

The motion of bodies round a centre affords another well known instance of a constant force. As the motion of matter left to itself is uniform and rectilinear, it is obvious that a body moving in the circumference of a curve, must have a continual tendency to fly off at a tangent. This tendency is called a *centrifugal force*, while every force directed towards a centre is called a *central* or *centripetal force*. In circular motions the central force is equal, and directly contrary, to the centrifugal force. It tends constantly, to bring the body towards the centre, and in a very short interval of time, its effect is measured by the versed sine of the small arch described.

Let A (fig. 123.) be the centre of a force. Let a body in B be moving in the direction of the straight line BC, in which line it would continue to move if undisturbed; but being attracted by the centripetal force towards A, the body must necessarily depart from this line BC; and being drawn into the curve line BD, must pass between the lines AB and BC. It is evident, therefore, that the body in B being gradually turned off from the straight line BC, it will at first be convex towards that line, and concave towards A. And that the curve will always continue to have this concavity towards A, may thus appear: In the line BC, near to B, take any point, as E, from which the line EFG may be so drawn as to touch the curve line BD in some point, as F. Now, when the body is come to F, if the centripetal power were immediately to be suspended, the body would no longer continue to move in a curve line, but, being left to itself, would forthwith reassume a straight course, and that straight course would be in the line FG; for that line is in the direction of the body's motion of the point F. But the centripetal force continuing its energy, the body will be gradually drawn from this line FG so as to keep in the line FD, and make that line, near the point F, to be concave towards the point A; and in this manner the body may be followed in its course throughout the line BD, and every part of that line be shown to be concave towards the point A.

Again, the point A (fig. 124.) being the centre of a centripetal force, let a body at B set out in the direction

Digitized by Google

Theory of Universal Gravitation.

rection of the straight line BC, perpendicular to the line AB. It will be easily conceived, that there is no other point in the line BC so near to A as the point B; that AB is the shortest of all the lines which can be drawn from A to any part of the line BC; all others, as AD or AE, being longer than AB. Hence it follows, that the body setting out from it, if it moved in the line BC, would recede more and more from the point A. Now, as the operation of a centripetal force is to draw a body towards the centre of that force, if such a force act upon a resting body, it must necessarily put that body so into motion as to cause it move towards the centre of the force: if the body were of itself moving towards that centre, it would accelerate that motion, and cause it to move faster down; but if the body were in such a motion that it would of itself recede from the centre, it is not necessary that the action of a centripetal power should make it immediately approach the centre from which it would otherwise have receded; the centripetal force is not without effect if it cause the body to recede more slowly from that centre than otherwise it would have done. Thus, the smallest centripetal power, if it act on the body, will force it out of the line BC, and cause it to pass in a bent line between BC and the point A, as has been already explained. When the body, for instance, has advanced to the line AD, the effect of the centripetal force discovers itself by having removed the body out of the line BC, and brought it to cross the line AD somewhere between A and D, suppose at F. Now, AD being longer than AB, AF may also be longer than AB. The centripetal power may indeed be so strong, that AF shall be shorter than AB; or it may be so evenly balanced with the progressive motion of the body that AF and AB shall be just equal; in which case the body would describe a circle about the centre A: this centre of the force being also the centre of the circle.

If now the body, instead of setting out in the line BC perpendicular to AB, had set out in another line BG more inclined towards the line AB, moving in the curve line BH; then, as the body, if it were to continue its motion in the line BG, would for some time approach the centre A, the centripetal force would cause it to make greater advances towards that centre: But if the body were to set out in the line BI, reclined the other way from the perpendicular BC, and were to be drawn by the centripetal force into the curve line BK; the body, notwithstanding any centripetal force, would for some time recede from the centre; since some part at least of the curve line BK lies between the line BI and the perpendicular BC.

Let us next suppose a centripetal power directed toward the point A (fig. 109.), to act on a body in B, which is moving in the direction of the straight line BC, the line BC reclining off from AB. If from A the straight lines AD, AE, AF, are drawn to the line CB, prolonged beyond B to G, it appears that AD is inclined to the line GC more obliquely than AB, AE more obliquely than AD, and AF than AE; or, to speak more correctly, the angle under ADG is less than that under ABG, that under AEG is less than ADG, and AFG less than AEG. Now suppose the body to move in the curve line BHIK, it is likewise evident that the line BHIK being concave towards A and convex towards BC, it is more and more turned off from that line: so that in the point H, the line AK will be more obliquely inclined to the curve line BHIK than the same line AHD is inclined to BC at the point D; at the point I the inclination of the line AI to the curve line will be more different from the inclination of the same line AIE to the line BC at the point IE; and in the points K and F the difference of inclination will be still greater; and in both, the inclination at the curve will be less oblique than at the straight line BC. But the straight line AB is less obliquely inclined to BG than AD is inclined towards DG: therefore, although the line AH be less obliquely inclined towards the curve HB than the same line AHD is inclined towards DG, yet it is possible, that the inclination at H may be more oblique than the inclination at B. The inclination at H may indeed be less oblique than the other, or they may be both the same. This depends upon the degree of strength wherewith the centripetal force exerts itself during the passage of the body from B to H: and in like manner the inclinations at I and K depend entirely on the degree of strength wherewith the centripetal force acts on the body in its passage from H to K: if the centripetal force be weak enough, the lines AH and AI drawn from the centre A to the body at H and at I, shall be more obliquely inclined to the curve than the line AB is inclined towards BG. The centripetal force may be of such a strength as to render all these inclinations equal; or if stronger, the inclination at I and K will be less oblique than at B; and Sir Isaac Newton has particularly shown, that if the centripetal power decreases after a certain manner without the increase of distance, a body may describe such a curve line, that all the lines drawn from the centre to the body shall be equally inclined to that curve line.

339 Revolution of a body round a centre explained.

We must further remark, that if the centripetal power, while the body increases its distance from the centre, retain sufficient strength to make the lines drawn from the centre to the body to become at length less oblique to the curve: then, if this diminution of the obliquity continue, till at last the line drawn from the centre to the body shall cease to be obliquely inclined to the curve, and become perpendicular thereto; from this instant the body shall no longer recede from the centre, but in its following motion shall again descend, and describe a curve in all respects like that which it has described already, provided the centripetal power, everywhere at the same distance from the body, acts with the same strength. This return of the body may be proved by the following proposition: That if the body in any place, suppose at I, were to be stopped, and thrown directly backward with the velocity wherewith it was moving forward in that point I, then the body, by the action of the centripetal force upon it, would move back again over the path IHB, in which it had before advanced forward, and would arrive again at the point B in the same space of time as was taken up in its passage from B to I; the velocity of the body at its return from the point B being the same as that wherewith it first set out from that point.

The truth of this proposition may be illustrated in the following manner. Suppose, in fig. 110. that a body

Digitized by Google

body were carried after the following manner through the bent figure ABCDEF, composed of the straight lines AB, BC, CD, DE, EF: let the body then first be supposed to receive an impulse to some point within the concavity of the figure, as G. Now, as this body, when once moving in the straight line AB, will continue to move on in this line as long as it shall be left to itself; but being disturbed at the point B by the impulse given it, it will be turned out of this line AB into some other straight line, wherein it will afterwards continue to move as long as it shall be left to itself; therefore, let this impulse have strength sufficient to turn the body into the line BC; then let the body move on undisturbed from B to C: but at C let it receive another impulse pointed also towards G, and of sufficient strength to turn the body into the line CD; at D let a third impulse turn it into the line DE; and at E let another turn it into EF. Now, if the body, while moving on in the line EF, be stopped and turned back again with the same velocity with which it was moving forward, then by the repetition of the former impulse at E, the body will be turned into the line ED, and move in it from E to D with the same velocity as that wherewith it was moving forward in this line: then by a repetition of the impulse at D, when the body shall have returned to that point, it will be turned into the line DC; and by the repetition of the former impulses at C and at B, the body will be brought back again into the line BA, with the velocity wherewith it first moved in that line.

To illustrate this still farther, let DE and FE be continued beyond E. In DE thus continued, take at pleasure the length EH, and let HI be so drawn as to be equidistant from the line GE; then, from the second law of motion, it follows, that after the impulse on the body on E, it will move through the space EI in the same time it would have employed in moving from E to H with the velocity it had in the line DE. In FE prolonged, take EK equal to EI, and draw KL equidistant from GE. Then because the body is thrown back in the line FE, with the same velocity with which it went forward in that line, if, when the body was turned to E, it were permitted to go straight on, it would pass through EK in the same time as it took up in passing through EI, when it went forward in the line EF. But if, at the body's return to the point E, such an impulse directed toward the point D were to be given it as was sufficient to turn it into the line DE, it is plain that this impulse must be equal to that which originally turned the body out of the line DE into EF; and that the velocity with which the body will return into the line ED is the same as that wherewith it moved before through this line from D to E. Because EK is equal to EI, and KL and HI being each equidistant from GE, are by consequence equidistant from each other; it follows, that the two triangular figures IEH and KEL, are altogether like and equal to each other. EK therefore being equal to EI, and EL equal to KH, and KL equal to HL, it is plain, that the body, after its return to E, being turned out of the line FE into ED by an impulse acting upon it in E after the manner above mentioned, it will receive such a velocity by this impulse as will carry it through EL in the same time it would have taken to go through EK, if it had passed through it undisturbed. It has already been observed, that the time in which the body would pass over EK, with the velocity wherewith it returns, is equal to the time it took up in going forward from E to I; that is, to the time in which it would have gone through EH with the velocity wherewith it moved from D to E; therefore the time in which the body will pass from E to L, after its return into the line ED, is the same as would have been taken up by the body in passing through the line EH with the velocity wherewith it first moved in the line DE. Since, therefore, EL and EH are equal, the body returns into the line DE with the velocity which it had before in that line.—Again, we may affirm, that the second impulse in E is equal to the first; for, as the impulse in E, whereby the body was turned out of the line DE into the line EF, is of such strength, that if the body had been at rest when this impulse had acted upon it, it would have communicated as much motion to it, as would have been sufficient to carry it through a length equal to HI, in the time wherein the body would have passed from E to H, or in the time wherein it passed from E to I. In the same manner, on the return of the body, the impulse in E, whereby it is turned out of the line FE into ED, is of such strength, that if it had acted on the body at rest, it would have caused it move through a length equal to KL in the same time as the body would employ in passing through EK with the velocity wherewith it returns in the line FE: therefore the second impulse, had it acted on the body at rest, would have caused it to move through a length equal to KL, in the same space of time as would have been taken up by the body in passing through a length equal to HI were the first impulse to act on the body while at rest; that is, the effects of the first and second impulse on the body when at rest would be the same; for KL and HI are equal: consequently the second impulse is equal to the first. Thus, if the body be returned through FE with the velocity wherewith it moved forward, it has been shown how, by the repetition of the impulse which acted on it in E, the body will return again into the line DE with the velocity which it had before in that line. By the same method of reasoning it may be proved, that when the body is returned back to D, the impulse which before acted on that point will throw the body into the line DC with the velocity which it first had in that line; and the other impulses being successively repeated, the body will at length be brought back again into the line BA with the velocity wherewith it set out in that line.—Thus these impulses, by acting over again in an inverted order all their operations on the body, bring it back again through the path in which it had proceeded forward; and this obtains equally whatever be the number of straight lines whereof this curve figure is composed. Now, by a method of reasoning of which Sir Isaac Newton made much use, and which he introduced into geometry, thereby greatly enriching that science, we might make a transition from this figure, composed of a number of straight lines, to a figure of one continued curvature, and from a number of separate impulses repeated at distinct intervals to a continued centripetal force, and show that because what has been here advanced holds universally true whatever be the number

Digitized by Google

ber of straight lines whereof the curve figure ACF is composed, and however frequently the impulses at the angles of this figure are repeated; therefore the same will still remain true although this figure should be converted into one of a continued curvature; and these distinct impulses should be changed into a continual centripetal force.

This being allowed, suppose the body in K to have the line AK no longer obliquely inclined to its motion. In this case, if the body be turned back in the manner we have been considering, it must be directed back perpendicularly to AK: but if it had proceeded forward, it would likewise have moved in a direction perpendicular to AK: consequently, whether it move from this point K backward or forward, it must describe the same kind of course. Therefore, since by being turned back it will go over again the line KIHB, if it be permitted to go forward, the line KL, which it shall describe, will be altogether similar to the line KHB.

In like manner we may determine the nature of the motion, if the line wherein the body sets out be inclined, as in fig. 127. down toward the line BA drawn between the body and the centre. If the centripetal power so much increases in strength as the body approaches, that it can bend the path in which the body moves to that degree as to cause all the lines, AH, AI, AK, to remain no less oblique to the motion of the body than AB is oblique to BC, the body shall continually more and more approach the centre. But if the centripetal power increases in so much less a degree as to permit the line drawn from the centre to the body, as it accompanies the body in its motion, at length to become more and more erect to the curve wherein the body moves, and in the end, suppose at K, to become perpendicular to it; from that time the body shall rise again. This is evident from what has been said above; because, for the very same reason, here also, the body will proceed from the point K to describe a line altogether similar to that in which it has moved from B to K. Thus it happens as in the pendulum, which, all the time it approaches a perpendicular position towards the horizon, descends more and more; but as soon as it is come into that situation, it immediately rises again by the same degrees as it descended before: so here the body more and more approaches the centre all the time it is moving from B to K; but thenceforward it rises from the centre again by the same degrees as it approached before.

If, as in fig. 127. the line BC be perpendicular to AB; then, as has already been observed, the centripetal power may be so balanced with the progressive motion of the body, that it may keep moving round the centre A constantly at the same distance; as the body does when whirled about any point to which it is tied by a string. If the centripetal power be too weak to produce this effect, the motion of the body will presently become oblique to the line drawn from itself to the centre; but if it be stronger, the body must constantly keep moving in a curve to which a line drawn from it to the body is perpendicular.

If the centripetal power change with the change of distance, in such a manner that the body, after its motion has become oblique to the line drawn from itself to the centre, shall again become perpendicular thereto; then the body shall, in its subsequent motion, return again to the distance of AB, and from that distance take a course similar to the former: and thus, if the body move in a space void of all resistance, which has been all along supposed, it will continue in a perpetual motion about the centre, descending and ascending from it alternately. If the body, setting out from B (fig. 126.) in the line BC perpendicular to AB, describe the line BDE, which in D shall be oblique to the line AD, but in E shall again become erect to AE, drawn from the body in E to the centre A; then from this point E the body shall describe the line EFG entirely similar to BDE, and at G shall be at the same distance as it was at B; and the line AG shall be erect to the body's motion. Therefore the body shall proceed to describe from G the line GHI altogether similar to the line GFE, and at I it will have the same distance from the centre as it had at E; and also have the line AI erect to its motion: so that its subsequent motion must be in the line IKL similar to IKG, and the distance AL equal to AG. Thus the body will go on in a perpetual round without ceasing, alternately enlarging and contracting its distance from the centre.

If it so happen that the point E fall upon the line BA, continued beyond A; then the point G will fall upon B, I on E, and L also on B; so that the body will in this case describe a simple curve line round the centre A, like the line BDEF in fig. 126. in which it will revolve from P to E, and from E to B, without end. If AE in fig 126. should happen to be perpendicular to AB, in this case also a simple line will be described; for the point G will fall on the line BA prolonged beyond A; the point I on the line AE prolonged beyond A; and the point L on B; so that the body will describe a line like the curve line BEGI in fig. 128. in which the opposite points B and G are equally distant from A; and the opposite points E and L are also equally distant from the same point A. In other cases the body will have a course of a more complicated nature.

Thus it must be apparent how a body, while it is constantly attracted towards the centre, may notwithstanding by its progressive motion keep itself from falling down to the centre, describing about it an endless circuit, sometimes approaching and sometimes receding from it. Hitherto, however, we have supposed, that the centripetal power is everywhere of equal strength at the same distance from the centre: and this is indeed the case with that power which keeps the planets in their orbits; but a body may be kept on in a perpetual circuit round a centre, although the centripetal power be kept moving in any curve line whatever, that shall have its concavity turned everywhere towards the centre of the force. To illustrate this, we shall in the first place propose the case of a body moving in the incurvated figure ABCDE (fig. 129.), which is composed of the straight lines, AB, BC, CD, DE, and AE; the motion being carried on in the following manner. Let the body first move in the line AB with any uniform velocity. When it is arrived at the point B, let it receive an impulse directed towards any point F taken within the figure; and let the impulse be of such a strength as to turn the body out of the line AB into the line BC: The body after this impulse, while

Theory of Universal Gravitation.

while left to itself, will continue moving in the line BC. At C let the body receive another impulse directed towards the same point F, of such strength as to turn it from the line CB into CD. At D, let the body, by another impulse, directed likewise towards the point F, be turned out of the line CD into DE. At E, let another impulse, directed likewise towards the point F, turn the body from the line DE into EA: and thus the body will, by means of these impulses, be carried through the whole figure ABCDE.

Again, when the body is come to the point A, if it there receive another impulse directed like the rest to the point F, and of such a degree of strength as to turn it into the line AB, wherein it first moved; the body will then return into this line with the same velocity it had originally. To understand this, let AB be prolonged beyond B at pleasure, suppose to G; and from G let GH be drawn; which, if produced, should always continue equidistant from BF, i. e. let GH be drawn parallel to BF, in the time, then, in which the body would have moved from B to G, had it not received a new impulse in B; by the means of that impulse it will have acquired a velocity which will carry it from B to H. After the same manner, if CI be taken equal to BH, and IK be drawn parallel to CF, the body will have moved from C to K, with the velocity which it has in the line CD, in the same time it would have employed in moving from C to I with the velocity it had in the line BC. Therefore, since CI and BH are equal, the body will move through CK in the same time as it would have taken up in moving from B to G with the velocity wherewith it moved through the line AB. Again, DL being taken equal to CK, and LM drawn parallel to DF, the body will for the same reason as before, move through DM with the velocity which it has in the line DE, in the same time it would employ in moving through BG with its original velocity. Lastly, if EN be taken equal to DM, and NO be drawn parallel to EF; likewise, if AP be taken equal to EO, and PQ be drawn parallel to AF; then the body, with the velocity wherewith it runs into the line AB, will pass through AQ in the time it would have employed in passing through BG with its original velocity. Now as all this follows directly from what has been delivered concerning oblique impulses impressed upon bodies in motion; so we must here observe farther, that it can be proved by geometry, that AQ will always be equal to BG; which, being granted, it follows, that the body has returned into the line AB with the same velocity which it had when it first moved in that line; for the velocity with which it returns into the line AB will carry it over the line AQ in the same time as would have been taken up in its passing over an equal line BG with the original velocity.

340 A body may be moved in any curvilinear direction by means of centripetal force.

The conclusion naturally deduced from the above reasoning is, that by means of a centripetal and projectile force, a body may be carried round any fixed point as a curve figure which shall be concave towards it, as that marked ABC, fig. 130. and when it is returned to that point from whence it set out, it shall recover again the velocity with which it departed from that point. It is not indeed always necessary that it should return again into its first course, for the curve line may have some such figure as ABCDBE in fig. 131. In this curve line, if the body set out from B in the direction BF, and moved through the line BCD till it returned to B; here the body would not enter again into the line BCD, because the two parts BD and BC of the curve line make an angle at the point B: so that the centripetal power, which at the point B would turn the body from the line BF into the curve, will not be able to turn it into the line BC from the direction in which it returns to the point B. A forcible impulse must be given the body in the point B to produce that effect. If, at the point B, whence the body sets out, the curve line return into itself, as in fig. 130. then the body, upon its arrival again at B, may return into its former course, and thus make an endless circuit about the centre.

341 Calculation of the force requisite to carry a body in any curve line.

The force requisite to carry a body in any curve line proposed, is to be deduced from the curvature which the figure has in any part of it. Sir Isaac Newton has laid down the following proposition as a foundation for discovering this, viz. that if a line be drawn from some fixed point to the body, and remaining by one extreme united to that point, it be carried round along with the body; then if the power whereby the body is kept in its course be always pointed to this fixed point as a centre, this line will move over equal spaces in equal portions of time. Suppose a body were moving through the curve line ABCD (fig. 132.), and passed over the arches AB, BC, CD in equal portions of time; then if a point, as E, can be found, from whence the line EA being drawn to the body in accompanying it in its motion, it shall make the spaces EAB, EBC, and ECD, over which it passes, equal where the times are equal; then is the body kept in this line by a power always pointed to E as a centre. To prove this, suppose a body set out from the point A, fig. 133, to move in a straight line AB; and after it had moved for some time in that line, it were to receive an impulse directed to some point, as C. Let it receive that impulse at D, and thereby be turned into the line DE; and let the body after this impulse, take the same time in passing from D to E that is employed in passing from A to D. Then the straight lines CA, CD, and CE being drawn, the triangular spaces CAD and CDE are proved to be equal in the following manner. Let EF be drawn parallel to CD. Then it follows, from the second law of motion, that since the body was moving in the line AB when it received the impulse in the direction DC, it will have moved after that impulse through the line DE in the same time as it would have moved through DF, provided it had received no disturbance in D. But the time of the body's moving from D to E is supposed to be equal to the time of its moving through AD; therefore the time which the body would have employed in moving through DF, had it not been disturbed in D, is equal to the time wherein it moved through AD: consequently DF is equal in length to AD; for if the body had gone on to move through the line AB without interruption, it would have moved through all the parts of it with the same velocity, and have passed over equal parts of that line in equal portions of time. Now CF being drawn, since AD and DF are equal, the triangular space CDF is equal to the triangular space CAD. Further, the line EF being parallel to CD, it follows from the 37th proposition of Euclid's first book, that the triangle

Theory of Universal Gravitation.

angle CED is equal to the triangle CFD: therefore the triangle CED is equal to the triangle CAD.

In like manner, if the body receive at E another impulse directed toward the point C, and be turned by that impulse into the line EG; if it move afterwards from E to G, in the same space of time as was taken up by its motion from D to E, or from A to D; then CG being drawn, the triangle CEG is equal to CDE. A third impulse at G, directed as the two former to C, whereby the body shall be turned into the line GH, will have also the like effect with the rest. If the body move over GH in the same time as it took up in moving over EG, the triangle CGH will be equal to the triangle CEG. Lastly, if the body at H be turned by a fresh impulse directed towards C into the line HI, and at I by another impulse directed also to C be turned into the line IK; and if the body move over each of the lines HI and IK in the same time as it employed in moving over each of the preceding lines AD, DE, EG, and GH: then each of the triangles CHI and CIK will be equal to each of the preceding. Likewise, as the time in which the body moves over ADE is equal to the time of its moving over EGH, and to the time of its moving over HIK; the space CADE will be equal to the space CEGH and to the space CHIK. In the same manner, as the time in which the body moved over ADEG is equal to the time of its moving over GHIK, so the space CADEG will be equal to the space CGHIK. From this principle Sir Isaac Newton demonstrates the above-mentioned proposition, by making the transition from this incurvated figure composed of straight lines, to a figure of continued curvation; and by showing, that since equal spaces are described in equal times in this present figure composed of straight lines, the same relation between the spaces described, and the times of their description, will also have place in a figure of one continued curvature. He also deduces from this proposition the reverse of it; and proves, that whenever equal spaces are continually described, the body is acted upon by a centripetal force directed to the centre at which the spaces terminate.

342 Comparison of the centrifugal force with gravitation.

As the effect of a central force in a very small interval of time is measured by the versed sine of the small arch described, we may easily compare the centrifugal force produced by the rotation of the earth with gravitation. At the equator, a body in consequence of the rotation of the earth describes an arch of 15″ of the circumference of the earth, in 1″ of time. The radius of the equator is about 19634778 French feet; the versed sine of which is 0.0389704 feet. At the equator a body falls 11.23585 French feet in a second. The centrifugal force is to gravity as 0.0389704 to 1123585, or nearly as 1 to 288.3. The centrifugal force diminishes gravity, and bodies only fall in consequence of the excess of the last above the first. If the whole force whose effect would be evident, were there no rotation, be called *gravity;* then at the equator the centrifugal force is about $\frac{1}{289}$ of gravity. If the earth revolved 17 times faster than it does, the arch described in a second would be 17 times greater, and its versed sine 289 times longer; the centrifugal force would then be equal to gravity, and at the equator, bodies would cease to have any weight.

In general the expression of a uniformly accelerating force, acting constantly towards the same point, is equal to twice the space which it causes the body to describe, divided by the square of the time. Every accelerating force may be supposed constant for a very small interval of time, and acting in the same direction. The space described by a body moving in a circle in consequence of the central force, is the versed sine of the small arch described; and this versed sine is very nearly equal to the square of the arch divided by radius. The expression of the accelerating force is then the square of the arch described, divided by the square of the time, and by radius. The arch divided by the time gives the velocity. Hence the centripetal and centrifugal forces are equal to the square of the velocity divided by radius.

We have seen that gravity is equal to the square of the acquired velocity divided by twice the space gone through. Of course the centrifugal force is equal to gravity, if the velocity of the revolving body be that which it would acquire by falling from a height equal to half the radius of the circumference described. The velocities of different revolving bodies are as the circumferences which they describe divided by the time of their revolution. These circumstances are as their radii. The squares of the velocity of course are as the squares of the radii divided by the squares of the times. Hence centrifugal forces are to each other as the radii of the circumferences described divided by the squares of the times of the revolutions. Hence in different parallels of latitude, the centrifugal forces produced by the rotation of the earth are proportional to the radii of these parallels.

These remarks will give the reader an idea of the laws of motion. For a more particular investigation he must have recourse to those articles that treat particularly of Dynamics.

Chap. II. *Of Universal Gravitation.*

The principles of dynamics being understood, let us make use of them to examine the motions of the heavenly bodies, in order to detect the general laws which produce and regulate these motions.

343 Planets revolve round the sun.

We have seen that the planets and comets move in ellipses round the sun, and that the areas described by their radii vectors are proportional to the time. The principles of dynamics laid down in the last chapter, inform us that this could not happen unless each of these bodies were constantly acted on by a force turning them from the straight line in the direction of the centre of these radii vectors. Hence it follows, that the planets are constantly acted upon by a force which urges them towards the sun as a centre.

344 in consequence of a force residing in the sun.

Let us suppose that the planets revolve round the sun in circles, which is not very far from the truth. In that case, the squares of their velocities are proportional to the squares of the radii of their orbits, divided by the squares of the times of their revolution. But by the laws of Kepler, the squares of the times are as the cubes of the radii of the orbits of the planet, or of the distance. Therefore, the squares of the velocity are reciprocally as these radii. Perhaps this reasoning will be better understood by employing symbols. Let $t=$ the

the time, $v=$ the velocity, and $r=$ the radius, we have $v^2 \doteqdot \frac{r^2}{t^2}$. But $t^2 \doteqdot r^3$, therefore, substituting r^3 in the first formula, we have $v^2 \doteqdot \frac{r^2}{r^3}$, but $\frac{r^2}{r^3} = \frac{1}{r}$, therefore we have $v^2 \doteqdot \frac{1}{r}$, or v^2 always reciprocally proportional to r. We have seen formerly that the central forces of different bodies revolving in a circle, are as the squares of the velocity divided by the radii of their orbits. Therefore, the tendency of the planets to the sun, then, are reciprocally as the squares of the radii of their orbits, or their distance from the sun. This will be better understood if we express it by symbols. We have $v^2 \doteqdot \frac{1}{r}$. Let c denote the central force, $c \doteqdot \frac{v^2}{r}$; for v^2 substitute its equivalent $\frac{1}{r}$, and we have $c \doteqdot \frac{1}{r^2}$.

It is true that the orbits of the planets are not exactly circular; but as the law of the squares of the times, proportional to the cubes of the distances, is independent of the eccentricity of the planetary orbits, it is natural to suppose, that it would exist, even though the eccentricity were destroyed. The law, therefore, that the tendency to the sun is inversely as the square of the distance, is clearly indicated by this ratio.

345 **This force inversely as the square of the distance.** Analogy leads us to suppose, that this law, which extends from one planet to another, holds also with respect to the same planet in all its different distances from the sun. That this is actually the case, follows with certainty from the elliptical orbits of the planets. When the planet is in its perihelion, its velocity is a maximum, and its tendency to separate from the sun in consequence of this velocity overcoming the tendency towards the sun, the radius vector increases in length, and forms obtuse angles with the direction of the planet. Hence it opposes, and of course, tends to diminish the velocity, till the planet reaches its aphelion. Then the radius vector becomes perpendicular to the curve, the velocity is at its minimum; and the tendency to separate from the sun being less than the tendency towards the sun, the planet approaches towards it, describing the second part of its elliptical orbit. In that part, the tendency to the sun increases the velocity of the planet, as in the former part it had diminished it: the planet accordingly comes to its perihelion with a maximum of velocity. Now the curvature of the ellipse being the same at the perihelion and aphelion, the radii of the equicurve circles will be the same, and, of course, the centrifugal forces in these two points will be to each other as the squares of the velocity. The sectors described in the same times being equal, the velocities at the aphelion and perihelion are reciprocally as the corresponding distances of the planet from the sun. Of course, the squares of the velocities are reciprocally as the squares of these distances, or at the perihelion and aphelion the centrifugal forces are equal to the tendency of the planet towards the sun. Therefore this tendency is inversely as the square of the distance of the planet from the sun.

346 **Tendency the same in all the planets.** We see then, in general, that all the planets tend towards the sun, with a force inversely as the square of their distance. Newton demonstrated, that this force would cause them, if projected with a given velocity, to describe ellipses round the sun as a centre. He demonstrated farther, that this tendency is the same in all the planets, varying only according to their distances. Hence it follows, that if they were all at rest, and placed at the same distance from the sun, they would all, in consequence of this tendency, *fall* into the sun at the same instant; the same result must be applied also to the comets, for in them also the squares of the times are undoubtedly proportional to the cubes of their distance from the sun.

347 **and satellites.** The satellites tend equally to the sun with the planets around which they revolve. Were not the moon under the influence of this tendency, instead of describing a circle round the earth, it would soon abandon it altogether. Unless the satellites of Jupiter and the moon tended towards the sun, irregularities would be perceptible in their orbits, which they do not exhibit. The planets, comets, and satellites, then, all tend to the sun in consequence of the action of the same force. While the satellites move round their planet, the entire system of planet and satellites is carried round the sun, and retained in their orbits by the same force. Of course, the motion of the satellites round the planet, is merely the same as if the planet were altogether at rest, and not acted upon by any foreign body.

348 **Hence the sun's centre attracts all bodies.** Thus we have been led, without assuming any hypothesis, by the necessary consequence of the laws of the celestial movements, to consider the centre of the sun as the focus of a *force*, which extends itself indefinitely through space, diminishing inversely as the squares of the distance, and which *attracts* all bodies within the sphere of its activity. Each of Kepler's laws points out a property of this attractive force. The law of the areas proportional to the times, informs us, that the force is directed towards the sun; the elliptical figure of the planets proves to us, that its intensity diminishes as the square of the distance augments; and the law of the squares of the times proportional to the cubes of the distance, informs us, that the tendency, or *gravitation* of all the planets to the sun is the same, provided the distances were the same. We may call this force *solar attraction*, supposing, for the sake of a distinct conception, that it is a *force* residing in the sun.

349 **Satellites tend to their primaries.** The tendency or gravitation of the satellites towards their planets is a necessary consequence of the areas described by their radii vectors being proportional to the times; that this gravitation is inversely as the square of their distance, is indicated by the ellipticity of their orbits. This ellipticity, indeed, being scarcely apparent in most of the satellites of Jupiter, Saturn, and Herschel, would leave some uncertainty, did not the third law, namely, the squares of the times being inversely as the cubes of their distance, demonstrate, that from one satellite to another, the tendency to the planet is inversely as the square of the distance.

350 **Moon's tendency the same with gravitation.** This proof, indeed, is wanting with respect to our moon; but the defect may be supplied by the following considerations. *Gravity*, or the weight by which a body tends towards the earth, extends itself to the top of the highest mountains, and the very trifling diminution which it experiences at that height, cannot permit us to doubt, that it would still be sensible at a considerably

Theory of Universal Gravitation.

considerably greater distance from the earth's centre. Is it not natural to extend it as far as the moon, and to suppose that the force which retains that satellite in its orbit, is its *gravitation* towards the earth, just as it is the solar attraction which retains the planets in their orbits? The forces at least seem to be of the same nature; they both act upon every particle of bodies, and cause them to move at the same rate; for the solar attraction acts equally upon all bodies placed at the same distance from the sun, just as gravitation causes all bodies to fall from the same height with the same velocity. A body projected horizontally, falls upon the earth at some distance after describing a curve sensibly parabolic. It would fall at a greater distance, if the force of projection were more considerable; and, if projected with a certain velocity, it would not fall back at all, but revolve round the earth like a satellite. To make it move in the orbit of the moon, it would be necessary only to give it the same height and the same projecting force. But what demonstrates the identity of gravitation and of the force which retains the moon in its orbit is, that if we suppose gravity to diminish inversely as the square of the distance from the centre of the earth, at the distance of the moon it will be precisely equal to the moon's tendency to the earth.

Let A in fig. 134. represent the earth, B the moon, BCD the moon's orbit; which differs little from a circle of which A is the centre. If the moon in B were left to itself to move with the velocity it has in the point B, it would leave the orbit, and proceed straight forward in the line BE which touches the orbit in B. Suppose the moon would upon this condition move from B to E in the space of one minute of time: By

351 Her motion particularly explained.

the action of the earth upon the moon, whereby it is retained in its orbit, the moon will really be found at the end of this minute in the point F, from whence a straight line drawn to A shall make the space BFA in the circle equal to the triangular space BEA; so that the moon in the time wherein it would have moved from B to E, if left to itself, has been impelled towards the earth from E to F. And when the time of the moon's passing from B to F is small, as here it is only one minute, the distance between E and F scarce differs from the space through which the moon would descend in the same time if it were to fall directly down from B toward A without any other motion. AB, the distance of the moon from the earth, is about 60 of the semidiameters of the latter; and the moon completes her revolution round the earth in about 27 days 7 hours and 43 minutes: therefore the space EF will here be found by computation to be about $16\frac{1}{12}$ feet. Consequently, if the power by which the moon is retained in its orbit be near the surface of the earth greater than at the distance of the moon in the duplicate proportion of that distance, the number of feet a body would descend near the surface of the earth, by

352 Calculation of the velocity of falling bodies.

the action of this power upon it, in one minute would be equal to the number $16\frac{1}{12}$ multiplied twice into the number 60; that is, to 58050. But how fast bodies fall near the surface of the earth may be known by the pendulum; and by the exactest experiments, they are found to descend the space of $16\frac{1}{12}$ feet in one second; and the spaces described by falling bodies being in the duplicate proportion of the times of their fall, the number of feet a body would describe in its fall near the surface of the earth in one minute of time will be equal to $16\frac{1}{12}$ twice multiplied by 60; the same as would be caused by the power which acts upon the moon.

353 Earth and moon move about their common centre of gravity.

In this computation the earth is supposed to be at rest: but it would have been more exact to have supposed it to move, as well as the moon, about their common centre of gravity; as will be easily understood from what has been already said concerning the motion of the sun and primary planets about their common centre of gravity. The action of the sun upon the moon is also here neglected; and Sir Isaac Newton shows, if you take in both these considerations, the present computation will best agree to a somewhat greater distance of the moon and earth, viz. to $60\frac{1}{2}$ semidiameters of the latter, which distance is more conformable to astronomical observations: and these computations afford an additional proof that the action of the earth observes the same proportion to the distance which is here contended for.

We see then that the force which retains the moon in its orbit is *gravitation*, or that force which causes heavy bodies to fall to the ground. This comparison between gravity and the lunar tendency to the earth shows us, that, in our calculations, we ought to measure distance from the centre of gravity of the sun and of the planets; for this is obviously the case with the earth, and its tendency to the sun is precisely the same with that of the other planets.

354 Planets react upon the sun.

The sun and the planets which have satellites, possessing, as we have seen, an attracting force inversely as the square of the distance, one is tempted to give the same property to the other planets also. The sphericity common to all these bodies, indicates clearly, that their particles are retained round their centre of gravity, by a force which at equal distances attracts them equally to that centre. But this important point is not left to analogical reasoning. We have seen, that if the planets and comets were placed at equal distances from the sun, their gravitation towards it would be proportional to their masses. But it may be considered as a general matter of fact, to which there is no exception, that action and reaction are equal and contrary. Of course all these bodies react upon the sun, and *attract* it in proportion to their mass, and consequently possess an attractive force proportional to their mass, and inversely as the square of their distance. The satellites also, in consequence of the same principle, attract the planets and the sun according to the same law. This attracting force is then common to all the heavenly bodies.

This force does not disturb the elliptical motion of the plants round the sun, when we consider only their mutual action. For the relative movement of a system of bodies does not change by giving them a common motion. Neither is the elliptical motion of the satellites disturbed by the revolution of the planets round the sun, for the very same reason.

The attractive force does not belong to these bodies only as wholes; but it belongs to every particle of matter of which each of them is composed. If the sun acted only upon the centre of the earth, without attracting every one of the particles of which it is composed individually, there would result *tides* incomparably greater, and very different from those that we observe.

Digitized by Google

Theory of Universal Gravitation.

observe. Besides, every body on the earth gravitates towards its centre, in proportion to its mass. It reacts of course upon the earth, and attracts it in the same ratio. Unless that were the case, or if any part of the earth, however small, did not attract the other part as it is attracted by it, the centre of gravity of the earth would be moved in space, in consequence of gravitation; which is impossible.

355 General law of gravitation.

All these phenomena, compared with the laws of motion, lead us to this grand conclusion: *All the particles of matter mutually attract each other, in proportion to their masses, and inversely as the squares of their distances.* This is called *universal gravitation*, and was the discovery which crowned the happy industry, the consummate skill, and the unrivalled sagacity of Newton.

In universal gravitation, we readily perceive a cause of the irregularities and disturbances perceptible in the planetary motions. For as the planets and comets act upon each other, they ought to deviate a little from that exact ellipticity, which they would follow if they obeyed only the action of the sun. The satellites, disturbed equally by their mutual attraction, and by that of the sun, must deviate also from these laws. We see also, that the particles of which each heavenly body is composed, provided they be at liberty to move, ought to form themselves into a sphere, and that the result of their mutual action at the surface of this sphere ought to produce all the phenomena of gravity. We see also, that the rotation of the heavenly bodies round an axis ought to alter this sphericity somewhat by flattening them at the poles, and that the result of their mutual action not passing exactly through their centres of gravity, ought to produce in their axis of rotation motions similar to those which we perceive. We see also, that the particles of the ocean, unequally attracted by the sun and moon, ought to have an oscillation similar to the tides. But it will be necessary to consider the effects of gravitation more particularly; in order to show that it is established in the completest manner by all the phenomena. This shall be the subject of the next chapter.

Chap. III. *Of the Effects of Gravitation.*

We shall in this chapter consider, in the first place, several points which could only be ascertained by the assistance of gravitation, and afterwards examine the several subjects hinted at towards the conclusion of the last chapter.

Sect. I. *Of the Masses of the Planets.*

It would appear, at first view, impossible to ascertain the respective masses of the sun and planets, and to calculate the velocity with which heavy bodies fall towards each when at a given distance from their centres; yet these points may be determined from the theory of gravitation without much difficulty.

356 Calculation of the densities of the planets.

It follows from the theorems relative to centrifugal forces, given in the first chapter of this part, that the gravitation of a satellite towards its planet is to the gravitation of the earth towards the sun, as the mean distance of the satellite from its primary, divided by the square of the time of its sidereal revolution, or the mean distance of the earth from the sun divided by the square of a sidereal year. To bring these gravitations to the same distance from the bodies which produce them, we must multiply them respectively by the squares of the radii of the orbits which are described: and, as at equal distances the masses are proportional to the attractions, the mass of the earth is to that of the sun as the cube of the mean radius of the orbit of the satellite, divided by the square of the time of its sidereal motion, is to the cube of the mean distance of the earth from the sun, divided by the square of the sidereal year.

Let us apply this result to Jupiter. The mean distance of his 4th satellite subtends an angle of 1530″.86 decimal seconds. Seen at the mean distance of the earth from the sun, it would appear under an angle of 7964″.75 decimal seconds. The radius of the circle contains 636619″.8 decimal seconds. Therefore the mean radii of the orbit of Jupiter's 4th satellite and of the earth's orbit are to each other as these two numbers. The time of the sidereal revolution of the 4th satellite is 16.6890 days; the sidereal year is 365.2564 days. These data give us $\frac{1}{1066.08}$ for the mass of Jupiter, that of the sun being represented by 1. It is necessary to add unity to the denominator of this fraction, because the force which retains Jupiter in his orbit is the sum of the attractions of Jupiter and the sun. The mass of Jupiter is then $\frac{1}{1067.08}$. The mass of Saturn and Herschel may be calculated in the same manner. That of the earth is best determined by the following method:

If we take the mean distance of the earth from the sun for unity, the arch described by the earth in a second of time will be the ratio of the circumference to the radius divided by the number of seconds in a sidereal year. If we divide the square of that arch by the diameter, we obtain $\frac{1479565}{10^{20}}$ for its versed sine, which is the deflection of the earth towards the sun in a second. But on that parallel of the earth's surface the square of the sine of whose latitude is $\frac{1}{3}$, a body falls in a second $16\frac{1}{9}$ feet. To reduce this attraction to the mean distance of the earth from the sun, we must divide the number by the feet contained in that distance; but the radius of the earth at the above-mentioned parallel is 19614648 French feet. If we divide this number by the tangent of the solar parallax, we obtain the mean radius of the earth's orbit expressed in feet. The effect of the attraction of the earth at a distance equal to the mean radius of its orbit, is equal to $\frac{16\frac{1}{9}}{19614648}$ multiplied by the cube of the tangent of the solar parallax $= \frac{1479560.5}{10^{20}}$. Hence the masses of the sun and earth are to each other as the numbers 1479560.5 and 4.486113; therefore the mass of the earth is $\frac{1}{329809}$, that of the sun being unity.

M. de la Place calculated the masses of Mars and Venus from the secular diminution of the obliquity of the ecliptic, and from the mean acceleration of the moon's motion. The mass of Mercury he obtained from its volume, supposing the densities of that planet and

Digitized by Google

Theory of Universal Gravitation.

and of the earth reciprocally as their mean distance from the sun, a rule which holds, with respect to the earth, Jupiter, and Saturn. The following table exhibits the masses of the different planets, that of the sun

357 being unity:

Table of the masses.

Mercury	$\frac{1}{2025810}$
Venus	$\frac{1}{383137}$
Earth	$\frac{1}{329809}$
Mars	$\frac{1}{1846082}$
Jupiter	$\frac{1}{1067.09}$
Saturn	$\frac{1}{3359.40}$
Herschel	$\frac{1}{19504}$

The densities of bodies are proportional to their masses divided by their bulks; and, when bodies are nearly spherical, their bulks are as the cubes of their semidiameters, of course the densities in that case are as the masses divided by the cubes of the semidiameters. For greater exactness, we must take that semidiameter of a planet which corresponds to the parallel, the square of the sine of which is equal to $\frac{1}{3}$, and which is equal to the third of the sum of the radius of the pole, and twice the radius of the equator. This method gives us the densities of the principal planets as follows, that of the sun being unity:

358 Of their densities.

Earth	3.93933
Jupiter	0.86014
Saturn	0.49512
Herschel	1.13757

359 Of gravity at their surfaces.

To have the intensity of gravitation at the surface of the sun and planets, let us consider, that, if Jupiter and the earth were exactly spherical, and destitute of their rotatory motion, gravitation at their equators would be proportional to the masses of these bodies divided by the squares of their diameters. But at the mean distance of the sun from the earth, the diameters of the equators of Jupiter and of the earth are to each other as the numbers 626.26 and 54.5. If then we represent the weight of a body at the earth's equator by 1, the same body, if transported to the equator of Jupiter, would weigh 2.509. But the difference of the centrifugal forces on the surface of the earth and Jupiter renders it necessary to diminish this last number by about $\frac{1}{9}$. The same body at the surface of the sun would weigh 27.65.

Sect. II. *Of the Perturbations in the Elliptical Orbit of the Planets.*

If the planets were influenced only by the sun, they would describe ellipses round that luminary: but they act upon one another, and from these various attractions there result disturbances in their elliptical motions, discoverable by observation, and which it is necessary to determine, in order to be able to construct accurate tables of the planetary motions. The rigorous solution of this problem is above the reach of the mathematical analysis; mathematicians have been obliged to satisfy themselves with approximations.

360 Secular and periodical inequalities.

The disturbances in the elliptical motions of the planets may be divided into two classes. The first class affects the elements of the elliptical motion: they increase very slowly, and have been called *secular* inequalities. The other class depends upon the configuration of the planets, either with respect to each other, or with respect to their nodes and perihelions, and are renewed every time that the relative situation of the planets becomes the same. They are called *periodical* inequalities, to distinguish them from the *secular*, whose periods are much longer and altogether independent of the mutual configuration of the planets. Before proceeding farther, we beg leave to introduce the following quotation from Dr Pemberton, because it will convey some notion of these disturbances in a very familiar manner to our readers.

361 Motion of the aphelion accounted for.

"The only inequalities which have been observed common to all the planets are, the motion of the aphelion and the nodes. The transverse axis of each orbit does not remain always fixed, but moves about the sun with a very slow progressive motion; nor do the planets keep constantly in the same planes, but change them and the lines by which these planes intersect each other by insensible degrees. The first of these inequalities, which is the motion of the aphelion, may be accounted for, by supposing the gravitation of the planets towards the sun to differ a little farther from the forementioned reciprocal duplicate proportion of the distances; but the second, which is the motion of the nodes, cannot be accounted for by any power directed towards the sun; for no such power can give it any lateral impulse to divert it from the plane of its motion into any new plane, but of necessity must be derived from some other centre. Where that power is lodged, remains to be discovered. Now it is proved, as shall afterwards be explained, that the three primary planets, Saturn, Jupiter, and the Earth, which have satellites revolving about them, are endowed with a power of causing bodies, in particular those satellites, to gravitate towards them with a force which is reciprocally in the duplicate proportion of their distances; and the planets are, in all respects in which they come under our consideration, so similar and alike, that there is no reason to question but they have all the same property, though it be sufficient for the present purpose to have it proved of Jupiter and Saturn only; for these planets contain much greater quantities of matter than the rest, and proportionally exceed the others in power. But the influence of these two planets being allowed, it is evident how the planets come to shift their places continually; for each of the planets moving in a different plane, the action of Jupiter and Saturn upon the rest will be oblique to the planes of their motion, and therefore will gradually draw them into new ones. The same action of these two planets upon the rest will likewise cause a progressive motion of the aphelion; so that there will be no necessity for having recourse to the other cause for this motion, which was before hinted at, viz. the gravitation of the planets toward the sun differing from the exact duplicate proportion

Digitized by Google

Theory of Universal Gravitation.

portion of their distances. And, in the last place, the action of Jupiter and Saturn upon each other will produce in their motions the same inequalities as their joint action produces upon the rest. All this is effected in the same manner as the sun produces the same kind of inequalities and many others in the motion of the moon and other secondary planets; and therefore will be best apprehended by what is said afterwards. Those other irregularities in the motion of the secondary planets have place likewise here, but are too minute to be observable, because they are produced and rectified alternately, for the most part in the time of a single revolution; whereas the motion of the aphelion and nodes, which increase continually, become sensible after a long series of years. Yet some of these other inequalities are discernible in Jupiter and Saturn; in Saturn chiefly: for when Jupiter, who moves faster than Saturn, approaches to a conjunction with him, his action upon the latter will a little retard the motion of that planet; and by the reciprocal action of Saturn, he will himself be accelerated. After conjunction, Jupiter will again accelerate Saturn, and be likewise retarded in the same degree as before the first was retarded and the latter accelerated. Whatever inequalities besides are produced in the motion of Saturn by the action of Jupiter upon that planet, will be sufficiently rectified by placing the focus of Saturn's ellipsis, which should otherwise be the sun, in the common centre of gravity of the sun and Jupiter. And all the inequalities of Jupiter's motions, caused by the action of Saturn upon him, are much less considerable than the irregularities of Saturn's motion. This one principle, therefore, of the planets having a power as well as the sun to cause bodies gravitate towards them, which is proved by the motion of the secondary planets to obtain in fact, explains all the irregularities relating to the planetary motions ever observed by astronomers (c).

362 Jupiter and Saturn influence each other's motions.

363 Method of correcting the planetary motions.

"Sir Isaac Newton after this proceeds to make an improvement in astronomy, by applying this theory to the farther correction of their motions. For as we have here observed the planets to possess a principle of gravitation as well as the sun; so it will be explained at large hereafter, that the third law of motion, which makes action and reaction equal, is to be applied in this case, and that the sun does not only attract each planet, but is also itself attracted by them; the force wherewith the planet is acted on, bearing to the force wherewith the sun itself is acted upon at the same time, the proportion which the quantity of matter in the sun bears to the quantity of matter in the planet. From the action of the sun and planet being thus mutual, Sir Isaac Newton proves that the sun and planet will describe about their common centre of gravity similar ellipses; and then, that the transverse axis of the ellipsis, which would be described about the sun at rest in the same time, the same proportion as the quantity of solid matter in the sun and planet together bears to the first of two mean proportionals between this quantity and the quantity of matter in the sun only.

364 Sun moves round the common centre of gravity of him and the planets.

"It will be asked, perhaps, how this correction can be admitted, when the cause of the motions of the planets was before found, by supposing them to be the centre of the power which acted upon them? for, according to the present correction, this power appears rather to be directed to the common centre of gravity. But whereas the sun was at first concluded to be the centre to which the power acting on the planets was directed, because the spaces described in equal times round the sun were found to be equal; so Sir Isaac Newton proves, that if the sun and planet move round their common centre of gravity, yet, to an eye placed in the planet, the spaces which will appear to be described about the sun will have the same relation to the times of their description as the real spaces would if the sun were at rest. I further asserted, that, supposing the planets to move round the sun at rest, and to be attracted by a power which should everywhere act with degrees of strength reciprocally in the duplicate proportions of their distances; then the periods of the planets must observe the same relations to their distances as astronomers have found them to do. But here it must not be supposed, that the observations of astronomers absolutely agree without any the least difference: and the present correction will not cause a deviation from any one astronomer's observations so much as they differ from one another; for in Jupiter, where this correction is greatest, it hardly amounts to the 3000th part of the whole axis.

"Upon this head, I think it not improper to mention a reflection made by our excellent author upon these small inequalities in the planets motions, which contains in it a very strong philosophical argument against the eternity of the world. It is this, that these inequalities must continually increase by slow degrees, till they render at length the present frame of nature unfit for the purposes it now serves. And a more convincing proof cannot be desired against the present constitution's having existed from eternity than this, that a certain period of years will bring it to an end. I am aware, that this thought of our author has been represented even as impious, and as no less than casting a reflection upon the wisdom of the Author of nature for framing a perishable work. But I think so bold an assertion ought to have been made with singular caution: for if this remark upon the increasing irregularities in the heavenly motions be true in fact, as it really is, the imputation must return upon the assertor, that this does not detract from the divine wisdom. Certainly we cannot pretend to know all the omniscient Creator's purposes in making this world, and therefore cannot pretend to determine how long he designed it should last; and it is sufficient if it endure the time designed by the Author. The body of every animal shows

365 Argument against the eternity of the world.

(c) Professor J. Robison, however, informs us in his paper on the *Georgium Sidus* (Edinburgh Philosophical Transactions, Vol. I.), That *all* the irregularities in the planetary motions *cannot* be accounted for from the laws of gravitation; for which reason he was obliged to suppose the existence of planets beyond the orbit of Saturn, even before the discovery of the *Georgium Sidus*. M. de la Lande also has observed some unaccountable inequalities in the motion of Saturn for more than 30 years past.

Digitized by Google

shows the unlimited wisdom of the Author, no less, nay, in many respects more, than the larger frame of nature: and yet we see they are all designed to last but a small space of time."

366 Deflection of the planets towards each other.

Sir Isaac Newton had no sooner discovered the universality and reciprocity of the deflections of the planets and the sun, than he also suspected that they were continually deflected towards each other. He immediately obtained a general notion of what should be the more general results of such a mutual action. They may be conceived in this way.

Let S (fig. 135.) represent the sun, E the earth, and I Jupiter, describing concentric orbits round the centre of the system. Make $IS : EA = EI^2 : SI^2$. Then, if

367 General result of such mutual action.

IS be taken to represent the deflection of the sun towards Jupiter, EA will represent the deflection of the Earth to Jupiter. Draw EB equal and parallel to SI, and complete the parallelogram EBAD. ED will represent the disturbing force of Jupiter. It may be resolvent into EF perpendicular to ES, and EG in the direction of SE. By the first of these the earth's angular motion round the sun is affected, and by the second its deflection towards him is diminished or increased.

In consequence of this first part of the disturbing force, the angular motion is increased, while the earth approaches from quadrature to conjunction with Jupiter (which is the case represented in the figure), and is diminished from the time that Jupiter is in opposition till the earth is again in quadrature, westward of his opposition. The earth is then accelerated till Jupiter is in conjunction with the sun; after which it is retarded till the earth is again in quadrature.

The earth's tendency to the sun is diminished while Jupiter is in the neighbourhood of his opposition or conjunction, and increased while he is in the neighbourhood of his stationary positions. Jupiter being about 1000 times less than the sun, and 5 times more remote, IS must be considered as representing $\frac{1}{25000}$th of the earth's deflection to the sun, and the forces ED and EG are to be measured on this scale.

In consequence of this change in the earth's tendency to the sun, the aphelion sometimes advances by the diminution, and sometimes retreats by the augmentation. It advances when Jupiter chances to be in opposition when the earth is in its aphelion; because this diminution of its deflection towards the sun makes it later before its path is brought from forming an obtuse angle with the *radius vector*, to form a right angle with it. Because the earth's tendency to the sun is, on the whole, more diminished by the disturbing force of Jupiter than it is increased, the aphelion of the earth's orbit advances on the whole.

In like manner the aphelia of the inferior planets advance by the disturbing forces of the superior: but the aphelion of a superior planet retreats; for these reasons, and because Jupiter and Saturn are larger and more powerful than the inferior planets, the aphelia of them all advance while that of Saturn retreats.

In consequence of the same disturbing forces, the node of the disturbed planet retreats on the orbit of the disturbing planet; therefore they all retreat on the ecliptic, except that of Jupiter, which advances by retreating on the orbit of Saturn, from which it suffers the greatest disturbance. This is owing to the particular position of the nodes and the inclinations of the orbits.

The inclination of a planetary orbit increases while the planet approaches the node, and diminishes while the planet retires from it.

368 A peculiarity explained in the motions of Jupiter and Saturn.

M. de la Place has completed this deduction of the planetary inequalities, by explaining a peculiarity in the motions of Jupiter and Saturn, which has long employed the attention of astronomers. The accelerations and retardations of the planetary motions depend, as has been shown, on their configurations, or the relative quarters of the heavens in which they are. Those of Mercury, Venus, the Earth, and Mars, arising from their mutual deflections, and their more remarkable deflections to the great planets Jupiter and Saturn, nearly compensate each other, and no traces of them remain after a few revolutions: but the positions of the aphelia of Saturn and Jupiter are such, that the retardations of Saturn sensibly exceed the accelerations, and the anomalistic period of Saturn increases almost a day every century; on the contrary, that of Jupiter diminishes. M. de la Place shows, that this proceeds from the position of the aphelia, and the almost perfect commensurability of their revolutions; five revolutions of Jupiter making 21,675 days, while two revolutions of Saturn make 21,538 differing only 137 days.

Supposing the relation to be exact, the theory shows, that the mutual actions of these planets must produce mutual accelerations and retardations of their mean motions, and ascertains the periods and limits of the secular equations thence arising. These periods include several centuries. Again, because this relation is not precise, but the odd days nearly divide the periods already found, there must arise an equation of this secular equation, of which the period is immensely longer, and the maximum very minute. He shews that this retardation of Saturn is now at its maximum, and is diminishing again, and will, in the course of years, change to an acceleration.

This investigation of the small inequalities is the most intricate problem in mechanical philosophy, and has been completed only by very slow degrees, by the arduous efforts of the greatest mathematicians, of whom M. de la Grange is the most eminent. Some of his general results are very remarkable.

He demonstrates, that since the planets move in one direction, in orbits nearly circular, no mutual disturbances make any permanent change in the mean distances and mean periods of the planets, and that the periodic changes are confined within very narrow limits. 369

369 Oscillation of the planetary system.

The orbits can never deviate sensibly from circles. None of them ever has been or will be a comet moving in a very eccentric orbit. The ecliptic will never coincide with the equator, nor change its inclination above two degrees. In short, the solar planetary system oscillates, as it were, round a medium state, from which it never swerves very far.

This theory of the planetary inequalities, founded on the universal law of mutual deflection, has given to our tables a precision, and a coincidence with observation, that surpasses all expectation, and insures the legitimacy of the theory. The inequalities are most sensible in the motions of Jupiter and Saturn; and these present themselves in such a complicated state, and their periods are so long, that ages were necessary for discovering them

Digitized by Google

Theory of Universal Gravitation.

by mere observation. In this respect, therefore, the theory has outstripped the observations on which it is founded. It is very remarkable, that the periods which the Indians assign to these two planets, and which appeared so inaccurate that they hurt the credit of the science of those ancient astronomers, are now found precisely such as must have obtained about three thousand years before the Christian era; and thus they give an authenticity to that ancient astronomy. The periods which any nation of astronomers assign to those two planets would afford no contemptible mean for determining the age in which it was observed.

370 Authenticity of the Indian astronomy.

The following circumstance pointed out by La Place is remarkable: Suppose Jupiter and Saturn in conjunction in the first degree of Aries; twenty years after, the conjunction will happen in Sagittarius; and after other twenty years, in Leo. It will continue in these three signs for 200 years. In the year 200 it will happen in Taurus, Capricornus, and Virgo; in the next 200 years, it will happen in Gemini, Aquarius, and Libra; and in the next 200 years, it will happen in Cancer, Pisces, and Scorpio: then all begins again in Aries. It is probable that these remarkable periods of the oppositions of Jupiter and Saturn, progressive for 40 years, and oscillating during 160 more, occasioned the astrological division of the heavens into the four *trigons*, of fire, air, earth, and water. These relations of the signs, which compose a trigon, point out the repetitions of the chief irregularities of the solar system.

371 Origin of the astrological division of the heavens.

M. de la Place observes (in 1796), that the planet Herschel gives evident marks of the action of the rest; and that when these are computed and taken into the account of its bygone motions, they put it beyond doubt that it was seen by Flamstead in 1690, by Mayer in 1756, and by Monnier in 1769.

SECT. III. *Of the Disturbances in the Elliptical Motion of the Comets.*

Before the time of Sir Isaac Newton it was supposed that they moved in straight lines: and Descartes, finding that such a motion would interfere with his vortices, removed them entirely out of the solar system. Sir Isaac Newton, however, distinctly proves from astronomical observation, that the comets pass through the planetary regions, and are generally invisible at a greater distance than that of Jupiter. Hence, finding that they were evidently within the sphere of the sun's action, he concludes, that they must necessarily move about the sun as the planets do; and he proves, that the power of the sun being reciprocally in the duplicate proportion of the distance, every body acted upon by him must either fall directly down, or move about him in one of the conic sections; viz. either the ellipsis, parabola, or hyperbola. If a body which descends towards the sun as low as the orbit of any planet, move with a swifter motion than the planet, it will describe an orbit of a more oblong figure than that of the planet, and have at least a longer axis. The velocity of the body may be so great, that it shall move in a parabola, so that having once passed the sun, it shall ascend for ever without returning, though the sun will still continue in the focus of that parabola; and with a velocity still greater, they will move in an hyperbola. It is, however, most probable, that the comets move in very eccentric ellipses, such as is represented in fig. 136. where S represents the sun, C the comet, and ABDE its orbit; wherein the distance of S and D far exceeds that of S and A. Hence those bodies are sometimes found at a moderate distance from the sun, and appear within the planetary regions; at other times they ascend to vast distances, far beyond the orbit of Saturn, and thus become invisible.

372 Comets generally invisible until they come nearer than Jupiter.

That the comets do move in this manner is proved by our author from computations built upon the observations made by many astronomers. These computations were made by Sir Isaac Newton himself upon the comet which appeared toward the latter end of the year 1680 and beginning of 1681, and the same were prosecuted more at large by Dr Halley upon this and other comets. They depend on this principle, that the eccentricity of the orbits of the comets is so great, that if they are really elliptical, yet that part of them which comes under our view approaches so near to a parabola that they may be taken for such without any sensible error, as in the foregoing figure the parabola FAG, in the lower part of it about A, differs very little from the ellipsis DEAB; on which foundation Sir Isaac teaches a method of finding the parabola in which any comet moves, by three observations made upon it in that part of its orbit where it agrees nearest with a parabola: and this theory is confirmed by astronomical observations; for the places of the comets may thus be computed as exactly as those of the primary planets. Our author afterwards shows how to make use of any small deviation from the parabola which may be observed, to determine whether the orbits of the comets be elliptical or not; and thus to know whether or not the same comet returns at different seasons. On examining by this rule the comet of 1680, he found its orbit to agree more exactly with an ellipsis than a parabola, though the ellipsis be so very eccentric, that it cannot perform its revolution in 500 years. On this Dr Halley observed, that mention is made in history of a comet with a similar large tail, which appeared three several times before. The first was before the death of Julius Cæsar; and each appearance happened at the interval of 575 years, the last coinciding with the year 1680. He therefore calculated the motion of this comet to be in such an eccentric orbit, that it could not return in less than 575 years: which computation agrees yet more perfectly with the observations made on this comet than any parabolic orbit will do. To compare together different appearances of the same comet, is indeed the only method of discovering with certainty the form of its orbit; for it is impossible to discover the form of one so exceedingly eccentric from observations taken in a small part of it. Sir Isaac Newton therefore proposes to compare the orbits, on the supposition that they are parabolical, of such comets as appear at different times; for if we find the same orbit described by a comet at different times, in all probability it will be the same comet that describes it. Here he remarks from Dr Halley, that the same orbit very nearly agrees to two appearances of a comet about the space of 75 years distance; so that if these two appearances were really of the same comet, the transverse axis of its orbit would be 18 times that of the axis of the earth's orbit; and therefore, when at its greatest distance from the sun, this comet would be removed not less than 35 times the mean distance of the earth from the same luminary.

The

Theory of Universal Gravitation.

375 They are affected by the planets. The comets may be considerably affected by the planets. The very important phenomenon of the return of the comet of 1682, which was to decide whether they were revolving planets describing ellipses, or bodies which come but once into the planetary regions, and then retire for ever, caused the astronomers to consider this matter with great care. Halley had shown, in a rough way, that this comet must have been considerably affected by Jupiter. Their motion near the aphelion must be very slow, so that a very small change of velocity or direction, while in the planetary regions, must considerably affect their periods. Halley thought that the action of Jupiter might change it half a year. M. Clairaut, by considering the disturbing forces of Jupiter and Saturn through the whole revolution, showed that the period then running would exceed the former nearly two years (618 days), and assigned the middle of April 1759 for the time of its perihelion. It really passed its perihelion on the 12th of March. This was a wonderful precision, when we reflect that the comet had been seen but a very few days in its former apparitions.

A comet observed by Mr Prosperin and others in 1771 has greatly puzzled the astronomers. Its motions appear to have been extremely irregular, and it certainly came so near Jupiter, that his momentary influence was at least equal to the sun's. It has not been recognised since that time, although there is a great probability that it is continually among the planets.

376 Consequence of a comet and planet meeting. It is by no means impossible, that, in the course of ages, a comet may actually meet one of the planets. The effect of such a concourse must be dreadful; a change of the axis of diurnal rotation must result from it, and the sea must desert its former bed and overflow the new equatorial regions. The shock and the deluge must destroy all the works of man, and most of the race. The remainder, reduced to misery, must long struggle for existence, and all remembrance of former arts and events must be lost, and every thing must be invented anew. There are not wanting traces of such devastations in this globe: strata and things are now found on mountain tops which were certainly at the bottom of the ocean in former times; remains of tropical animals and plants are now dug up in the circumpolar regions.

SECT. IV. *Of the Irregularities in the Moon's Motion.*

The moon is acted on at once by the sun and the earth: but her motion round the earth is only disturbed by the difference of the sun's action on these two bodies. If the sun were at an infinite distance it would act upon them both equally and in a parallel direction; of course, their relative motion would not be disturbed. But its distance, though very great, when compared with that of the moon, cannot be considered as infinite. The moon is alternately nearer and farther from the sun than the earth, and the straight line which joins the centre of the sun and moon forms angles more or less acute with the radius vector of the earth. Of course the sun acts unequally, and in different directions, upon the earth and moon; and from that diversity of action, there ought to result irregularities in the lunar motions, depending on the respective situation of the sun and moon.

Some of these inequalities, however, would take place, though the moon if undisturbed by the sun had moved in a circle concentrical to the earth, and in the plane of the earth's motion; others depend on the elliptical figure and oblique situation of the moon's orbit. One of the former is, that the moon does not describe equal spaces in equal times, but is continually accelerated as she passes from the quarter to the new or full, and is retarded again by the like degrees in returning from the new and full to the next quarter: but here we consider not so much the absolute as the apparent motions of the moon with respect to us. These two may be distinguished in the following manner: Let S in fig. 137. represent the sun, A the earth moving in its orbit BC, DEFG the moon's orbit, and H the place of the moon in her orbit. Suppose the earth to have moved from A to I. Because it has been shown that the moon partakes of all the progressive motion of the earth, and likewise that the sun attracts both the earth and moon equally when they are at the same distance from it, or that the mean action of the sun upon the moon is equal to its action upon the earth; we must therefore consider the earth as carrying about with it the moon's orbit: so that when the earth is removed from A to I, the moon's orbit shall likewise be removed from its former situation into that denoted by KLMN. But now the earth being in I, if the moon were found in O, so that OI should be parallel to HA, though the moon would really have moved from H to O, yet it would not have appeared to a spectator upon the earth to have moved at all, because the earth has moved as much as itself; so that the moon would still appear in the same place with respect to the fixed stars. But if the moon be observed in P, it will then appear to have moved, its apparent motion being measured by the angle under OIP. And if the angle under PIS be less than the angle under HAS, the moon will have approached nearer its conjunction with the sun. Now, to explain particularly the inequality of the moon's motion already mentioned, let S in fig. 138. represent the sun, A the earth, BCDE the moon's orbit, C the place of the moon when in the latter quarter. Here it will be nearly at the same distance from the sun as the earth is. In this case, therefore, they will be both equally attracted, the earth in the direction AS, and the moon in that of CS. Whence, as the earth, in moving round the sun, is continually descending towards it, so the moon in this situation must in any equal portion of time descend as much; and therefore the position of the line AC in respect of AS, and the change which the moon's motion produces in the angle CAS, will not be altered by the sun: but as soon as the moon is advanced from the quarter towards the new or conjunction, suppose to G, the action of the sun upon it will have a different effect. Were the sun's action upon the moon here to be applied in the direction GH parallel to AS, if its action on the moon were equal to its action on the earth, no change would be wrought by the sun on the apparent motion of the moon round the earth. But the moon receiving a greater impulse in G than the earth receives in A, were the sun to act in the direction GH, yet it would accelerate the description of the space DAG, and cause the angle under DAG to decrease faster than it otherwise would. The sun's action will have this effect upon account of the obli-

377 Inequalities of the moon's motion explained.

quity

Theory of Universal Gravitation.

quity of its direction to that in which the earth attracts the moon. For the moon by this means is drawn by two forces oblique to one another; one drawing from G towards A, the other from G towards H; therefore the moon must necessarily be impelled toward D. Again, because the sun does not act in the direction GH parallel to SA, but in the direction GS oblique to it, the sun's action on the moon will, by reason of this obliquity, farther contribute to the moon's acceleration. Suppose the earth, in any short space of time, would have moved from A to I, if not attracted by the sun, the point I being in the straight line CE, which touches the earth's orbit in A. Suppose the moon in the same time would have moved in her orbit from G to K, and besides have partook of all the progressive motion of the earth. Then, if KL be drawn parallel to AI, and taken equal to it, the moon, if not attracted to the sun, would be found in L. But the earth, by the sun's action, is removed from I. Suppose it were moved down to M in the line IMN parallel to SA, and if the moon were attracted but as much, and in the same direction as the earth is here supposed to be attracted, so as to have descended during the same time in the line LO parallel also to AS, down as far as P, till LP were equal to IM, the angle under PMN would be equal to that under LIN; that is, the moon will appear advanced as much farther forward than if neither it nor the earth had been subject to the sun's action. But this is on the supposition that the actions of the sun upon the earth and moon are equal; whereas the moon being acted upon more than the earth, did the sun's action draw the moon in the line LO parallel to AS, it would draw it down so far as to make LP greater than IM, whereby the angle under PMN will be rendered greater than that under LIN. But, moreover, as the sun draws the earth in a direction oblique to IN, the earth will be found in its orbit somewhat short of the point M. However, the moon is attracted by the sun still more out of the line LO than the earth is out of the line IN; therefore this obliquity of the sun's action will yet farther diminish the angle under PMN. Thus the moon at the point G receives an impulse from the sun whereby her motion is accelerated; and the sun producing this effect in every place between the quarter and the conjunction, the moon will move from the quarter with a motion continually more and more accelerated; and therefore, by acquiring from time to time an additional degree of velocity in its orbit, the spaces which are described in equal times by the line drawn from the earth to the moon will not be everywhere equal, but those toward the conjunction will be greater than those toward the quarter. But in the moon's passage from the conjunction D to the next quarter, the sun's action will again retard the moon, till, at the next quarter at E, it be restored to the first velocity which it had in C. When the moon moves from E to the full, or opposition to the sun in B, it is again accelerated; the deficiency of the sun's action on the moon from what it has upon the earth producing here the same effect as before the excess of its action.

Let us now consider the moon in Q as moving from F towards B. Here, if she were attracted by the sun in a direction parallel to AS, yet being acted on less than the earth, as the latter descends towards the sun, the moon will in some measure be left behind. Therefore, QF being drawn parallel to SB, a spectator on the earth would see the moon move as if attracted from the point Q in the direction QF, with a degree of force equal to that whereby the sun's action on the moon falls short of its action on the earth. But the obliquity of the sun's action has here also an effect. In the time the earth would have moved from A to I without the influence of the sun, let the moon have moved in its orbit from Q to R. Drawing, therefore, RT parallel and equal to AI, the moon, by the motion of its orbit, if not attracted by the sun, must be found in T: and therefore, if attracted in a direction parallel to SA, would be in the line TV parallel to AS; suppose in W. But the moon in Q being farther off the sun than the earth, it will be less attracted; that is TW will be less than IM; and if the line SM be prolonged towards X, the angle under XMW will be less than XIT. Thus, by the sun's action, the moon's passage from the quarter to the full would be accelerated, if the sun were to act on the earth and moon in a direction parallel to AS; and the obliquity of the sun's action will still increase this acceleration: For the action of the sun on the moon is oblique to the line SA the whole time of the moon's passage from Q to T, and will carry her out of the line TV towards the earth. Here we suppose the time of the moon's passage from Q to T so short, that it shall not pass beyond the line SA. The earth will also come a little short of the line IN, as was already mentioned; and from these causes the angle under XMW will be still farther lessened. The moon, in passing from the opposition B to the next quarter, will be retarded again by the same degrees as it was accelerated before its appulse to the opposition; and thus the moon, by the sun's action upon it, is twice accelerated and twice restored to its first velocity every circuit it makes round the earth; and this inequality of the moon's motion about the earth is called by astronomers its variation.

771 Effect of the sun's attraction in different parts of the moon's orbit.

The next effect of the sun upon the moon is, that it gives the orbits of the latter in the quarters a greater degree of curvature than it would receive from the earth alone: and, on the contrary, in the conjunction and opposition the orbit is less inflected. When the moon is in the conjunction with the sun at D, the latter attracting her more forcibly than it does the earth, the moon is by that means impelled less to the earth than otherwise it would be, and thus the orbit is less incurvated; for the power by which the moon is impelled towards the earth being that by which it is inflected from a rectilinear course, the less that power is, the less it will be inflected. Again, when the moon is in the opposition in B farther removed from the sun than the earth is, it follows, then, that though the earth and moon are both continually descending toward the sun, that is, are drawn by the sun towards itself out of the place they would otherwise move into, yet the moon descends with less velocity than the earth: insomuch that, in any given space of time from its passing the point of opposition, it will have less approached the earth than otherwise it would have done; that is, its orbit, in respect to the earth, will approach nearer to a straight line. Lastly, when the motion is in the quarter in F, and equally distant from the sun as the earth, it

Digitized by Google

Theory of Universal Gravitation.

it was before observed, that they would both descend with equal velocity towards the sun, so as to make no change in the angle FAS; but the length of the line FA must necessarily be shortened. Therefore the moon, in moving from F toward the conjunction with the sun, will be impelled more toward the earth by the sun's action than it would have been by the earth alone, if neither the earth nor the moon had been acted upon by the sun: so that, by this additional impulse, the orbit is rendered more curve than it otherwise should be. The same effect will also be produced in the other quarter.

379 Moon comes nearest the earth when least attracted by it.

A third effect of the sun's action, and which follows from that just now explained, is, that though the moon undisturbed by the sun might move in a circle, having the earth for its centre, by the sun's action, if the earth were to be in the very middle or centre of the moon's orbit, yet the moon would be nearer the earth at the new and full than in the quarters. This may at first appear somewhat difficult to be understood, that the moon should come nearest to the earth when it is least attracted by it; yet, upon a little consideration, it will evidently appear to flow from that very cause, because her orbit, in the conjunction and opposition, is rendered less curve: for the less curve the orbit is, the less will the moon have descended from the place it would move into without the action of the earth. Now, if the moon were to move from any place without further disturbance from that action, since it would proceed on the line touching the orbit in that place, it would continually recede from the earth; and therefore, if the power of the earth upon the moon be sufficient to retain it at the same distance, this diminution of that power will cause the distance to increase, though in a less degree. But, on the other hand, in the quarters, the moon being pressed in a less degree towards the earth than by the earth's single action, will be made to approach it: so that, in passing from the conjunction or opposition to the quarters, the moon ascends from the earth; and in passing from the quarters to the opposition or conjunction, it descends again, becoming nearer in these last-mentioned places than in the other.

All the inequalities we have mentioned are different in degree as the sun is more or less distant from the earth; being greatest when the earth is in its perihelion, and smallest when it is in its aphelion: for in the quarters, the nearer the moon is to the sun, the greater is the addition to the earth's action upon it by the power of the sun; and, in the conjunction and opposition, the difference between the sun's action upon the earth and upon the moon is likewise so much the greater.

380 Cause of the dilatation of the moon's orbit.

This difference in the distance between the earth and the sun produces a further effect upon the moon's motion; causing her orbit to dilate when less remote from the sun, and become greater than when at a farther distance: For it is proved by Sir Isaac Newton, that the action of the sun by which it diminishes the earth's power over the moon in the conjunction or opposition, is about twice as great as the addition to the earth's action by the sun in the quarters; so that, upon the whole, the power of the earth on the moon is diminished by the sun, and therefore is most diminished when that action is strongest: but as the earth, by its approach to the sun, has its influence lessened, the moon, being less attracted, will gradually recede from the earth; and as the earth, in its recess from the sun, recovers by degrees its former power, the orbit of the moon must again contract. Two consequences follow from hence, viz. that the moon will be more remote from the earth when the latter is nearest the sun, and also will take up a longer time in performing its revolution through the dilated orbit than through the more contracted.

These irregularities would be produced, if the moon, without being acted upon unequally by the sun, should describe a perfect circle about the earth, and in the plane of its motion; but though neither of these circumstances take place, yet the above-mentioned inequalities occur, only with some little variation with regard to the degree of them; but some others are observed to take place, from the moon's motion being performed in the manner already described: For, as the moon describes an ellipsis, having the earth in one of its foci, this curve will be subjected to various changes, neither preserving constantly the same figure nor position; and because the plane of this ellipsis is not the same with that of the earth's orbit, it thence follows, that the former will continually change; so that neither the inclination of the two planes towards each other, nor the line in which they intersect, will remain for any length of time unaltered.

381 Action of the sun causes the plane of the moon's orbit to change.

As the moon does not move in the same plane with the earth, the sun is but seldom in the plane of her orbit, viz. only when the line made by the common intersection of the two planes, if produced, will pass through the sun. Thus, let S in fig. 139. denote the sun, T the earth, ATB the plane of the earth's orbit, CDEF the moon's orbit; the part CDE being raised above, and the part CFE depressed under the former. Here the line CE, in which the two planes intersect each other, being continued, passes through the sun in S. When this happens, the action of the sun is directed in the plane of the moon's orbit, and cannot draw her out of this plane, as will evidently appear from an inspection of the figure; but in other cases the obliquity of the sun's action to the plane of the orbit will cause this plane continually to change.

Let us now suppose, in the first place, the line in which the two planes intersect each other to be perpendicular to the line which joins the earth and sun. Let T, in fig. 140, 141, 142, 143. represent the earth; S the sun; the plane of the scheme the plane of the earth's orbit, in which both the sun and earth are placed. Let AC be perpendicular to ST, which joins the earth and sun; and let the line AC be that in which the plane of the moon's orbit intersects the orbit of the earth. On the centre T describe in the plane of the earth's motion the circle ABCD; and in the plane of the moon's orbit describe the circle AECF; one half of which, AEC, will be elevated above the plane of this scheme, and the other half, AFC, as much depressed below it. Suppose then the moon to set out from the point A in fig. 127. in the direction of the plane AEC. Here she will be continually drawn out of this plane by the action of the sun; for this plane AEC, if extended, will not pass through the sun, but above it; so that the sun, by drawing the moon directly toward itself, will force it continually

Digitized by Google

continually more and more from that plane towards the plane of the earth's motion in which itself is, causing it to describe the line AKGHI, which will be convex to the plane AEC, and concave to the plane of the earth's motion. But here this power of the sun, which is said to draw the moon toward the plane of the earth's motion, must be understood principally of as much only of the sun's action upon the moon as it exceeds the action of the same upon the earth: For suppose the last-mentioned figure to be viewed by the eye placed in the plane of that scheme, and in the line CTA, on the side A, it will appear as the straight line DTB in fig. 126. and the plane AECF as another straight line FE, and the curve line AKGHI under the form of the line TKGHI. Now it is plain, that the earth and moon being both attracted by the sun, if the sun's action upon both was equally strong, the earth T, and with it the plane AECF, or the line FTE, would be carried towards the sun with as great velocity as the moon, and therefore the moon not drawn out of it by the sun's action, except only from the small obliquity of direction of this action upon the moon to that of the sun's action upon the earth, which arises from the moon being out of the plane of the earth's motion, and is not considerable: but the action of the sun upon the moon being greater than upon the earth all the time the moon is nearer to the sun than the earth is, it will be drawn from the plane AEC, or the line TE, by that excess, and made to describe the curve line AGI or TGI. But it is the custom of astronomers, instead of considering the moon as moving in such a curve line, to refer its motion continually to the plane which touches the true line wherein it moves at the point where at any time the moon is. Thus, when the moon is in the point A, its motion is considered as being in the plane AEC, in whose direction it then attempts to move; and when in the point K, fig. 144. its motion is referred to the plane which passes through the earth and touches the line AKGHI in the point K. Thus the moon, in passing from A to I, will continually change the plane of her motion in the manner we shall now more particularly explain.

Let the plane which touches the line AKI in the point K, fig. 141, intersect the plane of the earth's orbit in the line LTM. Then, because the line AKI is concave to the plane ABC, it falls wholly between that plane and the plane which touches it in K, so that the plane MKL will cut the plane AEC before it meets the plane of the earth's motion, suppose in the line YT, and the point A will fall between K and L. With a radius equal to TY or TL describe the semicircle LYM. Now, to a spectator on the earth, the moon when in A will appear to move in the circle AECF; and when in K, will appear to be moving in the semicircle LYM. The earth's motion is performed in the plane of this scheme; and to a spectator on the earth the sun will always appear to move in that plane. We may therefore refer the apparent motion of the sun to the circle ABCD described in this plane about the earth. But the points where this circle in

352 Nodes of the moon's orbit.

which the sun seems to move, intersecting the circle in which the moon is seen at any time to move, are called the nodes of the moon's orbit at that time. When the moon is seen moving in the circle AECD, the points A and C are the nodes of the orbit; when she appears in the semicircle LYM, then L and M are the nodes. It will now appear, from what has been said, that while the moon has moved from A to K, one of the nodes has been carried from A to L, and the other as much from C to M. But the motion from A to L and from C to M is backward in regard to the motion of the moon, which is the other way from A to K, and from thence toward C. Again, the angle which the plane wherein the moon at any time appears makes with the plane of the earth's motion, is called the inclination of the moon's orbit at that time: we shall now therefore proceed to show,

353 Inclination of her

that this inclination of the orbit, when the moon is in K, is less than when she was in A; or, that the plane LYM, which touches the line of the moon's motion in K, makes a less angle with a plane of the earth's motion, or with the circle ABCD, than the plane AEC makes with the same. The semicircle LYM intersects the semicircle AEC in Y, and the arch AY is less than LY, and both together less than half a circle. But it is demonstrated by spheric geometry, that when a triangle is made, as here, by three arches of circles AL, AY, and YL, the angle under YAB without the triangle is greater than the angle YLA within, if the two arches AY, YL, taken together, do not amount to a semicircle. If the two arches make a complete semicircle, the two angles will be equal; but if the two arches taken together exceed a semicircle, the inner angle YLA is greater than the other. Here then the two arches AL and LY together being less than a semicircle, the angle under ALY is less than the angle under BAE. But from the doctrine of the sphere it is also evident, that the angle under ALY is equal to that in which the plane of the circle LYKM, that is, the plane which touches the line AKGHI in K, is inclined to the plane of the earth's motion ABC; and the angle under BAE is equal to that in which the plane AEC is inclined to the same plane. Therefore the inclination of the former plane is less than that of the latter. Suppose, now, the moon to be advanced to the point G in fig. 142. and in this point to be distant from its node a quarter part of the whole circle; or, in other words, to be in the mid-way between its two nodes. In this case the nodes will have receded yet more, and the inclination of the orbit be still more diminished; for suppose the line AKGHI to be touched in the point G by a plane passing through the earth T, let the intersection of this plane with the plane of the earth's motion be the line WTO, and the line TP its intersection with the plane LKM. In this plane let the circle NGO be described with the semidiameter TP or NT cutting the other circle LKM in P. Now, the line AKGI is convex to the plane LKM which touches it in K; and therefore the plane NGO, which touches it in G, will intersect the other touching plane between G and K, that is, the point P will fall between these two points, and the plane continued to the plane of the earth's motion will pass beyond L; so that the points N and O, or the places of the nodes when the moon is in G, will be farther from A and C than L and M; that is, will have moved farther backward. Besides, the inclination of the plane NGO to the plane of the earth's motion ABC is less than the inclination of the plane LKM to the same; for here also the

Theory of Universal Gravitation.

the two arches LP and NP, taken together, are less than a semicircle, each of them being less than a quadrant, as appears, because GN, the distance of the moon in G from its node N, is here supposed to be a quarter part of a circle. After the moon is passed beyond G, the case is altered; for then these arches will be greater than quarters of a circle; by which means the inclination will be again increased, though the nodes still go on to move the same way. Suppose the moon in H (fig. 143.), and that the plane which touches the line AKGI in H intersects the plane of the earth's motion in the line QTR, and the plane NGO in the line TV, and besides, that the circle QHR be described in that plane; then, for the same reason as before, the point V will fall between H and G, and the plane RVQ will pass beyond the last plane OVN, causing the points Q and K to fall farther from A and C than N and O. But the arches NV, VQ are each greater than the quarter of a circle: consequently the angle under BQV will be greater than that under BNV. Lastly, when the moon is by this attraction of the sun drawn at length into the plane of the earth's orbit, the node will have receded yet more, and the inclination be so much increased, as to become somewhat more than at first: for the line AKGHI being convex to all the planes which touch it, the part HI will wholly fall between the plane QVR and the plane ABC; so that the point I will fall between B and R; and, drawing ITW, the point W will be farther removed from A than Q. But it is evident, that the plane which passes through the earth T, and touches the line AGI in the point I, will cut the plane of the earth's motion ABCD in the line ITW, and be inclined to the same in the angle under HIB; so that the node which was first in A, after having passed into L, N, and Q, comes at last in the point W, as the node which was at first in C has passed from thence successively through the points M, O, and R, to I. But the angle HIB, which is now the inclination of the orbit to the plane of the ecliptic, is manifestly not less than the angle under ECB or EAB, but rather something greater. Thus the moon, while it passes from the plane of the earth's motion in the quarter, till it comes again into the same plane, has the nodes of its orbit continually moved backward, and the inclination of it at first diminished till it comes to G in fig. 128. which is near to its conjunction with the sun, but afterwards is increased again almost by the same degrees, till upon the moon's arrival again to the plane of the earth's motion, the inclination of the orbit is restored to something more than its first magnitude, though the difference is not very great, because the points I and C are not far distant from each other.

In like manner, if the moon had departed from the quarter at C, it should have described the curve line CXW in fig. 140. between the planes AH and ADC, which would be convex to the former planes and concave to the latter; so that here also the nodes would continually recede, and the inclination of the orbit gradually diminish more and more, till the moon arrived near its opposition to the sun in X; but from that time the inclination should again increase till it become a little greater than at first. This will easily appear by considering, that as the action of the sun upon the moon, by exceeding its action upon the earth, drew it out of the plane AEC towards the sun, while the moon passed from A to I; so during its passage from C to W, the moon being all that time farther from the sun than the earth, it will be attracted less; and the earth, together with the plane AECF, will as it were be drawn from the moon, in such a manner, that the path the moon describes shall appear from the earth as it did in the former case by the moon being drawn away.

384
Motion of the nodes explained.

Such are the changes which the nodes and inclination of the moon's orbit undergo when the nodes are in the quarters; but when the nodes by their motion, and the motion of the sun together, come to be situated between the quarter and conjunction or opposition, their motion and the change made in the inclination of the orbit are somewhat different.—Let AGH, in fig. 145. be a circle described in the plane of the earth's motion, having the earth in T for its centre, A the point opposite to the sun, and G a fourth part of the circle distant from A. Let the nodes of the moon's orbit be situated in the line BTD, and B the node falling between A, the place where the moon would be in the full, and G the place where she would be in the quarter. Suppose BEDF to be the plane in which the moon attempts to move when it proceeds from the point B: then, because the moon in B is more distant from the sun than the earth, it will be less attracted by the sun, and will not descend towards the sun so fast as the earth, consequently it will quit the plane BEDF, which is supposed to accompany the earth, and describe the line BIK convex to it, till such time as it comes to the point K, where it will be in the quarter; but from thenceforth being more attracted than the earth, the moon will change its course, and the following part of the path it describes will be concave towards the plane BED or BGD, and continue concave to the plane BGD till it crosses that plane in L just as in the preceding case. Now, to show that the nodes, while the moon is passing from B to K, will proceed forward, or move the same way with the moon, and at the same time the inclination of the orbit will increase when the moon is in the point I, let the line MIN pass through the earth T, and touch the path of the moon in I, cutting the plane of the earth's motion in the line MTN, and the line BED, in TO. Because the line BIK is convex to the plane BED, which touches it in B, the plane NIM must cross the plane DEB before it meets the plane CGB; and therefore the point M will fall from G towards B; and the node of the moon's orbit being translated from B towards M is moved forward.

Again the angle under OMG, which the plane MON makes with the plane BGC, is greater than the angle OBG, which the plane BOD makes with the same. This appears from what has been already demonstrated, because the arches BO and OM are each of them less than the quarter of a circle; and therefore, taken both together, are less than a semicircle. But further, when the moon is come to the point K in its quarter, the nodes will be advanced yet farther forward, and the inclination of the orbit also more augmented. Hitherto we have referred the moon's motion to that plane, which, passing through the earth, touches the path of the moon in the point where the moon is, as we have already said that the custom of

R 2 astronomers

Digitized by Google

Theory of Universal Gravitation.

astronomers is. But in the point K no such plane can be found: on the contrary, seeing the line of the moon's motion on one side the point K is convex to the plane BED, and on the other side concave to the same, so that no plane can pass through the points T and K, but will cut the line BKL in that point; therefore instead of such a touching plane, we must make use of PKQ, which is equivalent, and with which the line BKL shall make a less angle than with any other plane; for this does as it were touch the line BK in the point K, since it cuts it in such a manner that no other plane can be drawn so as to pass between the line BK and the plane PKQ. But now it is evident, that the point P, or the node, is removed from M towards G, that is, has moved yet further forward; and it is likewise as manifest, that the angle under KPG, or the inclination of the moon's orbit in the point K, is greater than the angle under IMG, for the reason already given.

After the moon has passed the quarter, her plane being concave to the plane AGCH, the nodes will recede as before till she arrives at the point L; which shows, that considering the whole time of the moon's passing from B to L, at the end of that time the nodes shall be found to have receded, or to be placed more backward, when the moon is in L than when it was in B; for the moon takes a longer time in passing from K to L than in passing from B to K; and therefore the nodes continue to recede a longer time than they moved forwards; so that their recess must surmount their advance. In the same manner, while the moon is in its passage from K to L, the inclination of the orbit shall diminish till the moon come to the point in which it is one quarter part of a circle distant from its node, suppose in the point R; and from that time the inclination will again increase. Since, therefore, the inclination of the orbit increases while the moon is passing from B to K, and diminishes itself again only while the moon is passing from K to R, then augments again while the moon passes from B to L; it thence comes to be much more increased than diminished, and thus will be distinguishably greater when the moon comes to L than when it sets out from B. In like manner, when the moon is passing from L on the other side the plane AGCH, the node will advance forward as long as the moon is between the point L and the next quarter; but afterwards it will recede till the moon come to pass the plane AGCH again, in the point V between B and A: and because the time between the moon's passing from L to the next quarter is less than the time between that quarter and the moon's coming to the point V, the node will have receded more than it has advanced; so that the point V will be nearer to A than L is to C. So also the inclination of the orbit, when the moon is in V, will be greater than when she was in L; for this inclination increases all the time the moon is betwixt L and the next quarter, decreasing only when she is passing from this quarter to the mid-way between the two nodes, and from thence increases again during the whole passage through the other half of the way to the next node.

In this manner we see, that at every period of the moon the nodes will have receded, and thereby have approached towards a conjunction with the sun: but this will be much forwarded by the motion of the earth, or the apparent motion of the sun himself. In the last scheme the sun will appear to have moved from S towards W. Let us suppose it had appeared to have moved from S to W while the moon's node has receded from B to V; then drawing the line WTX, the arch VX will represent the distance of the line drawn between the nodes from the sun when the moon is in V; whereas the arch BA represented that distance when the moon was in B. This visible motion of the sun is much greater than that of the node; for the sun appears to revolve quite round in one year, while the node is near nineteen in making its revolution. We have also seen that when the moon was in the quadrature, the inclination of her orbit decreased till she came to the conjunction or opposition, according to the node it set out from; but that afterwards it again increased till it became at the next node rather greater than at the former. When the node is once removed from the quarter nearer to a conjunction with the sun, the inclination of the moon's orbit, when she comes into the node, is more sensibly greater than it was in the node preceding; the inclination of the orbit by this means more and more increasing till the nodes come into conjunction with the sun: at which time it has been shown that the latter has no power to change the plane of her orbit. As soon, however, as the nodes are got out of conjunction towards the other quarters, they begin to recede as before; but the inclination of the orbit in the appulse of the moon to each succeeding node is less than at the preceding, till the nodes come again into the quarters. This will appear as follows: Let A, in fig. 146. represent one of the moon's nodes placed between the point of opposition B and the quarter C. Let the plane ADE pass through the earth T, and touch the path of the moon in A. Let the line AFGH be the path of the moon in her passage from A to H, where she crosses again the plane of the earth's moon. This line will be convex towards the plane ADE, till the moon comes to G, where she is in the quarter; and after this, between G and H, the same line will be concave towards this plane. All the time this line is convex towards the plane ADE, the nodes will recede; and, on the contrary, move forward when the line is concave towards that plane. But the moon is longer in passing from A to G, and therefore the nodes go backward farther than they proceed; and therefore, on the whole, when the moon has arrived at H, the nodes will have receded, that is, the point H will fall between B and E. The inclination of the orbit will decrease till the moon is arrived at the point F in the middle between A and H. Through the passage between F and G the inclination will increase, but decrease again in the remaining part of the passage from G to H, and consequently at H must be less than at A. Similar effects, both with respect to the nodes and inclination of the orbit, will take place in the following passage of the moon on the other side of the plane ABEC from H, till it comes over that plane again in I.

Thus the inclination of the orbit is greatest when the line drawn between the moon's nodes will pass through the sun, and least when this line lies in the quarters; especially if the moon at the same time be in conjunction with the sun, or in the opposition. In the

Theory of Universal Gravitation.

the first of these cases the nodes have no motion; in all others, the nodes will each month have receded: and this retrograde motion will be greatest when the nodes are in the quarters, for in that case they will have no progressive motion during the whole mouth; but in all other cases they at some times go forward, viz. whenever the moon is between either of the quarters and the node which is less distant from that quarter than the fourth part of a circle.

385 Irregularities arising from the moon's motion in an ellipsis.

We have now only to explain those irregularities of the lunar motion which arise from her motion in an ellipsis. From what has been already said it appears, that the earth acts on the moon in the reciprocal duplicate proportion of the distance; therefore the moon, if undisturbed by the sun, would move round the earth in a true ellipsis, and a line drawn from the earth to the sun would pass over equal spaces in equal times. We have, however, already shown, that this equality is disturbed by the sun, and likewise how the figure of the orbit is changed each month; that the moon is nearer the earth at the new and full, and more remote in the quarters than it would be without the sun. We must, however, pass by those monthly changes, and consider the effect which the sun will have in the different situations of the axis of the orbit in respect of that luminary. This action varies the force wherewith the moon is drawn towards the earth. In the quarters the force of the earth is directly increased by the sun, but diminished at the new and full; and in the intermediate places the influence of the earth is sometimes lessened, sometimes assisted, by the action of that luminary. In these intermediate places, however, between the quarters and the conjunction or opposition, the sun's action is so oblique to that of the earth on the moon, as to produce that alternate acceleration and retardation of her motion so often mentioned. But besides this effect, the power by which the moon attracts the earth towards itself, will not be at full liberty to act with the same force as if the sun acted not at all on the moon; and this effect of the sun's action, whereby it corroborates or weakens the action of the earth, is here only to be considered; and by means of this influence it comes to pass, that the power by which the moon is impelled towards the earth is not perfectly in the reciprocal duplicate proportion of the distance, and of consequence the moon will not describe a perfect ellipsis. One particular in which the lunar orbit will differ from a perfect elliptic figure, consists in the places where the motion of the moon is perpendicular to the line drawn from itself to the earth. In an ellipsis, after the moon should have set out in the direction perpendicular to this line, drawn from itself to the earth, and at its greatest distance from the earth, its motion would again become perpendicular to this line drawn between itself and the earth, and the moon be at its nearest distance from the earth, when it should have performed half its period: after having performed the other half period of its motion, it would again become perpendicular to the forementioned line, and the moon return to the place when it set out, and have recovered again its greatest distance. But the moon in its real motion, after setting out as before, sometimes makes more than half a revolution before its motion comes again to be perpendicular to the line drawn from itself to the earth, and the moon is at its nearest distance, and then performs more than another half of an entire revolution before its motion can a second time recover its perpendicular direction to the line drawn from the moon to the earth, and the former arrive again at its greatest distance from the earth. At other times the moon will descend to her nearest distance before she has made half a revolution, and recover again its greatest distance before she has made an entire revolution. The place where the moon is at its greatest distance is called

386 Apogeon and perigeon of the moon.

the *moon's apogeon*, and the place of her greatest distance her *perigeon;* and this change of place, where the moon comes successively to its greatest distance from the earth, is called the *motion of the apogeon*. The manner in which this motion of the apogeon is caused by the sun, comes now to be explained.

Sir Isaac Newton has shown, that if the moon were attracted towards the earth by a composition of two powers, one of which was reciprocally in the duplicate proportion of the distance from the earth, and the other reciprocally in the triplicate proportion of the same distance; then, though the line described by the moon would not be in reality an ellipsis, yet the moon's motion might be perfectly explained by an ellipsis whose

387 Motion in antecedence and consequence explained.

axis should be made to move round the earth: this motion being in consequence, as astronomers express themselves, that is, the same way as the moon itself moves, if the moon be attracted by the sum of the two powers; but the axis must move in antecedence, or the contrary way, if the moon be acted upon by the difference of these forces. We have already explained what is meant by duplicate proportion, namely, that if three magnitudes, as A, B, and C, are so related that the second B bears the same proportion to the third C as the first A bears to the second B; then the proportion of the first A to the third C is the duplicate of the

388 Triplicate proportion explained.

proportion of the first A to the second B. Now if a fourth magnitude as D be assumed, to which D shall bear the same proportion as A bears to B, and B to C; then the proportion of A to D is the triplicate of the proportion of A to B.

389 Motion of the moon's apogeon determined.

Let now T (fig. 147, 148.) denote the earth, and suppose the moon in the point A its apogeon or greatest distance from the earth, moving in the direction AF perpendicular to AB, and acted upon from the earth by two such forces as already mentioned. By that power alone, which is reciprocally in the duplicate proportion of the distance, if the moon set out with a proper degree of velocity, the ellipsis AMB may be described: but if the moon be acted upon by the sum of the forementioned powers, and her velocity in the point A be augmented in a certain proportion; or if that velocity be diminished in a certain proportion *, and the moon be acted upon by the difference of those powers; in both these cases the line AE, which shall be described by the moon, shall thus be determined. Let the point M be that into which the moon would have arrived in any given point of time, had it moved in the ellipsis AMB; draw MT and likewise CTD in such a manner that the angle ATM shall bear the same proportion to the angle under ATC, as the velocity with which the ellipsis must have been described bears to the difference between this velocity and that with which the moon must set out from the point A, in order to describe the path AE. Let the angle ATC be taken towards the moon, as in fig. 133.

* See Newton's Principia, book i. prop. 44. corol. 2.

if

Theory of Universal Gravitation.

if the moon be attracted by the sum of the powers; but the contrary way (as in fig. 134.) if by their difference. Then let the line AB be moved into the position CD, and the ellipsis AMB into the situation CND, so that the point M be translated to L; then the point L shall fall upon the path of the moon AE. Now the angular motion of the line AT, whereby it is removed into the situation CT, represents the motion of the apogeon; by the means of which the motion of the moon might be fully explained by the ellipsis AMB, if the action of the sun upon it was directed to the centre of the earth, and reciprocally in the triplicate proportion of the moon's distance from it; but that not being so, the motion of the apogeon will not proceed in the regular manner now described. It is, however, to be observed here, that in the first of the two preceding cases, where the apogeon moves forward, the whole centripetal power increases faster, with the decrease of distance, than if the entire power were reciprocally in the duplicate proportion of the distance; because one part only is already in that proportion, and the other part, which is added to this to make up the whole power, increases faster with the decrease of distance. On the other hand, when the centripetal power is the difference between these two bodies, it increases less with the decrease of the distance, than if it were simply in the reciprocal duplicate proportion of the distance. Therefore, if we choose to explain the moon's motion by an ellipsis, which may be done without any sensible error, we may collect in general, that when the power by which the moon is attracted to the earth, by varying the distance, increases in a greater than the duplicate proportion of the distance diminished, a motion in consequence must be ascribed to the apogeon; but that when the attraction increases in a smaller proportion than that just mentioned, the apogeon must have given to it a motion in antecedence. It is then observed by Sir Isaac Newton, that the former of these cases obtains when the moon is in the conjunction and opposition, and the latter when she is in the quarters; so that in the former the apogeon moves according to the order of the signs; in the other, the contrary way. But, as has been already mentioned, the disturbance given to the action of the earth by the sun in the conjunction and opposition, being near twice as great as in the quarters, the apogeon will advance with a greater velocity than recede, and in the compass of a whole revolution of the moon will be carried in consequence.

390 **Inequality in the motion of the apogeon.**

Sir Isaac shows, in the next place, that when the line AB coincides with the line that joins the sun and earth, the progressive motion of the apogeon, when the moon is in conjunction or opposition, exceeds the retrograde, in the quadratures, more than in any other situation of the line AB. On the contrary, when the line AB makes right angles with that which joins the earth and sun, the retrograde motion will be more considerable, nay, is found so great as to exceed the progressive; so that in this case the apogeon, in the compass of an entire revolution of the moon, is carried in antecedence. Yet from the considerations already mentioned, the progressive motion exceeds the other; so that, on the whole, the motion of the apogeon is in consequence. The line AB also changes its situation with that which joins the earth and sun by such slow degrees, that the inequalities of the motion of the apogeon, arising from this last consideration, are much greater than what arise from the other.

391 **Occasions another inequality in the eccentricity of the moon's orbit.**

This unsteady motion of the apogeon gives rise to another inequality in the motion of the moon herself, so that it cannot at all times be explained by the same ellipsis. For whenever the apogeon moves in consequence, the motion of the luminary must be referred to an orbit more eccentric than what the moon would describe, if the whole power by which the moon was acted upon in its passing from the apogeon changed according to the reciprocal duplicate proportion of its distance from the earth, and by that means the moon did describe an immoveable ellipsis: and when the apogeon moves in antecedence, the moon's motion must be referred to an orbit less eccentric. In the former of the two figures last referred to, the true place of the moon L falls without the orbit AMB, to which its motion is referred: whence the orbit ALE truly described by the moon, is less incurvated in the point A than is the orbit AMB: therefore this orbit is more oblong, and differs farther from a circle than the ellipsis would, whose curvature in A were equal to that of the line ALB: that is, the proportion of the distance of the earth T from the centre of the ellipsis to its axis, will be greater in AMB than in the other; but that other is the ellipsis which the moon would describe, if the power acting upon it in the point A were altered in the reciprocal duplicate proportion of the distance; and consequently the moon being drawn more forcibly toward the earth, it will descend nearer to it. On the other hand, when the apogeon recedes, the power acting on the moon increases with the decrease of distance, in less than the duplicate proportion of the distance; and therefore the moon is less impelled towards the earth, and will not descend so low. Now, suppose, in the former of these figures, that the apogeon A is in the situation where it is approaching towards the conjunction or opposition of the sun; in this case its progressive motion will be more and more accelerated. Here suppose the moon, after having descended from A through the orbit AE as far as F, where it is come to its nearest distance from the earth, ascends again up the line FG. As the motion of the apogeon is here more and more accelerated, it is plain that the cause of its motion must also be on the increase: that is, the power by which the moon is drawn to the earth, will decrease with the increase of the moon's distance in her ascent from F, in a greater proportion than that wherewith it is increased with the decrease of distance in the moon's distance to it. Consequently the moon will ascend to a greater distance than AT from whence it is descended; therefore the proportion of the greatest distance of the moon to the least is increased. But farther, when the moon again descends, the power will increase yet farther with the decrease of distance than in the last ascent it increased with the augmentation of distance. The moon therefore must descend nearer to the earth than it did before, and the proportion of the greatest distance to the least be yet more increased. Thus, as long as the apogeon is advancing to the conjunction or opposition, the proportion of the greatest distance of the moon from the earth to the least will continually increase; and the elliptical orbit to which the moon's motion is referred will

Digitized by Google

will become more and more eccentric. As soon, however, as the apogeon is past the conjunction or opposition with the sun, its progressive motion abates, and with it the proportion of the greatest distance of the moon from the earth to the least will also diminish: and when the apogeon becomes retrograde, the diminution of this proportion will be still farther continued, until the apogeon comes into the quarter; from thence this proportion, and the eccentricity of the orbit, will increase again. Thus the orbit of the moon is most eccentric when the apogeon is in conjunction with the sun, or in opposition to it, and least of all when the apogeon is in the quarters. These changes in the nodes, the inclination of the orbit to the plane of the earth's motion, in the apogeon and in the eccentricity, are varied like the other inequalities in the motion of the moon, by the different distance of the earth from the sun being greatest when their cause is greatest: that is, when the earth is nearest the sun.

392 Computation of the lunar inequalities.

Sir Isaac Newton has computed the very quantity of many of the moon's inequalities. That acceleration of the moon's motion which is called the *variation*, when greatest, removes the luminary out of the place in which it would otherwise be found, somewhat more than half a degree. If the moon, without disturbance from the sun, would have described a circle concentrical to the earth, his action will cause her approach nearer in the conjunction and opposition than in the quarters, nearly in the proportion of 69 to 70. It has already been mentioned, that the nodes perform their period in almost 19 years. This has been found by observation; and the computations of Sir Isaac assigned to them the same period. The inclination of the moon's orbit, when least, is an angle about one-eighteenth of that which constitutes a right angle; and the difference between the greatest and least inclination, is about one-eighteenth of the least inclination, according to our author's computation: which is also agreeable to the general observations of astronomers.

There is one empirical equation of the moon's motion which the comparison of ancient and modern eclipses obliges the astronomers to employ, without being able to deduce it, like the rest, *à priori*, from the theory of an universal force inversely proportional to the square of the distance. It has therefore been considered as a stumbling block in the Newtonian philosophy.

393 The secular equation of the moon's mean distance.

This is what is called *the secular equation of the moon's mean motion*. The mean motion is deduced from a comparison of distant observations. The time between them, being divided by the number of intervening revolutions, gives the average time of one revolution, or the mean lunar period. When the ancient Chaldean observations are compared with those of Hipparchus, we obtain a certain period; when those of Hipparchus are compared with some in the 9th century, we obtain a period somewhat shorter; when the last are compared with those of Tycho Brahe, we obtain one still shorter; and when Brahe's are compared with those of our day, we obtain the shortest period of all—and thus the moon's mean motion appears to accelerate continually; and the accelerations appear to be in the duplicate ratio of the times. The acceleration for the century which ended in 1700 is about 9 seconds of a degree; that is to say, the whole motion of the moon during the 17th century must be increased 9 seconds, in order to obtain its motion during the 18th; and as much must be taken from it, or added to the computed longitude, to obtain its motion during the 16th: and the double of this must be taken from the motion during the 16th, to obtain its motion during the 15th, &c. Or it will be sufficient to calculate the moon's mean longitude for any time past or to come by the secular motion which obtains in the present century, and then to add to this longitude the product of 9 seconds, multiplied by the square of the number of centuries which intervene. Thus having found the mean longitude for the year 1200, add 9 seconds, multiplied by 36, for six centuries. By this method we shall make our calculation agree with the most ancient and all intermediate observations. If we neglect this correction, we shall differ more than a degree from the Chaldean observation of the moon's place in the heavens.

The mathematicians having succeeded so completely in deducing all the observed inequalities of the planetary motions, from the single principle, that the deflecting forces diminished in the inverse duplicate ratio of the distances, were fretted by this exception, the reality of which they could not contest. Many opinions were formed about its cause. Some have attempted to deduce it from the action of the planets on the moon; others have deduced it from the oblate form of the earth, and the translation of the ocean by the tides; others have supposed it owing to the resistance of the ether in the celestial spaces; and others have imagined that the action of the deflecting force requires time for its propagation to a distance: But their deductions have been proved unsatisfactory, and have by no means the precision and evidence that have been attained in the other questions of physical astronomy. At last M. de la Place, of the Royal Academy of Sciences at Paris, has happily succeeded, and deduced the secular equation of the moon from the Newtonian law of planetary deflection. It is produced in the following manner.

394 Deduced from the Newtonian law of planetary deflection.

Suppose the moon revolving round the earth, undisturbed by any deflection toward the sun, and that the time of her revolution is exactly ascertained. Now let the influence of the sun be added. This diminishes her tendency to the earth in opposition and conjunction, and increases it in the quadratures: but the diminutions exceed the augmentations both in quantity and duration; and the excess is equivalent to $\frac{1}{179}$th of her tendency to the earth. Therefore this diminished tendency cannot retain the moon in the same orbit: she must retire farther from the earth, and describe an orbit which is less incurvated by $\frac{1}{179}$th part; and she must employ a longer time in a revolution. The period therefore which we observe, is not that which would have obtained had the moon been influenced by the earth alone. We should not have known that her natural period was increased, had the disturbing influence of the sun remained unchanged; but this varies in the inverse triplicate ratio of the earth's distance from the sun, and is therefore greater in our winter, when the earth is nearer to the sun. This is the source of the annual equation, by which the lunar period in January is made to exceed that in July nearly 24 minutes. The angular velocity of the moon is diminished in general $\frac{1}{179}$, and this numerical coefficient varies in the inverse ratio of the cube

of

Theory of Universal Gravitation.

of the earth's distance from the sun. If we expand this inverse cube of the earth's distance into a series arranged according to the sines and cosines of the earth's mean motion, making the earth's mean distance unity, we shall find that the series contains a term equal to $\frac{3}{2}$ of the square of the eccentricity of the earth's orbit. Therefore the expression of the diminution of the moon's angular velocity contains a term equal to $\frac{1}{179}$ of this velocity multiplied by $\frac{3}{2}$ of the square of the earth's eccentricity; or equal to the product of the square of the eccentricity, multiplied by the moon's angular velocity, and divided by 119,33 ($\frac{2}{3}$ of 179). Did this eccentricity remain constant, this product would also be constant, and would still be confounded with the general diminution, making a constant part of it: but the eccentricity of the earth's orbit is known to diminish, and its diminution is the result of the universality of the Newtonian law of the planetary deflections. Although this diminution is exceedingly small, its effect on the lunar motion becomes sensible by accumulation in the course of ages. The eccentricity diminishing, the diminution of the moon's angular motion must also diminish, that is, the angular motion must increase.

During the 18th century, the square of the earth's eccentricity has diminished 0,00000015325, the mean distance from the sun being $=1$. This has increased the angular motion of the moon in that time 0,00000001285. As this augmentation is gradual, we must multiply the angular motion during the century by the half of this quantity, in order to obtain its accumulated effect. This will be found to be 9″ very nearly, which exceeds that deduced from a most careful comparison of the motion of the last two centuries, only by a fraction of a second.

As long as the diminution of the square of the eccentricity of the earth's orbit can be supposed proportional to the time, this effect will be as the squares of the times. When this theory is compared with observations, the coincidence is wonderful indeed. The effect on the moon's motion is periodical, as the change of the solar eccentricity is, and its period includes millions of years. Its effect on the moon's longitude will amount to several degrees before the secular acceleration change to a retardation.

Those who are not familiar with the disquisitions of modern analysis, may conceive this question in the following manner.

Let the length of a lunar period be computed for the earth's distance from the sun for every day of the year. Add them into one sum, and divide this by their number, the quotient will be the mean lunar period. This will be found to be greater than the arithmetical medium between the greatest and the least. Then suppose the eccentricity of the earth's orbit to be greater, and make the same computation. The average period will be found still greater, while the medium between the greatest and least periods will hardly differ from the former. Something very like this may be observed without any calculation, in a case very similar. The angular velocity of the sun is inversely as the square of his distance. Look into the solar tables, and the greatest diurnal motion will be found 3673″, and the least 3433″. The mean of these is 3553″, but the medium of the whole is 3548″. Now make a similar observation in tables of the motion of the planet Mars, whose eccentricity is much greater. We shall find that the medium between the greatest and least exceeds the true medium of all in a much greater proportion.

It has been supposed by some philosophers that the moon was originally a comet, which passing very near the earth, had been made to revolve round her by the force of attraction. But if we calculate ever so far backwards, we still find the moon revolving round the earth as the planets round the sun, which could not be the case if this opinion were true. Hence it follows, that neither the moon nor any of the satellites have ever been comets.

Sect. V. *Of Irregularities in the Satellites of Jupiter.*

The subserviency of the eclipses of Jupiter's satellites to geography and navigation had occasioned their motions to be very carefully observed, ever since these uses of them were first suggested by Galileo; and their theory is as far advanced as that of the primary planets. It has peculiar difficulties. Being very near to Jupiter, the great deviation of his figure from perfect sphericity makes the relation between their distances from his centre and their gravitations toward it vastly complicated. But this only excited the mathematicians so much the more to improve their analysis; and they saw, in this little system of Jupiter and his attendants, an epitome of the solar system, where the great rapidity of the motions must bring about in a short time every variety of configuration or relative position, and thus give us an example of those mutual disturbances of the primary planets, which require thousands of years for the discovery of their periods and limits. We have derived some very remarkable and useful pieces of information from this investigation; and have been led to the discovery of the eternal durability of the solar system, a thing which Newton greatly doubted of.

Mr Pound had observed long ago, that the irregularities of the three interior satellites were repeated in a period of 437 days; and this observation is found to be just to this day.

		Days.	H.	M.
247 revolutions of the	first occupy	437	3	44
123	second	437	3	42
61	third	437	3	36
26	fourth	435	14	16

This naturally led mathematicians to examine their motions, and see in what manner their relative positions or configurations, as they are called, corresponded to this period: and it is found, that the mean longitude of the first satellite, *minus* thrice the mean longitude of the second, *plus* twice the mean longitude of the third, always made 180 degrees. This requires that the mean motion of the first, added to twice that of the third, shall be equal to thrice the mean motion of the second. This correspondence of the mean motions is of itself a singular thing, and the odds against its probability seems infinitely great; and when we add to this the particular positions of the satellites in any one moment, which is necessary for the above constant relation of their longitudes, the improbability of the coincidence, as a thing quite fortuitous, becomes infinitely greater. Doubts were first entertained of the coincidence,

Digitized by Google

Theory of Universal Gravitation.

coincidence, because it was not indeed accurate to a second. The result of the investigation is curious. When we follow out the consequences of mutual gravitation, we find, that although neither the primitive motions of projection, nor the points of the orbit from which the satellites were projected, were *precisely* such as suited these observed relations of their revolutions and their contemporaneous longitudes; yet if they differed from them only by very minute quantities, the mutual gravitations of the satellites would in time bring them into those positions, and those states of mean motion, that would induce the observed relations; and when they are once induced they will be continued for ever. There will indeed be a small equation, depending on the degree of unsuitableness of the first motions and positions; and this causes the whole system to oscillate, as it were, a little, and but a very little way on each side of this exact and permanent state. The permanency of these relations will not be destroyed by any secular equations arising from external causes; such as the action of the fourth satellite, or of the sun, or of a resisting medium; because their mutual actions will distribute this equation as it did the original error.

For a full discussion of this curious but difficult subject, we refer the reader to the dissertations of La Grange and La Place, and to the tables lately published by Delambre. These mathematicians have shown, that if the mass of Jupiter be represented by unity, that of his satellites will be represented by the following numbers.

First satellite	0.0000172011
Second satellite	0.0000237103
Third satellite	0.0000872128
Fourth satellite	0.0000544681

Sect. VI. *Of Saturn's Ring.*

395 Saturn's ring.

The most important addition (in a philosophical view) which has been made to astronomical science since the discovery of the aberration of light and the nutation of the earth's axis, is that of the rotation of Saturn's ring. The ring itself is an object quite peculiar; and when it was discovered that all the bodies which had any immediate connexion with a planet gravitated toward that planet, it became an interesting question to ascertain what was the nature of this ring? What supports this immense arch of heavy matter without its resting on the planet? What maintains it in perpetual concentricity with the body of Saturn, and keeps its surface in one invariable position?

The theory of universal gravitation tells us what things are possible in the solar system; and our conjectures about the nature of this ring must always be regulated by the circumstance of its gravitation to the planet. Philosophers had at first supposed it to be a luminous atmosphere, thrown out into that form by the great centrifugal force arising from a rotation: but its well-defined edge, and, in particular, its being two very narrow rings, extremely near each other, yet perfectly separate, rendered this opinion of its constitution more improbable.

396 Discovery of Dr Herschel relating to it.

Dr Herschel's discovery of brighter spots on its surface, and that those spots were permanent during the whole time of his observation, seem to make it more probable that the parts of the ring have a solid connexion. Mr Herschel has discovered, by the help of these spots, that the ring turns round its axis, and that this axis is also the axis of Saturn's rotation. The time of rotation is 10h. $32\frac{1}{4}'$. But the other circumstances are not narrated with the precision sufficient for an accurate comparison with the theory of gravity. He informs us, that the radii of the four edges of the ring are 590, 751, 774, 830, of a certain scale, and that the angle subtended by the ring at the mean distance from the earth is $46\frac{2}{7}''$. Therefore its elongation is $23\frac{1}{7}''$. The elongation of the second Cassinian satellite is 56″, and its revolution is 2d. 17h. 44′. This should give, by the third law of Kepler, 17h. 10′ for the revolution of the outer edge of the ring, or rather of an atom of that edge, in order that it may maintain itself in equilibrio. The same calculation applied to the outer edge of the inner ring gives about 13h. 36′; and we obtain 11h. 16′ for the inner edge of this ring. Such varieties are inconsistent with the permanent appearance of a spot. We may suppose the ring to be a luminous fluid or vapour, each particle of which maintains its situation by the law of planetary revolution. In such a state, it would consist of concentric strata, revolving more slowly as they were more remote from the planet, like the concentric strata of a vortex, and therefore having a relative motion incompatible with the permanency of any spot. Besides, the rotation observed by Herschel is too rapid even for the innermost part of the ring. We think therefore that it consists of cohering matter, and of considerable tenacity, at least equal to that of a very clammy fluid, such as melted glass.

We can tell the figure which a fluid ring must have, so that it may maintain its form by the mutual gravitation of its particles to each other, and their gravitation to the planet. Suppose it cut by a meridian. It may be in equilibrio if the section is an ellipse, of which the longer axis is directed to the centre of the planet, and very small in comparison with its distance from the centre of the planet, and having the revolution of its middle round Saturn, such as agree with the Keplerean law. These circumstances are not very consistent with the dimensions of Saturn's inner ring. The distance between the middle of its breadth and the centre of Saturn is 670, and its breadth is 161′, nearly one-fourth of the distance from the centre of Saturn. De la Place says, that the revolution of the inner ring observed by Herschel is very nearly that required by Kepler's law: but we cannot see the grounds of this assertion. The above comparison with the second Cassinian satellite shows the contrary. The elongation of that satellite is taken from Bradley's observations, as is also its periodic time. A ring of detached particles revolving in 10h. $32\frac{1}{4}'$ must be of much smaller diameter than even the inner edge of Saturn's ring. Indeed the quantity of matter in it might be such as to increase the gravitation considerably; but this would be seen by its disturbing the seventh and sixth satellites, which are exceedingly near it. We cannot help thinking, therefore, that it consists of matter which has very considerable tenacity. An equatorial zone of matter, tenacious like melted glass, and whirled briskly round, might be thrown off, and, retaining its great velocity, would stretch out while whirling, enlarging in diameter and diminishing in thickness or breadth, or both, till the centrifugal force was balanced by the united force of gravity 397 Its probable consistency.

Digitized by Google

Theory of Universal Gravitation.

gravity and tenacity. We find the equilibrium will not be sensibly disturbed by considerable deviations, such as equal breadth, or even want of flatness. Such inequalities appear on the ring at that time of its disparition, when its edge is turned to the sun or to us. The appearances of its different sides are then considerably different.

Such a ring or rings must have an oscillatory motion round the centre of Saturn, in consequence of their mutual action, and the action of the sun, and their own irregularities: but there will be a certain position which they have a tendency to maintain, and to which they will be brought back, after deviating from it, by the ellipticity of Saturn, which is very great. The sun will occasion a nutation of Saturn's axis and a precession of his equinoxes, and this will drag along with it both the rings and the neighbouring satellites.

The atmosphere which surrounds a whirling planet cannot have all its parts circulating according to the third law of Kepler. The mutual attrition of the planet, and of the different strata, arising from their different velocities, must accelerate the slowly moving strata, and retard the rapid, till all acquire a velocity proportional to their distance from the axis of rotation; and this will be such that the momentum of rotation of the planet and its atmosphere remains always the same. It will swell out at the equator, and sink at the poles, till the centrifugal force at the equator balances the height of a superficial particle. The greatest ratio which the equatorial diameter can acquire to the polar axis is that of four to three, unless a cohesive force keeps the particles united, so that it constitutes a liquid, and not an elastic fluid like air; and an elastic fluid cannot form an atmosphere bounded in its dimensions, unless there be a certain rarity which takes away all elasticity. If the equator swells beyond the dimension which makes the gravitation balance the centrifugal force, it must immediately dissipate.

If we suppose that the atmosphere has extended to this limit, and then condenses by cold, or any chemical or other cause different from gravity, its rotation necessarily augments, preferring its former momentum,
398 and the limit will approach the axis; because a greater
and origin. velocity produces a greater centrifugal force, and requires a greater gravitation to balance it. Such an atmosphere may therefore desert, in succession, zones of its own matter in the plane of its equator, and *leave* them revolving in the form of rings. It is not unlikely that the rings of Saturn may have been furnished in this very way; and the zones, having acquired a common velocity in their different strata, will preserve it; and they are susceptible of irregularities arising from local causes at the time of their separation, which may afford permanent spots.

Sect. VII. *Of the Atmospheres of the Planets.*

By *atmosphere* is meant a rare, transparent, compressible, and elastic fluid surrounding a body. It is supposed that all the heavenly bodies possess atmospheres. The atmosphere of the earth is familiar to all its inhabitants. Observation points out the atmospheres of the sun and of Jupiter; but that of the other planets is scarcely perceptible.

The atmosphere becomes rarer in proportion to its distance from the body to which it belongs, in consequence of its elasticity, which causes it to dilate the more the less it is compressed. If its most remote parts were still possessed of elasticity, they would separate indefinitely, and the whole would be scattered through space. To prevent this effect, it is necessary that the elasticity should diminish at a greater rate than the compressing force, and that when it reaches a certain degree of rarity its elasticity should vanish altogether.

All the atmospherie strata must gradually acquire the same rotatory motion with the bodies to which they belong in consequence of the continual friction to which their different parts must be subjected, which will gradually accelerate or retard the different parts till a common motion is produced. In all these changes, and indeed in all those which the atmosphere undergoes, the sum of the products of the particles of the body and of its atmosphere multiplied by the areas described round their common centres of gravity by their radii vectors projected in the plane of the equator continue always the same, the times being the same. If we suppose then, by any cause whatever, the height of the atmosphere is diminished, and a portion of it condenses on the surface of the planet; the consequence will be, that the rotatory motion of the planet and of its atmosphere will be accelerated. For the radii vectors of the areas described by the particles of the primitive atmosphere becoming shorter, the sum of the products of all these particles by the corresponding areas cannot remain the same unless the rotatory motion augment.

At the upper surface of the atmosphere the fluid is retained only by its weight. Its figure is such that the direction resulting from the combination of the centrifugal forces and the attracting forces is perpendicular to it. It is flattened at the poles, and more convex at the equator. But this flattening has its limits. When a maximum the axis of the poles is to that at the equator as 2 to 3.

At the equator the atmosphere can only extend to the place where the centrifugal force and gravitation exactly balance each other; for if it pass that limit, it will be dissipated altogether. Hence it follows that the solar atmosphere does not extend as far as Mercury; consequently it is not the cause of the zodiacal light which appears to extend beyond even the earth's orbit.

The place where the centrifugal force and gravitation balance each other is so much the nearer a body the more rapid its rotatory motion is. If we suppose the atmosphere to extend to that limit, and then to condense by cooling, &c. at the surface of the planet, the rotatory motion will increase in rapidity in proportion to this condensation, and the limit of the height of the atmosphere will constantly approach the planet. The atmosphere would of course abandon successively zones of fluid in the plane of the equator, which would continue to circulate round the body. We have shown in the last section that Saturn's ring may owe its origin to this cause.

We may add also, that the action of another body may considerably change the constitution of this atmosphere. Thus, supposing that the moon had originally an atmosphere, the limit will be that distance from the moon where the centrifugal force, arising from the moon's rotation, added to the gravitation 399

399 Probable reason why we see no atmosphere about the moon.

tion to the earth, balances the gravitation to the moon. If the moon be $\frac{1}{39}$th of the earth, this limit will be about $\frac{1}{9}$th of the moon's distance from the earth. If at this distance the elasticity of the atmosphere is not annihilated by its rarefaction, it will be all taken off by the earth, and accumulate round it. This may be the reason why we see no atmosphere about the moon.

Sect. VII. *Of the Tides.*

400 Cause of the tides discovered by Kepler.

The cause of the tides was discovered by Kepler, who, in his *Introduction to the Physics of the Heavens*, thus explains it: "The orb of the attracting power which is in the moon, is extended as far as the earth; and draws the waters under the torrid zone, acting upon places where it is vertical, insensibly on confined seas and bays, but sensibly on the ocean, whose beds are large, and where the waters have the liberty of reciprocation, that is, of rising and falling." And in the 70th page of his *Lunar Astronomy*—"But the cause of the tides of the sea appears to be the bodies of the sun and moon drawing the waters of the sea." This hint being given, the immortal Sir Isaac Newton improved it, and wrote so amply on the subject, as to make the theory of the tides in a manner quite his own, by discovering the cause of their rising on the side of the earth opposite to the moon. For Kepler believed that the presence of the moon occasioned an impulse which caused another in her absence.

It has been already observed, that the power of gravity diminishes as the square of the distance increases; and therefore the waters at Z on the side of the earth

Fig. 149. ABCDEFGH next the moon M, are more attracted than the central parts of the earth O by the moon, and the central parts are more attracted by her than the waters on the opposite side of the earth at *n*: and therefore the distance between the earth's centre and the waters on its surface under and opposite to the moon will be increased. For, let there be three bodies at H, O, and D: if they are all equally attracted by the body M, they will all move equally fast towards it, their mutual distances from each other continuing the same. If the attraction of M is unequal, then that body which is most strongly attracted will move fastest, and this will increase its distance from the other body. Therefore, by the law of gravitation, M will attract H more strongly than it does O, by which the distance between H and O will be increased; and a spectator on O will perceive H rising higher toward Z. In like manner, O being more strongly attracted than D, it will move farther towards M than D does: consequently, the distance between O and D will be increased; and a spectator on O, not perceiving his own motion, will see D receding farther from him towards *n*; all effects and appearances being the same, whether D recedes from O, or O from D.

Suppose now there is a number of bodies, as A, B, C, D, E, F, G, H, placed round O, so as to form a flexible or fluid ring: then, as the whole is attracted towards M, the parts at H and D will have their distance from O increased; whilst the parts at B and F being nearly at the same distance from M as O is, these parts will not recede from one another; but rather, by the oblique attraction of M, they will approach nearer to O. Hence the fluid ring will form itself into an ellipse ZIBL *n* KFNZ, whose longer axis *n* OZ produced will pass through M, and its shorter axis BOF will terminate in B and F. Let the ring be filled with fluid particles, so as to form a sphere round O; then, as the whole moves towards M, the fluid sphere being lengthened at Z and *n*, will assume an oblong or oval form. If M is the moon, O the earth's centre, ABC DEFGH the sea covering the earth's surface, it is evident, by the above reasoning, that whilst the earth by its gravity falls towards the moon, the water directly below her at B will swell and rise gradually towards her; also the water at D will recede from the centre [strictly speaking, the centre recedes from D], and rise on the opposite side of the earth; whilst the water at B and F is depressed, and falls below the former level. Hence, as the earth turns round its axis from the moon to the moon again in $24\frac{1}{2}$ hours, there will be two tides of flood and two of ebb in that time, as we find by experience.

401 Why the tides are high at full moon.

As this explanation of the ebbing and flowing of the sea is deduced from the earth's constantly falling towards the moon by the power of gravity, some may find a difficulty in conceiving how this is possible, when the moon is full, or in opposition to the sun; since the earth revolves about the sun, and must continually fall towards it, and therefore cannot fall contrary ways at the same time: or if the earth is constantly falling towards the moon, they must come together at last. To remove this difficulty, let it be considered, that it is not the centre of the earth that describes the annual orbit round the sun, but the (E) common centre of gravity of the earth and moon together; and that whilst the earth is moving round the sun, it also describes a circle round that centre of gravity; going as many times round it in one revolution about the sun as there are lunations or courses of the moon round the earth in a year: and therefore the earth is constantly falling towards the moon from a tangent to the circle it describes round the said common centre of gravity. Let M be Fig. 150. the moon, TW part of the moon's orbit, and C the centre of gravity of the earth and moon; whilst the moon goes round her orbit, the centre of the earth describes the circle *dge* round C, to which circle *gak* is a tangent; and therefore when the moon has gone from M to a little past W, the earth has moved from *g* to *e*; and in that time has fallen towards the moon, from the tangent at *a* to *e*: and so on, round the whole circle.

The sun's influence in raising the tides is but small in

(E) This centre is as much nearer the earth's centre than the moon's as the earth is heavier, or contains a greater quantity of matter than the moon, namely, about 40 times. If both bodies were suspended on it, they would hang *in equilibrio*. So that dividing 240,000 miles, the moon's distance from the earth's centre, by 40, the excess of the earth's weight above the moon's, the quotient will be 6000 miles, which is the distance of the common centre of gravity of the earth and moon from the earth's centre.

Digitized by Google

in comparison of the moon's; for though the earth's diameter bears a considerable proportion to its distance from the moon, it is next to nothing when compared to its distance from the sun. And therefore the difference of the sun's attraction on the sides of the earth under and opposite to him, is much less than the difference of the moon's attraction on the sides of the earth under and opposite to her; and therefore the moon must raise the tides much higher than they can be raised by the sun.

402 Influence of the sun in raising tides.

403 Why they are not highest when the moon is in the meridian.

On this theory, the tides ought to be highest directly under and opposite to the moon; that is, when the moon is due north and south. But we find, that in open seas, where the water flows freely, the moon M is generally past the north and south meridian, as at *p*, when it is high water at Z and at *n*. The reason is obvious: for though the moon's attraction was to cease altogether when she was past the meridian, yet the motion of ascent communicated to the water before that time would make it continue to rise for some time after; much more must it do so when the attraction is only diminished; as a little impulse given to a moving ball will cause it still to move farther than otherwise it could have done; and as experience shows that the day is hotter about three in the afternoon, than when the sun is on the meridian, because of the increase made to the heat already imparted.

The tides answer not always to the same distance of the moon from the meridian at the same places; but are variously affected by the action of the sun, which brings them on sooner when the moon is in her first and third quarters, and keeps them back later when she is in her second and fourth: because, in the former case, the tide raised by the sun alone would be earlier than the tide raised by the moon: and, in the latter case later.

The moon goes round the earth in an elliptic orbit; and therefore, in every lunar month, she approaches nearer to the earth than her mean distance, and recedes farther from it. When she is nearest, she attracts strongest, and so raises the tides most: the contrary happens when she is farthest, because of her weaker attraction. When both luminaries are in the equator, and the moon in perigee, or at her least distance from the earth, she raises the tides highest of all, especially at her conjunction and opposition; both because the equatorial parts have the greatest centrifugal force from their describing the largest circle, and from the concurring actions of the sun and moon. At the change, the attractive forces of the sun and moon being united, they diminish the gravity of the waters under the moon, and their gravity on the opposite side is diminished by means of a greater centrifugal force. At the full, whilst the moon raises the tide under and opposite to her, the sun, acting in the same line, raises the tide under and opposite to him; whence their conjoint effect is the same as at the change; and, in both cases, occasion what we call the *Spring Tides*. But at the quarters the sun's action on the waters at O and H diminishes the effect of the moon's action on the waters at Z and N; so that they rise a little under and opposite to the sun at O and H, and fall as much under and opposite to the moon at Z and N; making what we call the *Neap Tides*, because the sun and moon then act cross-wise to each other. But these tides happen not till some time after; because in this, as in other cases, the actions do not produce the greatest effect when they are at the strongest, but some time afterward.

The sun being nearer the earth in winter than in summer, is of course nearer to it in February and October than in March and September; and therefore the greatest tides happen not till some time after the autumnal equinox, and return a little before the vernal.

The sea, being thus put in motion, would continue to ebb and flow several times, even though the sun and moon were annihilated, or their influence should cease; as, if a bason of water were agitated, the water would continue to move for some time after the bason was left to stand still; or, like a pendulum, which, having been put in motion by the hand, continues to make several vibrations without any new impulse.

When the moon is in the equator, the tides are equally high in both parts of the lunar day, or time of the moon's revolving from the meridian to the meridian again, which is 24 hours 50 minutes. But as the moon declines from the equator towards either pole, the tides are alternately higher and lower at places having north or south latitude. For one of the highest elevations, which is that under the moon, follows her towards the pole to which she is nearest; and the other declines towards the opposite pole; each elevation describing parallels as far distant from the equator, on opposite sides, as the moon declines from it to either side; and consequently the parallels described by these elevations of the water are twice as many degrees from one another as the moon is from the equator; increasing their distance as the moon increases her declination, till it be at the greatest, when the said parallels are, at a mean state, 47 degrees from one another: and on that day, the tides are most unequal in their heights. As the moon returns towards the equator, the parallels described by the opposite elevations approach towards each other, until the moon comes to the equator, and then they coincide. As the moon declines towards the opposite pole, at equal distances, each elevation describes the same parallel in the other part of the lunar day, which its opposite elevation described before. Whilst the moon has north declination, the greatest tides in the northern hemisphere are when she is above the horizon; and the reverse whilst her declination is south. Let NESQ be the earth, NSC its axis, EQ the equator, T ♋ the tropic of Cancer, *t* ♑ the tropic of Capricorn, *a b* the arctic circle, *c d* the antarctic, N the north pole, S the south pole, M the moon, F and G the two eminences of water, whose lowest parts are at *a* and *d*, at N and S, and at *b* and *c*, always 90 degrees from the highest. Now, when the moon is in her greatest north declination at M, the highest elevation G under her is on the tropic of Cancer T ♋, and the opposite elevation F on the tropic of Capricorn *t* ♑; and these two elevations describe the tropics by the earth's diurnal rotation. All places in the northern hemisphere ENQ have the highest tides when they come into the position *b* ♋ Q, under the moon; and the lowest tides when the earth's diurnal rotation carries them into the position *a* TE, on the side opposite the moon; the reverse happens at the same time in the southern hemisphere ESQ, as is evident to sight. The Fig. 151 152, 153.

Theory of Universal Gravitation.

The axis of the tides *a* C *d* had now its poles *a* and *d* (being always 90 degrees from the highest elevations) in the arctic and antarctic circles; and therefore it is plain, that at these circles there is but one tide of flood, and one of ebb, in the lunar day. For, when the point *a* revolves half round to *b* in 12 lunar hours, it has a tide of flood; but when it comes to the same point *a* again in 12 hours more, it has the lowest ebb. In seven days afterward, the moon M comes to the equinoctial circle, and is over the equator EQ, when both elevations describe the equator; and in both hemispheres, at equal distances from the equator, the tides are equally high in both parts of the lunar day. The whole phenomena being reversed, when the moon has south declination, to what they were when her declination was north, require no farther description.

In the three last-mentioned figures, the earth is orthographically projected on the plane of the meridian; but in order to describe a particular phenomenon, we now project it on the plane of the ecliptic. Let HZON be the earth and sea, FED the equator, T the tropic of Cancer, C the arctic circle, P the north pole, and the curves, 1, 2, 3, &c. 24 meridians or hour circles, intersecting each other in the poles: AGM is the moon's orbit, S the sun, M the moon, Z the water elevated under the moon, and N the opposite equal elevation. As the lowest parts of the water are always 90 degrees from the highest, when the moon is in either of the tropics (as at M), the elevation Z is on the tropic of Capricorn, and the opposite elevation N on the tropic of Cancer; the low-water circle HCO touches the polar circles at C; and the high-water circle ETP 6 goes over the poles at P, and divides every parallel of latitude into two equal segments. In this case, the tides upon every parallel are alternately higher and lower; but they return in equal times: the point T, for example, on the tropic of Cancer, (where the depth of the tide is represented by the breadth of the dark shade) has the shallower tide of flood at T than when it revolves half round from thence to 6, according to the order of the numeral figures; but it revolves as soon from 6 to T as it did from T to 6. When the moon is in the equinoctial, the elevations Z and N are transferred to the equator at O and H, and the high and low-water circles are got into each other's former places; in which case the tides return in unequal times, but are equally high in both parts of the lunar day; for a place at 1 (under D) revolving as formerly, goes sooner from 1 to 11 (under F) than from 11 to 1, because the parallel it describes is cut into unequal segments by the high-water circle HCO: but the points 1 and 11 being equidistant from the pole of the tides at C, which is directly under the pole of the moon's orbit MGA, the elevations are equally high in both parts of the day.

Fig. 151.

404 Tides turn on the axis of the moon's orbit.

And thus it appears, that as the tides are governed by the moon, they must turn on the axis of the moon's orbit, which is inclined $23\frac{1}{2}$ degrees to the earth's axis at a mean state: and therefore the poles of the tides must be so many degrees from the poles of the earth, or in opposite points of the polar circles, going round these circles in every lunar day. It is true, that according to fig. 153. when the moon is vertical to the equator ECQ, the poles of the tides seem to fall in with the poles of the world N and S: but when we consider that FGH is under the moon's orbit, it will appear, that when the moon is over H, in the tropic of Capricorn, the north pole of the tides (which can be no more than 90 degrees from under the moon) must be at C in the arctic circle, not at P the north pole of the earth; and as the moon ascends from H to G in her orbit, the north pole of the tides must shift from *c* to *a* in the arctic circle, and the south poles as much in the antarctic.

It is not to be doubted, but that the earth's quick rotation brings the poles of the tides nearer to the poles of the world than they would be if the earth were at rest, and the moon revolved about it only once a month; for otherwise the tides would be more unequal in their height and times of their returns, than we find they are. But how near the earth's rotation may bring the poles of its axis and those of the tides together, or how far the preceding tides may affect those which follow, so as to make them keep up nearly to the same heights and times of ebbing and flowing, is a problem more fit to be solved by observation than by theory.

Those who have opportunity to make observations, and choose to satisfy themselves whether the tides are really affected in the above manner by the different positions of the moon, especially as to the unequal times of their return, may take this general rule for knowing when they ought to be so affected. When the earth's axis inclines to the moon, the northern tides, if not retarded in their passage through shoals and channels, nor affected by the winds, ought to be greatest when the moon is above the horizon, least when she is below it, and quite the reverse when the earth's axis declines from her; but in both cases, at equal intervals of time. When the earth's axis inclines sidewise to the moon, both tides are equally high, but they happen at unequal intervals of time. In every lunation the earth's axis inclines once to the moon, once from her, and twice sidewise to her, as it does to the sun every year; because the moon goes round the ecliptic every month, and the sun but once in a year. In summer, the earth's axis inclines towards the moon when new; and therefore the day-tides in the north ought to be highest, and night-tides lowest, about the change: at the full, the reverse. At the quarters, they ought to be equally high, but unequal in their returns: because the earth's axis then inclines sidewise to the moon. In winter, the phenomena are the same at full moon as in summer at new. In autumn the earth's axis inclines sidewise to the moon when new and full; therefore the tides ought to be equally high and uneven in their returns at these times. At the first quarter, the tides of flood should be least when the moon is above the horizon, greatest when she is below it; and the reverse at her third quarter. In spring, the phenomena of the first quarter answer to those of the third quarter in autumn; and *vice versa*. The nearer any tide is to either of the seasons, the more the tides partake of the phenomena of these seasons; and in the middle between any two of them the tides are at a mean state between those of both.

In open seas, the tides rise but to very small heights in proportion to what they do in wide-mouthed rivers, opening in the direction of the stream of tide. For in channels growing narrower gradually, the water is accumulated

Theory of Universal Gravitation.

cumulated by the opposition of the contracting bank; like a gentle wind, little felt on an open plain, but strong and brisk in a street; especially if the wider end of the street be next the plain, and in the way of the wind.

405 Irregularities of tides accounted for.

The tides are so retarded in their passage through different shoals and channels, and otherwise so variously affected by striking against capes and headlands, that to different places they happen at all distances of the moon from the meridian, consequently at all hours of the lunar day. The tide propagated by the moon in the German ocean, when she is three hours past the meridian, takes 12 hours to come from thence to London bridge, where it arrives by the time that a new tide is raised in the ocean. And therefore, when the moon has north declination, and we should expect the tide at London to be greatest when the moon is above the horizon, we find it is least; and the contrary when she has south declination. At several places it is high water three hours before the moon comes to the meridian; but that tide which the moon pushes as it were before her, is only the tide opposite to that which was raised by her when she was nine hours past the opposite meridian.

There are no tides in lakes, because they are generally so small, that when the moon is vertical she attracts every part of them alike, and therefore by rendering all the water equally light, no part of it can be raised higher than another. The Mediterranean and Baltic seas have very small elevations, because the inlets by which they communicate with the ocean are so narrow, that they cannot, in so short a time, receive or discharge enough to raise or sink their surfaces sensibly.

For a more complete discussion of this important subject, we refer the reader to the article TIDE.

SECT. IX. *Of the Precession of the Equinoxes, and the Nutation of the Earth's Axis.*

406 Precession of the equinoctial points, &c.

It now remains to consider the precession of the equinoctial points, with its equations, arising from the nutation of the earth's axis as a physical phenomenon, and to endeavour to account for it upon those mechanical principles which have so happily explained all the other phenomena of the celestial motions.

407 Observations of Newton and others on this subject.

This did not escape the penetrating eye of Sir Isaac Newton; and he quickly found it to be a consequence, and the most beautiful proof, of the universal gravitation of all matter to all matter; and there is no part of his immortal work where his sagacity and fertility of resource shine more conspicuously than in this investigation. It must be acknowledged, however, that Newton's investigation is only a shrewd guess, founded on assumptions, of which it would be extremely difficult to demonstrate either the truth or falsity, and which required the genius of a Newton to pick out in such a complication of abstruse circumstances. The subject has occupied the attention of the first mathematicians of Europe since his time; and is still considered as the most curious and difficult of all mechanical problems. The most elaborate and accurate dissertations on the precession of the equinoxes are those of Sylvabella and Walmesly, in the Philosophical Transactions, published about the year 1754; that of Thomas Simpson, published in his Miscellaneous Tracts; that of Father Frisius, in the Memoirs of the Berlin Academy, and afterwards, with great improvements, in his Cosmographia; that of Euler in the Memoirs of Berlin; that of D'Alembert in a separate dissertation; and that of De la Grange on the Libration of the Moon, which obtained the prize in the Academy of Paris in 1769. We think the dissertation of Father Frisius the most perspicuous of them all, being conducted in the method of geometrical analysis; whereas most of the others proceed in the fluxionary and symbolic method, which is frequently deficient in distinct notions of the quantities under consideration, and therefore does not give us the same perspicuous conviction of the truth of the results. In a work like ours, it is impossible to do justice to the problem, without entering into a detail which would be thought extremely disproportioned to the subject by the generality of our readers. Yet those who have the necessary preparation of mathematical knowledge, and wish to understand the subject fully, will find enough here to give them a very distinct notion of it; and in the article ROTATION, they will find the fundamental theorems, which will enable them to carry on the investigation. We shall first give a short sketch of Newton's investigation, which is of the most palpable and popular kind, and is highly valuable, not only for its ingenuity, but also because it will give our unlearned readers distinct and satisfactory conceptions of the chief circumstances of the whole phenomena.

Sketch of Newton's investigation

Let S (fig. 154.) be the sun, E the earth, and M the moon, moving in the orbit NMCD n, which cuts the plane of the ecliptic in the line of the nodes N n, and has one half raised above it, as represented in the figure, the other half being hid below the ecliptic. Suppose this orbit folded down; it will coincide with the ecliptic in the circle N $m\,c\,d\,n$. Let EX represent the axis of this orbit, perpendicular to its plane, and therefore inclined to the ecliptic. Since the moon gravitates to the sun in the direction MS which is all above the ecliptic, it is plain that this gravitation has a tendency to draw the moon towards the ecliptic. Suppose this force to be such that it would draw the moon down from M to i in the time that she would have moved from M to t, in the tangent to her orbit. By the combination of these motions, the moon will desert her orbit, and describe the line M r, which makes the diagonal of the parallelogram; and if no farther action of the sun be supposed, she will describe another orbit M λ n', lying between the orbit MCD n and the ecliptic, and she will come to the ecliptic, and pass through it in a point n', nearer to M than n is, which was the former place of her descending node. By this change of orbit, the line EX will no longer be perpendicular to it; but there will be another line E x, which will now be perpendicular to the new orbit. Also the moon, moving from M to r, does not move as if she had come from the ascending node N, but from a point N lying beyond it; and the line of the nodes of the orbit in this new position is N$'n$. Also the angle MN$'m$ is less than the angle MNm.

Thus the nodes shift their places in a direction opposite to that of her motion, or move to the westward; the axis of the orbit changes its position, and the orbit itself changes its inclination to the ecliptic. These momentary changes are different in different parts of the orbit, according to the position of the line of the nodes.

Digitized by Google

Theory of Universal Gravitation.

nodes. Sometimes the inclination of the orbit is increased, and sometimes the nodes move to the eastward. But, in general, the inclination increases from the time that the nodes are in the line of syzigee, till they get into quadrature, after which it diminishes till the nodes are again in syzigee. The nodes advance only while they are in the octants after the quadratures, and while the moon passes from quadrature to the node, and they recede in all other situations. Therefore the recess exceeds the advance in every revolution of the moon round the earth, and, on the whole, they recede.

What has been said of one moon, would be true of each of a continued ring of moons surrounding the earth, and they would thus compose a flexible ring, which would never be flat, but waved, according to the difference (both in kind and degree) of the disturbing forces acting on its different parts. But suppose these moons to cohere, and to form a rigid and flat ring, nothing would remain in this ring but the excess of the contrary tendencies of its different parts. Its axis would be perpendicular to its plane, and its position in any moment will be the mean position of all the axes of the orbits of each part of the flexible ring; therefore the nodes of this rigid ring will continually recede, except when the plane of the ring passes through the sun, that is, when the nodes are in syzigee; and (says Newton) the motion of these nodes will be the same with the mean motion of the nodes of the orbit of one moon. The inclination of this ring to the ecliptic will be equal to the mean inclination of the moon's orbit during any one revolution which has the same situation of the nodes. It will therefore be least of all when the nodes are in quadrature, and will increase till they are in syzigee, and then diminish till they are again in quadrature.

Suppose this ring to contract in dimensions, the disturbing forces will diminish in the same proportion, and in this proportion will all their effects diminish. Suppose its motion of revolution to accelerate, or the time of a revolution to diminish; the linear effects of the disturbing forces being as the squares of the times of their action, and their angular effects as the times, those errors must diminish also on this account; and we can compute what those errors will be for any diameter of the ring, and for any period of its revolution. We can tell, therefore, what would be the motion of the nodes, the change of inclination, and deviation of the axis, of a ring which would touch the surface of the earth, and revolved in 24 hours; nay, we can tell what these motions would be, should this ring adhere to the earth. They must be much less than if the ring were detached; for the disturbing forces of the ring must drag along with it the whole globe of the earth. The quantity of motion which the disturbing forces would have produced in the ring alone, will now (says Newton) be produced in the whole mass; and therefore the velocity must be as much less as the quantity of matter is greater: But still this can be computed.

Now there is such a ring on the earth: for the earth is not a sphere, but an elliptical spheroid. Sir Isaac Newton therefore engaged in a computation of the effects of the disturbing force, and has exhibited a most beautiful example of mathematical investigation. He first asserts, that the earth *must* be an elliptical spheroid, whose polar axis is to its equatorial diameter as 229 to 230. Then he demonstrates, that if the sine of the inclination of the equator be called π, and if t be the number of days (sidereal) in a year, the annual motion of a detached ring will be $360^\circ \times \frac{3\sqrt{1-\pi^2}}{4t}$. He then shows that the effect of the disturbing force on this ring is to its effect on the matter of the same ring, distributed in the form of an elliptical stratum (but still detached) as 5 to 2; therefore the motion of the nodes will be $360^\circ \times \frac{3\sqrt{1-\pi^2}}{10t}$, or $16' 16'' 24'''$ annually. He then proceeds to show, that the quantity of motion in the sphere is to that in an equatorial ring revolving in the same time, as the matter in the sphere to the matter in the ring, and as three times the square of a quadrantal arch to two squares of a diameter, jointly: Then he shows, that the quantity of matter in the terrestrial sphere is to that in the protuberant matter of the spheroid, as 52900 to 461 (supposing all homogeneous). From these premises it follows, that the motion of $16' 16'' 24'''$, must be diminished in the ratio of 10717 to 100, which reduces it to $9'' 07'''$ annually. And this (he says) is the precession of the equinoxes, occasioned by the action of the sun; and the rest of the $50\frac{1}{3}''$, which is the observed precession, is owing to the action of the moon, nearly five times greater than that of the sun. This appeared a great difficulty: for the phenomena of the tides show that it *cannot* much exceed twice the sun's force.

409 His determination of the form and dimensions of the earth demonstrated by M'Laurin.

Nothing can exceed the ingenuity of this process. Justly does his celebrated and candid commentator, Daniel Bernoulli, say (in his Dissertation on the Tides, which shared the prize of the French Academy with M'Laurin and Euler), that Newton saw through a veil what others could hardly discover with a microscope in the light of the meridian sun. His determination of the form and dimensions of the earth, which is the foundation of the whole process, is not offered as any thing better than a probable guess, *in re difficillima;* and it has been since demonstrated with geometrical rigour by M'Laurin.

His next principle, that the motion of the nodes of the rigid ring is equal to the mean motion of the nodes of the moon, has been most critically discussed by the first mathematicians, as a thing which could neither be proved nor refuted. Frisius has at least shown it to be a mistake, and that the motion of the nodes of the ring is double the mean motion of the nodes of a single moon; and that Newton's own principles should have produced a precession of $18\frac{1}{4}$ seconds annually, which removes the difficulty formerly mentioned.

His third assumption, that the quantity of motion of the ring must be shared with the included sphere, was acquiesced in by all his commentators, till D'Alembert and Euler, in 1749, showed that it was not the quantity of motion round an axis of rotation which remained the same, but the quantity of momentum or rotatory effort. The quantity of motion is the product of every particle by its velocity; that is, by its distance from the axis; while its momentum, or power of producing rotation, is as the square of that distance, and is to be had by taking the sum of each particle multiplied by the square of its distance from the axis. Since the earth

Digitized by Google

earth differs so little from a perfect sphere, this makes no sensible difference in the result. It will increase Newton's precession about three-fourths of a second.

410 Examination of the phenomenon of precession on mechanical principles.

We proceed now to the examination of this phenomenon upon the fundamental principles of mechanics.

Because the mutual gravitation of the particles of matter in the solar system is in the inverse ratio of the squares of the distance, it follows, that the gravitations of the different parts of the earth to the sun or to the moon are unequal. The nearer particles gravitate more than those that are more remote.

Let PQ *p* E (fig. 155.), be a meridional section of the terrestrial sphere, and PO *pq* the section of the inscribed sphere. Let CS be a line in the plane of the ecliptic passing through the sun, so that the angle ECS is the sun's declination. Let NCM be a plane passing through the centre of the earth at right angles to the plane of the meridian PQ *p* E; NCM will therefore be the plane of illumination.

In consequence of the unequal gravitation of the matter of the earth to the sun, every particle, such as B, is acted on by a disturbing force parallel to CS, and proportional to BD, the distance of the particle from the plane of illumination; and this force is to the gravitation of the central particle to the sun, as three times BD is to CS, the distance of the earth from the sun.

Let AB *a* be a plane passing through the particle B, parallel to the plane EQ of the equator. This section of the earth will be a circle, of which A *a* is a diameter, and Q *q* will be the diameter of its section with the inscribed sphere. These will be two concentric circles, and the ring by which the section of the spheroid exceeds the section of the sphere will have AQ for its breadth; P *p* is the axis of figure.

Let EC be presented by the symbol -	a
OC or PC - - - - -	b
EO their difference $=\frac{a^2-b^2}{a+b}$ -	d
CL - - - - - -	x
QL - - - - -	$\sqrt{d^2-x^2}$
The periphery of a circle to radius 1 -	Π
The disturbing force at the distance 1 from the plane NCM - -	f
The sine of declination ECS -	m
The cosine of ECS - - -	n

It is evident, that with respect to the inscribed sphere, the disturbing forces are completely compensated, for every particle has a corresponding particle in the adjoining quadrant, which is acted on by an equal and opposite force. But this is not the case with the protuberant matter which makes up the spheroid. The segments NS *s n* and MT *t m* are more acted on than the segments NT *t n* and MS *s m*; and thus there is produced a tendency to a conversion of the whole earth, round an axis passing through the centre C, perpendicular to the plane PQ *p* E. We shall distinguish this motion from all others to which the spheroid may be subject, by the name LIBRATION. The axis of this libration is always perpendicular to that diameter of the equator over which the sun is, or to that meridian in which he is.

PROB. I. To determine the momentum of libration corresponding to any position of the earth respecting the sun, that is, to determine the accumulated energy of the disturbing forces on all the protuberant matter of the spheroid.

Let B and *b* be two particles in the ring formed by the revolution of AQ, and so situated, that they are at equal distances from the plane NM; but on opposite sides of it. Draw BD, *b d*, perpendicular to NM, and FLG perpendicular to LT.

Then, because the momentum, or power of producing rotation, is as the force and as the distance of its line of direction from the axis of rotation, jointly, the combined momentum of the particles B and *b*, will be $f.\mathrm{BD}.\mathrm{DC}-f.bd.dc$, (for the particles B and *b* are urged in contrary directions). But the momentum of B is $f.\mathrm{BF}.\mathrm{DC}+f.\mathrm{FD}.\mathrm{DC}$, and that of *b* is $f.b.\mathrm{G}.d\mathrm{C}-f.d\mathrm{G}.d\mathrm{C}$; and the combined momentum is $f.\mathrm{BF}.\mathrm{D}d-f.\mathrm{FD}.\overline{\mathrm{DC}+d\mathrm{C}},=2f.\mathrm{BF}.\mathrm{LF}-2f.\mathrm{LT}.\mathrm{TC}$.

Because m and n are the sine and cosine of the angle ECS or LCT, we have $\mathrm{LT}=m.\mathrm{CL}$, and $\mathrm{CT}=n.\mathrm{CL}$, and $\mathrm{LF}=m.\mathrm{BL}$, and $\mathrm{BF}=n.\mathrm{BL}$. This gives the momentum $=2fmn\,\overline{\mathrm{BL}^2-\mathrm{CL}^2}$.

The breadth AQ of the protuberant ring being very small, we may suppose, without any sensible error, that all the matter of the line AQ is collected in the point Q; and, in like manner, that the matter of the whole ring is collected in the circumference of its inner circle, and that B and *b* now represent, not single particles, but the collected matter of lines such as AQ, which terminate at B and *b*. The combined momentum of two such lines will therefore be $2mnf.\mathrm{AQ}.\overline{\mathrm{BL}^2-\mathrm{CL}^2}$.

Let the circumference of each parallel of latitude be divided into a great number of indefinitely small and equal parts. The number of such parts in the circumference, of which Q *q* is the diameter, will be $\Pi\cdot\mathrm{QL}$. To each pair of these there belongs a momentum $2mnf\cdot\mathrm{AQ}\cdot\overline{\mathrm{BL}^2-\mathrm{CL}^2}$. The sum of all the squares of BL, which can be taken round the circle, is one half of as many squares of the radius CL: for BL is the sine of an arch, and the sum of its square and the square of its corresponding cosine is equal to the square of the radius. Therefore the sum of all the squares of the sines, together with the sum of all the squares of the cosines, is equal to the sum of the same number of squares of the radius; and the sum of the squares of the sines is equal to the sum of the squares of the corresponding cosines; therefore the sum of the squares of the radius is double of either sum. Therefore $\int\Pi\cdot\mathrm{QL}\cdot\mathrm{BL}^2=\frac{1}{2}\Pi\cdot\mathrm{QL}\cdot\mathrm{QL}^2$. In like manner the sum of the number $\Pi\cdot\mathrm{QL}$ of CL^2s will be $=\Pi\cdot\mathrm{QL}\cdot\mathrm{CL}^2$. These sums, taken for the semicircle, are $\frac{1}{4}\Pi\cdot\mathrm{QL}\cdot\mathrm{QL}^2$, and $\frac{1}{2}\Pi\,\mathrm{QL}\cdot\mathrm{CL}^2$, or $\Pi\cdot\mathrm{QL}\cdot\frac{1}{4}\mathrm{QL}^2$, and $\Pi\cdot\mathrm{QL}.\frac{1}{2}\mathrm{CL}^2$: therefore the momentum of the whole ring will be $2mnf\cdot\mathrm{AQ}\cdot\mathrm{QL}\cdot\Pi\cdot(\frac{1}{4}\mathrm{QL}^2-\frac{1}{2}\mathrm{CL}^2)$: for the momentum of the ring is the combined momenta of a number of pairs, and this number is $\frac{1}{2}\Pi\cdot\mathrm{QL}$.

By the ellipse we have $\mathrm{OC}:\mathrm{QL}=\mathrm{EO}:\mathrm{AQ}$, and $\mathrm{AQ}=\mathrm{QL}\frac{\mathrm{EO}}{\mathrm{OC}},=\mathrm{QL}\frac{d}{b}$; therefore the momentum of the ring is $2mnf\frac{d}{b}\mathrm{QL}^2\Pi\,(\frac{1}{4}\mathrm{QL}^2-\frac{1}{2}\mathrm{CL}^2),=mnf\frac{a}{b}\,\mathrm{QL}^2\Pi\,(\frac{1}{2}\mathrm{QL}^2-\mathrm{CL}^2)$: but $\mathrm{QL}^2=b^2-x^2$; therefore

$\frac{1}{2}\mathrm{QL}^2$

Theory of Universal Gravitation.

$\frac{1}{2}QL^2 - CL^2 = \frac{1}{2}b^2 - \frac{1}{2}x^2 - x^2, = \frac{1}{2}b^2 - \frac{3}{2}x^2, = \frac{b^2-3x^2}{2}$; therefore the momentum of the ring is $mnf\frac{b}{d}\Pi\,(b^2-x^2)\left(\frac{b^2-3x^2}{2}\right) = mnf\frac{d}{b}\Pi\left(\frac{b^4-4b^2x^2+3x^4}{2}\right), = mnf\frac{d}{2b}\Pi\,(b^4-4b^2x^2+3x^4)$. If we now suppose another parallel extremely near to A a, as represented by the dotted line, the distance L l between them being $\dot{x}$, we shall have the fluxion of the momentum of the spheroid $mnf\frac{d}{2b}\Pi\,(b^4\dot{x}-4b^2x^2\dot{x}+3x^4\dot{x})$, of which the fluent is $mnf\frac{d}{2b}\Pi\left(b^4x-4b^2\frac{x^3}{3}+\frac{3x^5}{5}\right)$. This expresses the momentum of the zone EA a Q, contained between the equator and the parallel of latitude A a. Now let x become $=b$, and we shall obtain the momentum of the hemispheroid $= mnf\frac{d}{2b}\Pi\,(b^5-\frac{4}{3}b^5+\frac{3}{5}b^5)$, and that of the spheroid $= mnf\frac{d}{b}\Pi\,(b^5-\frac{4}{3}b^5+\frac{3}{5}b^5) = \frac{4}{15}mnfd\,\Pi b^4$.

This formula does not express any motion, but only a pressure tending to produce motion, and particularly tending to produce a libration by its action on the cohering matter of the earth, which is affected as a number of levers. It is similar to the common mechanical formula $w.\,d$, where w means a weight, and d its distance from the fulcrum of the lever.

It is worthy of remark, that the momentum of this protuberant matter is just $\frac{1}{5}$ of what it would be if it were all collected at the point O of the equator: for the matter in the spheroid is to that in the inscribed sphere as a^2 to b^2, and the contents of the inscribed sphere is $\frac{4}{3}\Pi\,b^3$. Therefore $a^2 : a^2-b^2 = \frac{4}{3}\Pi\,b^3 : \frac{4}{3}\Pi\,b^3\frac{a^2-b^2}{a^2}$, which is the quantity of protuberant matter. We may, without sensible error, suppose $\frac{a^2-b^2}{a} = 2d$; then the protuberant matter will be $\frac{4}{3}\Pi b^2 d$. If all this were placed at O, the momentum would be $\frac{4}{3}\Pi\,db^2f\cdot OH\cdot HC, = \frac{4}{3}mnfdb^4$, because $OH\cdot HC = mnb^2$; now $\frac{4}{3}$ is 5 times $\frac{4}{15}$.

Also, because the sum of all the rectangles OH·HC round the equator is half of as many squares of OC, it follows that the momentum of the protuberant matter placed in a ring round the equator of the sphere, or spheroid, is one half of what it would be if collected in the point G or E; whence it follows that the momentum of the protuberant matter in its natural place is two-fifths of what it would be if it were disposed in an equatorial ring. It was in this manner, that Sir Isaac Newton was enabled to compare the effect of the sun's action on the protuberant matter of the earth, with his effect on a rigid ring of moons. The preceding investigation of the momentum is nearly the same with his, and appears to us greatly preferable in point of perspicuity to the fluxionary solutions given by later authors. These indeed have the appearance of greater accuracy, because they do not suppose all the protuberant matter to be condensed on the surface of the inscribed sphere: nor were we under the necessity of doing this; only it would have led to very complicated expressions, had we supposed the matter in each line AQ collected in its centre of oscillation or gyration. We made a compensation for the error introduced by this which may amount to $\frac{1}{113}$ of the whole, and should not be neglected, by taking d as equal to $\frac{a^2-b^2}{2a}$ instead of $\frac{a^2-b^2}{a+b}$. The consequence is, that our formula is the same with that of the later authors.

Thus far Sir Isaac Newton proceeded with mathematical rigour; but in the application he made two assumptions, or, as he calls them hypotheses, which have been found to be unwarranted. The first was, that when the ring of protuberant matter is connected with the inscribed sphere, and subjected to the action of the disturbing force, the same quantity of motion is produced in the whole mass as in the ring alone. The second was, that the motion of the nodes of a rigid ring of moons is the same with the mean motion of the nodes of a solitary moon. But we are now able to demonstrate, that it is not the quantity of motion, but of momentum, which remains the same, and that the nodes of a rigid ring move twice as fast as those of a single particle. We proceed therefore to, 411

Effects of the libratory momentum of the earth's protuberant matter.

PROB. II. To determine the deviation of the axis, and the retrograde motion of the nodes which result from this libratory momentum of the earth's protuberant matter.

But here we must refer our readers to some fundamental propositions of rotatory motions which are demonstrated in the article ROTATION.

If a rigid body is turning round an axis A, passing through its centre of gravity with the angular velocity a, and receives an impulse which alone would cause it to turn round an axis B, also passing through its centre of gravity, with the angular velocity b, the body will now turn round a third axis C, passing through its centre of gravity, and lying in the plane of the axis A and B, and the sine of the inclination of this third axis to the axis A will be to the sine of the inclination to the axis B as the velocity b to the velocity a.

When a rigid body is made to turn round any axis by the action of an external force, the quantity of momentum produced (that is, the sum of the products of every particle by its velocity and by its distance from the axis) is equal to the momentum or similar product of the moving force or forces.

If an oblate spheroid, whose equatorial diameter is a, and polar diameter b, be made to librate round an equatorial diameter, and the velocity of that point of the equator which is farthest from the axis of libration be v, the momentum of the spheroid is $\frac{4}{15}\Pi\,a^2b^2v$.

The two last are to be found in every elementary book of mechanics.

Let ANan (fig. 156.) be the plane of the earth's equator, cutting the ecliptic CNKn in the line of the nodes or equinoctial points Na. Let OAS be the section of the earth by a meridian passing through the sun, so that the line OCS is in the ecliptic, and CA is an arch of an hour-circle or meridian, measuring the sun's declination. The sun not being in the plane of the equator, there is, by prop. 1. a force tending to produce a libration round an axis ZOz at right angles to the diameter Aa of that meridian in which the sun is situated, and

Theory of Universal Gravitation.

and the momentum of all the disturbing forces is $\frac{4}{15} m n f d \Pi b^4$. The product of any force by the moment $\dot{t}$ of its action expresses the momentary increment of velocity; therefore the momentary velocity, or the velocity of libration granted in the time $\dot{t}$ is $\frac{4}{15} m n f d \Pi b^4 \dot{t}$. This is the absolute velocity of a point at the distance 1 from the axis, or it is the space which would be uniformly described in the moment $\dot{t}$, with the velocity which the point has acquired at the end of that moment. It is double the space actually described by the libration during that moment; because this has been an uniformly accelerated motion, in consequence of the continued and uniform action of the momentum during this time. This must be carefully attended to, and the neglect of it has occasioned very faulty solutions of this problem.

Let v be the velocity produced in the point A, the most remote from the axis of libration. The momentum excited or produced in the spheroid is $\frac{4}{15} \Pi a^2 b^2 v$ (as above), and this must be equal to the momentum of the moving force, or to $\frac{4}{15} m n f d \Pi b^4 \dot{t}$; therefore we obtain $v = \frac{\frac{4}{15} m n f d \Pi b^4 \dot{t}}{\frac{4}{15} \Pi a^2 b}$, that is, $v = m n f d \dot{t} \frac{b^2}{a^2}$ or very nearly $m n f d \dot{t}$, because $\frac{b^2}{a^2} = 1$ very nearly. Also, because the product of the velocity and time gives the space uniformly described in that time, the space described by A in its libration round Z $\varkappa$ is $m n f d \dot{t}^2$, and the angular velocity is $\frac{m n f d \dot{t}}{a}$.

Let $\dot{r}$ be the momentary angle of diurnal rotation. The arch A r, described by the point A of the equator in this moment $\dot{t}$ will therefore be $a\dot{r}$, that is, $a \times \dot{r}$, and the velocity of the point A is $\frac{a\dot{r}}{\dot{t}}$, and the angular velocity of rotation is $\frac{\dot{r}}{\dot{t}}$.

Here then is a body (fig. 157.) turning round an axis OP, perpendicular to the plane of the equator $\varkappa o \varkappa$, and therefore situated in the plane ZP$\varkappa$; and it turns round this axis with the angular velocity $\frac{\dot{r}}{\dot{t}}$. It has received an impulse, by which alone it would librate round the axis Z $\varkappa$, with the angular velocity $\frac{m n f d \dot{t}}{a}$. It will therefore turn round neither axis, but round a third axis OP′, passing through O, and lying in the plane ZP $\varkappa$, in which the other two are situated, and the sine P′Π of its inclination to the axis of libration Z $\varkappa$ will be to the sine P′p of its inclination to the axis OP of rotation as $\frac{\dot{r}}{\dot{t}}$ to $\frac{m n f d \dot{t}}{a}$.

Now A, in fig. 156. is the summit of the equator both of libration and rotation: $m n f d \dot{t}^2$ is the space described by its libration in the time $\dot{t}$; and $a\dot{r}$ is the space or arch Ar (fig. 156.) described in the same time by its rotation: therefore, taking A r to A c (perpendicular to the plane of the equator of rotation, and lying in the equator of libration), as $a\dot{r}$ to $m n f d \dot{t}^2$, and completing the parallelogram A $r m c$, A m will be the compound motion of A, and $a\dot{r} : m n d f \dot{t}^2 = 1 : \frac{m n f d \dot{t}^2}{a\dot{r}}$, which will be the tangent of the angle m A r, or of the change of position of the equator. But the axes of rotation are perpendicular to their equator; and therefore the angle of deviation $\dot{w}$ is equal to this angle r A m. This appears from fig. 5.; for Π P′ : P′p=O′p : P′p,=OP : tan. POP; and it is evident that $a\dot{r} : m n f d \dot{t}^2 = \frac{\dot{r}}{\dot{t}} \dot{m} n f d \frac{\dot{t}}{a}$, as is required by the composition of rotations.

In consequence of this change of position, the plane of the equator no longer cuts the plane of the ecliptic in the line N n. The plane of the new equator cuts the former equator in the line AO, and the part AN of the former equator lies between the ecliptic and the new equator AN′, while the part A n of the former equator is above the new one A n'; therefore the new node N′, from which the point A was moving, is removed to the westward, or farther from A; and the new node n', to which A is approaching, is also moved westward, or nearer to A; and this happens in every position of A. The nodes therefore, or equinoctial points, continually shift to the westward, or in a contrary direction to the rotation of the earth; and the axis of rotation always deviates to the east side of the meridian which passes through the sun.

This account of the motions is extremely different from what a person should naturally expect. If the earth were placed in the summer solstice, with respect to us who inhabit its northern hemisphere, and had no rotation round its axis, the equator would begin to approach the ecliptic, and the axis would become more upright; and this would go on with a motion continually accelerating, till the equator coincided with the ecliptic. It would not stop here, but go as far on the other side, till its motion were extinguished by the opposing forces; and it would return to its former position, and again begin to approach the ecliptic, playing up and down like the arm of a balance. On this account this motion is very properly termed *libration*: but this very slow libration, compounded with the incomparably swifter motion of diurnal rotation, produces a third motion extremely different from both. At first the north pole of the earth inclines forward toward the sun; after a long course of years it will incline to the left hand, as viewed from the sun, and be much more inclined to the ecliptic, and the plane of the equator will pass through the sun. The south pole will come into view, and the north pole will begin to decline from the sun; and this will go on (the inclination of the equator diminishing all the while) till, after a course of years, the north pole will be turned quite away from the sun, and the inclination of the equator will be restored to its original quantity. After this the phenomena will have another period similar to the former, but the axis will now deviate to the right hand. And thus, although both the earth and sun should not move from their places, the inhabitants of the earth would have a complete succession of the seasons accomplished in a period of many centuries. This would be prettily illustrated by an iron ring poised very nicely on a cap like the card of of a mariner's compass, having its centre of gravity coinciding with the point of the cap, so that it may whirl round in any position. As this is extremely difficult to execute, the cap may be pierced a little deeper, which will cause the ring to maintain a horizontal position with a very small force. When the ring is whirling very steadily, and pretty briskly, in the direction of the hours of a watch-dial, hold a strong magnet above the middle of the nearer semicircle (above the 6 hour point) at the distance of three or four inches. We shall immediately observe the ring rise from the 9 hour point, and sink at the 3 hour point, and gradually acquire a motion of precession and nutation, such as has been described.

If the earth be now put in motion round the sun, or the sun round the earth, motions of libration and deviation will still obtain, and the succession of their different phases, if we may so call them, will be perfectly analogous to the above statement. But the quantity of deviation, and change of inclination, will now be prodigiously diminished, because the rapid change of the sun's position quickly diminishes the disturbing forces, annihilates them by bringing the sun into the plane of the equator, and brings opposite forces into action.

We see in general that the deviation of the axis is always at right angles to the plane passing through the sun, and that the axis, instead of being raised from the ecliptic, or brought nearer to it, as the libration would occasion, deviates sidewise; and the equator, instead of being raised or depressed round its east and west points, is twisted sidewise round the north and south points; or at least things have this appearance: but we must now attend to this circumstance more minutely.

The composition of rotation shows us that this change of the axis of diurnal rotation is by no means a translation of the former axis (which we may suppose to be the axis of figure) into a new position, in which it again becomes the axis of diurnal motion; nor does the equator of figure, that is, the most prominent section of the terrestrial spheroid, change its position, and in this new position continue to be the equator of rotation. This was indeed supposed by Sir Isaac Newton; and this supposition naturally resulted from the train of reasoning which he adopted. It was strictly true of a single moon, or of the imaginary orbit attached to it; and therefore Newton supposed that the whole earth did in this manner deviate from its former position, still, however, turning round its axis of figure. In this he has been followed by Walmesly, Simpson, and most of his commentators. D'Alembert was the first who entertained any suspicion that this might not be certain; and both he and Euler at last showed that the new axis of rotation was really a new line in the body of the earth, and that its axis and equator of figure did not remain the axis and equator of rotation. They ascertained the position of the real axis by means of a most intricate analysis, which obscured the connexion of the different positions of the axis with each other, and gave us only a kind of momentary information. Father Frisius turned his thoughts to this problem, and fortunately discovered the composition of rotations as a general principle of mechanical philosophy. Few things of this kind have escaped the penetrating eyes of Sir Isaac Newton. Even *this* principle had been glanced at by him. He affirms it in express terms with respect to a body that is perfectly spherical (cor. 22. prop. 66. book i.). But it was reserved for Frisius to demonstrate it to be true of bodies of any figure, and thus to enrich mechanical science with a principle which gives simple and elegant solutions of the most difficult problems.

But here a very formidable objection naturally offers itself. If the axis of the diurnal motion of the heavens is not the axis of the earth's spheroidal figure, but an imaginary line in it, round which even the axis of figure must revolve; and if this axis of diurnal rotation has so greatly changed its position, that it now points at a star at least 12 degrees distant from the pole observed by Timochares, how comes it that the equator has the very same situation on the surface of the earth that it had in ancient times? No sensible change has been observed in the latitudes of places.

The answer is very simple and satisfactory: Suppose that in 12 hours the axis of rotation has changed from the position PR (fig. 158.) to $p\,r$, so that the north pole, instead of being at P, which we may suppose to be a particular mountain, is now at p. In this 12 hours the mountain P, by its rotation round $p\,r$, has acquired the position π. At the end of the next 12 hours, the axis of rotation has got the position $\pi\,\varrho$, and the axis of figure has got the position $p\,r$, and the mountain P is now at p. Thus, on the noon of the following day, the axis of figure PR is in the situation which the real axis of rotation occupied at the intervening midnight. This goes on continually, and the axis of figure follows the position of the axis of rotation, and is never further removed from it than the deviation of 12 hours, which does not exceed $\frac{1}{700}$th part of one second, a quantity altogether imperceptible. Therefore the axis of figure will always sensibly coincide with the axis of rotation, and no change can be produced in the latitudes of places on the surface of the earth.

412 Application of this reasoning to nutation and precession.

We have hitherto considered this problem in the most general manner; let us now apply the knowledge we have gotten of the deviation of the axis or of the momentary action of the disturbing force to the explanation of the phenomena; that is, let us see what precession and what nutation will be accumulated after any given time of action.

For this purpose we must ascertain the precise deviation which the disturbing forces are competent to produce. This we can do by comparing the momentum of libration with the gravitation of the earth to the sun, and this with the force which would retain a body on the equator while the earth turns round its axis.

The gravitation of the earth to the sun is in the proportion of the sun's quantity of matter M directly, and to the square of the distance A inversely, and may therefore be expressed by the symbol $\frac{M}{A^2}$. The disturbing force at the distance 1 from the place of illumination is to the gravitation of the earth's centre to the sun as 3 to A, (A being measured on the same scale which measures the distance from the plane of illumination). Therefore $\frac{3M}{A^3}$ will be the disturbing force f of our formula.

Let p be the centrifugal force of a particle at the distance 1 from the axis of rotation; and let t and T be the time of rotation and of annual revolution, viz.

 sidereal

Theory of Universal Gravitation.

sidereal day and year. Then $p : \frac{M}{A^2} = \frac{1}{t^2} : \frac{A}{T^2}$. Hence we derive $\frac{3M}{A^3} = 3p\frac{t^2}{T^2}$. But since $\dot{r}$ was the angular velocity of rotation, and consequently $1 \times \dot{r}$ the space described, and $\frac{1 \times \dot{r}}{\dot{t}}$ the velocity; and since the centrifugal force is as the square of the velocity divided by the radius, (this being the measure of the generated velocity, which is the proper measure of any accelerating force), we have $p = \frac{1^2 \times \dot{r}^2}{1^2 \times \dot{t}^2}, = \frac{\dot{r}^2}{\dot{t}^2}$, and $f = \frac{3\dot{r}^2}{\dot{t}^2} \times \frac{t^2}{T^2}$. Now the formula $f\,m\,n\,d\frac{\dot{t}^2}{a}$ expressed the sine of the angle. This being extremely small, the sine may be considered as equal to the arc which measures the angle. Now, substitute for it the value now found, viz. $\frac{3\dot{r}^2}{\dot{t}^2} \times \frac{t^2}{T^2}$, and we obtain the angle of deviation $\dot{w} = \dot{r}\frac{3t^2}{T^2}m\,n\frac{d}{a}$, and this is the simplest form in which it can appear. But it is convenient, for other reasons, to express it a little differently: d is nearly equal to $\frac{a^2 - b^2}{2a^2}$ therefore $\dot{w} = \dot{r} \times \frac{3t^2}{2T^2}m\,n\frac{a^2 - b^2}{a^2}$, and this is the form in which we shall now employ it.

The small angle $\dot{r}\frac{3t^2}{2T^2}m\,n\frac{a^2 - b^2}{a^2}$ is the angle in which the new equator cuts the former one. It is different at different times, as appears from the variable part $m\,n$, the product of the sine and cosine of the sun's declination. It will be a maximum when the declination is in the solstice, for $m\,n$ increases all the way to 45°, and the declination never exceeds $23\frac{1}{2}$. It increases, therefore, from the equinox to the solstice, and then diminishes.

Let ESL (fig. 159.) be the ecliptic, EAC the equator, BAD the new position which it acquires by the momentary action of the sun, cutting the former in the angle $BAE = \dot{r}\frac{3t^2}{2T^2}m\,n\frac{a^2 - b^2}{a^2}$. Let S be the sun's place in the ecliptic, and AS the sun's declination, the meridian AS being perpendicular to the equator. Let $\frac{a^2 - b^2}{a^2}$ be k. The angle BAE is then $= \dot{r}\frac{3t^2}{2T^2}k\,m\,n$. In the spherical triangle BAE we have sin. B : sin. AE = sin. A : sin. BE, or = A : BE, because very small angles and arches are as their sines. Therefore BE, which is the momentary precession of the equinoctial point E, is equal to $A\frac{\text{sin. AE}}{\text{sin. B}}, = \dot{r} \times \frac{3t^2}{2T^2}k\,m\,n\frac{\text{sin. R. ascens.}}{\text{sin. obl. ecl.}}$.

413 Various modes of application.

The equator EAC, by taking the position BAD, recedes from the ecliptic in the colure of the solstices CL, and CD is the change of obliquity or the nutation. For let CL be the solstitial colure of BAD, and cl the solstitial colure of EAC. Then we have sin. B : sin. E = sin. LD : sin. lc; and therefore the difference of the arches LD and lc will be the measure of the difference of the angles B and E. But when BE is indefinitely small, CD may be taken for the difference of LD and lc, they being ultimately in the ratio of equality. Therefore CD measures the change of the obliquity of the ecliptic, or the nutation of the axis with respect to the ecliptic.

The real deviation of the axis is the same with the change in the position of the equator, Pp being the measure of the angle EAB. But this not being always made in a plane perpendicular to the ecliptic, the change of obliquity generally differs from the change in the position of the axis. Thus, when the sun is in the solstice, the momentary change of the position of the equator is the greatest possible; but being made at right angles to the plane in which the obliquity of the ecliptic is computed, it makes no change whatever in the obliquity, but the greatest possible change in the precession.

In order to find CD the change of obliquity, observe that in the triangle CAD, R : sin. AC, or R : cos. AE = sin. A : sin. CD, = A : CD (because A and CD are exceedingly small). Therefore the change of obliquity (which is the thing commonly meant by nutation) $CD = A \times \text{cos. AE}, = \dot{r}\frac{3t^2}{2T^2}k\,m\,n$, cos. $AE' = \dot{r}\frac{3t^2}{2T^2}k \times$ sin. declin. $\times$ cos. declin. $\times$ cos. R. ascens.

But it is more convenient for the purposes of astronomical computation to make use of the sun's longitude SE. Therefore make

The sun's longitude ES	- -	$= z$
Sine of the sun's long.	- -	$= x$
Cosine	- - -	$\sqrt{1 - x^2} = y$
Sine obliq. eclipt.	- -	$23\frac{1}{2} = p$
Cosine obliq.	- - -	$= q$

In the spherical triangle EAS, right-angled at A (because AS is the sun's declination perpendicular to the equator), we have R : sin. ES = sin. E : sin. AS, and sin. AS $= p\,x$. Also R : cos. AS = cos. AE : cos. ES, and cos. ES or y = cos. AS $\times$ cos. AE. Therefore $p\,x\,y$ = sin. AS cos. AS $\times$ cos. AE, $= m\,n \times$ cos. AE. Therefore the momentary nutation $CD = \dot{r} \times \frac{3t^2}{2T^2}k\,p\,x\,y$.

We must recollect that this angle is a certain fraction of the momentary diurnal rotation. It is more convenient to consider it as a fraction of the sun's annual motion, that so we may directly compare his motion on the ecliptic with the precession and nutation corresponding to his situation in the heavens. This change is easily made, by augmenting the fraction in the ratio of the sun's angular motion to the motion of rotation, or multiplying the fraction by $\frac{T}{t}$; therefore the momentary nutation will be $\dot{r}\frac{3t}{2T}k\,p\,x\,y$. In this value $\frac{3tkp}{2T}$ is a constant quantity, and the momentary nutation is proportional to $x\,y$, or to the product of the sine and cosine of the sun's longitude, or to the sine of twice the sun's longitude; for $x\,y$ is equal to half the sine of twice z.

If therefore we multiply this fraction by the sun's momentary angular motion, which we may suppose, with abundant accuracy, proportional to $\dot{z}$, we obtain the fluxion of the nutation, the fluent of which will express

Digitized by Google

press the whole nutation while the sun describes the arch z of the ecliptic, beginning at the vernal equinox. Therefore, in place of y put $\sqrt{1-x^2}$, and in place of $\dot{z}$ put $\frac{\dot{x}}{\sqrt{1-x^2}}$, and we have the fluxion of the nutation for the moment when the sun's longitude is z, and the fluent will be the whole nutation. The fluxion resulting from this process is $\frac{3\,t\,k\,p}{2\mathrm{T}}\,x\dot{x}$, of which the fluent is $\frac{3\,t\,k\,p}{4\mathrm{T}}x^2$. This is the whole change produced on the obliquity of the ecliptic while the sun moves along the arch z ecliptic, reckoned from the vernal equinox. When this arch is 90°, x is 1, and therefore $\frac{3\,t\,k\,p}{4\mathrm{T}}$ is the nutation produced while the sun moves from the equinox to the solstice.

414 The real and momentary change greatest at the solstices, and at the equinoxes nothing.

The momentary change of the axis and plane of the equator (which is the measure of the changing force) is $\frac{3\,t\,k}{2\mathrm{T}}m\,n$.

The momentary change of the obliquity of the ecliptic is $\frac{3\,t\,k\,p}{2\mathrm{T}}\,x\dot{x}$.

The whole change of obliquity is $\frac{3\,t\,k\,p}{4\mathrm{T}}\,x^2$.

Hence we see that the force and the real momentary change of position are greatest at the solstices, and diminish to nothing at the equinoxes.

The momentary change of obliquity is greatest at the octants, being proportional to $x\dot{x}$ or to $x\,y$.

The whole accumulated change of obliquity is greatest at the solstices, the obliquity itself being then smallest.

415 Quantity of precession in a given time.

We must in like manner find the accumulated quantity of the precession after a given time, that is, the arch BE for a finite time.

We have ER : CD = sin. EA : sin. CA (or cos. EA) = tan. EA : 1, and EB : ER = 1 : sin. B. Therefore EB : CD = tan. EA : sin. B. But tan. EA = cos. E × tan. ES, = cos. E × $\frac{\text{sin. long.}}{\text{cos. long.}} = \frac{q\,x}{\sqrt{1-x^2}}$.

Therefore EB : CD $= \frac{q\,x}{\sqrt{1-x^2}}p$, and CD = EB : $\frac{\text{sin. obliq. eclip.}}{\text{tan. long. ☉}}$. If we now substitute for CD its value found in N° 40, viz. $\frac{3\,t\,k\,p}{2\mathrm{T}}\,x\dot{x}$, we obtain EB $= \frac{3\,t}{2\mathrm{T}} \times \frac{k q x^2 \dot{x}}{\sqrt{1-x^2}}$, the fluxion of the precession of the equinoxes occasioned by the action of the sun. The fluent of the variable part $\frac{x\dot{x}}{\sqrt{1-x^2}} = x\,\dot{y}$, of which the fluent is evidently a segment of a circle whose arch is z and sine x, that is, $= \frac{z - x\sqrt{1-x^2}}{2}$, and the whole precession, while the sun describes the arch z, is $\frac{3\,t}{2\mathrm{T}} \times \frac{k\,q}{2}\left(z - x\sqrt{1-x^2}\right)$. This is the precession of the equinoxes while the sun moves from the vernal equinox along the arch z of the ecliptic.

In this expression, which consists of two parts, $\frac{3\,t\,k\,q}{4\mathrm{T}}$ z, and $\frac{3tkq}{4\mathrm{T}}\left(-x\sqrt{1-x^2}\right)$, the first is incomparably greater than the second, which never exceeds 1″, and is always compensated in the succeeding quadrant. The precession occasioned by the sun will be $\frac{3\,t\,k\,q}{4\mathrm{T}}\,z$, and from this expression we see that the precession increases uniformly, or at least increases at the same rate with the sun's longitude z, because the quantity $\frac{3tkq}{4\mathrm{T}}$ is constant.

In order to make use of these formulæ, which are now reduced to very great simplicity, it is necessary to determine the values of the two constant quantities $\frac{3tkp}{4\mathrm{T}}$, $\frac{3tkq}{4\mathrm{T}}$, which we shall call N and P, as factors of the nutation and precession. Now t is one sidereal day, and T is 366¼. k is $\frac{a^2-b^2}{a^2}$, which according to Sir Isaac Newton is $\frac{231^2-230^2}{231^2}, = \frac{1}{115}$; p and q are the sine and cosine of 23° 28′, viz. 0,39822 and 0,91729. 416 Mode of using the formulæ.

These data give N $= \frac{1}{141030}$ and P $= \frac{1}{61224}$, of which the logarithms are 4.85069 and 5.21308, viz. the arithmetical complements of 5.14931 and 4.78692.

417 Example of the utility of the investigation.

Let us, for an example of the use of this investigation, compute the precession of the equinoxes when the sun has moved from the vernal equinox to the summer solstice, so that z is 90°, or 324000″.

Log. 324000″ = z - - - -	5.51055
Log. P - - - - - -	5.21308
Log. 5″,292 - - - - -	0.72363

The precession therefore in a quarter of a year is 5,292 seconds; and, since it increases uniformly, it is 21″,168 annually.

418 Assumptions on which the computation proceeds.

We must now recollect the assumptions on which this computation proceeds. The earth is supposed to be homogeneous, and the ratio of its equatorial diameter to its polar axis is supposed to be that of 231 to 230. If the earth be more or less protuberant at the equator, the precession will be greater or less in the ratio of this protuberance. The measures which have been taken of the degrees of the meridian are very inconsistent among themselves; and although a comparison of them all indicates a smaller protuberance, nearly $\frac{1}{312}$ instead of $\frac{1}{231}$, their differences are too great to leave much confidence in this method. But if this figure be thought more probable, the precession will be reduced to about 17″ annually. But even though the figure of the earth were accurately determined, we have no authority to say that it is homogeneous. If it be denser towards the centre, the momentum of the protuberant matter will not be so great as if it were equally dense with the inferior parts, and the precession will be diminished on this account. Did we know the proportion of the matter in the moon to that in the sun, we could

Digitized by Google

Theory of Universal Gravitation.

could easily determine the proportion of the whole observed annual precession of $50\frac{1}{3}''$ which is produced by the sun's action. But we have no unexceptionable data for determining this; and we are rather obliged to infer it from the effect which she produces in disturbing the regularity of the precession, as will be considered immediately. So far, therefore, as we have yet proceeded in this investigation, the result is very uncertain. We have only ascertained unquestionably the law which is observed in the solar precession. It is probable, however, that this precession is not very different from 20″ annually; for the phenomena of the tides show the disturbing force of the sun to be very nearly $\frac{2}{5}$ of the disturbing force of the moon. Now 20″ is $\frac{2}{5}$ of 50″.

419 **Effect of the moon's action on the protuberant matter of the earth.** But let us now proceed to consider the effect of the moon's action on the protuberant matter of the earth; and as we are ignorant of her quantity of matter, and consequently of her influence in similar circumstances with the sun, we shall suppose that the disturbing force of the moon is to that of the sun as m to 1. Then (*cæteris paribus*) the precession will be to the solar precession π in the ratio of the force and of the time of its action jointly. Let t and T therefore represent a periodical month and year, and the lunar precession will be $=\frac{m\pi t}{T}$. This precession must be reckoned on the plane of the lunar orbit, in the same manner as the solar precession is reckoned on the ecliptic. We must also observe, that $\frac{m\pi t}{T}$ represents the lunar precession only on the supposition that the earth's equator is inclined to the lunar orbit in an angle of $23\frac{1}{2}$ degrees. This is indeed the mean inclination; but it is sometimes increased to above 28°, and sometimes reduced to 18°. Now in the value of the solar precession the cosine of the obliquity was employed. Therefore whatever is the angle E contained between the equator and the lunar orbit, the precession will be $=\frac{m\pi t}{T}\cdot\frac{\text{Cos. E}}{\text{Cos. }23\frac{1}{2}^{\circ}}$, and it must be reckoned on the lunar orbit.

Now let ♈ B (fig. 160.) be the immoveable plane of the ecliptic, ♈ ED♎F the equator in its first situation, before it has been deranged by the action of the moon, AGRDBH the equator in its new position, after the momentary action of the moon. Let EGNFH be the moon's orbit, of which N is the ascending node, and the angle N=5° 8′ 46″.

Let N ♈ the long. of the node be	z
Sine N ♈	x
Cosine N ♈	y
Sine ♈ $=23\frac{1}{2}$	a
Cosine ♈	b
Sine N=5.8.46	c
Cosine N	d
Circumference to radius 1,=6,28	e
Force of the moon	m
Solar precession (supposed $=14\frac{1}{2}''$ by observation)	π
Revolution of ☾ $=27\text{d}\frac{1}{3}$	t
Revolution of ☉ $=366\frac{1}{4}$	T
Revolution of N =18 years 7 months	n

420 **Lunar precession in a month reduced to the ecliptic.** In order to reduce the lunar precession to the ecliptic, we must recollect that the equator will have the same inclination at the end of every half revolution of the sun or of the moon, that is, when they pass through the equator, because the sum of all the momentary changes of its position begins again each revolution. Therefore if we neglect the motion of the node during one month, which is only $1\frac{1}{2}$ degree, and can produce but an insensible change, it is plain that the moon produces, in one half revolution, that is, while she moves from H to G, the greatest difference that she can in the position of the equator. The point D, therefore, half way from G to H, is that in which the moveable equator cuts the primitive equator, and DE and DF are each 90°. But S being the solstitial point, ♈ S is also 90°. Therefore DS=♈ E. Therefore, in the triangle DGE, we have sin. ED : sin. G = sin. EG : sin. D, = EG : D. Therefore D = EG × sin. G, = EG × sin. E nearly. Again, in the triangle ♈ DA we have sin. A : sin. ♈ D (or cos. ♈ E)=sin. D : sin. ♈ A, = D : ♈ A. Therefore $\Upsilon\,\text{A}=\frac{\text{D}\cdot\text{Cos. }\Upsilon\,\text{E}}{\text{Sin. A}},=\frac{\text{EG}\cdot\text{Sin. E}\cdot\text{Cos.}\Upsilon\,\text{E}}{\text{Sin. }23\frac{1}{2}},=\frac{m\pi t}{T}\,\frac{\text{Sin. E}\cdot\text{Cos. E}\cdot\text{Cos. }\Upsilon\,\text{E}}{\text{Sin. }\Upsilon\cdot\text{Cos. }\Upsilon}$.

This is the lunar precession produced in the course of one month, estimated on the ecliptic, not constant like the solar precession, but varying with the inclination of the angle E or F, which varies both by a change in the angle N, and also by a change in the position of N on the ecliptic.

421 **Nutation in the same time.** We must find in like manner the nutation SR produced in the same time, reckoned on the colure of the solstices RL. We have R : sin. DS=D : RS, and RS=D · sin. DS, =D · sin. ♈ E. But D=EG · sin. E. Therefore RS=ED · sin. E · sin. ♈ E, $=\frac{m\pi t\ \text{Cos. E}}{\text{T}\cdot\text{Cos. }\Upsilon}\times\text{sin. E}\times\text{sin. }\Upsilon\,\text{E}$. In this expression we must substitute the angle N, which may be considered as constant during the month, and the longitude ♈ N, which is also nearly constant, by observing that sin. E : sin. ♈ N=sin. N : sin. ♈ E. Therefore $\text{RS}=\frac{m\pi t}{\text{T}}\times\frac{\text{Sin. N}\cdot\text{Sin. }\Upsilon\,\text{N}\cdot\text{Cos. E}}{\text{Cos. }\Upsilon}$. But we must exterminate the angle E, because it changes by the change of the position of N. Now, in the triangle ♈ EN we have cos. E=cos. ♈ N · sin. N · sin. ♈ — cos. N · cos. ♈, $=yca-db$. And because the angle E is necessarily obtuse, the perpendicular will fall without the triangle, the cosine of E will be negative, and we shall have cos. E=$bd-acy$. Therefore the nutation for one month will be $=\frac{m\pi t}{T}\times\frac{cx(bd-acy)}{b}$, the node being supposed all the while in N.

422 **may be considered as momentary parts of the moon's action.** These two expressions of the monthly precession and nutation may be considered as momentary parts of the moon's action, corresponding to a certain position of the node and inclination of the equator, or as the fluxions of the whole variable precession and nutation, while the node continually changes its place, and in the space of 18 years makes a complete tour of the heavens.

423 **Precession and nutation compared.** We must, therefore, take the motion of the nodes as the fluent of comparison, or we must compare the fluxions of the node's motion with the fluxions of the precession and nutation; therefore, let the longitude of the node be z, and its monthly change $=\dot{z}$; we shall then have

t:

Digitized by Google

Theory of Universal Gravitation.

$t : n = \dot{z} : e$, and $t = \frac{n\dot{z}}{e}, = \frac{n\dot{x}}{e} \frac{}{\sqrt{1-x^2}}$. Let T be $=1$, in order that n may be 18,6, and substitute for t its value in the fluxion of the nutation, by putting $\sqrt{1-x^2}$ in place of y. By this substitution we obtain $m \pi n \frac{c}{e b} \left(\frac{d b x \dot{x}}{\sqrt{1-x^2}} - a c x \dot{x}^2 \right)$. The fluent of this is $m \pi n \frac{c}{e b} \left(-d b \sqrt{1-x^2} - \frac{a c x^2}{2} \right)$. (*Vide* Simpson's Fluxions, § 77.) But when x is $=o$, the nutation must be $=o$, because it is from the position in the equinoctial points that all our deviations are reckoned, and it is from this point that the periods of the lunar action recommence. But if we make $x=o$ in this expression, the term $-\frac{a c x^2}{2}$ vanishes, and the term $-db\sqrt{1-x^2}$ becomes $=-db$; therefore our fluent has a constant part $+db$; and the complete fluent is $m \pi n \frac{c}{e b} \left(db - db\sqrt{1-x^2} - \frac{a c x^2}{2} \right)$. Now this is equal to $m \pi n \frac{c}{e b}$ ($d b \times$ versed sine, $z - \frac{1}{4} a c \times$ versed sine $2z$) : For the versed sine of z is equal to ($1-$cos. z) ; and the square of the sine of an arch is $\frac{1}{2}$ the versed sine of twice that arch.

This, then, is the whole nutation while the moon's ascending node moves from the vernal equinox to the longitude ♈ N $= z$. It is the expression of a certain number of seconds, because π, one of its factors, is the solar precession in seconds; and all the other factors are numbers, or fractions of the radius 1; even e is expressed in terms of the radius 1.

The fluxion of the precession, or the monthly precession, is to that of the nutation as the cotangent of ♈ E is to the sine of ♈. This also appears by considering fig. 159. Pp measures the angle A, or change of position of the equator; but the precession itself, reckoned on the ecliptic, is measured by Po, and the nutation by po; and the fluxion of the precession is equal to the fluxion of nutation $\times \frac{\text{cot. ♈ E}}{\text{sine ♈}}$, but cot. ♈ E $= \frac{a d + b c y}{c x}$; therefore $\frac{\text{cot. ♈ E}}{\text{sine ♈}} = \frac{a d + b c\sqrt{1-x^2}}{c x}$: This, multiplied into the fluxion of the nutation, gives $\frac{m \pi n}{a b e} \left(\frac{a b d^2}{\sqrt{1-xx}} + (b^2-a^2) d c - a b c^2 . \sqrt{1-xx} \right) \dot{x}$ for the monthly precession. The fluent of this $\frac{m \pi n}{a b e} \left(a d^2 b z + (b^2-a^2) d c x - \frac{1}{2} a b c^2 z - \frac{1}{2} a b c^2 x \sqrt{1-x^2} \right)$, or it is equal to $\frac{m \pi n}{a b e} \left((d^2 - \frac{1}{2} c^2) a b z + (b^2-a^2) d c x - \frac{1}{4} a b c^2 \text{ sine } 2z \right)$.

Let us now express this in numbers: When the node has made a half revolution, we have $z=180°$, whose versed sine is 2, and the versed sine of $2z$, or 360°, is $=0$; therefore, after half a revolution of the node, the nutation becomes $\frac{m \pi n c}{e b} 2 b d$. If, in this expression, we supposed $m = 2\frac{1}{2}$, and $\pi = 14\frac{1}{2}''$, we shall find the nutation to be $19\frac{1}{5}''$.

Now the observed nutation is about 18″. This requires m to be $2\frac{1}{10}$, and $\pi = 16\frac{1}{4}''$. But it is evident, that no astronomer can pretend to warrant the accuracy of his observations of the nutation within 1″.

To find the lunar precession during half a revolution of the node, observe, that then z becomes $= \frac{e}{2}$, and the sine of z and of $2z$ vanish, d^2 becomes $1-c^2$, and the precession becomes $\frac{m \pi n}{2} (d^2 - \frac{1}{2} c^2), = \frac{m \pi n}{2} (1 - \frac{3}{2} c^2)$, and the precession in 18 years is $m \pi n \overline{1 - \frac{3}{2} c^2}$.

We see, by comparing the nutation and precession for nine years, that they are as $\frac{4 c d}{e}$ to $1 - \frac{3}{2} c^2$, nearly as 1 to $17\frac{2}{5}$. This gives 313″ of precession, corresponding to 18″, the observed nutation, which is about 35″ of precession annually produced by the moon.

424 And thus we see that the inequality produced by the moon in the precession of the equinoxes, and, more particularly, the nutation occasioned by the variable obliquity of her orbit, enables us to judge of her share in the whole phenomenon; and therefore informs us of her disturbing force, and therefore of her quantity of matter. This phenomenon, and those of the tides, are the only facts which enable us to judge of this matter: and this is one of the circumstances which has caused this problem to occupy so much attention. Dr Bradley, by a nice comparison of his observations with the mathematical theory, as it is called, furnished him by Mr Machin, found that the equation of precession computed by that theory was too great, and that the theory would agree better with the observations, if an ellipse were substituted for Mr Machin's little circle. He thought that the shorter axis of this ellipse, lying in the colure of the solstices, should not exceed 16″. Nothing can more clearly show the astonishing accuracy of Bradley's observations than this remark: for it results from the theory, that the pole must really describe an ellipse, having its shorter axis in the solstitial colure, and the ratio of the axes must be that of 18 to 16,8; for the mean precession during half a revolution of the node is $\frac{m \pi n}{2} \left(d^2 - \frac{c^2}{2} \right)$; and therefore for the longitude z, it will be $\frac{z m \pi n}{e} \left(d^2 - \frac{c^2}{2} \right)$; when this is taken from the true precession for that longitude, it leaves the equation of precession $\frac{m \pi n}{a b e} \left((b^2-a^2) d c \text{ sine } z - \frac{1}{4} a b c \text{ sine } 2z \right)$; therefore when the node is in the solstice, and the equation greatest, we have it $= \frac{m \pi n c d}{a b e} (b^2-a^2)$. We here neglect the second term as insignificant.

Gives the disturbing force and matter of the moon.

This

Theory of Universal Gravitation.

This greatest equation of precession is to $\frac{2m\pi ncd}{c}$, the nutation of 18″, as b^2-a^2 to $2ab$; that is, as radius to the tangent of twice the obliquity of the ecliptic. This gives the greatest equation of precession 16″,8, not differing half a second from Bradley's observations.

425 Greatest equation of precession.

Thus have we attempted to give some account of this curious and important phenomenon. It is curious, because it affects the whole celestial motions in a very intricate manner, and received no explanation from the more obvious application of mechanical principles, which so happily accounted for all the other appearances. It is one of the most illustrious proofs of Sir Isaac Newton's sagacity and penetration, which catched at a very remote analogy between this phenomenon and the libration of the moon's orbit.—It is highly important to the progress of practical and useful astronomy, because it has enabled us to compute tables of such accuracy, that they can be used with confidence for determining the longitude of a ship at sea. This alone fixes its importance: but it is still more important to the philosopher, affording the most incontestable proof of the universal and mutual gravitation of all matter to all matter. It left nothing in the solar system unexplained from the theory of gravity but the acceleration of the moon's mean motion; and this has at last been added to the list of our acquisitions by M. de la Place.

Quæ toties animos veterum torsere Sophorum,
Quæque scholas frustra rauco certamine vexant,
Obvia conspicimus, nube pellente Mathesi.
Jam dubios nulla caligine prægravat error
Queis superum penetrare domos, atque ardua cœli
Scandere sublimis genii concessit acumen.
Nec fas est propius mortali attingere divos.

HALLEY.

SECT. X. *Of the Libration of the Moon.*

The only phenomena which still remain to be explained are the libration of the moon and the motion of the nodes of her equator. The moon, in consequence of her rotation round her axis, is a little flattened towards the poles; but the attraction of the earth must have lengthened the axis of the moon directed towards that planet. If the moon were homogeneous and fluid, she would assume the form of an ellipsoid, whose shorter axis would pass through her poles of rotation; the longer axis would be directed towards the earth, and in the plane of the moon's equator; and the mean axis, situated in the same plane, would be perpendicular to the two others. The excess of the longer over the shorter would be quadruple the excess of the mean axis over the shorter, and would amount to about $\frac{1}{29711}$, the shorter axis being represented by unity.

It is easy to see, that if the longer axis of the moon deviate a little from the direction of the radius vector, which joins together the centres of the earth and moon, the attraction of the earth will tend to bring it towards that radius just as gravity tends to bring a pendulum towards the vertical position. If the rotation of the satellite had been at first sufficiently rapid to overcome this tendency, the time of a rotation would not have been equal to that of a revolution round the earth, and their difference would have discovered to us successively all the points of the moon's surface. But the angular motions of rotation and revolution having been at first but very little different, the force with which the longer axis separated from the radius vector was not sufficient to overcome the tendency toward the radius vector occasioned by the attraction of the earth. This last tendency, therefore, has rendered the two motions rigidly equal. And, as a pendulum driven from the vertical direction by a very small force constantly returns to it, making small oscillations on each side, in like manner the longer axis of the moon ought to oscillate on each side of the radius vector of her orbit. The libration of the moon then depends upon the small difference which originally subsisted between the angular motions of the moon's rotation and revolution.

Thus we see, that the theory of gravitation explains the equality which subsists between the mean rotation and revolution of the moon. It is only necessary to suppose, that the original difference between them was small. In that case the attraction of the earth would soon reduce them to a state of equality.

The singular coincidence of the nodes of the moon's equator, with those of its orbit, is also owing to the attraction of the earth. This was first demonstrated by La Grange. The planes of the equator and of the orbit of the moon, and the plane which passes through its centre, parallel to the ecliptic, have always nearly the same intersection. The secular movements of the ecliptic neither alter the coincidence of the nodes of these three planes, nor their mean inclination, which the attraction of the earth keeps always the same.

We have now examined all the phenomena of the heavenly bodies, and have found that they are all explicable on the theory of gravitation, and indeed necessary consequences of that theory. The exact coincidence of all the phenomena must be considered as a complete demonstration of the truth of the theory; and indeed places it beyond the reach of every possible objection. With respect to the nature of this force called *gravitation*, nothing whatever is known, nor is it likely that any thing ever will be known. The discussion being evidently above the reach of the human faculties, all the different theories which have been published, explaining it by ethers, &c. have only served to show the weakness of human reason, when it attempts to leave the plain path of experience, and indulge in fancy and conjecture.

APPENDIX.

APPENDIX.

In the preceding article we have endeavoured to give as full a view as possible of astronomy; avoiding, at the same time, the introduction of minute details upon those subjects which are not essential, that the readers attention might not be distracted and diverted from objects of primary importance. But for the sake of those persons who may wish to indulge their taste for practical astronomy, we have thought proper to subjoin an appendix; in which we shall give, in the first place, the rules for calculating eclipses, and in the second, a description of the most important astronomical instruments.

I. *Method of Calculating Eclipses.*

The method of constructing tables for the calculation of eclipses will be understood from the following observations.

The motions of the sun and moon are observed to be continually accelerated from the apogee to the perigee, and as gradually retarded from the perigee to the apogee; being slowest of all when the mean anomaly is nothing, and swiftest of all when it is six signs.

When the luminary is in its apogee or perigee, its place is the same as it would be if its motion were equable in all parts of its orbit. The supposed equable motions are called *mean;* the unequable are justly called the *true.*

The mean place of the sun or moon is always forwarder than the true place, whilst the luminary is moving from its apogee to its perigee: and the true place is always forwarder than the mean, whilst the luminary is moving from its perigee to its apogee. In the former case, the anomaly is always less than six signs; and in the latter case, more.

It has been found, by a long series of observations, that the sun goes through the ecliptic, from the vernal equinox to the same equinox again, in 365 days 5 hours 48 minutes 55 seconds; from the first star of Aries to the same star again, in 365 days 6 hours 9 minutes 24 seconds; and from his apogee to the same again, in 365 days 6 hours 14 minutes 0 seconds.—The first of these is called the *solar year;* the second the *sidereal year;* and the third the *anomalistic year.* So that the solar year is 20 minutes 29 seconds shorter than the sidereal; and the sidereal year is four minutes 36 seconds shorter than the anomalistic. Hence it appears, that the equinoctial point, or intersection of the ecliptic and equator at the beginning of Aries, goes backward with respect to the fixed stars, and that the sun's apogee goes forward.

It is also observed, that the moon goes through her orbit from any given fixed star to the same star again, in 27 days 7 hours 43 minutes 4 seconds at a mean rate; from her apogee to her apogee again, in 27 days 13 hours 18 minutes 43 seconds; and from the sun to the sun again, in 29 days 12 hours 44 minutes $3\frac{1}{10}$ seconds. This shows that the moon's apogee moves forward in the ecliptic, and that at a much quicker rate than the sun's apogee does: since the moon is 5 hours 55 minutes 39 seconds longer in revolving from her apogee to her apogee again, than from any star to the same star again.

The moon's orbit crosses the ecliptic in two opposite points, which are called her *nodes:* and it is observed, that she revolves sooner from any node to the node again, than from any star to the star again, by 2 hours 38 minutes 22 seconds; which shows that her nodes move backward, or contrary to the order of signs in the ecliptic.

The time in which the moon revolves from the sun to the sun again (or from change to change) is called a *lunation;* which, according to Dr Pound's mean measures, would always consist of 29 days 12 hours 44 minutes 3 seconds 2 thirds 58 fourths, if the motions of the sun and moon were always equable. Hence 12 mean lunations contain 354 days 8 hours 48 minutes 36 seconds 35 thirds 40 fourths, which is 10 days 21 hours 11 minutes 23 seconds 24 thirds 20 fourths less than the length of a common Julian year, consisting of 365 days 6 hours; and 13 mean lunations contain 383 days 21 hours 32 minutes 39 seconds 38 thirds 38 fourths, which exceeds the length of a common Julian year, by 18 days 15 hours 32 minutes 39 seconds 38 thirds 38 fourths.

The mean time of a new moon being found for any given year and month, as suppose for March 1700 old style, if this mean new moon falls later than the 11th day of March, then 12 mean lunations added to the time of this mean new moon will give the time of the mean new moon in March 1701, after having thrown off 365 days. But when the mean new moon happens to be before the 11th of March, we must add 13 mean lunations, in order to have the time of mean new moon in March the year following; always taking care to subtract 365 days in common years, and 366 days in leap years, from the sum of this addition.

Thus, A. D. 1700, old style, the time of mean new moon in March was the 8th day, at 16 hours 11 minutes 25 seconds after the noon of that day (viz. at 11 minutes 25 seconds past four in the morning of the 9th day), according to common reckoning. To this we must add 13 mean lunations, or 383 days 21 hours 32 minutes 39 seconds 38 thirds 38 fourths, and the sum will be 392 days 13 hours 44 minutes 4 seconds 38 thirds 38 fourths: from which subtract 365 days, because the year 1701 is a common year, and there will remain 27 days 13 hours 44 minutes 4 seconds 38 thirds 38 fourths for the time of mean new moon in March, A. D. 1701.

Carrying on this addition and subtraction till A. D. 1703, we find the time of mean new moon in March that year to be on the 6th day, at 7 hours 21 minutes, 17 seconds 49 thirds 46 fourths past noon; to which add 13 mean lunations, and the sum will be 390 days 4 hours 53 minutes 57 seconds 28 thirds 20 fourths; from which subtract 366 days, because the year 1704 is a leap-year, and there will remain 24 days 4 hours 53 minutes 57 seconds 28 thirds 20 fourths, for the time of mean new moon in March A. D. 1704.

In this manner was the first of the following tables constructed to seconds, thirds, and fourths; and then wrote out to the nearest seconds. The reason why we chose to begin the year with March, was to avoid the inconvenience of adding a day to the tabular time in leap-years after February, or subtracting a day therefrom

from in January and February in those years; to which all tables of this kind are subject, which begin the year with January, in calculating the times of new or full moons.

The mean anomalies of the sun and moon, and the sun's mean motion from the ascending node of the moon's orbit, are set down in Table III. from 1 to 13 mean lunations. These numbers, for 13 lunations, being added to the radical anomalies of the sun and moon, and to the sun's mean distance from the ascending node, at the time of mean new moon in March 1700 (Table I.) will give their mean anomalies, and the sun's mean distance from the node, at the time of mean new moon in March 1701; and being added for 12 lunations to those for 1701, give them for the time of mean new moon in March 1702. And so on as far as you please to continue the table (which is here carried on to the year 1800), always throwing off 12 signs when their sum exceeds 12, and setting down the remainder as the proper quantity.

If the number belonging to A. D. 1700 (in Table I.) be subtracted from those belonging to 1800, we shall have their whole differences in 100 complete Julian years; which accordingly we find to be 4 days 8 hours 10 minutes 52 seconds 15 thirds 40 fourths, with respect to the time of mean new moon. These being added together 60 times (always taking care to throw off a whole lunation when the days exceed $29\frac{1}{2}$) make up 60 centuries or 6000 years, as in Table VI. which was carried on to seconds, thirds, and fourths: and then wrote out to the nearest seconds. In the same manner were the respective anomalies and the sun's distance from the node found, for these centurial years; and then (for want of room) wrote out only to the nearest minutes, which is sufficient in whole centuries. By means of these two tables, we may find the time of any mean new moon in March, together with the anomalies of the sun and moon, and the sun's distance from the node at these times, within the limits of 6000 years either before or after any given year in the 18th century; and the mean time of any new or full moon in any given month after March, by means of the third and fourth tables, within the same limits, as shown in the precepts for calculation.

Thus it would be a very easy matter to calculate the time of any new or full moon, if the sun and moon moved equably in all parts of their orbits. But we have already shown, that their places are never the same as they would be by equable motions, except when they are in apogee or perigee; which is when their mean anomalies are either nothing or six signs: and that their mean places are always forwarder than their true places, whilst the anomaly is less than six signs; and their true places are forwarder than the mean, whilst the anomaly is more.

Hence it is evident, that whilst the sun's anomaly is less than six signs, the moon will overtake him, or be opposite to him, sooner than she could if his motion were equable; and later whilst his anomaly is more than six signs. The greatest difference that can possibly happen between the mean and true time of new or full moon, on account of the inequality of the sun's motion, is 3 hours 48 minutes 28 seconds: and that is, when the sun's anomaly is either 3 signs 1 degree, or 8 signs 29 degrees; sooner in the first case, and later in the last.—In all other signs and degrees of anomaly, the difference is gradually less, and vanishes when the anomaly is either nothing or six signs.

The sun is in his apogee on the 30th of June, and in his perigee on the 30th of December, in the present age: so that he is nearer the earth in our winter than in our summer.—The proportional difference of distance, deduced from the difference of the sun's apparent diameter at these times, is as 983 to 1017.

The moon's orbit is dilated in winter, and contracted in summer; therefore the lunations are longer in winter than in summer. The greatest difference is found to be 22 minutes 29 seconds; the lunations increasing gradually in length whilst the sun is moving from his apogee to his perigee, and decreasing in length whilst he is moving from his perigee to his apogee.—On this account the moon will be later every time in coming to her conjunction with the sun, or being in opposition to him, from December till June, and sooner from June till December, than if her orbit had continued of the same size all the year round.

As both these differences depend on the sun's anomaly, they may be fitly put together into one table, and called *The annual or first equation of the mean to the true syzigy*, (See Table VII.). This equational difference is to be subtracted from the time of the mean syzigy when the sun's anomaly is less than six signs, and added when the anomaly is more.—At the greatest it is 4 hours 10 minutes 57 seconds, viz. 3 hours 48 minutes 28 seconds, on account of the sun's unequal motion, and 22 minutes 29 seconds, on account of the dilatation of the moon's orbit.

This compound equation would be sufficient for reducing the mean time of new or full moon to the true time thereof, if the moon's orbit were of a circular form, and her motion quite equable in it. But the moon's orbit is more elliptical than the sun's, and her motion in it is so much the more unequal. The difference is so great, that she is sometimes in conjunction with the sun, or in opposition to him, sooner by 9 hours 47 minutes 54 seconds, than she would be if her motion were equable; and at other times as much later. The former happens when her mean anomaly is 9 signs 4 degrees, and the latter when it is 2 signs 26 degrees. See Table IX.

At different distances of the sun from the moon's apogee, the figure of the moon's orbit becomes different. It is longest of all, or most eccentric, when the sun is in the same sign and degree either with the moon's apogee or perigee; shortest of all, or least eccentric, when the sun's distance from the moon's apogee is either three signs or nine signs; and at a mean state when the distance is either 1 sign 15 degrees, 4 signs 15 degrees, 7 signs 15 degrees, or 10 signs 15 degrees. When the moon's orbit is at its greatest eccentricity, her apogeal distance from the earth's centre is to her perigeal distance therefrom, as 1067 is to 933; when least eccentric, as 1043 is to 957; and when at the mean state, as 1055 is to 945.

But the sun's distance from the moon's apogee is equal to the quantity of the moon's mean anomaly at the time of new moon, and by the addition of 6 signs it becomes equal in quantity to the moon's mean anomaly at the time of full moon. Therefore, a table may be constructed so as to answer to all the various inequalities depending on the different eccentricities of the moon's orbit, in the syzigies, and called *The second*

cond equation of the mean to the true syzigy. (See Table IX.): and the moon's anomaly, when equated by Table VIII. may be made the proper argument for taking out this second equation of time; which must be added to the former equated time, when the moon's anomaly is less than six signs, and subtracted when the anomaly is more.

There are several other inequalities in the moon's motion, which sometimes bring on the true syzigy a little sooner, and at other times keep it back a little later, than it would otherwise be; but they are so small, that they may be all omitted except two; the former of which (see Table X.) depends on the difference between the anomalies of the sun and moon in the syzigies, and the latter (see Table XI.) depends on the sun's distance from the moon's nodes at these times. The greatest difference arising from the former is 4 minutes 58 seconds; and from the latter, 1 minute 34 seconds.

The tables here inserted being calculated by Mr Ferguson according to the methods already given, he gives the following directions for their use.

To calculate the True Time of New or Full Moon.

426 Directions for the use of those tables.

PRECEPT I. If the required time be within the limits of the 18th century, write out the mean time of new moon in March, for the proposed year, from Table I. in the old style, or from Table II. in the new; together with the mean anomalies of the sun and moon, and the sun's mean distance from the moon's ascending node. If you want the time of full moon in March, add the half lunation at the foot of Table III. with its anomalies, &c. to the former numbers, if the new moon falls before the 15th of March; but if it falls after, subtract the half lunation, with the anomalies, &c. belonging to it, from the former numbers, and write down the respective sums or remainders.

II. In these additions or subtractions, observe, that 60 seconds make a minute, 60 minutes make a degree, 30 degrees make a sign, and 12 signs make a circle. When you exceed 12 signs in addition, reject 12, and set down the remainder. When the number of signs to be subtracted is greater than the number you subtract from, add 12 signs to the lesser number, and then you will have a remainder to set down. In the tables signs are marked thus ^{s}, degrees thus $^\circ$, minutes thus $'$, and seconds thus $''$.

III. When the required new or full moon is in any given month after March, write out as many lunations with their anomalies, and the sun's distance from the node from Table III. as the given month is after March, setting them in order below the number taken out for March.

IV. Add all these together, and they will give the mean time of the required new or full moon, with the mean anomalies and sun's mean distance from the ascending node, which are the arguments for finding the proper equations.

V. With the number of days added together, enter Table IV. under the given month; and against that number you have the day of mean new or full moon in the left-hand column, which set before the hours, minutes, and seconds, already found.

But (as it will sometimes happen) if the said number of days fall short of any in the column under the given month, add one lunation and its anomalies, &c. (from Table III.) to the foresaid sums, and then you will have a new sum of days wherewith to enter Table IV. under the given month, where you are sure to find it the second time, if the first falls short.

VI. With the signs and degrees of the sun's anomaly, enter Table VII. and therewith take out the annual or first equation for reducing the mean syzigy to the true; taking care to make proportions in the table for the odd minutes and seconds of anomaly, as the table gives the equation only to whole degrees.

Observe, in this and every other case of finding equations, that if the signs are at the head of the table, their degrees are at the left hand, and are reckoned downwards; but if the signs are at the foot of the table, their degrees are at the right hand, and are counted upward; the equation being in the body of the table, under or over the signs, in a collateral line with the degrees. The titles *Add* or *Subtract* at the head or foot of the tables where the signs are found, show whether the equation is to be added to the mean time of new or full moon, or to be subtracted from it. In this table, the equation is to be subtracted, if the signs of the sun's anomaly are found at the head of the table; but it is to be added, if the signs are at the foot.

VII. With the signs and degrees of the sun's mean anomaly, enter Table VIII. and take out the equation of the moon's mean anomaly; subtract this equation from her mean anomaly, if the signs of the sun's anomaly be at the head of the table; but add it if they are at the foot; the result will be the moon's equated anomaly, with which enter Table IX. and take out the second equation for reducing the mean to the true time of new or full moon; adding this equation, if the signs of the moon's anomaly are at the head of the table, but subtracting it if they are at the foot; and the result will give you the mean time of the required new or full moon twice equated, which will be sufficiently near for common almanacs.—But when you want to calculate an eclipse, the following equations must be used: thus,

VIII. Subtract the moon's equated anomaly from the sun's mean anomaly, and with the remainder in signs and degrees enter Table X. and take out the third equation, applying it to the former equated time, as the titles *Add* or *Subtract* do direct.

IX. With the sun's mean distance from the ascending node enter Table XI. and take out the equation answering to that argument, adding it to, or subtracting it from, the former equated time, as the titles direct, and the result will give the time of new or full moon, agreeing with well regulated clocks or watches very near the truth. But to make it agree with the solar or apparent time, you must apply the equation of natural days, taken from an equation-table, as it is leap-year, or the first, second, or third after. This, however, unless in very nice calculations, needs not be regarded, as the difference between true and apparent time is never very considerable.

The method of calculating the time of any new or full moon without the limits of the 18th century will be shown further on. And a few examples compared with the precepts will make the whole work plain.

N. B. The tables begin the day at noon, and reckon forward from thence to the noon following.—Thus, March the 31st, at 22 h. 30 m. 25 sec. of tabular time is April 1st (in common reckoning) at 30 m. 25 sec. after 10 o'clock in the morning.

Full Moon, May,	7	22	24	28	10	7	27	45	9	2	42	42	0	4	49	35
First Equation,	+	3	16	36	9	3	57	18	+	1	14	36	Sun from Node, and Arg. 4th equation.			
Time once equated,	8	1	41	4	1	3	30	27	9	3	57	18				
Second Equation,	—	9	47	53	Arg. 3d equation.				Arg. 2d equation.							
Time twice equated,	7	15	53	11												
Third Equation,		—	2	36												
Time thrice equated,	7	15	50	35												
Fourth Equation,			+	15												
The Full Moon,	7	15	50	50												

Ans. May 7th at 15 h. 50 min. 50 sec. past noon, viz. May 8th at 3 h. 50 sec. in the morning.

To calculate the time of New and Full Moon in a given year and month of any particular century between the Christian era and the 18th century.

Precept I. Find a year of the same number in the 18th century with that of the year in the century proposed, and take out the mean time of new moon in March, old style, for that year, with the mean anomalies and sun's mean distance from the node at that time, as already taught.

II. Take as many complete centuries of years from Table VI. as, when subtracted from the above-said year in the 18th century, will answer to the given year; and take out the first mean new moon and its anomalies, &c. belonging to the said centuries, and set them below those taken out for March in the 18th century.

III. Subtract the numbers belonging to these centuries from those of the 18th century, and the remainders will be the mean time and anomalies, &c. of new moon in March, in the given year of the century proposed.— Then, work in all respects for the true time of new or full moon, as shown in the above precepts and examples.

IV. If the days annexed to these centuries exceed the number of days from the beginning of March taken out in the 18th century, add a lunation and its anomalies, &c. from Table III. to the time and anomalies of new moon in March, and then proceed in all respects as above. This circumstance happens in Example V.

True Full Moon, April,	6	8	25	4												

Hence it appears, that the true time of Full Moon in April A. D. 30, old style, was on the 6th day, at 25 m. 4 s. past eight in the evening.

To Calculate the true time of New or Full Moon in any given year and month before the Christian era.

Precept I. Find a year in the 18th century, which being added to the given number of years before Christ diminished by one, shall make a number of complete centuries.

II. Find this number of centuries in Table VI. and subtract the time and anomalies belonging to it from those of the mean new moon in March, the above found year of the 18th century; and the remainder will denote the time and anomalies, &c. of mean new moon in March, the given year before Christ.—Then, for the true time thereof in any month of that year, proceed as above taught.

EXAMPLE IV.

Required the true time of New Moon in May, Old Style, the year before Christ 585?

The years 584 added to 1716, make 2300, or 23 centuries.

By the Precepts.	New Moon.				Sun's Anomaly.				Moon's Anomaly.				Sun from Node.			
	D.	H.	M.	S.	s.	°	'	"	s.	°	'	"	s.	°	'	"
March 1716,	11	17	33	29	8	22	50	39	4	4	14	2	4	27	17	5
2300 years subtract,	11	5	57	53	11	19	47	0	1	5	59	0	7	25	27	0
March before Christ 585,	0	11	35	36	9	3	3	39	2	28	15	2	9	1	50	5
Add 3 Lunations,	88	14	12	9	2	27	18	58	2	17	27	1	3	2	0	42
May before Christ 585,	28	1	47	45	0	0	22	37	5	15	42	3	2	3	50	47
First Equation,		—	1	37	5	15	41	17			—	46	Sun from Node, and Arg. fourth equation.			
Time once equated,	28	1	46	8	6	14	41	20	5	19	41	17				
Second equation,	+	2	15	1	Arg. 3d. equation.				Arg. 2d equation.							
Time twice equated,	28	4	1	9												
Third Equation,		+	1	9												
Time thrice equated,	28	4	2	18												
Fourth equation.			+	12												
True New Moon,	28	4	2	30												

So the true time was May 28th, at 2 minutes 30 seconds past four in the afternoon.

These Tables are calculated for the meridian of London; but they will serve for any other place, by subtracting four minutes from the tabular time, for every degree that the meridian of the given place is westward of London, or adding four minutes for every degree that the meridian of the given place is eastward: as in

Time twice equated,	22	16	22	6												
Third Equation,		—	4	10												
Time thrice equated,	22	16	17	56												
Fourth Equation,			—	51												
Full Moon at London,	22	16	17	5												
Add for Babylon,		2	25	41												
True time there,	22	18	42	46												

So that, on the meridian of London, the true time was October 23d, at 17 minutes 5 seconds past four in the morning; but at Babylon, the true time was October 23d, at 42 minutes 46 seconds past six in the morning.—This is supposed by some to have been the year of the creation.

Of Calculating Eclipses, &c.

To calculate the true time of New or Full Moon in any given year and month after the 18th century.

Precept I. Find a year of the same number in the 18th century with that of the year proposed, and take out the mean time and anomalies, &c. of new moon in March, old style, for that year, in Table I.

II. Take so many years from Table VI. as when added to the above-mentioned year in the 18th century will answer to the given year in which the new or full moon is required; and take out the first new moon, with its anomalies for these complete centuries.

III. Add all these together, and then work in all respects as above shown, only remember to subtract a lunation and its anomalies, when the above-said addition carries the new moon beyond the 31st of March; as in the following example.

EXAMPLE VII.

Required the true time of New Moon in July, Old Style, A. D. 2180?

Four centuries or (400 years) added to A. D. 1780, make 2100.

By the Precepts.	New Moon.				Sun's Anomaly.				Moon's Anomaly.				Sun from Node.

Third Equation,		+	3	56												
Time thrice equated,	8	6	21	47												
Fourth Equation,	-	+	1	8												
True time, July,	8	6	22	55												

In keeping by the old style, we are always sure to be right, by adding or subtracting whole hundreds of years to or from any given year in the 18th century. But in the new style we may be very apt to make mistakes, on account of the leap year's not coming in regularly every fourth year: and therefore, when we go without the limits of the 18th century, we had best keep to the old style, and at the end of the calculation reduce the time to the new. Thus, in the 22d century there will be fourteen days difference between the styles; and therefore the true time of new moon in this last example being reduced to the new style will be the 22d of July, at 22 minutes 55 seconds past six in the evening.

To calculate the true place of the Sun for any given moment of time.

Precept I. In Table XII. find the next lesser year in number to that in which the sun's place is sought, and write out his mean longitude and anomaly answering thereto: to which add his mean motion and anomaly for the complete residue of years, months, days, hours, minutes, and seconds, down to the given time, and this will be the sun's mean place and anomaly at that time, in the old style, provided the said time be in any year after the Christian era. *See the first following example.*

II. Enter Table XIII. with the sun's mean anomaly, and making proportions for the odd minutes and seconds thereof, take out the equation of the sun's centre: which, being applied to his mean place as the title *Add* or *Subtract* directs, will give his true place or longitude from the vernal equinox, at the time for which it was required.

III. To calculate the sun's place for any time in a given year before the Christian era, take out his mean longitude and anomaly for the first year thereof, and from these numbers subtract the mean motions and anomalies for the complete hundreds or thousands next above the given year; and to the remainders, add those for the residue of years, months, &c. and then work in all respects as above. *See the second example following.*

EXAMPLE.

EXAMPLE I.

Required the Sun's true place, March 20th, Old Style, 1764, at 22 hours 30 minutes 25 seconds past Noon? In common reckoning, March 21st, at 10 hours 30 minutes in the Forenoon.

		Sun's Longitude.				Sun's Anomaly.

Sun's true place at the same time - - -		6	0	0	0	or ♎	0	0	0

So that in the meridian of London, the sun was then just entering the sign ♎ Libra, and consequently was upon the point of the autumnal equinox.

If to the above time of the autumnal equinox at London, we add 2 h. 25 m. 41 sec. for the longitude of Babylon, we shall have for the time of the same equinox, at that place, October 23d, at 19 h. 22 m. 41 sec.; which, in the common way of reckoning, is October 24th, at 22 m. 41 sec. past seven in the morning.

And it appears by Example VI. that in the same year the true time of full moon at Babylon was October 23d, at 42 m. 46 sec. after six in the morning; so that the autumnal equinox was on the day next after the day of full moon.—The dominical letter for that year was G, and consequently the 24th of October was on a Wednesday.

To find the Sun's distance from the Moon's ascending node, at the time of any given new or full moon: and consequently, to know whether there is an eclipse at that time or not.

The sun's distance from the moon's ascending node is the argument for finding the moon's fourth equation in the syzigies; and, therefore, it is taken into all the foregoing examples in finding the times thereof. Thus, at the time of mean new moon in April 1764, the sun's mean

mean distance from the ascending node is $0^s\ 5^\circ\ 35'\ 2''$. See Example I.

The descending node is opposite to the ascending one, and they are just six signs distant from each other.

When the sun is within 17 degrees of either of the nodes at the time of new moon, he will be eclipsed at that time; and when he is within 12 degrees of either of the nodes at the time of full moon, the moon will be then eclipsed. Thus we find, that there will be an eclipse of the sun at the time of new moon in April 1764.

But the true time of that new moon comes out by the equations to be 50 minutes 46 seconds later than the mean time thereof, by comparing these times in the above example: and therefore we must add the sun's motion from the node during that interval to the above mean distance $0^s\ 5^\circ\ 35'\ 2''$, which motion is found in Table XII. for 50 minutes 46 seconds, to be $2'\ 12''$. And to this we must apply the equation of the sun's mean distance from the node in Table XV. found by the sun's anomaly, which, at the mean time of new moon in Example I. is $9^s\ 1^\circ\ 26'\ 19''$; and then we shall have the sun's true distance from the node, at the true time of new moon, as follows:

	Sun from Node. s	°	′	″
At the mean time of new moon in April 1764	0	5	35	2
Sun's motion from the node for 50 minutes			2	10
46 seconds				2
Sun's mean distance from node at true new moon	0	5	37	14
Equation of mean distance from node, add		2	5	0
Sun's true distance from the ascending node	0	7	42	14

Which being far within the above limit of 17 degrees, shows that the sun must then be eclipsed.

And now we shall show how to project this, or any other eclipse, either of the sun or moon.

To project an Eclipse of the Sun.

In order to this, we must find the 10 following elements by means of the tables.

1. The true time of conjunction of the sun and moon; and at that time, 2. The semidiameter of the earth's disk, as seen from the moon, which is equal to the moon's horizontal parallax. 3. The sun's distance from the solstitial colure to which he is then nearest. 4. The sun's declination. 5. The angle of the moon's visible path with the ecliptic. 6. The moon's latitude. 7. The moon's true horary motion from the sun. 8. The sun's semidiameter. 9. The moon's. 10. The semidiameter of the penumbra.

We shall now proceed to find these elements for the sun's eclipse in April 1764.

To find the true time of new moon. This, by Example I. is found to be on the first day of the said month, at 30 minutes 25 seconds after ten in the morning.

2. *To find the moon's horizontal parallax, or semidiameter of the earth's disk, as seen from the moon.* Enter Table XVII. with the signs and degrees of the moon's anomaly (making proportions, because the anomaly is in the table only to every 6th degree), and thereby take out the moon's horizontal parallax; which for the above time, answering to the anomaly $11^s\ 9^\circ\ 24'\ 21''$, is $54'\ 43''$.

3. *To find the sun's distance from the nearest solstice, viz. the beginning of Cancer, which is* 3^s *or* 90° *from the beginning of Aries.* It appears by Example I. (where the sun's place is calculated to the above time of new moon), that the sun's longitude from the beginning of Aries is then $0^s\ 12^\circ\ 10'\ 12''$: that is, the sun's place at that time is ♈ Aries, $12^\circ\ 10'\ 12''$.

	s	°	′	″
Therefore from - -	3	0	0	0
Subtract the sun's longitude or place	0	12	10	12
Remains the sun's distance from the solstice ♋	=2	17	49	48

Or $77^\circ\ 49'\ 48''$; each sign containing 30 degrees.

4. *To find the sun's declination.* Enter Table XIV. with the signs and degrees of the sun's true place, viz. $0^s\ 12^\circ$, and making proportions for the $10'\ 12''$, take out the sun's declination answering to his true place, and it will be found to be $4^\circ\ 49'$ north.

5. *To find the moon's latitude.* This depends on her distance from her ascending node, which is the same as the sun's distance from it at the time of new moon; and is thereby found in Table XVI.

But we have already found that the sun's equated distance from the ascending node, at the time of new moon in April 1764, is $0^s\ 7^\circ\ 42'\ 14''$. See above.

Therefore, enter Table XVI. with 0 signs at the top, and 7 and 8 degrees at the left hand, and take out $36'$ and $39''$, the latitude for 7°; and $41'\ 51''$, the latitude for 8°: and by making proportions between these latitudes for the $42'\ 14''$, by which the moon's distance from the node exceeds 7 degrees, her true latitude will be found to be $40'\ 18''$ north ascending.

6. *To find the moon's true horary motion from the sun.* With the moon's anomaly, viz. $11^s\ 9^\circ\ 24'\ 21''$, enter Table XVII. and take out the moon's horary motion; which, by making proportions in that Table, will be found to be $30'\ 22''$. Then, with the sun's anomaly, $9^s\ 1^\circ\ 26'\ 19''$, take out his horary motion $2'\ 28''$ from the same table; and subtracting the latter from the former, there will remain $27'\ 54''$ for the moon's true horary motion from the sun.

7. *To find the angle of the moon's visible path with the ecliptic.* This, in the projection of eclipses, may be always rated at $5^\circ\ 35'$, without any sensible error.

8, 9. *To find the semidiameters of the sun and moon.* These are found in the same table, and by the same arguments, as their horary motions. In the present case, the sun's anomaly gives his semidiameter $16'\ 6''$, and the moon's anomaly gives her semidiameter $14'\ 57''$.

10. *To find the semidiameter of the penumbra.* Add the moon's semidiameter to the sun's, and their sum will be the semidiameter of the penumbra, viz. $31'\ 3''$.

Now collect these elements, that they may be found the more readily when they are wanted in the construction of this eclipse.

Of Calculating Eclipses, &c.

		°	′	″
1. True time of new moon in April 1764 - -	1	10	30	25

10. Semidiameter of the penumbra			31	3

To project an Eclipse of the Sun geometrically.

Fig. 158. *a.* Make a scale of any convenient length, as AC, and divide it into as many equal parts as the earth's semidisk contains minutes of a degree; which, at the time of the eclipse in April 1764, is 54′ 53″. Then, with the whole length of the scale as a radius, describe the semicircle AMB upon the centre C; which semicircle shall represent the northern half of the earth's enlightened disk as seen from the sun.

Upon the centre C raise the straight line CH, perpendicular to the diameter ACB; so ACB shall be a part of the ecliptic, and CH its axis.

Being provided with a good sector, open it to the radius CA in the line of chords; and taking from thence the chord of $23\frac{1}{2}$ degrees in your compasses, set it off both ways from H, to *g* and to *h*, in the periphery of the semidisk; and draw the straight line *g* V*h*, in which the north pole of the disk will be always found.

When the sun is in Aries, Taurus, Gemini, Cancer, Leo, and Virgo, the north pole of the earth is enlightened by the sun: but whilst the sun is in the other six signs, the south pole is enlightened, and the north pole is in the dark.

And when the sun is in Capricorn, Aquarius, Pisces, Aries, Taurus, and Gemini, the northern half of the earth's axis C XII P lies to the right hand of the axis of the ecliptic, as seen from the sun; and to the left hand, whilst the sun is in the other six signs.

Open the sector till the radius (or distance of the two 90's) of the sines be equal to the length of V *h*, and take the sine of the sun's distance from the solstice (77° 49′ 48″) as nearly as you can guess, in your compasses, from the line of the sines, and set off that distance from V to P in the line *g* V *h*, because the earth's axis lies to the right hand of the axis of the ecliptic in this case, the sun being in Aries; and draw the straight line C XII P for the earth's axis, of which P is the north pole. If the earth's axis had lain to the left hand from the axis of the ecliptic, the distance VP would have been set off from V towards *g*.

To draw the parallel of latitude of any given place, as suppose London, or the path of that place on the earth's enlightened disk as seen from the sun, from sunrise till sunset, take the following method.

Subtract the latitude of London, $51°\frac{1}{2}$, from 90°, and the remainder $38°\frac{1}{2}$ will be the colatitude, which take in your compasses from the line of chords, making CA or CB the radius, and set it from *h* (where the earth's axis meets the periphery of the disk) to VI and VI, and draw the occult or dotted line VI K VI. Then, from the points where this line meets the earth's disk, set off the chord of the sun's declination 4° 49′ to D and F, and to E and G, and connect these points by the two occult lines F XII G and DLE.

Bisect LK XII in K, and through the point K draw the black line VI K VI. Then make CB the radius of a line of sines on the sector, take the colatitude of London $38°\frac{1}{2}$ from the sines in your compasses, and set it both ways from K to VI and VI. These hours will be just in the edge of the disk at the equinoxes, but at no other time in the whole year.

With the extent K VI taken into your compasses, set one foot in K (in the black line below the occult one) as a centre, and with the other foot describe the semicircle VI 7 8 9 10, &c. and divide it into 12 equal parts. Then from these points of division draw the occult lines 7*p*, 8*o*, 9*n*, &c. parallel to the earth's axis C XII P.

With the small extent K XII as a radius, describe the quadrantal arc XII *f*, and divide it into six equal parts, as XII, *a*, *ab*, *bc*, *cd*, *de*, and *ef*; and through the division points *a*, *b*, *c*, *d*, *e*, draw the occult lines VII *e* V, VIII *d* IV, IX *c* III, X *b* II, and XI *a* I, all parallel to VI K VI, and meeting the former occult lines 7 *p*, 8 *o*, &c. in the points VII VIII IX X XI, V IV III II and I: which points shall mark the several situations of London on the earth's disk, at these hours respectively, as seen from the sun; and the elliptic curve VI VII VIII, &c. being drawn through these points, shall represent the parallel of latitude, or path of London on the disk, as seen from the sun, from its rising to its setting.

N. B. If the sun's declination had been south, the diurnal path of London would have been on the upper side of the line VI K VI, and would have touched the line DLE in L. It is requisite to divide the horary spaces into quarters (as some are in the figure), and, if possible, into minutes also.

Make CB the radius of a line of chords on the sector, and take therefrom the chord of 5° 35′, the angle of the moon's visible path with the ecliptic, set it off from H to M on the left hand of CH, the axis of the ecliptic, because the moon's latitude is north ascending. Then draw CM for the axis of the moon's orbit, and bisect the angle MCH by the right line C*z*. If the moon's latitude had been north descending, the axis of her orbit would have been on the right hand from the axis of the ecliptic.——N. B. The axis of the moon's orbit lies the same way when her latitude is south ascending as when it is north ascending; and the same way when south descending as when north descending.

Take the moon's latitude 40′ 18″ from the scale CA in your compasses, and set it from *i* to *x* in the bisecting line C*z*, making *ix* parallel to C*y*: and through *x*, at right angles to the axis of the moon's orbit CM, draw the straight line N *wxy* S for the path of the penumbra's centre over the earth's disk.—The point *w*, in the axis of the moon's orbit, is that where the penumbra's centre approaches nearest to the centre of the earth's disk, and consequently in the middle of the general eclipses: the point *x* is that where the conjunction of

Digitized by Google

of the sun and moon falls, according to equal time by the tables; and the point *y* is the ecliptical conjunction of the sun and moon.

Take the moon's true horary motion from the sun, 27′ 54″, in your compasses, from the scale CA (every division of which is a minute of a degree), and with that extent make marks along the path of the penumbra's centre; and divide each space from mark to mark into 60 equal parts or horary minutes, by dots; and set the hours to every 60th minute, in such a manner, that the dot signifying the instant of new moon by the tables may fall into the point *x*, half way between the axis of the moon's orbit and the axis of the ecliptic; and then the rest of the dots will show the points of the earth's disk, where the penumbra's centre is at the instants denoted by them, in its transit over the earth.

Apply one side of a square to the line of the penumbra's path, and move the square backwards and forwards until the other side of it cuts the same hour and minute (as at *m* and *m*) both in the path of London and in the path of the penumbra's centre; and the particular minute or instant which the square cuts at the same time on both paths shall be the instant of the visible conjunction of the sun and moon, or greatest obscuration of the sun, at the place for which the construction is made, namely London, in the present example; and this instant is at $37\frac{1}{5}$ minutes past ten o'clock in the morning; which is 17 minutes five seconds later than the tabular time of true conjunction.

Take the sun's semidiameter, 16′ 6″, in your compasses, from the scale CA, and setting one foot on the path of London, at *m*, namely at $47\frac{1}{5}$ minutes past ten, with the other foot describe the circle UY, which shall represent the sun's disk as seen from London at the greatest obscuration.—Then take the moon's semidiameter, 14′ 57″, in your compasses from the same scale, and setting one foot on the path of the penumbra's centre at *m*, in the $47\frac{1}{5}$ minutes after ten, with the other foot describe the circle TY for the moon's disk, as seen from London, at the time when the eclipse is at the greatest, and the portion of the sun's disk which is hid or cut off by the moon's will show the quantity of the eclipse at that time; which quantity may be measured on a line equal to the sun's diameter, and divided into 12 equal parts for digits.

Lastly, take the semidiameter of the penumbra, 31′3″, from the scale CA in your compasses; and setting one foot in the line of the penumbra's centre path, on the left hand from the axis of the ecliptic, direct the other foot toward the path of London; and carry that extent backwards and forwards till both the points of the compasses fall into the same instants in both the paths: and these instants will denote the time when the eclipse begins at London.—Then do the like on the right hand of the axis of the ecliptic; and where the points of the compasses fall into the same instants in both the paths, they will show at what time the eclipse ends at London.

These trials give 20 minutes after nine in the morning for the beginning of the eclipse at London, at the points N and O; $47\frac{1}{5}$ minutes after ten, at the points *m* and *n*, for the time of greatest obscuration; and 18 minutes after twelve, at R and S, for the time when the eclipse ends; according to mean or equal time.

From these times we must subtract the equation of natural days, viz. 3 minutes, 48 seconds, in leap-year April 1. and we shall have the apparent times; namely, 9 hours 16 minutes 12 seconds for the beginning of the eclipse, 10 hours 43 minutes 42 seconds for the time of greatest obscuration, and 12 hours 14 minutes 12 seconds for the time when the eclipse ends. But the best way is to apply this equation to the true equal time of new moon, before the projection be begun; as is done in Example I. For the motion or position of places on the earth's disk answers to apparent or solar time.

In this construction it is supposed, that the angle under which the moon's disk is seen, during the whole time of the eclipse, continues invariably the same; and that the moon's motion is uniform and rectilineal during that time. But these suppositions do not exactly agree with the truth; and therefore, supposing the elements given by the tables to be accurate, yet the times and phases of the eclipse, deduced from its construction, will not answer exactly to what passeth in the heavens; but may be at least two or three minutes wrong, though done with the greatest care. Moreover, the paths of all places of considerable latitudes are nearer the centre of the earth's disk as seen from the sun than those constructions make them; because the disk is projected as if the earth were a perfect sphere, although it is known to be a spheroid. Consequently, the moon's shadow will go farther northward in all places of northern latitude, and farther southward in all places of southern latitude, than it is shown to do in these projections.——According to Meyer's Tables, this eclipse was about a quarter of an hour sooner than either these tables, or Mr Flamstead's, or Dr Halley's, make it; and was not annular at London. But M. de la Caille's make it almost central.

The Projection of Lunar Eclipses.

When the moon is within 12 degrees of either of her nodes at the time when she is full, she will be eclipsed; otherwise not.

We find by Example II. that at the time of mean full moon in May 1762, the sun's distance from the ascending node was only 4° 49′ 35″; and the moon being then opposite to the sun, must have been just as near her descending node, and was therefore eclipsed.

The elements for constructing an eclipse of the moon are eight in number, as follows:

1. The true time of full moon; and at that time, 2. The moon's horizontal parallax. 3. The sun's semidiameter. 4. The moon's. 5. The semidiameter of the earth's shadow at the moon. 6. The moon's latitude. 7. The angle of the moon's visible path with the ecliptic. 8. The moon's true horary motion from the sun.—Therefore,

1. *To find the true time of new or full moon.* Work as already taught in the precepts.—Thus we have the true time of full moon in May 1762 (see Example II. page 562) on the 8th day, at 50 minutes 50 seconds past three o'clock in the morning.

2. *To find the moon's horizontal parallax.* Enter Table XVII. with the moon's mean anomaly (at the above full) 9ˢ 2° 42′ 42″, and thereby take out her horizontal parallax; which, by making the requisite proportions, will be found to be 57′ 23″.

3, 4. *To find the semidiameters of the sun and moon.* Enter Table XVII. with their respective anomalies, the sun's being 10ˢ 7° 27′ 45″ (by the above example), and the moon's 9ˢ 2° 42′ 42″; and thereby take out their respective semidiameters; the sun's 15′ 56″, and the moon's 15′ 38″.

Digitized by Google

Of Calculating Eclipses, &c.

5. *To find the semidiameter of the earth's shadow at the moon.* Add the sun's horizontal parallax, which is always 10′, to the moon's, which in the present case is 37′ 23″, the sum will be 57′ 33″, from which subtract the sun's semidiameter 15′ 56″, and there will remain 41′ 37″ for the semidiameter of that part of the earth's shadow which the moon then passes through.

6. *To find the moon's latitude.* Find the sun's true distance from the ascending node (as already taught at the true time of full moon); and this distance increased by six signs will be the moon's true distance from the same node; and consequently the argument for finding her true latitude.

Thus, in Example II. the sun's mean distance from the ascending node was $0^s\ 40^\circ\ 49'\ 35''$, at the time of mean full moon; but it appears by the example, that the true time thereof was six hours 33 minutes 38 seconds sooner than the mean time; and therefore we must subtract the sun's motion from the node (found in Table XII.) during this interval from the above mean distance of $0^s\ 4^\circ\ 49'\ 35''$, in order to have his mean distance from it at the true time of full moon. Then to this apply the equation of his mean distance from the node, found in Table XV. by his mean anomaly $10^s\ 7^\circ\ 27'\ 45''$: and lastly add six signs: so shall the moon's true distance from the ascending node be found as follows:

		s	°	′	″
Sun from node at mean full moon	-	0	4	40	35
His motion from it in 6 hours	-			15	35
His motion from it in 33 minutes	-			1	26
His motion from it in 38 seconds	-				2
Sum, subtract from the uppermost line	-			17	3
Remains his mean distance at true full moon		0	4	32	32
Equation of his mean distance, add	-		1	38	0
Sun's true distance from the node	-	0	6	10	32
To which add	- - -	6	0	0	0
And the sum will be	- - -	6	6	10	32

Which is the moon's true distance from her ascending node at the true time of her being full; and consequently the argument for finding her true latitude at that time.—Therefore, with this argument enter Table XVI. making proportions between the latitudes belonging to the 6th and 7th degree of the argument at the left hand (the signs being at top) for the 10′ 32″, and it will give 32′ 21″ for the moon's true latitude, which appears by the table to be south descending.

7. *To find the angle of the moon's visible path with the ecliptic.* This may be stated at 5° 35′, without any error of consequence in the projection of the eclipse.

8. *To find the moon's true horary motion from the sun.* With their respective anomalies take out their horary motions from Table XVII. and the sun's horary motion subtracted from the moon's, leaves remaining the moon's true horary motion from the sun: in the present case 30′ 32″.

Now collect these elements together for use.

		D.	H.	M.	S.
1. True time of full moon in May 1762	-	8	3	50	50
			°	′	″
2. Moon's horizontal parallax	- -		0	57	23
3. Sun's semidiameter	- - -		0	15	56
4. Moon's semidiameter	- - -		0	15	38
5. Semidiameter of the earth's shadow at the moon			0	41	37
6. Moon's true latitude, south descending	-		0	32	21
7. Angle of her visible path with the ecliptic	-		5	35	0
8. Her true horary motion from the sun	-		0	30	52

These elements being found for the construction of the moon's eclipse in May 1762, proceed as follows:

Of Calculating Eclipses, &c.

Make a scale of any convenient length, as WX (fig. 159. *a*), and divide it into 60 equal parts, each part standing for a minute of a degree.

Draw the right line ACB (fig. 160. *a.*) for part of the ecliptic, and CD perpendicular thereto for the southern part of its axis; the moon having south latitude.

Add the semidiameters of the moon and earth's shadow together, which in this eclipse will make 57′ 15″; and take this from the scale in your compasses, and setting one foot on the point C as a centre, with the other foot describe the semicircle ADB; in one point of which the moon's centre will be at the beginning of the eclipse, and in another at the end thereof.

Take the semidiameter of the earth's shadow, 41′ 37″, in your compasses from the scale, and setting one foot in the centre C, with the other foot describe the semicircle KLM for the southern half of the earth's shadow, because the moon's latitude is south in this eclipse.

Make CD equal to the radius of a line of chords on the sector, and set off the angle of the moon's visible path with the ecliptic 5° 35′ from D to E, and draw the right line CFE for the southern half of the axis of the moon's orbit lying to the right hand from the axis of the ecliptic CD, because the moon's latitude is south descending.—It would have been the same way (on the other side of the ecliptic) if her latitude had been north descending, but contrary in both cases, if her latitude had been either north ascending or south ascending.

Bisect the angle DCE by the right line C*g*, in which line the true equal time of opposition of the sun and moon falls as given by the table.

Take the moon's latitude 32′ 21″, from the scale with your compasses, and set it from C to G in the line CG*g*; and through the point G, at right angles to CFE, draw the right line PHGFN for the path of the moon's centre. Then F shall be the point in the earth's shadow, where the moon's centre is at the middle of the eclipse; G, the point where her centre is at the tabular time of her being full; and H, the point where her centre is at the instant of her ecliptical opposition.

Take the moon's horary motion from the sun, 30′ 52″, in your compasses from the scale; and with that extent make marks along the line of the moon's path PGN: then divide each space from mark to mark into 60 equal parts, or horary minutes, and set the hours to the proper dots in such a manner, that the dot signifying the instant of full moon (viz. 50 minutes 50 seconds after III in the morning) may be in the point G, where the line of the moon's path cuts the line that bisects the angle DCE.

Take the moon's semidiameter, 15′ 38″, in your compasses from the scale, and with that extent, as a radius, upon the points N, F, and P, as centres, describe the circle Q for the moon at the beginning of the eclipse, when she touches the earth's shadow at V; the circle R for the moon at the middle of the eclipse; and the circle S for the moon at the end of the eclipse, just leaving the earth's shadow at W.

The point N denotes the instant when the eclipse began, namely, at 15 minutes 10 seconds after II in the morning; the point F the middle of the eclipse at 47 minutes 44 seconds past III; and the point P the end of the eclipse, at 18 minutes after V.—At the greatest obscuration the moon was 10 digits eclipsed.

TABLE I.

Description of Astronomical Instruments.

II. *Description of Astronomical Instruments serving to illustrate the Motions of the Heavenly Bodies.*

427 The orrery. The machine represented by fig. 161. is the GRAND ORRERY, first made in this kingdom by Mr Rowley for King George I. The frame of it, which contains the wheel-work, &c. and regulates the whole machine, is made of ebony, and about four feet in diameter; the outside thereof is adorned with 12 pilasters. Between these the 12 signs of the zodiac are neatly painted with gilded frames. Above the frame is a broad ring supported with 12 pillars. This ring represents the plane of the ecliptic; upon which are two circles of degrees, and between these the names and characters of the 12 signs. Near the outside is a circle of months and days, exactly corresponding to the sun's place at noon each day throughout the year. Above the ecliptic stand some of the principal circles of the sphere, agreeable to their respective situations in the heavens: viz. N° 10. are the two colures, divided into degrees and half degrees; N° 11. is one-half the equinoctial circle, making an angle of 23½ degrees. The tropic of Cancer and the arctic circle are each fixed parallel at their proper distance from the equinoctial. On the northern half of the ecliptic is a brass semicircle, moveable upon two points fixed in ♈ and ♎. This semicircle serves as a moveable horizon to be put to any degree of latitude upon the north part of the meridian, and the whole machine may be set to any latitude without disturbing any of the internal motions, by two strong hinges (N° 13.) fixed to the bottom-frame upon which the instrument moves, and a strong brass arch, having holes at every degree, through which a strong pin is put at every elevation. This arch and the two hinges support the whole machine when it is lifted up according to any latitude: and the arch at other times lies conveniently under the bottom-frame. When the machine is to be set to any latitude (which is easily done by two men, each taking hold of two handles conveniently fixed for the purpose), set the moveable horizon to the same degree upon the meridian, and hence you may form an idea of the respective altitude or depression of the planets both primary and secondary. The sun (N° 1.) stands in the middle of the whole system upon a wire, making an angle with the ecliptic of about 82 degrees. Next the sun is a small ball (2.), representing Mercury. Next to Mercury is Venus (3.), represented by a larger ball. The earth is represented (N° 4.) by an ivory ball, having some circles and a map sketched upon it. The wire which supports the earth makes an angle with the ecliptic of 66½ degrees, the inclination of the earth's axis to the ecliptic. Near the bottom of the earth's axis is a dial-plate (N° 9.), having an index pointing to the hours of the day as the earth turns round its axis. Round the earth is a ring supported by two small pillars, representing the orbit of the moon; and the divisions upon it answer to the moon's latitude. The motion of this ring represents the motion of the moon's orbit according to that of the nodes. Within this ring is the moon (N° 5.), having a black cap or case, by which its motion represents the phases of the moon according to her age. Without the orbits of the earth and moon is Mars (N° 6.). The next in order to Mars is Jupiter and his four moons (N° 7.). Each of these moons is supported by a wire fixed in a socket which turns about the pillar supporting Jupiter. These satellites may be turned by the hand to any position, and yet when the machine is put into motion, they will all move in their proper times. The outermost of all is Saturn, his five moons and his ring (N° 8.). These moons are supported and contrived similar to those of Jupiter. The machine is put into motion by turning a small winch (N° 14.); and the whole system is also moved by this winch, and by pulling out and pushing in a small cylindrical pin above the handle. When it is pushed in, all the planets, both primary and secondary, will move according to their respective periods by turning the handle. When it is drawn out, the motions of the satellites of Jupiter and Saturn will be stopped, while all the rest move without interruption. There is also a brass lamp, having two convex glasses to be put in room of the sun; and also a smaller earth and moon, made somewhat in proportion to their distance from each other, which may be put on at pleasure. The lamp turns round at the same time with the earth, and the glasses of it cast a strong light upon her; and when the smaller earth and moon are placed on, it will be easy to show when either of them will be eclipsed. When this machine is intended to be used, the planets must be duly placed by means of an ephemeris hereafter described; and you may place a small black patch or bit of wafer upon the middle of the sun. Right against the first degree of ♈, you may also place patches upon Venus, Mars, and Jupiter, right against some noted point in the ecliptic. Put in the handle, and push in the pin which is above it. One turn of this handle answers to a revolution of the ball which represents the earth about its axis; and consequently to 24 hours of time, as shown by the hour index (9.), which is marked and placed at the foot of the wire on which the ball of the earth is fixed. Again, when the index has moved the space of ten hours, Jupiter makes one revolution round its axis, and so of the rest. By these means the revolutions of the planets, and their motions round their own axes, will be represented to the eye. By observing the motions of the spots upon the surface of the sun and of the planets in the heavens, their diurnal rotation was first discovered, after the same manner as we in this machine observe the motions of their representatives by that of the marks placed upon them.

The ORRERY (fig. 162.) is a machine contrived by the late ingenious Mr James Ferguson. It shows the motions of the sun, Mercury, Venus, earth, and moon; and occasionally the superior planets, Mars, Jupiter, and Saturn, may be put on. Jupiter's four satellites are moved round him in their proper times by a small winch; and Saturn has his five satellites, and his ring which keeps its parallelism round the sun; and by a lamp put in the sun's place, the ring shows all its various phases already described.

In the centre, N° 1. represents the sun, supported by its axis, inclining almost 8 degrees from the axis of the ecliptic, and turning round in 25¼ days on its axis, of which the north pole inclines toward the eighth degree of Pisces in the great ecliptic (N° 11.), whereon the months and days are engraven over the signs and degrees in which the sun appears, as seen from the earth, on the different days of the year.

The

Description of Astronomical Instruments.

The nearest planet (N° 2.) to the sun is Mercury, which goes round him in 87 days, 23 hours, or $87\frac{2}{7}\frac{1}{3}$ diurnal rotations of the earth; but has no motion round its axis in the machine, because the time of its diurnal motion in the heavens is not known to us.

The next planet in order is Venus (N° 3.), which performs her annual course in 224 days 17 hours, and turns round her axis in 24 days 8 hours, or in $24\frac{1}{3}$ diurnal rotations of the earth. Her axis inclines 75 degrees from the axis of the ecliptic, and her north pole inclines towards the 20th degree of Aquarius, according to the observations of Bianchini. She shows all the phenomena described in Part II.

Next, without the orbit of Venus, is the earth (N° 4.) which turns round its axis, to any fixed point at a great distance, in 23 hours 56 minutes 4 seconds of mean solar time; but from the sun to the sun again, in 24 hours of the same time. N° 6. is a sidereal dial-plate under the earth, and N° 7. a solar dial-plate on the cover of the machine. The index of the former shows sidereal, and of the latter, solar time; and hence the former index gains one entire revolution on the latter every year, as 365 solar or natural days contain 366 sidereal days, or apparent revolutions of the stars. In the time that the earth makes $365\frac{1}{4}$ diurnal rotations on its axis, it goes once round the sun in the plane of the ecliptic; and always keeps opposite to a moving index (N° 10.) which shows the sun's daily change of place, and also the days of the months.

The earth is half covered with a black cap, for dividing the apparently enlightened half next the sun from the other half, which, when turned away from him, is in the dark. The edge of the cap represents the circle bounding light and darkness, and shows at what time the sun rises and sets to all places throughout the year. The earth's axis inclines $23\frac{1}{2}$ degrees from the axis of the ecliptic; the north pole inclines towards the beginning of Cancer, and keeps its parallelism throughout its annual course; so that in summer the northern parts of the earth incline towards the sun, and in winter from him: by which means, the different lengths of days and nights, and the cause of the various seasons, are demonstrated to sight.

There is a broad horizon, to the upper side of which is fixed a meridian semicircle in the north and south points, graduated on both sides from the horizon to 90° in the zenith or vertical point. The edge of the horizon is graduated from the east and west to the south and north points, and within these divisions are the points of the compass. From the lower side of this thin horizontal plate stand out four small wires, to which is fixed a twilight circle 18 degrees from the graduated side of the horizon all round. This horizon may be put upon the earth (when the cap is taken away), and rectified to the latitude of any place; and then by a small wire, called the *solar ray*, which may be put on so as to proceed directly from the sun's centre towards the earth's, but to come no farther than almost to touch the horizon, the beginning of twilight, time of sunrising, with his amplitude, meridian altitude, time of setting, amplitude then, and end of twilight, are shown for every day of the year, at that place to which the horizon is rectified.

The moon (N° 5.) goes round the earth, from between it and any fixed point at a great distance, in 27 days 7 hours 43 minutes, or through all the signs and degrees of her orbit, which is called her *periodical revolution;* but she goes round from the sun to the sun again, or from change to change, in 29 days 12 hours 35 minutes, which is her *synodical revolution;* and in that time she exhibits all the phases already described.

When the above-mentioned horizon is rectified to the latitude of any given place, the times of the moon's rising and setting, together with her amplitude, are shown to that place as well as the sun's; and all the various phenomena of the harvest-moon are made obvious to sight.

The moon's orbit (N° 9.) is inclined to the ecliptic (N° 11.) one half being above, and the other below it. The nodes, or points at o and o, lie in the plane of the ecliptic, as before described, and shift backward through all its sines and degrees in $18\frac{2}{3}$ years. The degrees of the moon's latitude to the highest at NL (north latitude) and lowest at SL (south latitude), are engraven both ways from her nodes at o and o, and as the moon rises and falls in her orbit according to its inclination, her latitude and distance from her nodes are shown for every day, having first rectified her orbit so as to set the nodes to their proper places in the ecliptic; and then as they come about at different and almost opposite times of the year, and then point towards the sun, all the eclipses may be shown for hundreds of years (without any new rectification) by turning the machinery backward for time past, or forward for time to come. At 17 degrees distance from each node, on both sides, is engraved a small sun; and at 12 degrees distance, a small moon which show the limits of solar and lunar eclipses; and when, at any change, the moon falls between either of these suns and the node, the sun will be eclipsed on the day pointed to by the annual index (N° 10); and as the moon has then north or south latitude, one may easily judge whether that eclipse will be visible in the northern or southern hemisphere: especially as the earth's axis inclines toward the sun or from him at that time. And when at any full the moon falls between either of the little moons and node, she will be eclipsed, and the annual index shows the day of that eclipse. There is a circle of $29\frac{1}{2}$ equal parts (N° 8.) on the cover of the machine, on which an index shows the days of the moon's age.

There are two semicircles (fig. 163.) fixed to an elliptical ring, which being put like a cap upon the earth, and the forked part F upon the moon, shows the tides as the earth turns round within them, and they are led round it by the moon. When the different places come to the semicircle A *a* E *b* B, they have tides of flood; and when they come to the semicircle CED, they have tides of ebb; the index on the hour-circle (fig. 162.) showing the times of these phenomena.

There is a jointed wire, of which one end being put into a hole in the upright stem that holds the earth's cap, and the wire laid into a small forked piece which may be occasionally put upon Venus or Mercury, shows the direct and retrograde motions of these two planets, with their stationary times and places as seen from the earth.

The

Digitized by Google

The whole machinery is turned by a winch or handle (N° 12.); and is so easily moved, that a clock might turn it without any danger of stopping.

To give a plate of the wheel-work of this machine would answer no purpose, because many of the wheels lie so behind others as to hide them from sight in any view whatever.

The PLANETARIUM (fig. 164.) is an instrument contrived by Mr William Jones of Holborn, London, mathematical instrument maker, who has paid considerable attention to those sort of machines, in order to reduce them to their greatest degree of simplicity and perfection. It represents in a general manner, by various parts of its machinery, all the motions and phenomena of the planetary system. This machine consists of, the Sun (in the centre), with the planets, Mercury, Venus, the Earth and Moon, Mars, Jupiter and his four moons, Saturn and his five moons; and to it is occasionally applied an extra long arm for the Georgian planet and his two moons. To the earth and moon is applied a frame CD, containing only four wheels and two pinions, which serve to preserve the earth's axis in its proper parallelism in its motion round the sun, and to give the moon her due revolution about the earth at the same time. These wheels are connected with the wheel-work in the round box below, and the wheel is set in motion by the winch H. The arm M that carries round the moon, points out on the plate C her age and phases for any situation in her orbit, and which accordingly are engraved thereon. In the same manner the arm points out her place in the ecliptic B, in signs and degrees, called her geocentric place; that is, as seen from the earth. The moon's orbit is represented by the flat rim A; the two joints of which, and upon which it turns, denoting her nodes. This orbit is made to incline to any desired angle. The earth of this instrument is usually made of a three inch or $1\frac{1}{2}$ globe, papered, &c. for the purpose; and by means of the terminating wire that goes over it, points out the changes of the seasons, and the different lengths of days and nights more conspicuously. This machine is also made to represent the Ptolemaic System, or such as is vulgarly received: which places the earth in the centre, and the planets and sun revolving about it. (It is done by an auxiliary small sun and an earth, which change their places in the instrument). At the same time, it affords a most manifest confutation of it: for it is plainly observed in this construction, (1.) That the planets Mercury and Venus, being both within the orbit of the sun, cannot at any time be seen to go behind it; whereas in nature we observe them as often to go behind as before the sun in the heavens. (2.) It shows, that as the planets move in circular orbits about the central earth, they ought at all times to be of the same apparent magnitudes; whereas, on the contrary, we observe their apparent magnitude in the heavens to be very variable, and so far different, that, for instance, Mars will sometimes appear as big as Jupiter nearly, and at other times you will scarcely know him from a fixed star. (3.) It shows that any of the planets might be seen at all distances from the sun in the heavens; or, in other words, that when the sun is setting, Mercury or Venus may be seen not only in the south but even in the east; which circumstances were never yet observed. (4.) You see by this planetarium that the motions of the planets should always be regular and uniformly the same; whereas, on the contrary, we observe them always to move with a variable velocity, sometimes faster, then slower, and sometimes not at all, as will be presently shown. (5.) By the machine you see the planets move all the same way, viz. from west to east continually: but in the heavens we see them move sometimes direct from west to east, sometimes retrograde from east to west, and at other times to be stationary. All which phenomena plainly prove this system to be a false and absurd hypothesis.

The truth of the Copernican or Solar System of the world is hereby most clearly represented. For taking the earth from the *centre*, and placing thereon the usual large brass ball for the sun, and restoring the earth to its proper situation among the planets, then every thing will be right, and agree exactly with celestial observations. For turning the winch H, (1.) You will see the planets Mercury and Venus go both before and behind the sun, or have two conjunctions. (2.) You will observe Mercury never to be more than a certain angular distance, 21°, and Venus 47°, from the sun. (3.) That the planets, especially Mars, will be sometimes much nearer to the earth than at others, and therefore must appear larger at one time than at another. (4.) You will see that the planets cannot appear at the earth to move with an uniform velocity; for when nearest they appear to move faster, and slower when most remote. (5.) You will observe the planets will appear at the earth to move sometimes directly from west to east, and then to become retrograde from east to west, and between both to be stationary or without any apparent motion at all. Which particulars all correspond exactly with observations, and fully prove the truth of this excellent system. Fig. 165. represents an apparatus to show these latter particulars more evidently. An hollow wire, with a slit at top, is placed over the arm of the planet Mercury or Venus at E. The arm DG represents a ray of light coming from the planet at D to the earth, and is put over the centre which carries the earth at F. The planets being then put in motion, the planet D, as seen in the heavens from the earth at F, will undergo the several changes of position as above described. The wire prop that is over Mercury at E, may be placed over the other superior planets, Mars, &c. and the same phenomena be exhibited.

By this machine you at *once* see all the planets in motion about the sun, with the same respective velocities and periods of revolution which they have in the heavens; the wheel-work being calculated to a minute of time, from the latest discoveries.

You will see here a demonstration of the earth's motion about the sun, as well as those of the rest of the planets: for if the earth were to be at rest in the heavens, then the time between any two conjunctions of the same kind, or oppositions, would be the same with the periodical time of the planets, viz. 88 days in Mercury, 225 in Venus, &c.; whereas you here observe this time, instead of being 225 days, is no less than 583 days in Venus, occasioned by the earth's moving in the mean time about the sun the same way with the planet. And this space of 583 days always passes between two like conjunctions of Venus in the heavens.

Description of Astronomical Instruments.

heavens. Hence the most important point of astronomy is satisfactorily demonstrated.

The diurnal rotation of the earth about its axis, and a demonstration of the cause of the different seasons of the year, and the different lengths of days and nights, are here answered completely: for as the earth is placed on an axis inclining to that of the ecliptic in an angle of $23\frac{1}{2}$ degrees, and is set in motion by the wheel-work, there will be evidently seen the different inclination of the sun's rays on the earth, the different quantity thereof which falls on a given space, the different quantity of the atmosphere they pass through, and the different continuance of the sun above the horizon at the same place in different times of the year; which particulars constitute the difference betwixt heat and cold in the summer and winter seasons.

As the globe of the earth is moveable about its inclined axis, so by having the horizon of London drawn upon the surface of it, and by means of the terminating wire going over it, by which is denoted, that on that side of the wire next the sun is the enlightened half of the earth, and the opposite side the darkened half, you will here see very naturally represented the cause of the different lengths of day and night, by observing the unequal portions of the circle which the island of Great Britain, or the city of London, or any other place, describes in the light and dark hemispheres at different times of the year, by turning the earth on its axis with the hand. But in some of the better orreries on this principle, the earth revolves about its axis by wheel-work.

As to the eclipses of the sun and moon, the true causes of them are here very clearly seen; for by placing the lamp (fig. 166.) upon the centre, in room of the brass ball denoting the sun, and turning the winch until the moon comes into a right line between the centres of the lamp (or sun) and earth, the shadow of the moon will fall upon the earth, and all who live on that part over which the shadow passes, will see the sun eclipsed more or less. On the other side, the moon passes (in the aforesaid case) through the shadow of the earth, and is by that means eclipsed. And the orbit A (fig. 164.) is so moveable on the two joints called nodes that any person may easily represent the due position of the nodes and intermediate spaces of the moon's orbit; and thence show when there will or will not be an eclipse of either luminary, and what the quantity of each will be.

While the moon is continuing to move round the earth, the lamp on the centre will so illumine the moon, that you will easily see all her phases, as new, dichotomized, gibbous, full, waning, &c. just as they appear in the heavens. You will moreover observe all the same phases of the earth as they appear at the moon.

The satellites of Jupiter and Saturn are moveable only by the hand; yet may all their phenomena be easily represented, excepting the true relative motions and distances. Thus, if that gilt globe which before represented the sun be made now to denote Jupiter, and four of the primary planets only be retained, then will the Jovian system be represented; and, by candle light only, you will see (the machine being in motion) the immersions and emersions of the satellites into and out of Jupiter's shadow. You will see plainly the manner in which they transit his body, and their occultations behind it. You will observe the various ways in which one or more of these moons may at times disappear. And if the machine be set by a white wall, &c. then by the projection of their shadows will be seen the reasons why those moons always appear on each side of Jupiter in a right line, why those which are most remote may appear nearest, and *è contrario*. And the same may be done for Saturn's five moons and his ring.

The Method of Rectifying the Orrery, and the proper Manner of placing the Planets in their true Situations.

Having dwelt thus much on the description of orreries, it may be useful to young readers, to point out the method by which the orrery should be first rectified, previous to the exhibition or using of it: and the following is extracted from Mr William Jones's description of his new *Portable Orrery*. "The method of showing the places, and relative aspects of the planets on any day of the year in the planetarium, must be done by the assistance of an *ephemeris* or *almanack*, which among other almanacks is published annually by the Stationers Company.

"The ephemeris contains a diary or daily account of the planets places in the heavens, in signs, degrees, and minutes, both as they appear to the eye supposed to be at the sun, and at the earth, throughout the year. The first of these positions is called the *heliocentric place*, and the latter, the *geocentric place*. The heliocentric place is that made use of in orreries; the geocentric place, that in globes. As an example for finding their places, and setting them right in the orrery, we will suppose the ephemeris (by *White*, which for this purpose is considered the best) at hand, wherein at the bottom of the *left-hand* page for every month is the heliocentric longitudes (or places) of all the planets to every six days of the month; which is near enough for common use: A copy of one of these tables for March 1784 is here inserted for the information of the tyro.

Days.	Day increas.	Helioc. long. ♄	Helioc. long. ♃	Helioc. long. ♂	Helioc. long. ⊖	Helioc. long. ♀	Helioc. long. ☿
1	3 11	16 ♑ 56	17 ♒ 11	1 ♋ 30	11 ♍ 37	0 ♐ 35	7 ♍ 58
7	3 35	16 56	17 43	4 23	17 37	10 7	25 23
31	3 59	17 7	18 15	7 15	23 36	19 38	11 ♐ 9
91	4 23	17 17	18 47	10 6	29 33	29 8	28 33
52	4 47	17 28	19 19	12 55	5 ♎ 30	8 ♑ 38	15 ♑ 49

"Now

"Now as an example, we will suppose, that in order to set the planets of the orrery, we want their heliocentric places for the 21st of this month. Looking into the table, we take the 19th day, which is the nearest to the day wanted: then, accordingly, we find the place of Saturn (♄), is in 17° 17′, or 17 degrees (rejecting the minutes, being in this case useless) of Capricornus (♑); of Jupiter (♃) in 18° of Aquarius (♒); Mars (♀) in 10° of Cancer (♋); the earth (⊖) in 29° of Virgo (♍); Venus (♂) in 29° of Sagittarius, (♐); Mercury (☿) in 28 degrees of the same sign; and in the same manner for any other day therein specified. Upon even this circumstance depends a very pleasing astronomical praxis, by which the young tyro may at any time be able to entertain himself in a most rational and agreeable manner, viz. he may in a minute or two represent the true appearance of the planetary system just as it really is in the heavens, and for any day he pleases, by assigning to each planet its proper place in its orbit; as in the following manner: For the 19th of March, as before, the place of Saturn is in 17° of Capricornus (♑); now laying hold of the arm of Saturn in the orrery, you place it over or against the 17° of Capricorn on the ecliptic circle, constantly placed on or surrounding the instrument; thus doing the same for the other planets, they will have the proper heliocentric places for that day.

"Now, in this situation of the planets, we observe, that if a person was placed on the earth, he would see Venus and Jupiter in the same line and place of the ecliptic, consequently in the heavens they would appear together or in conjunction; Mercury a little to the left or eastward of them, and nearer to the sun; Saturn to the right, or westward, farther from the sun; Mars directly opposite to Saturn; so that when Saturn appears in the west, Mars appears in the east, and *vice versa*. Several other curious and entertaining particulars, as depending on the above, may be easily represented and shown by the learner; particularly the foregoing when the winch is turned, and all the planets set into their respective motions."

We cannot close this detail on orreries more agreeably than by the following account of an instrument of that sort invented by Mr James Ferguson, to which he gives the name of a *Mechanical Paradox*, and which is actuated by means of what many, as he observes, even good mechanics, would be ready to pronounce impossible, viz. That the teeth of one wheel, taking equally deep into the teeth of three others, should affect them in such a manner, that in turning it any way round its axis, it should turn one of them the *same way*, another the *contrary way*, and the third *no way at all*.

The solution of the paradox is given under the article MECHANICS; after which our author proceeds to give the following account of its uses. "This machine is so much of an orrery, as is sufficient to show the different lengths of days and nights, the vicissitudes of the seasons, the retrograde motion of the nodes of the moon's orbit, the direct motion of the apogeal point of her orbit, and the months in which the sun and moon must be eclipsed.

"On the great immoveable plate A (see fig. 167.) are the months and days of the year, and the signs and degrees of the zodiac so placed, that when the annual index *h* is brought to any given day of the year, it will point to the degree of the sign in which the sun is on that day. The index is fixed to the moveable frame BC, and is carried round the immoveable plate, with it, by means of the knob *n*. The carrying this frame and index round the immoveable plate, answers to the earth's annual motion round the sun, and to the sun's apparent motion round the ecliptic in a year.

"The central wheel D (being fixed on the axis *a*, which is fixed in the centre of the immoveable plate) turns the thick wheel E round its own axis by the motion of the frame; and the teeth of the wheel E take into the teeth of the three wheels F, G, H, whose axes turn with one another, like the axes of the hour, minute, and second hands of a clock or watch, where the seconds are shown from the centre of the dial-plate.

"On the upper ends of these axes, are the round plates I, K, L; the plate I being on the axis of the wheel F, K on the axis of G, and L on the axis of H. So that whichever way these wheels are affected, their respective plates, and what they support, must be affected in the same manner; each wheel and plate being independent of the others.

"The two upright wires M and N are fixed into the plate I; and they support the small ecliptic OP, on which, in the machine, the signs and degrees of the ecliptic are marked. This plate also supports the small terrestrial globe *e*, on its inclining axis *f*, which is fixed into the plate near the foot of the wire N. This axis inclines $23\frac{1}{2}$ degrees from a right line, supposed to be perpendicular to the surface of the plate I, and also to the plane of the small ecliptic OP, which is parallel to that plate.

"On the earth *e* is the crescent *g*, which goes more than half way round the earth, and stands perpendicular to the plane of the small ecliptic OP, directly facing the sun Z: Its use is to divide the enlightened half of the earth next the sun from the other half which is then in the dark; so that it represents the boundary of light and darkness, and therefore ought to go quite round the earth; but cannot in a machine, because in some positions the earth's axis would fall upon it. The earth may be freely turned round on its axis by hand, within the crescent, which is supported by the crooked wire *w*, fixed to it, and into the upper plate of the moveable frame BC.

"In the plate K are fixed the two upright wires Q and R: they support the moon's inclined orbits ST in its nodes, which are the two opposite points of the moon's orbit where it intersects the ecliptic OP. The ascending node is marked ☊, to which the descending node is opposite below *e*, but hid from view by the globe *e*. The half ☊ T *e* of this orbit is on the north side of the ecliptic OP, and the other half *e* S ☊ is on the south side of the ecliptic. The moon is not in this machine; but when she is in either of the nodes of her orbit in the heavens, she is then in the plane of the ecliptic: when she is at T in her orbit, she is in her greatest north latitude; and when she is at S, she is in her greatest south latitude.

"In the plate L is fixed the crooked wire U U, which points downward to the small ecliptic OP, and shows the motion of the moon's apogee therein, and its place at any given time.

"The

Description of Astronomical Instruments.

"The ball Z represents the sun, which is supported by the crooked wire XY, fixed into the upper plate of the frame at X. A straight wire W proceeds from the sun Z, and points always towards the centre of the earth *e*; but toward different points of its surface at different times of the year, on account of the obliquity of its axis, which keeps its parallelism during the earth's annual course round the sun Z; and therefore must incline sometimes toward the sun, at other times from him, and twice in the year neither toward nor from the sun, but sidewise to him. The wire W is called *the solar ray*.

"As the annual-index *h* shows the sun's place in the ecliptic for every day of the year, by turning the frame round the axis of the immoveable plate A, according to the order of the months and signs, the solar ray does the same in the small ecliptic OP: for as this ecliptic has no motion on its axis, its signs and degrees still keep parallel to those on the immoveable plate. At the same time, the nodes of the moon's orbit ST (or points where it intersects the ecliptic OP) are moved backward, or contrary to the order of signs, at the rate of 19⅓ degrees every Julian year; and the moon's apogeal wire UU is moved forward, or according to the order of the signs of the ecliptic, nearly at the rate of 41 degrees every Julian year; the year being denoted by a revolution of the earth *e* round the sun Z; in which time the annual index *h* goes round the circles of months and signs on the immoveable plate A.

"Take hold of the knob *n*, and turn the frame round thereby; and in doing this, you will perceive that the north pole of the earth *e* is constantly before the crescent *g*, in the enlightened part of the earth toward the sun, from the 20th of March to the 23d of September; and the south pole all that time behind the crescent in the dark; and from the 23d of September to the 20th of March, the north pole as constantly in the dark behind the crescent, and the south pole in the light before it; which shows, that there is but one day and one night at each pole, in the whole year; and that when it is day at either pole, it is night at the other.

"From the 20th of March to the 23d of September, the days are longer than the nights in all those places of the northern hemisphere of the earth which revolve through the light and dark, and shorter in those of the southern hemisphere. From the 23d of September to the 20th of March, the reverse.

"There are 24 meridian semicircles drawn on the globe, all meeting in its poles: and as one rotation or turn of the earth on its axis is performed in 24 hours, each of these meridians is an hour distant from the other, in every parallel of latitude. Therefore, if you bring the annual index *h* to any given day of the year, on the immoveable plate, you may see how long the day then is at any place of the earth, by counting how many of these meridians are in the light, or before the crescent, in the parallel of latitude of that place; and this number being subtracted from 24 hours, will leave remaining the length of the night. And if you turn the earth round its axis, all those places will pass directly under the point of the solar ray, which the sun passes vertically over on that day, because they are just as many degrees north or south of the equator as the sun's declination is then from the equinoctial.

"At the two equinoxes, viz. on the 20th of March and 23d of September, the sun is in the equinoctial, and consequently has no declination. On these days, the solar ray points directly toward the equator, the earth's poles lie under the inner edge of the crescent, or boundary of light and darkness; and in every parallel of latitude there are 12 of the meridians or hour-circles before the crescent, and 12 behind it, which shows that the days and nights then are each 12 hours long at all places of the earth. And if the earth be turned round its axis, you will see that all places on it go equally through the light and the dark hemispheres.

"On the 21st of June, the whole space within the north polar circle is enlightened, which is 23½ degrees from the pole, all around; because the earth's axis then inclines 23½ degrees toward the sun: but the whole space within the south polar circle is in the dark; and the solar ray points toward the tropic of Cancer on the earth, which is 23½ degrees north from the equator. On the 20th of December the reverse happens, and the solar ray points toward the tropic of Capricorn, which is 24½ degrees south from the equator.

"If you bring the annual-index *h* to the beginning of January, and turn the moon's orbit ST by its supporting wires Q and R till the ascending node (marked ☊) comes to its place in the ecliptic OP, as found by an ephemeris, or by astronomical tables, for the beginning of any given year; and then move the annual index by means of the knob *n*, till the index comes to any given day of the year afterward, the nodes will stand against their places in the ecliptic on that day; and if you move on the index till either of the nodes comes directly against the point of the solar ray, the index will then be at the day of the year on which the sun is in conjunction with that node. At the times of those new moons, which happen within seventeen days of the conjunction of the sun with either of the nodes, the sun will be eclipsed; and at the times of those full moons, which happen within twelve days of either of these conjunctions, the moon will be eclipsed. Without these limits there can be no eclipses either of the sun or moon; because, in nature, the moon's latitude or declination from the ecliptic is too great for the moon's shadow to fall on any part of the earth, or for the earth's shadow to touch the moon.

"Bring the annual-index to the beginning of January, and set the moon's apogeal wire UU to its place in the ecliptic for that time, as found by astronomical tables; then move the index forward to any given day of the year, and the wire will point on the small ecliptic to the place of the moon's apogee for that time.

"The earth's axis *f* inclines always toward the beginning of the sign Cancer on the small ecliptic OP. And if you set either of the moon's nodes, and her apogeal wire to the beginning of that sign, and turn the plate A about, until the earth's axis inclines toward any side of the room (suppose the north side), and then move the annual-index round and round the immoveable plate A, according to the order of the months

Description of Astronomical Instruments.

months and signs upon it, you will see that the earth's axis and beginning of Cancer will still keep towards the same side of the room, without the least deviation from it; but the nodes of the moon's orbit ST will turn progressively towards all the sides of the room, contrary to the order of signs in the small ecliptic OP, or from east, by south, to west, and so on; and the apogeal wire UU will turn the contrary way to the motion of the nodes, or according to the order of the signs in the small ecliptic, from west, by south, to east, and so on quite round. A clear proof that the wheel F, which governs the earth's axis and the small ecliptic, does not turn any way round its own centre; that the wheel G, which governs the moon's orbit OP, turns round its own centre backward, or contrary both to the motion of the frame BC and thick wheel E; and that the wheel H, which governs the moon's apogeal wire UU, turns round its own centre forward, or in direction both of the motion of the frame and of the thick wheel E, by which the three wheels F, G, and H, are affected.

"The wheels D, E, and F, have each 39 teeth in the machine; the wheel G has 37, and H 44.

"The parallelism of the earth's axis is perfect in this machine; the motion of the apogee very nearly so; the motion of the nodes not quite so near the truth, though they will not vary sensibly therefrom in one year. But they cannot be brought nearer, unless larger wheels, with higher numbers of teeth, are used.

"In nature, the moon's apogee goes quite round the ecliptic in 8 years and 312 days, in the direction of the earth's annual motion; and the nodes go round the ecliptic, in a contrary direction, in 18 years and 225 days. In the machine, the apogee goes round the ecliptic OP in eight years and four-fifths of a year, and the nodes in 18 years and a half."

423 Cometarium.

The COMETARIUM, (fig. 168.). This curious machine shows the motion of a comet or eccentric body moving round the sun, describing equal areas in equal times, and may be so contrived as to show such a motion for any degrees of eccentricity. It was invented by the late Dr Desaguliers.

The dark elliptical groove round the letters *a b c d e f g h i k l m* is the orbit of the comet Y; this comet is carried round in the groove according to the order of letters, by the wire W fixed in the sun S, and slides on the wire as it approaches nearer to or recedes farther from the sun, being nearest of all in the perihelion *a*, and farthest in the aphelion *g*. The areas, *a* S *b*, *b* S *c*, *c* S *d*, &c. or contents of these several triangles, are all equal; and in every turn of the winch N, the comet Y is carried over one of these areas; consequently, in as much time as it moves from *f* to *g*, or from *g* to *h*, it moves from *m* to *a*, or from *a* to *b*; and so of the rest, being quickest of all at *a*, and slowest at *g*. Thus the comet's velocity in its orbit continually decreases from the perihelion *a* to the aphelion *g*; and increases in the same proportion from *g* to *a*.

The ecliptic orbit is divided into 12 equal parts or signs, with their respective degrees, and so is the circle *n o p q r s t u*, which represents a great circle in the heavens, and to which the comet's motion is referred by a small knob on the point of the wire W. Whilst the comet moves from *f* to *g* in its orbit, it appears to move only about five degrees in this circle, as is shown by the small knob on the end of the wire W; but in as short time as the comet moves from *m* to *a*, or from *a* to *b*, it appears to describe the large space *t n* or *n o* in the heavens, either of which spaces contains 120 degrees, or four signs. Were the eccentricity of its orbit greater, the greater still would be the difference of its motion, and *vice versa*.

ABCDEFGHIKLM is a circular orbit for showing the equable motion of a body round the sun S, describing equal areas ASB, BSC, &c. in equal times with those of the body Y in its elliptical orbit above mentioned; but with this difference, that the circular motion describes the equal arcs AB, BC, &c. in the same equal times that the elliptical motion describes the unequal arcs *a b*, *b c*, &c.

Now suppose the two bodies Y and 1 to start from the points *a* and A at the same moment of time, and, each having gone round its respective orbit, to arrive at these points again at the same instant, the body Y will be forwarder in its orbit than the body 1 all the way from *a* to *g*, and from A to G: but 1 will be forwarder than Y through all the other half of the orbit; and the difference is equal to the equation of the body Y in its orbit. At the points *a* A, and *g* G, that is, in the perihelion and aphelion, they will be equal; and then the equation vanishes. This shows why the equation of a body moving in an elliptic orbit is added to the mean or supposed circular motion from the perihelion to the aphelion, and subtracted from the aphelion to the perihelion, in bodies moving round the sun, or from the perigee to the apogee, and from the apogee to the perigee in the moon's motion round the earth.

This motion is performed in the following manner by the machine, fig. 169. ABC is a wooden bar (in the box containing the wheel-work), above which are the wheels D and E, and below it the elliptic plates FF and GG; each plate being fixed on an axis in one of its focuses, at E and K; and the wheel E is fixed on the same axis with the plate FF. These plates have grooves round their edges precisely of equal diameters to one another, and in these grooves is the cat-gut string *gg*, *gg* crossing between the plates at *h*. On H, the axis of the handle or winch N in fig. 216, is an endless screw in fig. 217. working in the wheels D and E, whose numbers of teeth being equal, and should be equal to the number of lines, *a* S, *b* S, *c* S, &c. in fig. 168. they turn round their axis in equal times to one another, and to the motion of the elliptic plates. For, the wheels D and E having equal numbers of teeth, the plate FF being fixed on the same axis with the wheel E, and turning the equally big plate GG by a cat-gut string round them both, they must all go round their axis in as many turns of the handle N as either of the wheels has teeth.

It is easy to see, that the end *h* of the elliptical plate FF being farther from its axis E than the opposite end I is, must describe a circle so much the larger in proportion, and therefore move through so much more space in the same time; and for that reason the end *h* moves so much faster than the end I, although it goes no sooner round the centre E. But then the quick-moving end *h* of the plate FF leads about the short end *h* K of the plate GG with the same velocity; and

Digitized by Google

Description of Astronomical Instruments.

and the slow-moving end I of the plate FF coming half round as to B, must then lead the long end k of the plate GG as slowly about: so that the elliptical plate FF and its axis E move uniformly and equally quick in every part of its revolution: but the elliptical plate GG, together with its axis K, must move very unequally in different parts of its revolution; the difference being always inversely as the distance of any point of the circumference of GG from its axis at K: or in other words, to instance in two points, if the distance K k be four, five, or six times as great as the distance K h, the point h will move in that position, four, five, or six times as fast as the point k does, when the plate GG has gone half round; and so on for any other eccentricity or difference of the distances K k and K h. The tooth I on the plate FF falls in between the two teeth at k on the plate GG; by which means the revolution of the latter is so adjusted to that of the former, that they can never vary from one another.

On the top of the axis of the equally-moving wheel D in fig. 169. is the sun S in fig. 168.: which sun, by the wire fixed to it, carries the ball I round the circle ABCD, &c. with an equable motion, according to the order of the letters: and on the top of the axis K of the unequally-moving ellipses GG, in fig. 169. is the sun S in fig. 168. carrying the ball Y unequally round in the elliptical groove *a b c d*, &c. N. B. This elliptical groove must be precisely equal and similar to the verge of the plate GG, which is also equal to that of FF.

In this manner machines may be made to show the true motion of the moon about the earth, or of any planet above the sun, by making the elliptical plates of the same eccentricities, in proportion to the radius, as the orbits of the planets are, whose motions they represent; and so their different equations in different parts of their orbits may be made plain to sight, and clearer ideas of these motions and equations acquired in half an hour, than could be gained from reading half a day about such motions and equations.

429 Celestial globe.

The IMPROVED CELESTIAL GLOBE, fig. 170. On the north pole of the axis, above the hour-circle, is fixed an arch MKH of $23\frac{1}{2}$ degrees; and at the end H is fixed an upright pin HG, which stands directly over the north pole of the ecliptic, and perpendicular to that part of the surface of the globe. On this pin are two moveable collets at E and H, to which are fixed the quadrantile wires N and O, having two little balls on their ends for the sun and moon, as in the figure. The collet D is fixed to the circular plate F, whereon the $29\frac{1}{2}$ days of the moon's age are engraven, beginning just under the sun's wire N; and as this wire is moved round the globe, the plate F turns round with it. These wires are easily turned, if the screw G be slackened; and when they are set to their proper places, the screw serves to fix them there, so as in turning the ball of the globe, the wires with the sun and moon go round with it; and these two little balls rise and set at the same times, and on the same points of the horizon, for the day to which they are rectified, as the sun and moon do in the heavens.

Because the moon keeps not her course in the ecliptic (as the sun appears to do) but has a declination of $5\frac{1}{3}$ degrees on each side from it in every lunation, her ball may be screwed as many degrees to either side of the ecliptic as her latitude or declination from the ecliptic amounts to at any given time.

The horizon is supported by two semicircular arches, because pillars would stop the progress of the balls when they go below the horizon in an oblique sphere.

To rectify this globe. Elevate the pole to the latitude of the place; then bring the sun's place in the ecliptic for the given day to the brazen meridian, and set the hour index at 12 at noon, that is, to the upper 12 on the hour circle; keeping the globe in that situation, slacken the screw G, and set the sun directly over his place on the meridian; which done, set the moon's wire under the number that expresses her age for that day on the plate F, and she will then stand over her place in the ecliptic, and show what constellation she is in. Lastly, fasten the screw G, and adjust the moon to her latitude, and the globe will be rectified.

Having thus rectified the globe, turn it round, and observe on what point of the horizon the sun and moon balls rise and set, for these agree with the points of the compass on which the sun and moon rise and set in the heavens on the given day; and the hour index shows the time of their rising and setting: and likewise the time of the moon's passing over the meridian.

This simple apparatus shows all the varieties that can happen in the rising and setting of the sun and moon; and makes the forementioned phenomena of the harvest moon plain to the eye. It is also very useful in reading lectures on the globes, because a large company can see this sun and moon go round, rising above and setting below the horizon at different times, according to the seasons of the year: and making their appulses to different fixed stars. But in the usual way, where there is only the places of the sun and moon in the ecliptic to keep the eye upon, they are easily lost sight of, unless they be covered with patches. 430

Trajectorium lunare.

The TRAJECTORIUM LUNARE, fig. 171. This machine is for delineating the paths of the earth and moon, showing what sort of curves they make in the ethereal regions. S is the sun, and E the earth, whose centres are 95 inches distant from each other; every inch answering to 1000,000 of miles. M is the moon, whose centre is $\frac{24}{100}$ parts of an inch from the earth's in this machine, this being in just proportion to the moon's distance from the earth. AA is a bar of wood, to be moved by hand round the axis g which is fixed in the wheel Y. The circumference of this wheel is to the circumference of the small wheel L (below the other end of the bar) as $365\frac{1}{4}$ days is to $29\frac{1}{2}$, or as a year is to a lunation. The wheels are grooved round their edges, and in the grooves is the cat-gut string GG crossing between the wheels at X. On the axis of the wheel L is the index F, in which is fixed the moon's axis M for carrying her round the earth E (fixed on the axis of the wheel L) in the time that the index goes round a circle of $29\frac{1}{2}$ equal parts, which are the days of the moon's age. The wheel Y has the months and days of the year all round its limb; and in the bar AA is fixed the index l, which points out the days of the months answering the days of the moon's age, shown by the index F, in the circle of $29\frac{1}{2}$ equal parts at the other end of the bar. On the

Description of Astronomical Instruments.

the axis of the wheel L is put the piece D, below the cock C, in which this axis turns round; and in D are put the pencils *e* and *m* directly under the earth E and moon M; so that *m* is carried round *e* as M is round E.

Lay the machine on an even floor, pressing gently on the wheel Y, to cause its spiked feet (of which two appear at P and P, the third being supposed to be hid from sight by the wheel) enter a little into the floor to secure the wheel from turning. Then lay a paper about four feet long under the pencils *e* and *m*, crosswise to the bar; which done, move the bar slowly round the axis *g* of the wheel Y; and as the earth D goes round the sun S, the moon M will go round the earth with a duly proportioned velocity; and the friction wheel W running on the floor, will keep the bar from bearing too heavily on the pencils *e* and *m*, which will delineate the paths of the earth and moon. As the index I points out the days of the months, the index F shows the moon's age on these days, in the circle of $29\frac{1}{2}$ equal parts. And as this last index points to the different days in its circle, the like numerical figures may be set to those parts of the curves of the earth's path and moon's where the pencils *e* and *m* are at those times respectively, to show the places of the earth and moon. If the pencil *e* be pushed a very little off, as if from the pencil *m*, to about $\frac{1}{40}$ part of their distance, and the pencil *m* pushed as much towards *e*, to bring them to the same distances again, though not to the same points of space; then, as *m* goes round *e*, *e* will go as it were round the centre of gravity between the earth *e* and moon *m*; but this motion will not sensibly alter the figure of the earth's path or the moon's.

If a pin, as *p*, be put through the pencil *m*, with its head towards that of the pin *q* in the pencil *e*, its head will always keep thereto as *m* goes round *e*, or as the same side of the moon is still obverted to the earth. But the pin *p*, which may be considered as an equatorial diameter of the moon, will turn quite round the point *m*, making all possible angles with the line of its progress, or line of the moon's path. This is an ocular proof of the moon's turning round her axis.

III. *A Description of the principal Astronomical Instruments by which Astronomers make the most accurate Observations.*

By practical astronomy is implied the knowledge of observing the celestial bodies with respect to their position and time of the year, and of deducing from those observations certain conclusions useful in calculating the time when any proposed position of these bodies shall happen.

For this purpose, it is necessary to have a room or place conveniently situated, suitably contrived, and furnished with proper astronomical instruments. It should have an uninterrupted view from the zenith down to (or even below) the horizon, at least towards its cardinal points; and for this purpose, that part of the roof which lies in the direction of the meridian, in particular, should have moveable covers, which may easily be moved and put on again; by which means an instrument may be directed to any point of the heavens between the horizon and the zenith, as well to the northward as southward.

This place, called an Observatory, should contain some, if not all, of the following instruments:

I. A Pendulum Clock, for showing equal time. This should show time in hours, minutes and seconds; and with which the observer, by hearing the beats of the pendulum, may count them by his ear, while his eye is employed on the motion of the celestial object he is observing. Just before the object arrives at the position described, the observer should look on the clock and remark the time, suppose it 9 hours 15 minutes 25 seconds: then saying, 25, 26, 27, 28, &c. responsive to the beat of the pendulum, till he sees through the instrument the object arrived at the position expected; which suppose to happen when he says 38, he then writes down 9 h. 15 min. 38 sec. for the time of observation, annexing the year and the day of the month. If two persons are concerned in making the observation, one may read the time audibly while the other observes through the instrument, the observer repeating the last second read when the desired position happens.

II. An Achromatic Refracting Telescope, or a reflecting one, of two feet at least in length, for observing particular phenomena. These instruments are particularly described under Optics.

III. A Micrometer, for measuring small angular distances. See Micrometer.

IV. Astronomical Quadrants, both mural and portable, for observing meridian and other altitudes of the celestial bodies. 431 Quadrants.

1. The *mural quadrant* is in the form of a quarter of a circle, contained under two radii at right angles to one another, and an arch equal to one fourth part of the circumference of the circle. It is the most useful and valuable of all the astronomical instruments; and as it is sometimes fixed to the side of a stone or brick wall, and the plane of it erected exactly in the plane of the meridian, it in this case receives the name of *mural quadrant* or *arch*.

Tycho Brahe was the first person who contrived this mural arch, viz. who first applied it to a wall; and Mr Flamstead, the first in England who, with indefatigable pains, fixed one up in the royal observatory at Greenwich.

These instruments have usually been made from five to eight feet radius, and executed by those late celebrated artists Sisson, Graham, Bird, and other eminent mathematical instrument makers in London. The construction of them being generally the same in all the sizes, we shall here describe one made by the late Joh. Sisson, under the direction of the late Mr Graham. Fig. 172. represents the instrument as already fixed to the wall. It is of copper, and of about five feet radius. The frame is formed of flat bars, and strengthened by edge bars affixed underneath perpendicularly to them. The radii HB, HA, being divided each into four equal parts, serve to find out the points D and E, by which the quadrant is freely suspended on its props or iron supports that are fastened securely in the wall.

One of the supports E is represented separately in *e* on one side of the quadrant. It is moveable by means of a long slender rod EF or *e f*, which goes into a hol-

Digitized by Google

Description of Astronomical Instruments.

low screw in order to restore the instrument to its situation when it is discovered to be a little deranged. This may be known by the very fine perpendicular thread HA, which ought always to coincide with the same point A of the limb, and carefully examined to be so by a small magnifying telescope at every observation. In order to prevent the unsteadiness of so great a machine, there should be placed behind the limb four copper ears with double cocks, I, K, I, K. There are others along the radii HA and HB. Each of these cocks contains two screws, into which are fastened the ears that are fixed behind the quadrant.

Over the wall or stone which supports the instrument, and at the same height as the centre, is placed horizontally the axis PO, which is perpendicular to the plane of the instrument, and which would pass through the centre if it was continued. The axis turns on two pivots P. On this axis is fixed at right angles another branch ON, loaded at its extremity with a weight N capable of equipoising with its weight that of the telescope LM; whilst the axis, by its extremity nearest the quadrant, carries the wooden frame PRM, which is fastened to the telescope in M. The counterpoise takes off from the observer the weight of the telescope when he raises it, and hinders him from either forcing or straining the instrument.

The lower extremity (V) of the telescope is furnished with two small wheels, which takes the limb of the quadrant on its two sides. The telescope hardly bears any more upon the limb than the small friction of these two wheels; which renders its motion so extremely easy and pleasant, that by giving it with the hand only a small motion, the telescope will run of itself over a great part of the limb, balanced by the counterpoise N.

When the telescope is to be stopped at a certain position, the copper hand T is to be made use of, which embraces the limb and springs at the bottom. It is fixed by setting a screw, which fastens it to the limb. Then, in turning the regulating screw, the telescope will be advanced; which is continued until the star or other object whose altitude is observing be on the horizontal fine thread in the telescope. Then on the plate X supporting the telescope, and carrying a vernier or nonius, will be seen the number of degrees and minutes, and even quarters of minutes, that the angular height of the object observed is equal to. The remainder is easily estimated within two or three seconds nearly.

There are several methods of subdividing the divisions of a mural quadrant, which are usually from five to ten minutes each; but that which is most commonly adopted is by the vernier or nonius, the contrivance of Peter Vernier a Frenchman. This vernier consists of a piece of copper or brass CDAB (fig. 173.), which is a small portion of X (fig. 172.) represented separately. The length CD is divided into 20 equal parts, and placed contiguously on a portion of the division of the limb of the quadrant containing 21 divisions, and thereby dividing this length into 20 equal parts. Thus the first division of the vernier piece marked 15, beginning at the point D, is a little matter backward, or to the left of the first division of the limb equal to 15. The second division of the vernier is to the left of the second division of the limb double of the first difference, or 30″; and so on unto the 20th and last division on the left of the vernier piece; where the 20 differences being accumulated each of the 20th part of the division of the limb, this last division will be found to agree exactly with the 21st division on the limb of the quadrant.

The index must be pushed the 20th part of a division, or 15″, to the right; for to make the second division on the vernier coincide with one of the divisions of the limb, in like manner is moving two 20ths, or 30″, we must look at the second division of the index, and there will be a coincidence with a division of the limb. Thus may be conceived that the beginning D of the vernier, which is always the line of reckoning, has advanced two divisions, or 30″, to the right, when the second division, marked 30 on the vernier, is seen to correspond exactly with one of the lines of the quadrant.

By means of this vernier may be readily distinguished the exactitude of 15″ of the limb of a quadrant five feet radius, and simply divided into 5′. By an estimation by the eye, afterwards, the accuracy of two or three seconds may be easily judged. On the side of the quadrant is placed the plate of copper which carries the telescope. This plate carries two verniers. The outer line CD divides five minutes into 20 parts, or 15″ each. The interior line AB answers to the parts of another division not having 90°, but 96 parts, of the quadrant. It is usually adopted by English astronomers on account of the facility of its subdivisions. Each of the 96 portions of the quadrant is equivalent to 56′ 15″ of the usual divisions. It is divided on the limb into 16 parts, and the arch of the vernier AB contains 25 of these divisions; and being divided itself into 24, immediately gives parts, the value of each of which is 8″ 47½‴. From this mode a table of reduction may easily be constructed, which will serve to find the value of this second mode of dividing in degrees, minutes, and seconds, reckoning in the usual manner, and to have even the advantage of two different modes; which makes an excellent verification of the divisions on the limb of the quadrant and observed heights by the vernier.

2. The *Portable Astronomical Quadrant*, is that instrument of all others which astronomers make the greatest use of, and have the most esteem for. They are generally made from 12 to 23 inches. Fig. 174. is a representation of the improved modern one, as made by the late Mr Sisson and by the present mathematical instrument makers. This is capable of being carried to any part of the world, and put up for observation in an easy and accurate manner. It is made of brass, and strongly framed together by crossed perpendicular bars. The arch AC, and telescope EF, are divided and constructed in a similar manner to the mural quadrant, but generally without the division of 96 parts. The counterpoise to the telescope T is represented at P, and also another counterpoise to the quadrant itself at P. The quadrant is fixed to a long axis, which goes into the pillar KR. Upon this axis is fixed an index, which points to and subdivides by a vernier the divisions of the azimuth circle K. This azimuth circle is extremely useful for taking the azimuth of a celestial body at the same time its altitude is observed. The

Description of Astronomical Instruments.

The upper end of the axis is firmly connected with the adjusting frame GH; and the pillar is supported on the crossed feet at the bottom of the pillar KR with the adjusting screws *a*, *b*, *c*, *d*.

When this instrument is set up for use or observation, it is necessary that two adjustments be very accurately made: One, that the plane or surface of the instrument be truly perpendicular to the horizon; the other, that the line supposed to be drawn from the centre to the first line of the limb, be truly on a level or parallel with the horizon. The first of these particulars is done by means of the thread and plummet *p*; the thread of which is usually of very fine silver wire, and it is placed opposite to a mark made upon the end of the limb of the instrument. The four screws at the foot, *a*, *b*, *c*, *d*, are to be turned until a perfect coincidence is observed of the thread upon the mark, which is accurately observed by means of a small telescope T, that fits to the limb. The other adjustment is effected by means of the spirit level L, which applies on the frame GH, and the small screws turned as before until the bubble of air in the level settles in the middle of the tube. The dotted tube EB is a kind of prover to the instrument: for by observing at what mark the centre of it appears against, or by putting up a mark against it, it will at any time discover if the instrument has been displaced. The screw S at the index, is the regulating or adjusting screw, to move the telescope and index, during the observation, with the utmost nicety.

432 Equatorial sector.

V. Astronomical *or* Equatorial Sector. This is an instrument for finding the difference in right ascension and declination between two objects, the distance of which is too great to be observed by the micrometer. It was the invention of the late ingenious Mr George Graham, F. R. S. and is constructed from the following particulars. Let AB (fig. 175.) represent an arch of a circle containing 10 or 12 degrees well divided, having a strong plate CD for its radius, fixed to the middle of the arch at D: let this radius be applied to the side of an axis HFI, and be moveable about a joint fixed to it at F, so that the plane of the sector may be always parallel to the axis HI; which being parallel to the axis of the earth, the plane of the sector will always be parallel to the plane of some hour-circle. Let a telescope CE be moveable about the centre C of the arch AB, from one end of it to the other, by turning a screw at G; and let the line of sight be parallel to the plane of the sector. Now, by turning the whole instrument about the axis HI, till the plane of it be successively directed, first to one of the stars and then to another, it is easy to move the sector about the joint F, into such a position, that the arch AB, when fixed, shall take in both the stars in their passage, by the plane of it, provided the difference of their declinations does not exceed the arch AB. Then, having fixed the plane of the sector a little to the westward of both the stars, move the telescope CE by the screw G; and observe by a clock the time of each transit over the cross hairs, and also the degrees and minutes upon the arch AB, cut by the index at each transit; then in the difference of the arches, the difference of the declinations, and by the difference of the times, we have the difference of the right ascensions of the stars.

The dimensions of this instrument are these: The length of the telescope, or the radius of the sector, is $2\frac{1}{2}$ feet; the breadth of the radius, near the end C, is $1\frac{1}{4}$ inch; and at the end D two inches. The breadth of the limb AB is $1\frac{1}{2}$ inch; and its length six inches, containing ten degrees divided into quarters, and numbered from either end to the other. The telescope carries a nonius or subdividing plate, whose length, being equal to sixteen quarters of a degree, is divided into fifteen equal parts; which, in effect, divides the limb into minutes, and, by estimation, into smaller parts. The length of the square axis HIF is eighteen inches, and of the part HI twelve inches; and its thickness is about a quarter of an inch: the diameters of the circles are each five inches: the thickness of the plates, and the other measures, may be taken at the direction of a workman.

This instrument may be rectified, for making observations, in this manner: By placing the intersection of the cross hairs at the same distance from the plane of the sector, as the centre of the object-glass, the plane described by the line of sight, during the circular motion of the telescope upon the limb, will be sufficiently true, or free from conical curvity; which may be examined by suspending a long plumb-line at a convenient distance from the instrument; and by fixing the plane of the sector in a vertical position, and then by observing, while the telescope is moved by the screw along the limb, whether the cross hairs appear to move along the plumb-line.

The axis *hfo* may be elevated nearly parallel to the axis of the earth, by means of a small common quadrant; and its error may be corrected, by making the line of sight follow the circular motion of any of the circumpolar stars, while the whole instrument is moved about its axis *hfo*, the telescope being fixed to the limb; for this purpose, let the telescope *kl* be directed to the star *a*, when it passes over the highest point of its diurnal circle, and let the division cut by the nonius be then noted; then, after twelve hours, when the star comes to the lowest point of its circle, having turned the instrument half round its axis, to bring the telescope into the position *mn*; if the cross hairs cover the same star supposed at *b*, the elevation of the axis *hfo* is exactly right; but if it be necessary to move the telescope into the position *uv*, in order to point to this star at *c*, the arch *mu*, which measures the angle *mfu* or *bfc*, will be known; and then the axis *hfo* must be depressed half the quantity of this given angle if the star passed below *b*, or must be raised so much higher if above it; and then the trial must be repeated till the true elevation of the axis be obtained. By making the like observations upon the same star on each side the pole, in the six-o'clock hour circle, the error of the axis, toward the east or west, may also be found and corrected, till the cross hairs follow the star quite round the pole; for supposing *aopbc* to be an arch of the meridian (or in the second practice of the six-o'clock hour circle), make the angle *afp* equal to half the angle *afc*, and the line *fp* will point to the pole; and the angle *ofp*, which is the error of the axis, will be equal to half the angle *bfo*, or *mfu*, found by the observation; because the difference of the two angles *afb*, *afc*, is double the difference of their halves *afo* and *afp*. Unless the star be very

Description of Astronomical Instruments.

very near the pole, allowance must be made for refractions.

VI. Transit and Equal Altitude Instruments.

433 Transit Instruments.

1. *The Transit Instrument* is used for observing objects as they pass over the meridian. It consists of a telescope fixed at right angles to a horizontal axis; which axis must be so supported that what is called the line of collimation, or line of sight of the telescope, may move in the plane of the meridian. This instrument was first made by the celebrated Mr Roemer in the year 1689, and has since received great improvements. It is made of various sizes, and of large dimensions in our great observatories; but the following is one of a size sufficiently large and accurate for all the useful purposes.

The axis AB (fig. 176.), to which the middle of the telescope is fixed, is about $2\frac{1}{2}$ feet long, tapering gradually towards its ends, which terminate in cylinders well turned and smoothed. The telescope CD, which is about four feet long, and $1\frac{1}{2}$ inch diameter, is connected with the axis by means of a strong cube or die G, and in which the two cones MQ, forming the axis, are fixed. This cube or stock G serves as the principal part of the whole machine. It not only keeps together the two cones, but holds the two sockets KH, of 15 inches length, for the two telescopic tubes. Each of these sockets has a square base, and is fixed to the cube by four screws. These sockets are cut down in the sides about eight inches, to admit more easily the tube of the telescope; but when the tube is inserted, it is kept in firm by screwing up the tightening screws at the end of the sockets at K and H. These two sockets are very useful in keeping the telescope in its greatest possible degree of steadiness. They also afford a better opportunity of balancing the telescope and rectifying its vertical thread, than by any other means.

In order to direct the telescope to the given height that a star would be observed at, there is fixed a semicircle AN on one of the supporters, of about $8\frac{1}{2}$ inches diameter, and divided into degrees. The index is fixed on the axis, at the end of which is a vernier, which subdivides the degrees into 12 parts, or five minutes. This index is moveable on the axis, and may be closely applied to the divisions by means of a tightening screw.

Two upright posts of wood or stone YY, firmly fixed at a proper distance, are to sustain the supporters of this instrument. These supporters are two thick brass plates RR, having well smoothed angular notches in their upper ends, to receive the cylindrical arms of the axis. Each of these notched plates is contrived to be moveable by a screw, which slides them upon the surfaces of two other plates immoveably fixed upon the two upright pillars; one plate moving in a horizontal, and the other in a vertical direction; or, which is more simple, these two modes are sometimes applied only on one side, as at V and P, the horizontal motion by the screw P, and the vertical by the screw V. These two motions serve to adjust the telescope to the planes of the horizon and meridian: to the plane of the horizon by the spirit-level EF, hung by DC on the axis MQ, in a parallel direction: and to the plane of the meridian in the following manner:

Observe by the clock when a circumpolar star seen through this instrument transits both above and below the pole; and if the times of describing the eastern and western parts of its circuit are equal, the telescope is then in the plane of the meridian: otherwise the screw P must be gently turned that it may move the telescope so much that the time of the star's revolution be bisected by both the upper and lower transits, taking care at the same time that the axis remains perfectly horizontal. When the telescope is thus adjusted, a mark must be set at a considerable distance (the greater the better) in the horizontal direction of the intersection of the cross wires, and in a place where it can be illuminated in the night-time by a lanthorn hanging near it; which mark being on a fixed object, will serve at all times afterwards to examine the position of the telescope by, the axis of the instrument being first adjusted by means of the level.

To adjust the Clock by the Sun's Transit over the Meridian. Note the times by the clock when the preceding and following edges of the sun's limb touch the cross wire. The difference between the middle time and 12 hours, shows how much the mean, or time by the clock, is faster or slower than the apparent or solar time for that day: to which the equation of time being applied, will show the time of mean noon for that day, by which the clock may be adjusted.

2. *The Equal Altitude Instrument*, is an instrument that is used to observe a celestial object when it has the same altitude on both the east and west sides of the meridian, or in the morning and afternoon. It principally consists of a telescope about 30 inches long, fixed to a sextantal or semicircular divided arch; the centre of which is fixed to a long vertical axis: but the particulars of this instrument the reader will see explained in Optics.

3. *Compound Transit Instrument.* Some instruments have been contrived to answer both kinds of observations, viz. either a transit or equal altitudes. Fig. 178. represents such an instrument, made first of all for Mr le Monnier, the French astronomer, by the late Mr Sisson, under the direction of Mr Graham, mounted and fixed up ready for observation.

AB is a telescope, which may be 3, 4, 5, or 6 feet long, whose cylindrical tube fits exactly into another hollow cylinder *a b*, perpendicular to the axis: these several pieces are of the best hammered plate brass. The cylindrical extremity of this axis MN are of solid bell metal, and wrought exquisitely true, and exactly the same size, in a lathe; and it is on the perfection to which the cylinders or trunnions are turned that the justness of the instrument depends. In the common focus of the object-glass and eye-glass is placed a reticle (fig. 177.), consisting of three horizontal and parallel fine-stretched silver wires, fixed by pins or screws to a brass circle, the middle one passing through its centre, with a fourth vertical wire likewise passing through the centre, exactly perpendicular to the former three.

The horizontal axis MN (fig. 178.) is placed on a strong brass frame, into the middle of which a steel cylinder GH is fixed perpendicularly, being turned truly round, and terminating in a conical point at its lower extremity; where it is let into a small hole drilled in the middle of the dove-tail slider; which slider is supported

Description of Astronomical Instruments.

supported by a hollow tube fixed to the supporting piece IK, consisting of two strong plates of brass joined together at right angles, to which are fixed two iron cramps L, L, by which it is fastened to the stone wall of a south window.

The upper part G of the steel spindle is embraced by a collar *def*, being in contact with the blunt extremity of three screws, whose particular use will be explained by and by. O is another cylindrical collar closely embracing the steel spindle at about a third part of its length from the top; by the means of a small screw it may be loosened or pinched close as occasion requires. From the bottom of this collar proceeds an arm or lever acted on by the two screws *g h*, whereby the whole instrument, excepting the supporting piece, may be moved laterally, so that the telescope may be made to point at a distant mark fixed in the vertical of the meridian. *i k* is a graduated semicircle of thin brass screwed to the telescope, whereby it may be elevated so as to point to a known celestial object in the day-time. *l m* is a spirit-level parallel to the axis of rotation on the telescope, on which two trunnions hang by two hooks at M and N. Along the upper side of the glass tube of the level slides a pointer to be set to the end of the air-bubble; and when the position of the axis of rotation is so adjusted by the screws that the air-bubble keeps to the pointer for a whole revolution of the instrument, the spindle GH is certainly perpendicular to the horizon, and then the line of collimation of the telescope describes a circle of equal altitude in the heavens. When the level is suspended on the axis, raise or depress the tube of the level by twisting the neb of the screw *n* till you bring either the end of the air-bubble to rest at any point towards the middle of the tube, to which slide the index: then lift off the level, and, turning the ends of it contrary ways, hang it again on the trunnions; and if the air-bubble rests exactly again, the index as before, the axis of rotation is truly horizontal: If not, depress that end of the axis which lies on the same side of the pointer as the bubble does, by turning the neb of the screw at N, till the bubble returns about halfway towards the pointer; then having moved the pointer to the place where it now rests, invert the ends of the level again, and repeat the same practice till the bubble rests exactly at the pointer in both positions of the level. If, after the telescope is turned upside down, that is, after the trunnions are inverted end for end, you perceive that the same point of a remote fixed object is covered by the vertical wire in the focus of the telescope, that was covered by it before the inversion, it is certain that the line of sight or collimation is perpendicular to the transverse axis; but if the said vertical wire covers any other point, the brass circle that carries the hairs must be moved by a screw-key introduced through the perforation in the side of the tube at X, till it appears to bisect the line joining these two points as near as you can judge; then, by reverting the axis to its former position, you will find whether the wires be exactly adjusted. N. B. The ball *o* is a counterpoise to the centre of gravity of the semicircle *ik*, without which the telescope would not rest in an oblique elevation without being fixed by a screw or some other contrivance.

The several before-mentioned verifications being accomplished, if the telescope be elevated to any angle with the horizon, and there stopped, all fixed stars which pass over the three horizontal wires of the reticle on the eastern side of the meridian in ascending, will have precisely the same altitudes when in descending they again cross the same respective wires on the west side, and the middle between the times of each respective equal altitude will be the exact moment of the star's culminating or passing the meridian. By the help of a good pendulum-clock, the hour of their true meridional transits will be known, and consequently the difference of right ascension of different stars. Now, since it will be sufficient to observe a star which has north declination two or three hours before and after its passing the meridian, in order to deduce the times of its arrival at that circle; it follows, that having once found the difference of right ascension of two stars about 60 degrees asunder, and you again observe the first of these stand at the same altitude both in the east and west side, you infer with certainty the moment by the clock at which the second star will be on the meridian that same night, and by this means the transit instrument may be fixed in the true plane of the meridian till the next day; when, by depressing it to some distant land objects, a mark may be discovered whereby it may ever after be rectified very readily, so as to take the transits of any of the heavenly bodies to great exactness, whether by night or day.

When such a mark is thus found, the telescope being directed carefully to it, must be fixed in that position by pinching fast the end of the arm or lever between the two opposite screws *g h;* and if at any future time, whether from the effect of heat or cold on the wall to which the instrument is fixed, or by any settling of the wall itself, the mark appears no longer well bisected by the vertical wire, the telescope may easily be made to bisect it again, by giving a small motion to the pinching screws.

The transit instrument is now considered as one of the most essential particulars of the apparatus of an astronomical observatory.

Besides the above, may be mentioned,

The EQUATORIAL, *or* PORTABLE OBSERVATORY; an instrument designed to answer a number of useful purposes in practical astronomy, independent of any particular observatory. It may be made use of in any steady room or place, and performs most of the useful problems in the science. The following is a description of one lately invented by Mr Ramsden, from whom it has received the name of the *Universal Equatorial.* 434 Portable observatory.

The principal parts of this instrument (fig. 179.) are, 1. The azimuth or horizontal circle A, which represents the horizon of the place, and moves on a long axis B, called the *vertical axis.* 2. The equatorial or hour circle C, representing the equator, placed at right angles to the polar axis D, or the axis of the earth, upon which it moves. 3. The semicircle of declination E, on which the telescope is placed, and moving on the axis of declination, or the axis of motion of the line of collimation F. These circles are measured and divided as in the following table:

Measures

Description of Astronomical Instruments.

Description of Astronomical Instruments.

Measures of the several circles and divisions on them.	Radius indec.		Limb divided to	Nonius of 30 gives seconds.	Divided on limb into parts of inc.	Divided by Nonius into parts of inc.
Azimuth or horizontal circle	5	1	15′	30″	45th	1350th
Equatorial or hour circle	5	1	15′ / 1′ in time	30′ / 2″	45th	1350th
Vertical semicircle for declination or latitude.	5	5	15′	30″	42d	1260th

4. The telescope, which is an achromatic refractor with a triple object-glass, whose focal distance is 17 inches, and aperture 2.45 inches, and furnished with six different eye-tubes; so that its magnifying powers extend from 44 to 168. The telescope in this equatorial may be brought parallel to the polar axis, as in the figure, so as to point to the pole star in any part of its diurnal revolution; and thus it has been observed near noon, when the sun has shone very bright. 5. The apparatus for correcting the error in altitude occasioned by refraction, which is applied to the eye-end of the telescope, and consists of a slide G moving in a groove or dove-tail, and carrying the several eye-tubes of the telescope, on which slide there is an index corresponding to five small divisions engraved on the dove-tail; a very small circle, called the refraction circle H, moveable by a finger-screw at the extremity of the eye-end of the telescope; which circle is divided into half minutes, one entire revolution of it being equal to 3′ 18″, and by its motion raises the centre of the cross hairs on a circle of altitude; and likewise a quadrant I of $1\frac{1}{2}$ inch radius, with divisions on each side, one expressing the degree of altitude of the object viewed, and the other expressing the minutes and seconds of error occasioned by refraction, corresponding to that degree of altitude: to this quadrant is joined a small round level K, which is adjusted partly by the pinion that turns the whole of this apparatus, and partly by the index of the quadrant; for which purpose the refraction circle is set to the same minute, &c. which the index points to on the limb of the quadrant; and if the minute, &c. given by the quadrant exceed the 3′ 18″ contained in one entire revolution of the refraction circle, this must be set to the excess above one or more of its entire revolutions; then the centre of the cross hairs will appear to be raised on a circle of altitude to the additional height which the error of refraction will occasion at that altitude.

This instrument stands on three feet L distant from each other 14.4 inches: and when all the parts are horizontal is about 29 inches high: the weight of the equatorial and apparatus is only 59 lb. avoirdupois, which are contained in a mahogany case weighing 58 lb.

The principal adjustment in this instrument is that of making the line of collimation to describe a portion of an hour-circle in the heavens; in order to which, the azimuth circle must be truly level; the line of collimation, or some corresponding line represented by the small brass rod M parallel to it, must be perpendicular to the axis of its own proper motion; and this last axis must be perpendicular to the polar axis: on the brass rod M there is occasionally placed a hanging level N, the use of which will appear in the following adjustments:

The azimuth circle may be made level by turning the instrument till one of the levels is parallel to an imaginary line joining two of the feet screws; then adjust that level with these two feet screws; turn the circle half round, i. e. 180°; and if the bubble be not then right, correct half the error by the screw belonging to the level, and the other half error by the two foot screws; repeat this till the bubble comes right; then turn the circle 90° from the two former positions, and set the bubble right, if it be wrong, by the foot screw at the end of the level; when this is done, adjust the other level by its own screw, and the azimuth circle will be truly level. The hanging level must then be fixed to the brass rod by two hooks of equal length, and made truly parallel to it: for this purpose make the polar axis perpendicular or nearly perpendicular to the horizon; then adjust the level by the pinion of the declination-semicircle; reverse the level, and if it be wrong, correct half the error by a small steel screw that lies under one end of the level, and the other half-error by the pinion of the declination-semicircle; repeat this till the bubble be right in both positions. In order to make the brass rod on which the level is suspended at right angles to the axis of motion of the telescope or line of collimation, make the polar axis horizontal, or nearly so: set the declination-semicircle to 0°, turn the hour-circle till the bubble comes right; then turn the declination-circle to 90°; adjust the bubble by raising or depressing the polar axis (first by hand till it be nearly right, afterwards tighten with an ivory key the socket which runs on the arch with the polar axis, and then apply the same ivory key to the adjusting screw at the end of the said arch till the bubble comes quite right); then turn the declination-circle to the opposite 90°; if the level be not then right, correct half the error by the aforesaid adjusting screw at the end of the arch, and the other half error by the two screws which raise or depress the end of the brass rod. The polar axis remaining nearly horizontal as before, and the declination-semicircle at 0°, adjust the bubble by the hour-circle; then turn the declination-semicircle to 90°, and adjust the bubble by raising or depressing the polar axis; then turn the hour-circle 12 hours; and if the bubble be wrong, correct half the error by the polar axis, and the other half error by the two pair of capstan screws at the feet of the two supports on one side of the axis of motion

tion of the telescope; and thus this axis will be at right angles to the polar axis. The next adjustment is to make the centre of cross hairs remain on the same object, while you turn the eye-tube quite round by the pinion of the refraction apparatus: for this adjustment, set the index on the slide to the first division on the dove-tail; and set the division marked 18″ on the refraction circle to its index; then look through the telescope, and with the pinion turn the eye-tube quite round; and if the centre of the hairs does not remain on the same spot during that revolution, it must be corrected by the four small screws, two and two at a time (which you will find upon unscrewing the nearest end of the eye-tube that contains the first eye-glass); repeat this correction till the centre of the hairs remains on the spot you are looking at during an entire revolution. In order to make the line of collimation parallel to the brass rod on which the level hangs, set the polar axis horizontal, and the declination circle to 90°, adjust the level by the polar axis; look through the telescope, on some distant horizontal object, covered by the centre of the cross hairs; then invert the telescope, which is done by turning the hour-circle half round; and if the centre of the cross hairs does not cover the same object as before, correct half the error by the uppermost and lowermost of the four small screws at the eye-end of the large tube of the telescope; this correction will give a second object now covered by the centre of the hairs, which must be adopted instead of the first object: then invert the telescope as before; and if the second object be not covered by the centre of the hairs, correct half the error by the same two screws which were used before: this correction will give a third object, now covered by the centre of the hairs, which must be adopted instead of the second object; repeat this operation till no error remains; then set the hour-circle exactly to 12 hours (the declination-circle remaining at 90° as before): and if the centre of the cross hairs does not cover the last object fixed on, set it to that object by the two remaining small screws at the eye-end of the large tube, and then the line of collimation will be parallel to the brass rod. For rectifying the nonius of the declination and equatorial circles, lower the telescope as many degrees, minutes, and seconds, below 0° or Æ on the declination semicircle as are equal to the complement of the latitude; then elevate the polar axis till the bubble be horizontal, and thus the equatorial circle will be elevated to the colatitude of the place; set this circle to 6 hours; adjust the level by the pinion of the declination-circle; then turn the equatorial circle exactly twelve hours from the last position; and if the level be not right, correct one-half of the error by the equatorial circle, and the other half by the declination-circle; then turn the equatorial circle back again exactly 12 hours from the last position; and if the level be still wrong, repeat the correction as before till it be right, when turned to either position; that being done, set the nonius of the equatorial circle exactly to 6 hours, and the nonius of the declination circle exactly to 0°.

Description of Astronomical Instruments.

The principal uses of this equatorial are,

1. To find your meridian by one observation only: for this purpose, elevate the equatorial circle to the colatitude of the place, and set the declination semicircle to the sun's declination for the day and hour of the day required; then move the azimuth and hour circles both at the same time, either in the same or contrary direction, till you bring the centre of the cross hairs in the telescope exactly to cover the centre of the sun; when that is done, the index of the hour-circle will give the apparent or solar time at the instant of observation; and thus the time is gained, though the sun be at a distance from the meridian; then turn the hour-circle till the index points precisely at 12 o'clock, and lower the telescope to the horizon, in order to observe some point there in the centre of your glass, and that point is your meridian mark found by one observation only; the best time for this operation is three hours before or three hours after 12 at noon.

2. To point the telescope on a star, though not on the meridian, in full daylight. Having elevated the equatorial circle to the colatitude of the place, and set the declination-semicircle to the star's declination, move the index of the hour-circle till it shall point to the precise time at which the star is then distant from the meridian, found in tables of the right ascension of the stars, and the star will then appear in the glass. Besides these uses peculiar to this instrument, it is also applicable to all the purposes to which the principal astronomical instruments, viz. a transit, a quadrant, and an equal altitude instrument are applied.

ASTROPE-WELLS, near Banbury in Oxfordshire, are recommended as excellent in many disorders. The water is a brisk, spirituous, pleasant-tasted chalybeate, and is also gently purgative. It should be drank from three to five quarts in the forenoon.

ASTROSCOPE, a kind of astronomical instrument, composed of two cones, on whose surface the constellations, with their stars, are delineated, by means whereof the stars may be easily known. The astroscope is the invention of William Schuckhard, formerly professor of mathematics at Tubingen, who published a treatise expressly on it in 1698.

ASTRUC, JOHN, a celebrated physician, was born in the year 1684, at the little town of Savoy, in the province of Languedoc. His father, who was a Protestant clergyman, bestowed particular pains upon the earliest part of his education. After which he went to the university of Montpelier, where he was created master of arts in the year 1700. He then began the study of medicine; and, in two years, obtained the degree of bachelor, having upon that occasion written a dissertation on the cause of fermentation, which he defended in a very spirited manner. On the 25th of January 1703 he was created doctor of physic; after which, before arriving at extensive practice, he applied to the study of medical authors, both ancient and modern, with uncommon assiduity. The good effects of this study soon appeared; for, in the year 1710, he published a treatise concerning muscular motion, from which he acquired very high reputation. In the year 1717, he was appointed to teach medicine at Montpelier; which he did with such perspicuity and elo-

Digitized by Google

quence, that it was universally said he had been born to be a professor. His fame soon rose to such a height, that the king assigned him an annual salary; and he was, at the same time, appointed to superintend the mineral waters in the province of Languedoc. But as Montpelier did not afford sufficient scope for his aspiring genius, he went to Paris with a great stock of manuscripts, which he intended to publish, after subjecting them to the examination of the learned. Soon after, however, he left it, having in the year 1729 accepted the office of first physician to the king of Poland. In this capacity he remained only for a short time, and he again returned to Paris. Upon the death of the celebrated Geoffroy, in the year 1731, he was appointed regius professor of medicine at Paris. The duties of this office he discharged in such a manner as to answer even the most sanguine expectations. He taught the practice of physic with so great applause, as to draw from other universities to that of Paris a great concourse of medical students, foreigners as well as natives of France. At the same time he was not more celebrated as a professor than a practitioner. And even at an advanced age, he persevered with unwearied assiduity in that intense study which first raised his reputation. Hence it is that he has been enabled to transmit to posterity so many valuable monuments of his medical erudition. He died, universally regretted, on the 15th of May 1766, in the 82d year of his age.

ASTURIA, an ancient kingdom of Spain, subdued by Augustus, emperor of Rome.—The inhabitants of this country, along with those of Cantabria, asserted their liberty long after the rest of Spain had received the Roman yoke. So great was their desire of liberty, that after being closely shut up by the Roman army, they endured the most terrible calamities of famine, even to the devouring of one another, rather than submit to the enemy. At length, however, the Asturians were for surrendering; but the Cantabrians opposed this measure, maintaining that they ought all to die sword in hand like brave men. Upon this the two nations quarrelled, notwithstanding their desperate situation; and a battle ensuing, 10,000 of the Asturians were driven to the intrenchments of the Romans, whom they begged in the most moving manner to receive them on any terms they pleased. But Tiberius, the emperor's son-in-law, refusing to admit them into the camp, some of these unhappy people put an end to their lives by falling upon their own swords; others lighting great fires threw themselves into them, while some poisoned themselves by drinking the juice of a venomous herb.

The campaign being put an end to by winter, the next year the Asturians summoned all their strength and resolution against the Romans; but notwithstanding their utmost efforts of valour and despair, they were entirely defeated in a most bloody battle, which lasted two days, and for that time entirely subdued. A few years afterwards they rebelled, in conjunction with the Cantabrians; but were soon reduced by the Romans, who massacred most of the young men that were capable of bearing arms. This did not prevent them from revolting anew in a short time afterwards; but without success, being obliged to submit to the Roman power, till the subversion of that empire by the Goths.

Asturias, anciently the kingdom of Asturia, is now a principality of modern Spain, bounded by Biscay on the east, Galicia on the west, Old Castile and Leon on the south, and the sea on the north. Its greatest length is about 110 miles, and its breadth 54. On the south it is separated from Old Castile and Leon by high mountains covered with woods. The province is tolerably fertile, but thinly inhabited. The inhabitants value themselves much on being descended from the ancient Goths. Even the poor peasants, who are fain to go to seek work in other provinces, call themselves *illustrious Goths* and *Mountaineers*, thinking it ignominious to marry even with great and rich families of another race. This pride is flattered by the respect paid them by the rest of the nation, and the privileges bestowed upon them by the government. The hereditary prince of Spain is styled *prince of the Asturias*. The Asturias contain 688 parishes, and the population is estimated at 348,000, including 2868 ecclesiastics, monks and nuns.

ASTYAGES, son of Cyaxares, the last king of the Medes. He dreamed, that from the womb of his daughter Mandane, married to Cambyses king of Persia, there sprung a vine that spread itself over all Asia. She being with child, he resolved to kill the infant as soon as born. Its name was Cyrus; and Harpagus being sent to destroy it, preserved it; which Astyages after a long time hearing of, he caused Harpagus to eat his own son. Harpagus called in Cyrus, who dethroned his grandfather, and thereby ended the monarchy of the Medes. See Media and Persia.

ASTYANAX, the only son of Hector and Andromache. After the taking of Troy, he was thrown from the top of a tower by Ulysses's orders.

ASTYNOMI, in *Grecian Antiquity*, magistrates in Athens, corresponding to the ædiles of the Romans; they were ten in number. See Ædile.

ASYLUM, a sanctuary, or place of refuge, where criminals shelter themselves from the hands of justice. The word is compounded of the privative particle α, and συλαω, *I hurt*; because no person could be taken out of an asylum without sacrilege.

The asyla of altars and temples were very ancient; and likewise those of tombs, statues, and other monuments of considerable personages. Thus, the temple of Diana at Ephesus was a refuge for debtors, the tomb of Theseus for slaves. Among the Romans, a celebrated asylum was opened by Romulus between the mounts Palatine and Capitoline, in order to people Rome, for all sorts of persons indiscriminately, fugitive slaves, debtors, and criminals of every kind. The Jews had their asyla; the most remarkable of which were, the six cities of refuge, the temple, and the altar of burnt-offerings.

It was customary among the Heathens to allow refuge and impunity even to the vilest and most flagrant offenders; some out of superstition, and others for the sake of peopling their cities: and it was by this means, and with such inhabitants, that Thebes, Athens, and Rome, were first stocked. We even read of asylums at Lyons and Vienne among the ancient Gauls; and there are some cities in Germany which still preserve the

Digitized by Google

the ancient right of asylum. Hence on the medals of several ancient cities, particularly in Syria, we meet with the inscription ΑΣΥΛΟΙ, to which is added ΙΕΡΑΙ. This quality of asylum was given them, according to M. Spanheim, in regard to their temples, and to the gods revered by them.

The emperors Honorius and Theodosius granting the like immunities to churches, the bishops and monks laid hold of a certain tract or territory, without which they fixed the bounds of the secular jurisdiction: and so well did they manage their privileges, that convents in a little time became next akin to fortresses; where the most notorious villains were in safety, and braved the power of the magistrate.

These privileges at length were extended not only to the churches and churchyards, but also to the bishops houses; whence the criminal could not be removed without a legal assurance of life, and an entire remission of the crime. The reason of the extension was, that they might not be obliged to live altogether in the churches, &c. where several of the occasions of life could not be decently performed.

But at length these asyla or sanctuaries were also stripped of most of their immunities, because they served to make guilt and libertinage more bold and daring. In England, particularly, they were entirely abolished. See SANCTUARY.

ASSYMETRY, the want of proportion between the parts of any thing; being the contrary of *symmetry*. Or, it is the relation of two quantities which have no common measure, as between 1 and $\surd 2$, or the side and diagonal of a square.

ASYMPTOTE, in *Geometry*, a line which continually approaches nearer to another; but, though continued infinitely, will never meet with it: Of these are many kinds. In strictness, however, the term *asymptotes* is appropriated to right lines, which approach nearer and nearer to some curves of which they are said to be *asymptotes*; but if they and their curves are indefinitely continued, they will never meet. See CONIC *Sections*.

ASYNDETON, in *Grammar*, a figure which omits the conjunctions in a sentence. As in *veni, vidi, vici*, where ET is left out: or in that of Cicero concerning Catiline, *abiit, excessit, evasit, erupit*: or in that verse of Virgil,

Ferte cito flammas, date vela, impellite remos.

Asyndeton stands opposed to polysyndeton, where the copulatives are multiplied.

ATABULUS, in *Physiology*, a provincial wind in Apulia, of a dry pinching quality, and very noxious in its effects. The ancient naturalists speak of the Atabulus in terms of horror, on account of the ravage it made among the fruits of the earth, which it scorched or withered up.

ATABYRIS, a very high mountain in the island of Rhodes, on which, according to Strabo and Diodorus Siculus, there stood a temple of Jupiter Atabyrius, whose worship a colony of Rhodians carried into Sicily, where a temple was built to the same deity at Agrigentum.

ATALANTA, an island in the Euripus of Euboea, near the Locri Opuntii, said to have been originally a city of the Locri, but torn from the continent in the time of an earthquake, and during an eruption of Mount Ætna. This happened in the fourth year of the 93d Olympiad, in the reign of Artaxerxes Mnemon.

ATALANTIS, ATLANTICA, or ATLANTIS. See ATLANTIS.

ATARAXY, a term used by the stoics and sceptics, to denote that calmness of mind which secures us from all emotions arising from vanity and self-conceit.

ATARGATIS FANUM, the temple of a goddess worshipped by the Syrians and Parthians, having the face of a woman and tail of a fish, and called *Derceto* by the Greeks. Her temple stood in the city Bambyce, called afterwards *Hieropolis*. It was extremely rich, insomuch that Crassus, in his march against the Parthians, spent several days in weighing the treasure. Vossius makes the name of this goddess Phœnician, from *Addir dag*, "the great fish."

ATARNEA, an ancient town of Mysia, situated between Adrymyttium and Pitane, remarkable for the marriage of Aristotle with the sister or concubine of the tyrant Hermias; also for the dotage of that philosopher.

ATAXY, in a general sense, the want of order: With physicians, it signifies irregularity of crises and paroxysms of fevers.

ATCHE, in commerce, a small silver coin used in Turkey, and worth only one-third of the English penny.

ATCHIEVEMENT, in *Heraldry*, denotes the arms of a person or family, together with all the exterior ornaments of the shield; as helmet, mantle, crest, scrolls, and motto, together with such quarterings as may have been acquired by alliances, all marshalled in order.

ATCHIEVE. This term is derived from the French *achever*, i. e. to finish or make an end of; but signifies, in its ordinary acceptation, to perform great actions or exploits.

ATE, the goddess of mischief, in the Pagan theology. She was daughter of Jupiter, and cast down from heaven at the birth of Hercules. For Juno having deceived Jupiter, in causing Eurystheus to be born before Hercules, Jupiter expressed his resentment on Ate, as the author of that mischief: and threw her headlong from heaven to the earth, swearing she should never return thither again (*Homer Il.* xix. 125.). The name of this goddess comes from *αταω*, *noceo*, "to hurt." Her being the daughter of Jupiter, means, according to mythologists, that no evil happens to us but by the permission of Providence; and her banishment to earth denotes the terrible effects of divine justice among men.

ATEGUA, or ATTEGUA, an ancient town of Spain, placed by some in the road from Antiquara, now Antequera, to Hispalis, or Seville; by others near Alcala Real; which last is the more probable situation, because the Flumen Salsum, now the Salado, was in its neighbourhood. Now *Tebala Vieja*, or *Teivela*.

ATELLA, an ancient town of Campania in Italy, between Capua and Neapolis. From this town the *Atellanæ fabulæ*, or *Atellani ludi*, took their name. Their were also called *Osci*, from their inventor, in whose territory Atella lay. They were generally a species of farce, interlarded with much ribbaldry and buffoonery; and sometimes were exordia or interludes presented between

Digitized by Google

between the acts of other plays. The actors in these farces were not reckoned among the common players, nor deemed infamous; but retained the rights of their tribe, and might be listed for soldiers, the privilege only of free men. The ruins of this town are still to be seen, about 11 miles from the modern Aversa, which was built out of its materials.

ATEMPO GIUSTO, in *Music*, signifies to sing or play in an equal, true, and just time.

ATERGATIS, in *Mythology*, a goddess of the Syrians, supposed to be the mother of Semiramis. She was represented with the face and breasts of a woman, but the rest of her body resembled a fish. Vossius says the term signifies *without fish*, and conjectures that the votaries of this deity abstained from fish.

ATERNUM, a town of Lucania in Italy, now *Aterni*, (Cluverius): Also a town in the territory of the Piceni, now *Pescara*, a port town of Naples, situated on the Adriatic. E. Long. 15. 25. N. Lat. 42. 30.

ATESTE, a town in Austrian Lombardy in Italy, now called *Este*. E. Long. 12. 6. N. Lat. 45. 25.

ATHAMADULET, the prime minister of the Persian empire, as the grand vizier is of the Turkish empire. He is great chancellor of the kingdom, president of the council, superintendant of the finances, and is charged with all foreign affairs.

ATHAMANTA, SPIGNEL. See BOTANY *Index*.

ATHANASIA, GOLDILOCKS. See BOTANY *Index*.

ATHANASIAN CREED; a formulary, or confession of faith, long supposed to have been drawn up by Athanasius bishop of Alexandria, in the fourth century, to justify himself against the calumnies of his Arian enemies. But it is now generally allowed among the learned not to have been his. Dr Waterland ascribes it to Hilary bishop of Arles, for the following among other reasons: 1. Because Honoratus of Marseilles, the writer of his life, tells us, that he composed an *Exposition of the Creed;* a properer title for the *Athanasian* than that of *Creed* simply which it now bears. 2. Hilary was a great admirer and follower of St Austin; and the whole composition of this creed is in a manner upon St Austin's plan, both with respect to the Trinity and incarnation. 3. It is agreeable to the style of Hilary, as far as we can judge from the little that is left of his works. Upon the whole he concludes, that Hilary, bishop of Arles, about the year 430, composed *the Exposition of Faith*, which now bears the name of the *Athanasian Creed*, for the use of the Gallican clergy, and particularly those of the diocese of Arles: That, about the year 570, it became famous enough to be commented upon; but that all this while, and for several years lower, it had not yet acquired the name of *Athanasian*, but was simply styled *The Catholic Faith:* That, before 670, Athanasius's admired name came in to recommend and adorn it, being in itself an excellent system of the Athanasian principles of the Trinity and incarnation, in opposition chiefly to the Arians, Macedonians and Apollinarians. This is the hypothesis of the learned author of the *Critical History of the Athanasian Creed.*

As to the reception of this creed in the Christian churches, we find, that it obtained in France in the time of Hincmar, or about 850: that it was received in Spain about 100 years later than in France, and in Germany much about the same time. As to our own country, we have clear and positive proofs of this creed being sung alternately in our churches in the tenth century. It was in common use in some parts of Italy, particularly in the diocese of Verona, about the year 960, and was received at Rome about the year 1014. As to the Greek and oriental churches, it has been questioned whether any of them ever received this creed at all; though some very considerable writers are of a contrary persuasion. It appears then, that the reception of this creed has been both general and ancient; and may vie with any, in that respect, except the Nicene or Constantinopolitan, the only general creed common to all the churches.

As to the matter of this creed, it is given as a summary of the true orthodox faith, and a condemnation of all heresies ancient and modern. Unhappily, however, it has proved a fruitful source of unprofitable controversy and unchristian animosity even down to the present time.

ATHANASIUS, ST, bishop of Alexandria, and one of the greatest defenders of the faith against the Arians, was born in Egypt. He followed St Alexander to the council of Nice, in 325, where he disputed against Arius, and the following year was made bishop of Alexandria; but, in 335, was deposed by the council of Tyre: when, having recourse to the emperor Constantine, the Arian deputies accused him of having hindered the exportation of corn from Alexandria to Constantinople; on which the emperor, without suffering him to make his defence, banished him to Treves. The emperor, two years after, gave orders that he should be restored to his bishopric: but, on his return to Alexandria, his enemies brought fresh accusations against him, and chose Gregory of Cappadocia to his see; which obliged Athanasius to go to Rome to reclaim it of Pope Julius. He was there declared innocent, in a council held in 342, and in that of Sardica in 347; and two years after was restored to his see by order of the emperor Constans: but after the death of that prince, he was again banished by the emperor Constantius, which obliged him to retire into the deserts. The Arians then elected one George in his room; who being killed in a popular sedition under Julian in 360, St Athanasius returned to Alexandria, but was again banished under Julian, and restored to his see under Jovian. He addressed to that emperor a letter, in which he proposed that the Nicene creed should be the standard of the orthodox faith, and condemned those who denied the divinity of the Holy Ghost. He was also banished by Valens in 367, and afterwards recalled. St Athanasius died on the 2d of May 375.

His works principally contain a defence of the mysteries of the Trinity, and of the incarnation and divinity of the Word and Holy Spirit. There are three editions of his works which are esteemed; that of Commelin, printed in 1600; that of Peter Nannius, in 1627; and that of Father Montfaucon. As to the creed which bears his name, see the preceding article.

ATHANATI, in Persian antiquity, a body of cavalry, consisting of 10,000 men, always complete. They were called *athanati* (a word originally Greek, and signifying *immortal*), because, when one of them happened to die, another was immediately appointed to succeed him.

ATHANOR. Chemists have distinguished by this name a furnace so constructed that it can always maintain an equal heat, and which shall last a long time without addition or fresh fuel.

The body of the athanor has nothing in it particular, and is constructed like ordinary furnaces. But at one of its sides, or its middle, there is an upright hollow tower, which communicates with the fireplace by one or more sloping openings, and which has a lid to close its upper opening. This furnace is now rarely used.

ATHAROTH, or ATROTH, in *Ancient Geography*, the name of several towns. Two appear to have been in Samaria, in the tribe of Ephraim; and one four miles to the north of Sebaste, or the city of Samaria; the other in the confines of Benjamin and Ephraim, yet so as to be in the district of Ephraim rather than Benjamin (Joshua). This is the *Atroth-Adder* mentioned by Joshua xvi. 5. from which to Upper Bethoron extends the greatest breadth of the tribe of Ephraim.

ATHEISM, the disbelief of a deity. See ATHEIST.

ATHEIST, a person who does not believe the existence of a Deity. Many people, both ancient and modern, have pretended to atheism, or have been reckoned atheists by the world; but it is justly questioned whether any man seriously adopted such a principle. These pretensions, therefore, must be founded on pride or affectation.

Atheism, as absurd and unreasonable as it is, has had its martyrs. Lucilio Vanini, an Italian, native of Naples, publicly taught atheism in France, about the beginning of the 17th century; and being convicted of it at Thoulouse, was condemned to death. Being pressed to make public acknowledgment of his crime, and to ask pardon of God, the king, and justice, he answered, he did not believe there was a God; that he never offended the king; and, as for justice, he wished it to the devil. He confessed that he was one of twelve, who parted in company from Naples to spread their doctrine in all parts of Europe. His tongue was first cut out, and then his body burnt, April 9. 1619.

Cicero represents it as a probable opinion, that they who apply themselves to the study of philosophy believe there are no gods. This must, doubtless, be meant of the academic philosophy, to which Cicero himself was attached, and which doubted of every thing. On the contrary, the Newtonian philosophers are continually recurring to a Deity, whom they always find at the end of their chain of natural causes. Some foreigners have even charged them with making too much use of the notion of a God in philosophy, contrary to the rule of Horace:

Nec Deus intersit, nisi dignus vindice nodus.

Among us, the philosophers have been the principal advocates for the existence of a Deity. Witness the writings of Sir Isaac Newton, Boyle, Ray, Cheyne, Nieuwentyt, &c. To which may be added many others, who, though of the clergy (as was also Ray), yet have distinguished themselves by their philosophical pieces in behalf of the existence of a God; *e. gr.* Derham, Bentley, Whiston, Samuel and John Clarke, Fenelon, &c. So true is that saying of Lord Bacon, that though a smattering of philosophy may lead a man into atheism, a deep draught will certainly bring him back again to the belief of a God and Providence.

ATHELING, ADELING, EDELING, ETHLING, or ETHELING, among the Anglo-Saxons, was a title of honour, properly belonging to the heir-apparent, or presumptive, to the crown. This honourable appellation was first conferred by King Edward the Confessor on Edgar, to whom he was great uncle, when, being without any issue of his own, he intended to make him his heir.

ATHELSTAN, a Saxon king of England, natural son of Edward the Elder, and grandson of the great Alfred. He succeeded to the crown in 925, and reigned 16 years. There was a remarkable law passed by this prince, which shows his just sentiments of the advantages of commerce, as well as the early attention to it in this country: it declared, that any merchant who made three voyages on his own account beyond the British channel or narrow seas, should be entitled to the privilege of a thane or gentleman.

ATHENÆA, in antiquity, a feast celebrated by the ancient Greeks in honour of Minerva, who was called *Athene*.

ATHENÆUM, in antiquity, a public place wherein the professors of the liberal arts held their assemblies, the rhetoricians declaimed, and the poets rehearsed their performances. These places, of which there were a great number at Athens, were built in the manner of amphitheatres, encompassed with seats, called *cunei*. The three most celebrated Athenæa were those at Athens, at Rome, and at Lyons; the second of which was built by the emperor Adrian.

ATHENÆUS, a physician, born in Cilicia, cotemporary with Pliny, and founder of the Pneumatic sect. He taught that the fire, air, water, and earth, are not the true elements, but that their qualities are, viz. heat, cold, moisture, and dryness; and to these he added a fifth element, which he called *spirit*, whence his sect had its name.

ATHENÆUS, a Greek grammarian, born at Naucratis in Egypt in the third century, one of the most learned men of his time. Of all his works we have none extant but his Deipnosophi, i. e. the sophists at table. There is an infinity of facts and quotations in this work which render it very agreeable to admirers of antiquity.

There was also a mathematician of this name, who wrote a treatise on mechanics, which is inserted in the works of the ancient mathematicians, printed at Paris in 1693, in folio, in Greek and Latin.

ATHENAGORAS, an Athenian philosopher, flourished about the middle of the 2d century, and was remarkable for his zeal for Christianity, and his great learning, as appears from the apology which he addressed to the emperors Marcus Aurelius Antoninus and Lucius Commodus.

Athenodorus ‖ Athens.

ATHENODORUS, a famous Stoic philosopher, born at Tarsus, went to the court of Augustus, and was made by him tutor to Tiberius. Augustus had a great esteem for him, and found him by experience a man of virtue and probity. He used to speak very freely to the emperor. He, before he left the court to return home, warned the emperor not to give himself up to anger, but whenever he should be in a passion, to rehearse the 24 letters of the alphabet before he resolved to say or do any thing. He did not live to see his bad success in the education of Tiberius.

ATHENOPOLIS, a town of the Massilienses, an ancient nation of Gaul. It is conjectured by Harduin to be the same with *Telo Martias*, now *Toulon;* by others to be the same with *Antipolis* or *Antibes*.

ATHENREE, a town of Ireland in the county of Galway, and province of Connaught. W. Long. 8. 5. N. Lat. 53. 14. It is governed by a portrieve, and hath a barrack for three companies of foot. It hath been a place of considerable strength; but, like the numerous churches and castles which surround it, has felt the resistless force of time. Some of the walls and towers, however, are still remaining, as monuments of its former grandeur.

ATHENS, a celebrated city of Greec, and capital of the ancient kingdom of Attica, situated in E. Long. 24. N. Lat. 38. 5. See ATTICA.

1 By whom founded.

In early times, that which was afterwards called the *citadel* was the whole city; and went under the name of *Cecropia*, from its founder Cecrops, whom the Athenians in after times affirmed to have been the first builder of cities, and called this therefore by way of eminence *Polis*, i. e. the city. In the reign of Erichthonius it lost the name of *Cecropia*, and acquired that of *Athens*, on what account is not certain; the most probable is, that it was so named in respect to the goddess Minerva, whom the Greeks call *Athene*, who was also esteemed its protectress. This old city was seated on the top of a rock in the midst of a large and pleasant plain, which, as the number of inhabitants increased, became full of buildings, which induced the distinction of Acro and Catapolis, i. e. of the upper and lower city. The extent of the citadel was 60 stadia; it was surrounded by olive trees, and fortified, as some say, with a strong pallisade; in succeeding times it was encompassed with a strong wall, in which there were nine gates, one very large one, and the rest small. The inside of the citadel was adorned with innumerable edifices. The most remarkable of which were, 1. The magnificent temple of Minerva, styled *Parthenon*, because that goddess was a virgin. The Persians destroyed it; but it was rebuilt with still greater splendour by the famous Pericles, all of the finest marble, with such skill and strength, that, in spite of the rage of time and barbarous nations, it remains perhaps the first antiquity in the world, and stands a witness to the truth of what ancient writers have recorded of the prodigious magnificence of Athens in her flourishing state. 2. The temple of Neptune and of Minerva; for it was divided into two parts: one sacred to the god, in which was the salt fountain said to have sprung up on the stroke of his trident; the other to the goddess protectress of Athens, wherein was the sacred olive which she produced, and her image which fell down from heaven in the reign of Erichthonius.

2 Remarkable buildings.

At the back of Minerva's temple was the public treasury, which was burnt to the ground through the knavery of the treasurers, who having misapplied the revenues of the state, took this short method of making up accounts.

The lower city comprehended all the buildings surrounding the citadel, the fort Munychia, and the havens Phalerum and Piræus, the latter of which was joined to the city by walls five miles in length; that on the north was built by Pericles, but that on the south by Themistocles; but by degrees the turrets which were at first erected on those walls were turned into dwelling-houses for the accommodation of the Athenians, whose large city was now become too small for them. The city, or rather the lower city, had 13 great gates, with the names of which it is not necessary to trouble the reader. Among the principal edifices which adorned it, we may reckon, 1. The temple of Theseus, erected by Conon, near its centre. Adjacent thereto, the young people performed their exercises. It was also a sanctuary for distressed persons, slaves or free. 2. The Olympian temple erected in honour of Jupiter, the honour of Athens, and of all Greece. The foundation of it was laid by Pisistratus; it was carried on but slowly in succeeding times, 700 years elapsing before it was finished, which happened under the reign of Adrian, who was particularly kind to Athens: this was the first building in which the Athenians beheld pillars. 3. The Pantheon, dedicated to all the gods: a most noble structure, supported by 120 marble pillars, and having over its great gate two horses carved by Praxiteles: it is yet remaining, as we shall have occasion to show hereafter when we come to speak of the present state of this famous city. In several parts of it were *staoi* or porticoes, wherein people walked in rainy weather, and from whence a sect of philosophers were denominated *Stoics*, because their master Zeno taught in those porticoes.

3 Ceramicus.

There were at Athens two places called *Ceramicus*, from Ceramus the son of Bacchus and Ariadne; one within the city, containing a multitude of buildings of all sorts; the other in the suburbs, in which was the academy and other edifices. The gymnasia of Athens were many; but the most remarkable were the Lyceum, Academia, and Cynosarges. The Lyceum stood on the banks of the Ilissus; some say it was built by Pisistratus, others by Pericles, others by Lycurgus. Here Aristotle taught philosophy, instructing such as came to hear him as they walked, whence his disciples are generally thought to derive the name of *Peripatetics*. The Ceramicus without the city was the distance of six stadia from its walls. The academy made part thereof; as to the name of which there is some dispute. Some affirm that it was so called from Academus, an ancient hero, who, when Helen was stolen by Theseus, discovered the place where she lay hid to Castor and Pollux: for which reason the Lacedemonians, when they invaded Attica, always spared this place. Dicæarchus writes, that Castor and Pollux had two Arcadians in their army, the one named *Echedemus*, the other *Marothus;* from the former of these he says this place took its name, and that the borough of Marathon was so called from the other. It was a marshy unwholesome place, till Cimon was at great pains to have it drained; and then it became extremely pleasant

Athens.

sant and delightful, being adorned with shady walks, where Plato read his lectures, and from thence his scholars were termed *Academics*. The Cynosarges was a place in the suburbs not far from the Lyceum: it was famous on many accounts; but particularly for a noble gymnasium erected there, appointed for the special use of such as were Athenians only by one side. In after times Themistocles derived to himself ill will, by carrying many of the nobility to exercise with him here, because, being but of the half blood, he could exercise nowhere else but in this gymnasium. Antisthenes instituted a sect of philosophers, who from the name of this district, as many think, were styled *Cynics*.

4 Cynosarges

5 Havens.

The havens of Athens were three. First, the Piræus, which was distant about 35 or 40 stadia from the city, till joined thereto by the long walls before-mentioned, after which it became the principal harbour of the city. It had three docks: Cantharos, Aphrodisium, and Zea; the first was so called from an ancient hero, the second from the goddess Venus who had there two temples, and the third from bread-corn. There were in this port five porticoes, which joining together formed one great one, called from thence *Macra Stoa*, or the grand portico. There were likewise two great markets or fora: one near the long portico, the other near the city. The second port was Munichia, a promontory not far distant from Piræus; a place very strong by nature, and afterwards rendered far stronger by art. It was of this that Epimenides said, if the Athenians foresaw what mischief it would one day produce to them, they would eat it away with their teeth. The third was Phalerum, distant from the city, according to Thucydides, 35 stadia, but according to Pausanias only 20. This was the most ancient harbour of Athens, as Piræus was the most capacious.

6 Present state.

Of this city, as it stands at present, we have the following account by Dr Chandler and other travellers. "It is now called *Athené*: and is not inconsiderable, either in extent or the number of inhabitants. It enjoys a fine temperature, and a serene sky. The air is clear and wholesome, though not so delicately soft as in Ionia. The town stands beneath the acropolis or citadel; not encompassing the rock as formerly, but spreading into the plain, chiefly on the west and north-west. Corsairs infesting it, the avenues were secured, and in 1676 the gates were regularly shut after sunset. It is now open again: but several of the gateways remain, and a guard of Turks patrols at midnight. Some masses of brick-work, standing separate, without the town, belonged perhaps to the ancient wall, of which other traces also appear. The houses are mostly mean and straggling; many with large courts or areas before them. In the lanes, the high walls on each side, which are commonly white-washed, reflect strongly the heat of the sun. The streets are very irregular; and anciently were neither uniform nor handsome. They have water conveyed in channels from Mount Hymettus, and in the bazar or market-place is a large fountain. The Turks have several mosques and public baths. The Greeks have convents for men and women; with many churches, in which service is regularly performed; and besides these, they have numerous oratories or chapels, some in ruins or consisting of bare walls, frequented only on the anniversaries of the saints to whom they are dedicated. A portrait of the owner on a board is placed in them on that occasion, and removed when the solemnity of the day is over.

"The city of Cecrops is now a fortress with a thick irregular wall, standing on the brink of precipices, and enclosing a large area about twice as long as broad. Some portions of the ancient wall may be discovered on the outside, particularly at the two extreme angles; and in many places it is patched with pieces of columns, and with marbles taken from the ruins. A considerable sum had been recently expended on the side next Hymettus, which was finished before we arrived. The scaffolding had been removed to the end toward Pentele; but money was wanting, and the workmen were withdrawn. The garrison consists of a few Turks, who reside there with their families, and are called by the Greeks *Castriani*, or the soldiers of the castle. The rock is lofty, abrupt, and inaccessible, except the front, which is towards the Piræus; and on that quarter is a mountainous ridge, within cannon-shot. It is destitute of water fit for drinking; and supplies are daily carried up in earthen jars, on horses and asses, from one of the conduits of the town.

7 Citadel, or city of Cecrops.

"The acropolis furnished a very ample field to the ancient virtuosi. It was filled with monuments of Athenian glory, and exhibited an amazing display of beauty, of opulence, and of art; each contending as it were for the superiority. It appeared as one entire offering to the Deity, surpassing in excellence and astonishing in richness. Heliodorus, named Periegetes, *the guide*, had employed on it 15 books. The curiosities of various kinds, with the pictures, statues, and pieces of sculpture, were so many and so remarkable, as to supply Polemo Periegetes with matter for four volumes: and Strabo affirms, that as many would be required in treating of other portions of Athens and of Attica. In particular, the number of statues was prodigious. Tiberius Nero, who was fond of images, plundered the acropolis as well as Delphi and Olympia; yet Athens, and each of these places, had not fewer than 3000 remaining in the time of Pliny. Even Pausanias seems here to be distressed by the multiplicity of his subject. But this banquet, as it were, of the senses has long been withdrawn; and is now become like the tale of a vision. The spectator views with concern the marble ruins intermixed with mean flat-roofed cottages, and extant amid rubbish; the sad memorials of a nobler people; which, however, as visible from the sea, should have introduced modern Athens to more early notice. They who reported it was only a small village, must, it has been surmised, have beheld the acropolis through the wrong end of their telescopes.

"The acropolis has now, as formerly, only one entrance, which fronts the Piræus. The ascent is by traverses and rude fortifications furnished with cannon, but without carriages, and neglected. By the second gate is the station of the guard, who sits cross-legged under cover, much at his ease, smoking his pipe, or drinking coffee, with his companions about him in like attitudes. Over this gateway is an inscription in large characters on a stone turned upside down, and black from the fires made below. It records a present of a pair of gates.

"Going farther up, you come to the ruins of the Propyléa, an edifice which graced the entrance of the 8 Propylea.

 citadel.

Digitized by Google

Athens. citadel. This was one of the structures of Pericles, who began it when Euthymenes was archon, 435 years before Christ. It was completed in five years, at the expence of 2012 talents. It was of marble, of the Doric order, and had five doors to afford an easy passage to the multitudes which resorted on business or devotion to the acropolis.

While this fabric was building, the architect Mnesicles, whose activity equalled his skill, was hurt by a fall, and the physicians despaired of his life: but Minerva, who was propitious to the undertaking, appeared, it was said, to Pericles, and prescribed a remedy, by which he was speedily and easily cured. It was a plant or herb growing round about the acropolis, and called afterwards *parthenium*.

9 Temple of Victory.

"The right wing of the Propylea was a temple of Victory. They related that Ægeus had stood there, viewing the sea, and anxious for the return of his son Theseus, who was gone to Crete with the tributary children to be delivered to the Minotaur. The vessel which carried them had black sails suiting the occasion of its voyage; and it was agreed, that, if Theseus overcame the enemy, their colour should be changed to white. The neglect of this signal was fatal to Ægeus, who, on seeing the sails unaltered, threw himself down headlong from the rock, and perished. The idol was named *Victory without wings;* it was said, because the news of the success of Theseus did not arrive but with the conqueror. It had a pomegranate in the right hand, and a helmet in the left. As the statue was without pinions, it was hoped the goddess would remain for ever on the spot.

"On the left wing of the Propylea, and fronting the temple of Victory, was a building decorated with paintings by Polygnotus, of which an account is given by Pausanias. This edifice, as well as the temple, was of the Doric order, the columns fluted, and without bases. Both contributed alike to the uniformity and grandeur of the design; and the whole fabric, when finished, was deemed equally magnificent and ornamental. The interval between Pericles and Pausanias consists of several centuries. The Propylea remained entire in the time of this topographer; and, as will be shown, continued nearly so to a much later period. It had then a roof of white marble, which was unsurpassed either in the size of the stones or in the beauty of their arrangement; and before each wing was an equestrian statue.

"The Propylea have ceased to be the entrance of the acropolis. The passage which was between the columns in the centre, is walled up almost to their capitals, and above is a battery of cannon. The way now winds before the front of the ancient structure; and turning to the left hand among rubbish and mean walls, you come to the back part, and to the five door-ways. The soil without is risen higher than the top of the two smaller. There, under the vault and cannon, lies a heap of large stones, the ruin of the roof.

"The temple of Victory, standing on an abrupt rock, has its back and one side encumbered with the modern ramparts. The columns in the front being walled up, you enter it by a breach in the side, within the Propylea. It was used by the Turks as a magazine for powder, until about the year 1656, when a sudden explosion, occasioned by lightning, carried away the roof, with a house erected on it, belonging to the officer who commanded in the acropolis, whose family, except a girl, perished. The women of the aga continued to inhabit this quarter, but it is now abandoned and in ruins.

10 Roof carried off by an explosion.

"The cell of the temple of Victory, which is of white marble, very thick, and strongly cemented, sufficiently witnesses the great violence it has undergone; the stones in many places being disjointed, as it were, and forced from their original position. Two of these making an acute angle, the exterior edges touching, without the crevice; and the light abroad being much stronger than in the room, which has a modern roof and is dark, the portion in contact becoming pellucid, had illumined the vacant space with a dim colour resembling that of amber. We were desired to examine this extraordinary appearance, which the Greeks regarded as a standing miracle, and which he Turks, who could not refute them, beheld with equal astonishment. We found in the gape some coals, which had been brought on a bit of earthen ware for the purpose of burning incense, as we supposed, and also a piece of wax-taper, which probably had been lighted in honour of the saint and author of the wonder; but our Swiss unfortunately carrying his own candle too far in, the smoke blackened the marble, and destroyed the phenomenon.

"The building opposite to the temple has served as a foundation for a square lofty tower of ordinary masonry. The columns of the front are walled up, and the entrance is by a low iron gate in the side. It is now used as a place of confinement for delinquents: but in 1676 was a powder magazine. In the wall of a rampart near it are some fragments of exquisite sculpture, representing the Athenians fighting with the Amazons. These belong to the frieze, which was then standing. In the second century, when Pausanias lived, much of the painting was impaired by age, but some remained, and the subjects were chiefly taken from the Trojan story. The traces are since vanished.

"The pediment of the temple of Victory, with that of the opposite wing, is described as remaining in 1676; but on each building a square tower had been erected. One of the steps in the front of the Propylea was entire, with the four columns, their entablature and the pediment. The portico, to which the five door-ways belonged, consisted of a large square room, roofed with slabs of marble, which were laid on two great marble beams, and sustained by four beautiful columns. These were Ionic, the proportions of this order best suiting that purpose, as taller than the Doric; the reason it was likewise preferred in the pronaos of the temple of Victory. The roof of the Propylea, after standing above 2000 years, was probably destroyed, with all the pediments, by the Venetians in 1687, when they battered the castle in front, firing red-hot bullets, and took it, but were compelled to resign it again to the Turks in the following year. The exterior walls, and in particular a side of the temple of Victory, retain many marks of their hostilities.

11 Temple of Minerva.

"The chief ornament of the acropolis was the Parthenon or great temple of Minerva, a most superb and magnificent fabric. The Persians had burned the edifice which before occupied the site, and was called *hecatompedon*,

Digitized by Google

Athens. *hecatompedon*, from its being 100 feet square. The zeal of Pericles and of all the Athenians was exerted in providing a far more ample and glorious residence for their favourite goddess. The architects were Callicrates and Ictinus; and a treatise on the building was written by the latter and Carpion. It was of white marble, of the Doric order, the columns fluted and without bases, the number in front eight; and adorned with admirable sculpture. The story of the birth of Minerva was carved in the front pediment; and in the back, her contest with Neptune for the country. The beasts of burden, which had conveyed up the materials, were regarded as sacred, and recompensed with pastures; and one, which had voluntarily headed the train, was maintained during life, without labour, at the public expence.

12 Her statue. "The statue of Minerva, made for this temple by Phidias, was of ivory, 26 cubits or 39 feet high. It was decked with pure gold to the amount of 44 talents, so disposed by the advice of Pericles as to be taken off and weighed if required. The goddess was represented standing, with her vestment reaching to her feet. Her helmet had a sphinx for the crest, and on the sides were griffins. The head of Medusa was on her breastplate. In one hand she held her spear, and in the other supported an image of Victory about four cubits high. The battle of the Centaurs and Lapithæ was carved on her sandals; and on her shield, which lay at her feet, the war of the gods and giants, and the battle of the Athenians and Amazons. By her spear was a serpent, in allusion to the story of Erichthonius; and on the pedestal, the birth of Pandora. The Sphinx, the Victory, and Serpent, were accounted eminently wonderful. This image was placed in the temple in the first year of the 87th Olympiad, in which the Peloponnesian war began. The gold was stripped off by the tyrant Lychares, when Demetrius Poliorcetes compelled him to fly. The same plunderer plucked down the golden shields in the acropolis, and carried away the golden Victories, with the precious vessels and ornaments provided for the Panathenæan festival.

"The Parthenon remained entire for many ages after it was deprived of the goddess. The Christians converted it into a church, and the Mahometans into a mosque. It is mentioned in the letters of Crusius, and miscalled the *Pantheon*, and the *temple of the unknown God*. The Venetians under Koningsmark, when they besieged the acropolis in 1687, threw a bomb, which demolished the roof, and setting fire to some powder, did much damage to the fabric. The floor, which is indented, still witnesses the place of its fall. This was the sad forerunner of farther destruction; the Turks breaking the stones, and applying them to the building of a new mosque, which stands within the ruin, or to the repairing their houses and the walls of the fortress. The vast pile of ponderous materials, which lay ready, is greatly diminished; and the whole structure will gradually be consumed and disappear.

13 Temple converted into a mosque. "The temple of Minerva in 1676 was, as Wheeler and Spon assert, the finest mosque in the world, without comparison. The Greeks had adapted the fabric to their ceremonial, by constructing at one end a semicircular recess for the holy tables, with a window; for before it was enlightened only by the door, obscurity being preferred under the heathen ritual, except on festivals, when it yielded to splendid illuminations: the reason, it has been surmised, why temples are commonly found simple and unadorned on the insides. In the wall beneath the window were inserted two pieces of the stone called *phengites* a species of marble discovered in Cappadocia in the time of Nero; and so transparent that he erected with it a temple to Fortune, which was luminous within when the door was shut. These pieces were perforated, and the light which entered was tinged with a reddish or yellowish hue. The picture of the Panagia or Virgin Mary, in mosaic, on the ceiling of the recess, remained; with two jasper columns belonging to the screen, which had separated that part from the nave; and within, a canopy supported by four pillars of porphyry, with Corinthian capitals of white marble, under which the table had been placed; and behind it, beneath the window, a marble chair for the archbishop; and also a pulpit standing on four small pillars in the middle aile. The Turks had white-washed the walls, to obliterate the portraits of saints, and the other paintings, with which the Greeks decorate their places of worship; and had erected a pulpit on the right hand for their iman or reader. The roof was disposed in square compartments; the stones massive; and some had fallen in. It had been sustained in the pronaos by six columns; but the place of one was then supplied by a large pile of rude masonry, the Turks not having been able to fill up the gap more worthily. The roof of the naos was supported by colonnades ranging with the door, on each side; and consisting of 22 pillars below, and of 23 above. The odd one was over the entrance, which by that disposition was left wide and unembarrassed. In the portico were suspended a few lamps, to be used in the mosque at the seasons when the Mussulmans assemble before day-break, or to be lighted up round the minaret, as is the custom during their Ramazan or Lent.

"It is not easy to conceive a more striking object than the Parthenon, though now a mere ruin. The columns within the naos have all been removed: but on the floor may be seen the circles which directed the workmen in placing them; and at the farther end is a groove across it, as for one of the partitions of the cell. The recess erected by the Christians is demolished; and from the rubbish of the ceiling the Turkish boys collect bits of the mosaic, of different colours, which composed the picture. We were told at Smyrna, that this substance had taken a polish, and been set in buckles. This cell is about half demolished; and in the columns which surround it is a large gap near the middle. On the walls are some traces of the paintings. Before the portico is a reservoir sunk in the rock, to supply the Turks with water for the purifications customary on entering their mosques. In it, on the left hand, is the rubbish of the pile erected to supply the place of a column; and on the right, a staircase, which leads out on the architrave, and has a marble or two with inscriptions, but worn so as not to be legible. It belonged to the minaret, which has been destroyed. 14 Magnificent ruin.

"The travellers, to whom we are indebted for an account of the mosque, have likewise given a description 15 Sculpture.

2

Athens.

tion of the sculpture then remaining in the front. In the middle of the pediment was seen a bearded Jupiter, with a majestic countenance, standing, and naked; the right arm broken. The thunderbolt, it has been supposed, was placed in that hand, and the eagle between his feet. On his right was a figure, it is conjectured, of Victory, clothed to the mid-leg; the head and arms gone. This was leading on the horses of a car, in which Minerva sat, young and unarmed; her head-dress, instead of a helmet, resembling that of a Venus. The generous ardour and lively spirit visible in this pair of celestial steeds, was such as bespoke the hand of a master, bold and delicate, of a Phidias or Praxiteles. Behind Minerva was a female figure, without a head, sitting with an infant in her lap; and in this angle of the pediment was the emperor Hadrian with his arm round Sabina, both reclining, and seeming to regard Minerva with pleasure. On the left side of Jupiter were five or six other trunks, to complete the assembly of deities into which he received her. These figures were all wonderfully carved, and appeared as big as life. Hadrian and his consort, it is likely, were complimented by the Athenians with places among the marble gods in the pediment, as benefactors. Both of them may be considered as intruders on the original company; and possibly their heads were placed on trunks, which before had other owners. They still possess their corner, and are easy to be recognised though not unimpaired. The rest of the statues are defaced, removed, or fallen. Morosini was ambitious to enrich Venice with the spoils of Athens; and by an attempt to take down the principal group, hastened their ruin. Nearly twenty years ago, Lord Elgin, then British ambassador at the Porte, procured an order from the Turkish government for the removal of some of these remains. Accordingly a considerable number of the bas-reliefs of the Parthenon were sent to England, along with many other precious antiquities, and they are now deposited in the British Museum.

16 Erectheum.

"Neptune and Minerva, once rival deities, were joint and amicable tenants of the Erectheum, in which was an altar of Oblivion. The building was double, a partition wall dividing it into two temples, which fronted different ways. One was the temple of Neptune Erectheus, the other of Minerva Polias. The latter was entered by a square portico connected with a marble skreen, which fronts towards the Propylea. The door of the cell was on the left hand: and at the farther end of the passage was a door leading down into the Pandroséum, which was contiguous.

17 Temple of Neptune Erectheus.

"Before the temple of Neptune Erectheus was an altar of Jupiter *the supreme*, on which no living thing was sacrificed, but they offered cakes without wine. Within it was the altar of Neptune and Erectheus; and two, belonging to Vulcan and a hero named *Butes*, who had transmitted the priesthood to his posterity, which were called *Butadæ*. On the walls were paintings of this illustrious family, from which the priestess of Minerva Polias was also taken. It was asserted that Neptune had ordained the well of salt water, and the figure of a trident in the rock, to be memorials of his contending for the country. The former, Pausanias remarks, was no great wonder, for other wells of a similar nature were found inland; but this when the south wind blew, afforded the sound of waves.

18 Of Minerva Polias.

"The temple of Minerva Polias was dedicated by all Attica, and possessed the most ancient statue of the goddess. The demi or towns had other deities, but their zeal for her suffered no diminution. The image, which they placed in the acropolis, then the city, was in after ages not only reputed consummately holy, but believed to have fallen down from heaven in the reign of Erichthonius. It was guarded by a large serpent, which was regularly served with offerings of honeyed cakes for his food. This divine reptile was of great sagacity, and attained to an extraordinary age. He wisely withdrew from the temple when in danger from the Medes; and, it is said, was living in the second century. Before this statue was an owl; and a golden lamp. This continued burning day and night. It was contrived by a curious artist, named *Callimachus*, and did not require to be replenished with oil oftener than once a year. A brazen palm-tree, reaching to the roof, received its smoke. Ariston had let the holy flame expire while Sylla besieged him, and was abhorred for his impiety. The original olive-tree, said to have been produced by Minerva, was kept in this temple. When the Medes set fire to the acropolis, it was consumed; but, they asserted, on the following day, was found to have shot up again as much as a cubit. It grew low and crooked, but was esteemed very holy. The priestess of Minerva was not allowed to eat of the new cheese of Attica; and, among her perquisites, was a measure of wheat, and one of barley, for every birth and burial. This temple was again burned when Callias was archon, 24 years after the death of Pericles. Near it was the tomb of Cecrops, and within it Erectheus was buried.

"The ruin of the Erectheum is of white marble; the architectural ornaments of very exquisite workmanship, and uncommonly curious. The columns of the front of the temple of Neptune are standing with the architrave; and also the skreen and portico of Minerva Polias, and with a portion of the cell retaining traces of the partition-wall. The order is Ionic. An edifice revered by ancient Attica, as holy in the highest degree, was in 1676 the dwelling of a Turkish family, and is now deserted and neglected; but many ponderous stones and much rubbish must be removed before the well and trident would appear. The former, at least, might probably be discovered. The portico is used as a powder-magazine; but we obtained permission to dig and examine the outside. The door-way of the vestibule is walled up, and the soil risen nearly to the top of the door-way of the Pandroseum. By the portico is a battery commanding the town, from which ascends an amusing hum. The Turks fire from it, to give notice of the commencement of Ramazan or of their Lent, and of Bairam or the holy-days, and on other public occasions.

"The Pandroseum is a small, but very particular building, of which no satisfactory idea can be communicated by description. The entablature is supported by women called *Caryatides*. Their story is thus related. The Greeks, victorious in the Persian war, jointly destroyed Carya, a city of the Peloponnesus, which had favoured the common enemy. They cut off

Digitized by Google

off the males, and carried into captivity the women, whom they compelled to retain their former dress and ornaments, though in a state of servitude. The architects of those times, to perpetuate the memory of their punishment, represented them, as in this instance, each with a burden on her head, one hand uplifted to it and the other hanging down by her side. The images were in number six, all looking toward the Parthenon. The four in front, with that next to the Propylea, remain, but mutilated, and their faces besmeared with paint. The soil is risen almost to the top of the basement on which they are placed. This temple was open or latticed between the statues; and in it also was a stunted olive-tree, with an altar of Jupiter Herceus standing under it. The Propylea are nearly in a line with the space dividing it from the Parthenon; which disposition, besides its other effects, occasioned the front and flank of the latter edifice to be seen at once by those who approached it from the entrance of the acropolis.

19 Of Jupiter Olympius.

"The ruin of the temple of Jupiter Olympius consists of prodigious columns, tall and beautiful, of the Corinthian order, fluted; some single, some supporting the architraves; with a few massive marbles beneath: the remnant of a vast heap, which only many ages could have consumed and reduced into so scanty a compass. The columns are of very extraordinary dimensions, being about six feet in diameter, and near 60 in height. The number without the cell was 116 or 120. Seventeen were standing in 1676; but a few years before we arrived, one was overturned with much difficulty, and applied to the building a new mosque in the bazar or market-place. This violence was avenged by the bashaw of Negropont, who made it a pretext for extorting from the vaiwode or governor 15 purses; the pillar being, he alleged, the property of their master the Grand Signior. It was an angular column, and of consequence in determining the dimensions of the fabric. We regretted that the fall of this mighty mass had not been postponed until we came, as it would have afforded an opportunity of inspecting and measuring some members which we found far too lofty to be attempted. On a piece of the architrave, supported by a couple of columns, are two parallel walls, of modern masonry, arched about the middle, and again near the top. You are told it has been the habitation of a hermit, doubtless of a stylite; but of whatever building it has been part, and for whatever purpose designed, it must have been erected thus high in air, while the immense ruin of this huge structure was yet scarcely diminished, and the heap inclined so as to render it accessible. It was remarked that two stones of a step in the front had coalesced at the extremity, so that no juncture could be perceived; and the like was discovered also in a step of the Parthenon. In both instances it may be attributed to a concretory fluid, which pervades the marble in the quarry. Some portion remaining in the pieces, when taken green as it were, and placed in mutual contact, it exuded and united them by a process similar to that in a bone of an animal when broken and properly set.

20 Detached pieces of antique sculpture, &c.

"Besides the more stable antiquities, many detached pieces are found in the town, by the fountains, in the streets, the walls, the houses, and churches. Among these are fragments of sculpture; a marble chair or two, which probably belonged to the gymnasia or theatres: a sun-dial at the catholicon or cathedral, inscribed with the name of the maker; and, at the archiepiscopal house close by, a very curious vessel of marble, used as a cistern to receive water, but once serving, it is likely, as a public standard or measure. Many columns occur; with some maimed statues; and pedestals, several with inscriptions, and almost buried in earth. A custom has prevailed, as at Chios, of fixing in the wall, over the gateways and doors of the houses, carved stones, most of which exhibit the funeral supper. In the courts of the houses lie many round stylæ, or pillars, once placed on the graves of the Athenians; and a great number are still to be seen applied to the same use in the Turkish burying grounds before the acropolis. These generally have concise inscriptions, containing the name of the person, and of the town and tribe to which the deceased belonged. Demetrius the Phalerian, who endeavoured to restrain sepulchral luxury, enacted, that no person should have more than one, and that the height should not exceed three cubits. Another species, which resembles our modern head-stones, is sometimes adorned with sculpture, and has an epitaph in verse. We saw a few mutilated Hermæ. These were busts, on long quadrangular bases, the heads frequently of brass, invented by the Athenians. Athens at present contains, according to Dr Clarke, 15,000 inhabitants. According to Mr Hobhouse it contains 1200 or 1300 houses, of which 300 are occupied by Albanians, 400 by Turks, and 500 or 600 by Greeks. The houses are ill built, and the streets narow. Of mosques, churches, and chapels of all sorts, it contains nearly 200. The town lies chiefly on the north and north-west side of the acropolis. The harbour of Piræus is now almost desolate, not a single house being near it, except a wretched hut called the customhouse. A few small vessels resort to it, to trade in oil, the staple production of Attica.

ATHERINA. See ICHTHYOLOGY *Index*.

ATHEROMA, in *Surgery*, a tumor without pain or discoloration of the skin, containing, in a membranous bag, matter resembling pap, intermixed with hard and stony particles. These tumors are usually cured by incision.

ATHERTON, or ATHERSTON, a town of Warwickshire in England, situated on the river Stour, in W. Long. 1. 30. N. Lat. 52. 40. It is a considerable town, and had formerly a monastery; but now is best known by its fair, which is the greatest in England for cheese. Population 2921 in 1811.

ATHESIS, in *Ancient Geography*, a river of the Cisalpine Gaul, which, rising in the Rhetian Alps, in Mount Brenna, in the county of Tirol, runs southwards and washes Tridentum and Verona, which last it divides; and after passing this, bends its course eastwards, in a parallel direction with the Po, and falls into the Adriatic between Fossa Claudia and Philistina: it separated the Euganei, an ancient people, from the Veneti. The people dwelling on it are called *Athesini* (Pliny). Its modern name is the *Adige*.

ATHLETÆ, in antiquity, persons of strength and agility, disciplined to perform in the public games. The word is originally Greek, ἀθλητης: formed from ἀθλος, *certamen*, "combat;" whence also ἀθλον, the prize or reward adjudged the victor.—Under athletæ were comprehended wrestlers, boxers, runners, leapers, throwers

throwers of the disk, and those practised in other exercises exhibited in the Olympic, Pythian, and other solemn sports: for the conquerors wherein there were established prizes.

ATHLETIC HABIT, denotes a strong hale constitution of body. Anciently it signified a full fleshy corpulent state, such as the athletæ endeavoured to arrive at. The athletic habit is esteemed the highest pitch of health; yet it is dangerous, and the next door to disease; since, when the body is no longer capable of being improved, the next alteration must be for the worse. The chief object of the athletic diet, was to obtain a firm, bulky, weighty body; by force of which, more than art and agility, they frequently overpowered their antagonist: hence they fed altogether on dry, solid, and viscous meats. In the earlier days, their chief food was dry figs and cheese, which was called *arida saginatio*, ξηρα τροφη, and Ασκησις διαξηρων ισχαδων. Oribasius, or, as others say, Pythagoras, first brought this into disuse, and substituted flesh in lieu thereof. They had a peculiar bread called κολλητια: They exercised, ate, and drank, without ceasing: they were not allowed to leave off eating when satiated; but were obliged to cram on till they could hold no more; by which means they at length acquired a degree of voracity which to us seems incredible, and a strength proportional. Witness what Pausanias relates of the four celebrated athletæ, Polydamus the Thessalian, Milo the Crotonian, Theagenes the Thasian, and Euthymus the Locrian: The second is said to have carried a bull on his back a considerable way, then to have knocked him down with a blow of his fist, and lastly, as some add, devoured him at a meal.

ATHLONE, a town of Westmeath in Ireland, lying in W. Long. 8. 0. N. Lat. 53. 20. It is situated on both sides of the Shannon, and both parts are united by a strong, high-raised, and well-built bridge, in the middle of which stands a monument, with some figures cut in marble, together with Queen Elizabeth's arms, and some inscriptions declaring the time and the founders of the building. The castle was founded by King John on some land belonging to St Peter's abbey, for which he granted a compensation. It is built on a high-raised round hill, resembling one of the Danish raths or forts. Here were formerly two convents or monasteries. Athlone was formerly strongly fortified, and considered as of very great importance. In the year 1691, a part of the English army under General Ginckle, in the very face of the Irish, who were strongly intrenched on the opposite shore, fording the river, formed, and took possession of the town, not losing more than 50 men in the attack; which is esteemed as bold and successful an enterprise as any recorded in history. There are generally two troops of horse and four companies of foot quartered at Athlone. This town gives the title of *earl* to the family of Ginckle, as a reward for the noble services performed by the general.

ATHOL, the most northern district of Perthshire in Scotland, extending in length 43 miles, and in breadth 30. It is bordered on the north by Badenoch, on the west by Lochaber, on the east and south-east by Mar and Gowrie, on the south by Stratherne and Perth Proper, and on the south-west by Braidalbane.

The country is very rough and mountainous, and contains part of the ancient Caledonian forest; but these mountains are intersected with fruitful valleys. Here are several villages, but no towns of any consideration. The most noted place is Blair Castle, seated on the river Tilt, near its influx into the Garie: a pleasant limpid stream that falls into the Tay. This castle belongs to the duke of Athol, who derives his title from this district, and lives here with great magnificence. In the same neighbourhood we see the pass of Gillicranky, rendered memorable by the battle fought here in the beginning of King William's reign, between that monarch's general M'Kay, and the Highlanders adhering to King James. See GILLICRANKY.

ATHOS, a celebrated mountain of Chalcidia in Macedonia, situated in E. Long. 26. 20. N. Lat. 40. 10. The ancients entertained extravagant notions concerning its height. Mela affirmed it to be so high as to reach above the clouds; and Martianus Capellinus, that it was six miles high. It was a received opinion that the summit of Mount Athos was above the middle region of the air, and that it never rained there; because the ashes left on the altars erected near the summit were always found as they were left, dry and unscattered. But if on many accounts it was famous among the ancients, it is no less so among the moderns. The Greeks, struck with its singular situation and the venerable appearance of its towering ascent, erected so many churches, monasteries, hermitages, &c. upon it, that it became in a manner inhabited by devotees, and from thence received the name of the *Holy Mountain;* which name it still retains, though many of those consecrated works are now decayed. According to the accounts of modern travellers, this mountain advances into the Archipelago, being joined to the continent by an isthmus about half a league in breadth. It is about 30 miles in circumference, and its height is only 3353 feet. It may be travelled over in about three days, and may be seen 90 miles off. There is a fine prospect from the top; but, like all other high mountains, the cold on its summit is excessive. It abounds with many different kinds of plants and trees, particularly the pine and fir. In the valleys grows a plant called *elegia*, whose branches serve to make pens for writing. In short, this mountain is said to be adorned with variety of herbage and evergreens, a multitude of springs and streams, and woods growing near the shore, so as to be one of the most agreeable places in the world.

It is now inhabited by Caloyers, a sort of Greek monks, of the order of St Basil, who never marry, though others of that church do. They abstain from flesh, and fare very hardly, their ordinary meal being olives pickled when they are ripe. They are about 6000 in all, and inhabit 24 large old monasteries, surrounded with high walls for a defence against banditti. They are respected by the Turks, and are not idle like others; but labour in the fields, and in various mechanic arts. The researches of Professor Carlyle for some years have at length completely dissipated the expectations long indulged of finding valuable manuscripts in these monasteries.

Through this mountain, or rather through the isthmus behind it, Xerxes king of Persia is said to have cut

Digitized by Google

cut a passage for his fleet when about to invade Greece. In this work he spent three whole years, and employed in it all the forces on board the fleet. He is also said, before the work was begun, to have written the following insolent and ridiculous letter to the mountain: "Athos, thou proud and aspiring mountain, that liftest up thy head to the very skies, I advise thee not to be so audacious as to put rocks and stones that cannot be cut in the way of my workmen. If thou makest that opposition, I will cut thee entirely down, and throw thee headlong into the sea." The truth of such a canal being cut was long denied, but has at length been proved. Its remains were distinctly seen by Dr Sibthorp, partly filled with water. (See Walpole's Memoirs relating to Turkey, 1817.)

ATHWART, in *Navigation*, is synonymous with across the line of the course.

Athwart the Fore-foot, is a phrase that denotes the flight of a cannon ball from one ship across the course of another, to intercept the latter, and oblige her to shorten sail, that the former may come near enough to examine her.

Athwart-Hause, expresses the situation of a ship, when she is driven by wind or tide, or any other accident, across the fore part of another.

Athwart-Ships, reaching across ships from one side to the other.

ATHY, a town of Ireland, in the county of Kildare, not far from the borders of Queen's county. W. Long. 7. 0. N. Lat. 53. 0. It is situated on the river Barrow; is governed by a sovereign, two bailiffs, and a recorder; and is, alternately with Naas, the assizes town.

ATIBAR, the name by which the inhabitants of the kingdom of Gago in Africa call gold dust; from which word, Europeans, and especially the French, have composed the word *tibir*, which also signifies gold dust among those who trade in that commodity.

ATIGNY, an ancient town of France, in the department of Ardennes, where several of the kings of France had their residence. It is seated on the river *Aisne*, in E. Long. 4. 47. N. Lat. 49. 30.

ATKINS, Sir Robert, lord chief baron of the exchequer, was born in 1621, and educated at the university of Oxford, from whence he removed to the inns of court, and became eminent in the law. He was made knight of the Bath, with many other persons of the first distinction, at the coronation of King Charles II. In 1672, he was appointed one of the judges of common pleas; in which honourable station he continued till 1679, when, foreseeing the troubles that soon after ensued, he thought fit to resign, and retire into the country. In 1689, he was made by King William lord chief baron of the exchequer; and about the same time executed the office of speaker to the house of lords, which had been previously refused by the marquis of Halifax. He distinguished himself by an unshaken zeal for the laws and liberties of his country. He wrote several pieces, which have been collected into one volume 8vo, under the title of *Parliamentary and Political Tracts*. The authors of the Biographia Britannica remark, that whoever inclines to be thoroughly informed of the true constitution of his country, of the grounds and reasons of the revolution, and of the danger of suffering prerogative to jostle law, cannot read a better or plainer book than those tracts of Sir Robert Atkins. He died in 1709, aged 88.

Atkins, *Sir Robert*, son of the preceding, was born in 1646, and was eminent for all the virtues that could adorn an English gentleman. He wrote The Ancient and Present State of Gloucestershire, in one large volume in folio; and died October 29. 1711.

ATKYNS, Richard, was descended from a good family, and was born at Tuffleigh in Gloucestershire in the year 1615. He was educated at Oxford, from whence he removed to Lincoln's-inn, and afterwards distinguished himself by his loyalty to King Charles I. for whom he raised a troop of horse at his own expence. At the Restoration he was made one of the deputy lieutenants of Gloucestershire, and distinguished himself by his attachment to the government. But at length being committed prisoner to the Marshalsea in Southwark for debt, he died there on the 14th of September 1677. He wrote several pieces, particularly A Treatise on the Original and Growth of Printing.

ATLANTIC ocean, that bounded by Europe and Africa on the east, and by America on the west.

ATLANTICA. See Atlantis.

ATLANTIDES, in *Astronomy*, a denomination given to the Pleiades, or seven stars, sometimes also called *Vergilliæ*. They are thus called, as being supposed by the poets to have been the daughters either of Atlas or his brother Hesperus, who were translated into heaven.

ATLANTIS, Atalantis, or Atlantica, an island mentioned by Plato and some others of the ancients, concerning the real existence of which many disputes have been raised. Homer, Horace, and the other poets make two Atlanticas, calling them *Hesperides* and *Elysian Fields*, making them the habitations of the blessed. The most distinct account of this island we have in Plato's Timæus, of which Mr Chambers gives the following abridgment. "The Atlantis was a large island in the western ocean, situated before or opposite to the straits of Gades. Out of this island there was an easy passage into some others, which lay near a large continent exceeding in bigness all Europe and Asia. Neptune settled in this island (from whose son Atlas its name was derived), and divided it among his ten sons. To the youngest fell the extremity of the island, called *Gadir*, which in the language of the country signifies *fertile*, or *abundant in sheep*. The descendants of Neptune reigned here from father to son, for a great number of generations, in the order of primogeniture, during the space of 9000 years. They also possessed several other islands; and passing into Europe and Africa, subdued all Libya as far as Egypt, and all Europe to Asia Minor. At length the island sunk under water; and for a long time afterwards the sea thereabouts was full of rocks and shelves."

Many of the moderns also are of opinion, that the existence of the Atlantis is not to be looked upon as entirely fabulous. Some take it to have been America; and from thence, as well as from a passage in Seneca's Medea, and some other obscure hints, they imagine that the new world was not unknown to the ancients. But allowing this to be the case, the abovementioned continent, which was said to lie beyond Atlantis,

Digitized by Google

lantis, would seem rather to have been the continent of America than Atlantis itself. The learned Rudbeck, professor in the university of Upsal, in a work entitled *Atlantica sive Manheim*, endeavours to prove that Sweden and Norway are the Atlantis of the ancients; but this its situation will by no means allow us to believe. By Kircher it is supposed to have been an island extending from the Canaries quite to the Azores; that it was really swallowed up by the ocean, as Plato asserts; and that these small islands are the shattered remains of it which were left standing.

ATLANTIS, *New*, is the name of a fictitious philosophical commonwealth, of which a description has been given by Lord Bacon. The New Atlantis is supposed to be an island in the South sea, to which the author was driven in a voyage from Peru to Japan. The composition is an ingenious fable, formed after the manner of the Utopia of Sir Thomas More, or Campanella's City of the Sun. Its chief design is to exhibit a model or description of a college, instituted for the interpretation of nature and the production of great and marvellous works, for the benefit of men, under the name of *Solomon's House*, or "the college of the six days work." This much, at least, is finished; and with great beauty and magnificence. The author proposed also a frame of laws, or of the best state or mould of a commonwealth. But this part is not executed.

ATLAS, king of Mauritania, a great astronomer, contemporary with Moses. From his taking observations of the stars from a mountain, the poets feigned him to have been turned into a mountain, and to sustain the heavens on his shoulders. Being an excellent astronomer, and the first who taught the doctrine of the sphere, they tell us that his daughters were turned into stars: seven of them forming the Pleiades, and other seven the Hyades.

ATLAS, a chain of mountains in Africa, lying between the 20th and 25th degree of north latitude, and supposed almost to divide the continent from east to west. They are said to have derived their name from Atlas king of Mauritania, who was a great astronomer. They are greatly celebrated by the ancients on account of their height, insomuch that the above-mentioned king, who is said to have been transformed into a mountain, was feigned to bear up the heavens on his shoulders. We are assured, however, by Dr Shaw, that the part of this chain of mountains which fell under his observation could not stand in competition either with the Alps or Apennines. He tells us, that if we conceive a number of hills, usually of the perpendicular height of 400, 500, or 600 yards, with an easy ascent, and several groves of fruit or forest trees, rising up in a succession of ranges above one another; and that if to this prospect we add now and then a rocky precipice, and on the summit of each imagine a miserable mud-walled village; we shall then have a just idea of the mountains of Atlas.

According to M. Chenier *, this mountain is formed by an endless chain of lofty eminences, divided into different countries, inhabited by a multitude of tribes, whose ferocity permits no stranger to approach. "I have not been able (continues he) to obtain a sufficient knowledge of these mountains to describe them accurately: What Leo Africanus has said of them is very vague; and his account is the less to be regarded at present, as it is now about three centuries since he wrote, and the face of the country has been in that time totally changed. Nothing perhaps would be more interesting to the curiosity of the philosopher, or conduce more to the improvement of our knowledge in natural history, than a journey over Mount Atlas. The climate, though extremely cold in winter, is very healthy and pleasant; the valleys are well cultivated, abound in fruits, and are diversified by forests and plentiful springs, the streams of which uniting at a little distance, form great rivers, and lose themselves in the ocean. According to the reports of the Moors, there are many quarries of marble, granite, and other valuable stone, in these mountains: It is probable there are also mines, but the inhabitants have no idea of these riches; they consider their liberty, which their situation enables them to defend, as the most inestimable of all treasures."

* Hist. of Morocco, i. 13.

ATLAS, in matters of literature, denotes a book of universal geography, containing maps of all the known parts of the world.

ATLAS, in *Commerce*, a silk-satin, manufactured in the East Indies. There are some plain, some striped, and some flowered, the flowers of which are either gold or only silk. There are atlasses of all colours, but most of them false, especially the red and the crimson. The manufacture of them is admirable; the gold and silk being worked together after such a manner as no workman in Europe can imitate; yet they are very far from having that fine gloss and lustre which the French know how to give to their silk stuffs. In the Chinese manufactures of this sort, they gild paper on one side with leaf-gold; then cut it in long slips, and weave it into their silks; which makes them with very little cost, look very rich and fine. The same long slips are twisted or turned about silk threads, so artificially, as to look finer than gold thread, though it be of no greater value.

ATMOSPHERE, a word generally used to signify the whole mass of fluid, consisting of air, aqueous and other vapours, electric fluid, &c. surrounding the earth to a considerable height.

1 Atmosphere composed of two different fluids.

The composition of that part of our atmosphere properly called air, was till lately very much unknown. In former times it was supposed to be a simple, homogeneous and elementary fluid. The experiments of Dr Priestley discovered, that the purest kind of air, which he called *dephlogisticated*, was in reality a compound, and might be artificially produced in various ways. His first conjectures concerning its component parts were, that it consisted of earth, nitrous acid, and phlogiston. Subsequent experiments rendered these conjectures dubious; and at last it was supposed that dephlogisticated air is a pure elementary substance, the vivifying principle to animals, and the acidifying principle throughout all nature. This dephlogisticated air, however, is but a small part of the composition of our atmosphere. According to the most accurate computations, the air we usually breathe is composed of only one-fourth of this dephlogisticated air, or perhaps less; the other three or four parts consisting of what Dr Priestley calls *phlogisticated*, and M. Lavoisier *mephitic air*. This by itself is absolutely noxious, and

Digitized by Google

Atmosphere.

and exceedingly poisonous to animals: though it seems only to be negatively so; for when mixed in a certain proportion with dephlogisticated air, it may be breathed with safety, which could not be if it contained any ingredient absolutely unfriendly to the human constitution. The other part, viz. the pure dephlogisticated air, seems to stand much in the same relation to plants that phlogisticated air does to animals; that is, it would prove poisonous and destroy them if they were to depend upon it entirely for their subsistence; but as they derive their nourishment partly from the air and partly from the soil, it thence happens, that the plants which are set to grow in dephlogisticated air do not die instantly, as animals do in the phlogisticated kind, but remain for some time weak and sickly.

2 Phlogisticated air poisonous to animals, and dephlogisticated air to vegetables.

3 A great quantity of electric fluid contained in the atmosphere.

The other component parts of our atmosphere are so various, and of such heterogeneous natures, that they do not admit of any kind of definition or analysis, one only excepted, namely, the *electric fluid*. This we know pervades the whole, but appears to be much more copious in the upper than in the lower atmospherical regions. See ELECTRICITY. To measure the absolute quantity of this fluid, either in the atmosphere or any other substance, is impossible. All that we can know on this subject is, that the electric fluid pervades the atmosphere; that it appears to be more abundant in the superior than the inferior regions; that it seems to be the immediate bond of connection between the atmosphere and the water which is suspended in it; and that, by its various operations, the phenomena of hail, rain, snow, lightning, and various other kinds of meteors, are occasioned.

4 Calculations of the height of the atmosphere.

Various attempts have been made to ascertain the height to which the atmosphere is extended all round the earth. These commenced soon after it was discovered, by means of the Torricellian tube, that air is a gravitating substance. Thus it also became known, that a column of air, whose base is a square inch, and the height that of the whole atmosphere, weighs 15 pounds: and that the weight of air is to that of mercury, as 1 to 10,800: whence it follows, that if the weight of the atmosphere be sufficient to raise a column of mercury to the height of 30 inches, the height of the aerial column must be 10,800 times as much, and consequently a little more than five miles high.

It was not, however, at any time supposed, that this calculation could be just; for as the air is an elastic fluid, the upper parts must expand to an immense bulk, and thus render the calculation above related exceedingly erroneous. By experiments made in different countries, it has been found, that the spaces which any portion of air takes up, are reciprocally proportional to the weights with which it is compressed. Allowances were therefore to be made in calculating the height of the atmosphere. If we suppose the height of the whole divided into innumerable equal parts, the density of each of which is as its quantity; and the weight of the whole incumbent atmosphere being also as its quantity; it is evident, that the weight of the incumbent air is everywhere as the quantity contained in the subjacent part; which makes a difference between the weights of each two contiguous parts of air. By a theorem in geometry, where the differences of magnitudes are geometrically proportional to the magnitudes themselves, these magnitudes are in continual arithmetical proportion; therefore, if, according to the supposition, the altitude of the air, by the addition of new parts into which it is divided, do continually increase in arithmetical proportion, its density will be diminished, or (which is the same thing) its gravity decreased, in continual geometrical proportion.

It is now easy, from such a series, by making two or three barometrical observations, and determining the density of the atmosphere at two or three different stations, to determine its absolute height, or its rarity, at any assignable height. Calculations accordingly were made upon this plan; but it having been found that the barometrical observations by no means corresponded with the density which, by other experiments, the air ought to have had, it was suspected that the upper parts of the atmospherical regions were not subject to the same laws with the lower ones. Philosophers therefore had recourse to another method for determining the altitude of the atmosphere, viz. by a calculation of the height from which the light of the sun is refracted, so as to become visible to us before he himself is seen in the heavens. By this method it was determined, that at the height of 45 miles the atmosphere had no power of refraction; and consequently beyond that distance was either a mere vacuum or the next thing to it, and not to be regarded.

5 Height of it determined from the beginning and end of twilight.

This theory soon became very generally received, and the height of the atmosphere was spoken of as familiarly as the height of a mountain, and reckoned to be as well ascertained, if not more so, than the heights of most mountains are. Very great objections, however, which have never yet been removed, arise from the appearances of some *meteors*, like large globes of fire, not unfrequently to be seen at vast heights above the earth (see METEOR). A very remarkable one of this kind was observed by Dr Halley in the month of March 1719, whose altitude he computed to have been between 69 and $73\frac{1}{2}$ English miles; its diameter 2800 yards, or upwards of a mile and a half; and its velocity about 350 miles in a minute. Others, apparently of the same kind, but whose altitude and velocity were still greater, have been observed; particularly that very remarkable one, August 18th, 1783, whose distance from the earth could not be less than 90 miles, and its diameter not less than the former; at the same time that its velocity was certainly not less than 1000 miles in a minute. Fire-balls, in appearance similar to these, though vastly inferior in size, have been sometimes observed at the surface of the earth. Of this kind Dr Priestley mentions one seen on board the Montague, 4th November 1749, which appeared as big as a large millstone, and broke with a violent explosion.

6 Objection from the appearance of meteors.

From analogical reasoning, it seems very probable, that the meteors which appear at such great heights in the air are not essentially different from those which, like the fire-ball just mentioned, are met with on the surface of the earth. The perplexing circumstances with regard to the former are, that at the great heights above mentioned, the atmosphere ought not to have any density sufficient to support flame, or to propagate sound; yet these meteors are commonly succeeded by one or more explosions, nay are sometimes said to be accompanied with a hissing noise as they pass over our heads. The meteor of 1719 was not

 only

Atmosphere.

only very bright, insomuch that for a short space it turned night into day, but was attended with an explosion heard over all the island of Britain, occasioning a violent concussion in the atmosphere, and seeming to shake the earth itself. That of 1783 also, though much higher than the former, was succeeded by explosions; and, according to the testimony of several people, a hissing noise was heard as it passed. Dr Halley acknowledged that he was unable to reconcile these circumstances with the received theory of the height of the atmosphere; as, in the regions in which this meteor moved, the air ought to have been 300,000 times more rare than what we breathe, and the next thing to a perfect vacuum.

In the meteor of 1783, the difficulty is still greater, as it appears to have been 20 miles farther up in the air. Dr Halley offers a conjecture, indeed, that the vast magnitude of such bodies might compensate for the thinness of the medium in which they moved. Whether or not this was the case indeed cannot be ascertained, as we have so few data to go upon; but the greatest difficulty is to account for the brightness of the light. Appearances of this kind are indeed with great probability attributed to electricity, but the difficulty is not thus removed. Though the electrical fire pervades with great ease the vacuum of a common air-pump, yet it does not in that case appear in bright well defined sparks, as in the open air, but rather in long streams resembling the aurora borealis. From some late experiments, indeed, Mr Morgan concludes, that the electrical fluid cannot penetrate a perfect vacuum *. If this is the case, it shows that the regions we speak of are not such a perfect vacuum as can be artificially made; but whether it is or not, the extreme brightness of the light shows that a fluid was present in those regions, capable of confining and condensing the electric matter as much as the air does at the surface of the ground; for the brightness of these meteors, considering their distance, cannot be supposed inferior to that of the brightest flashes of lightning.

* See *Electricity* Index.

7
Density of the air does not always keep pace with its gravity.

This being the case, it appears reasonable to conclude, that what is called the *density* of the air does not altogether keep pace with its gravity. The latter indeed must in a great measure be affected by the vapours, but above all by the quantity of the basis of fixed or dephlogisticated air contained in it: for Mr Kirwan has discovered that the basis of fixed air, when deprived of its elastic principle, is not greatly inferior to gold in specific gravity; and we cannot suppose that of dephlogisticated air to be much less. It is possible, therefore, that pure air, could it be deprived of all the water it contains, might have very little gravity; and as there is great reason to believe that the basis of dephlogisticated air is only one of the constituent parts of water, we see an evident reason why the air ought to become lighter, and likewise less fit for respiration, the higher up we go, though there is a possibility that its density, or power of supporting flame, may continue unaltered.

There are not yet, however, a sufficient number of facts to enable us to determine this question; though such as have been discovered seem rather to favour the above conjecture. Dr Boerhaave was of opinion that the gravity of the air depended entirely on the water it contained; and, by the means of alkaline salts, he was enabled to extract as much water from a quantity of air as was very nearly equivalent to its weight. By the calcination of metals we may extract as much of the basis of dephlogisticated air from a quantity of atmospherical air as is equivalent to the weight of air lost. Were it possible, therefore, to extract the whole of this, as well as all other vapours, and to preserve only the elastic principle, it is highly probable that its gravity would entirely cease. It has been found, by those who have ascended with aerostatic machines, or to the tops of high mountains, that the dephlogisticated air is found to be contained in smaller quantities in the atmosphere of those elevated regions than on the lower grounds. It is also found, that in such situations the air is much drier, and parts with water with much more difficulty, than on the ordinary surface. Salt of tartar, for instance, which at the foot of a mountain will very soon run into a liquid, remains for a long time exposed to the air on the top of it, without showing the least tendency to deliquesce. Nevertheless, it hath never been observed that fires did not burn as intensely on the tops of the highest mountains as on the plains. The matter indeed was put to the trial in the great eruption of Vesuvius in 1779, where, though the lava spouted up to the height of three miles above the level of the sea, the uppermost parts all the while were to appearance as much inflamed as the lowest.

8
Gravity of the upper regions of the atmosphere perhaps diminished by electricity.

The high degree of electricity, always existing in the upper regions of the atmosphere, must of necessity have a very considerable influence on the gravity of any heterogeneous particles floating in it. When we consider the effects of the electric fluid upon light bodies at the surface of the earth, it will readily be admitted, that in those regions where this fluid is very abundant, the gravity of the atmosphere may be much diminished without affecting its density. We know that it is the nature of any electrified substance to attract light bodies; and that, by proper management, they may even be suspended in the air, without either moving up or down for a considerable time. If this is the case with light terrestrial bodies, it cannot be thought very improbable that the aerial particles themselves, i. e. those which we call the basis of dephlogisticated air, and of aqueous or other vapour diffused among them, should be thus affected in the regions where electricity is so abundant. From this cause, therefore, also the gravity of the atmosphere may be affected without any alteration at all being made in its density; and hence may arise anomalies in the barometer hitherto not taken notice of.

9
Absolute height of the atmosphere undetermined.

It appears, therefore, that the absolute height of the atmosphere is not yet determined. The beginning and ending of twilight indeed show, that the height at which the atmosphere begins to refract the sun's light is about 44 or 45 English miles. But this may not improbably be only the height to which the aqueous vapours are carried: for it cannot be thought any unreasonable supposition, that light is refracted only by means of the aqueous vapour contained in the atmosphere; and that where this ceases, it is still capable of supporting the *electric* fire at least as bright and strong as at the surface. That it does extend much higher, is evident from the meteors already mentioned; for all these are undoubtedly carried along with the atmosphere;

Digitized by Google

atmosphere; otherwise that of 1783, which was seen for about a minute, must have been left 1000 miles to the westward, by the earth flying out below it in its annual course round the sun.

10 Of the pressure of the atmosphere.

It has already been mentioned, that the pressure of the atmosphere, when in its mean state, is equivalent to a weight of 15 pounds on every square inch. Hence Dr Cotes computed, that the pressure of the whole ambient fluid upon the earth's surface is equivalent to that of a globe of lead 60 miles in diameter. Hence also it appears, that the pressure upon a human body must be very considerable; for as every square inch of surface sustains a pressure of 15 pounds, every square foot, as containing 144 inches, must sustain a pressure of 2160; and if we suppose a man's body to contain 15 square feet of surface, which is pretty near the truth, he must sustain a weight of 32,400 pounds, or 16 tons, for his ordinary load. By this enormous pressure we should undoubtedly be crushed in a moment, were not all parts of our bodies filled either with air or some other elastic fluid, the spring of which is just sufficient to counterbalance the weight of the atmosphere. But whatever this fluid may be, we are sure that it is just able to counteract the atmospherical gravity and no more; for if any considerable pressure be superadded to that of the air, as by going into deep water, or the like, it is always severely felt, let it be ever so equable. If the pressure of the atmosphere is taken off from any part of the human body, the hand, for instance, when put in an open receiver from whence the air is afterwards extracted, the weight of the atmosphere then discovers itself, and we imagine the hand strongly sucked down into the glass. See PNEUMATICS.

11 Variation of the pressure, and its effects.

In countries at some distance from the equator, the pressure of the atmosphere varies considerably, and thus produces considerable changes on many terrestrial bodies. On the human body the quantity of pressure sometimes varies near a whole ton; and when it is thus so much diminished, most people find something of a listlessness and inactivity about them. It is surprising, however, that the spring of the internal fluid, already mentioned, which acts as a counterpoise to the atmospherical gravity, should in all cases seem to keep pace with it when the pressure is naturally diminished, and even when it is artificially augmented, though not when the pressure is artificially diminished. Thus in that kind of weather when the pressure of the air is least, we never perceive our veins to swell, or are sensible of any inward expansion in our bodies. On the contrary, the circulation is languid, and we seem rather to be oppressed by a weight.

12 Of difficulty of respiration on the tops of mountains.

Even in going up to the tops of mountains, where the pressure of the atmosphere is diminished more than three times what it usually is on the plain, no such appearances are observed. Some travellers indeed have affirmed, that on the tops of very high mountains, the air is so light as to occasion a great difficulty of respiration, and even violent retching and vomiting of blood. It does not appear, however, that these assertions are well founded. Mr Brydone found no inconvenience of this kind on the top of Mount Ætna; nor is any such thing mentioned by Mr Houel, who also ascended this mountain. Sir William Hamilton indeed says, that he did feel a difficulty of respiration, independent of any sulphureous steam. But, on the top of a volcano, the respiration may be affected by so many different causes, that it is perhaps impossible to assign the true one. The French mathematicians, when on the top of a very high peak of the Andes, did not make any complaint of this kind, though they lived there for some time. On the contrary, they found the wind so extremely violent, that they were scarcely able to withstand its force; which seems an argument for at least equal *density* of the atmosphere in the superior as in the inferior regions. Dr Heberden, who ascended to the top of Teneriffe, a mountain higher than Ætna, makes no mention of any difficulty of respiration.

13 M. Saussure's symptoms on the top of Mont Blanc accounted for.

M. Saussure, however, in his journey to the top of Mont Blanc, the highest of the Alps, felt very great uneasiness in this way. His respiration was not only extremely difficult, but his pulse became quick, and he was seized with all the symptoms of a fever. His strength was also exhausted to such a degree, that he seemed to require four times as long a space to perform some experiments on the top of the mountain as he would have done at the foot of it. It must be observed, however, that these symptoms did not begin to appear till he had ascended two miles and a half perpendicular above the level of the sea. The mountain is only about a quarter of a mile higher; and in this short space he was reduced to the situation just mentioned. But it is improbable that so small a difference, even at the end of his journey, should have produced such violent effects, had not some other cause concurred. A cause of this kind he himself mentions, viz. that the atmosphere at the top of the mountain was so much impregnated with fixed air, that lime-water, exposed to it, quickly became covered with a pellicle occasioned by the absorption of that fluid. Now it is known, that fixed air is extremely pernicious to animals, and would bring on symptoms similar to those above mentioned. There is no reason, therefore, to have recourse to the rarity of the atmosphere for solving a phenomenon which may more naturally be accounted for otherwise.

When the pressure of the atmosphere is augmented, by descending, in the diving-bell, to considerable depths in the sea, it does not appear that any inconvenience follows from its increase. Those who sit in the diving-bell are not sensible of any pressure as long as they remain in the air, though they feel it very sensible in going into the water: yet it is certain, that the pressure in both cases is the same: for the whole pressure of the atmosphere, as well as of the water, is sustained by the air in the diving-bell, and consequently communicated to those who sit in it.

But though artificial compression of the air, as well as natural rarefaction, can thus be borne, it is otherwise with artificial rarefaction. Animals in an air-pump show uneasiness from the very first, and cannot live for any time in an atmosphere rarefied artificially even as much as it appeared to be from the barometer on the top of Mont Blanc.

14 Variation of the atmospherical pressure accounted for.

It is not easy to assign the true reason of the variations of gravity in the atmosphere. Certain it is, however, that they take place only in a very small degree within the tropics; and seem there to depend on the heat of the sun, as the barometer constantly sinks near half an inch every day, and rises again to its former

station

Atmosphere.

station in the night time. In the temperate zones the barometer ranges from 28 to near 31 inches, by its various altitudes showing the changes that are about to take place in the weather. If we could know, therefore, the latent causes by which the weather is influenced, we should likewise certainly know those by which the gravity of the atmosphere is affected. In general they may be reduced to two, viz. an emission of latent heat from the vapour contained in the atmosphere, or of electric fluid from the same, or from the earth. To one or both of these causes, therefore, may we ascribe the variations of the gravity of the atmosphere; and we see that they both tend to produce the same effect with the solar heat in the tropical climates, viz. to rarefy the air, by mixing with it or setting loose a non-gravitating fluid, which did not act in such large proportion in any particular place before. No doubt, the action of the latent heat and electric fluid is the same in the torrid as in the temperate zones: but in the torrid zone the solar heat and excessive evaporation counteract them; so that whatever quantities may be discharged by the excessive deluges of rain, &c. which fall in those countries, they are instantly absorbed by the abundant fluid, and are quickly ready to be discharged again; while, in the temperate zones, the air becomes sensibly lighter, as well as warmer, by them for some time before they can be absorbed again.

15
Variation of the heat and cold of the atmosphere.

The variations of heat and cold to which the atmosphere is subject, have been the subject of much speculation. In general they seem to depend entirely upon the light of the sun reflected into the atmosphere from the earth; and where this deflection is deficient, even though the light should be present ever so much, the most violent degrees of cold are found to take place. Hence, on the tops of mountains, the cold is generally excessive, though by reason of the clearness of the atmosphere the light of the sun falls upon them in greater quantity than it can do on an equal space on the plain. In long winding passages also, such as the caverns of Ætna and Vesuvius, where the air has room to circulate freely, without any access of the sun, the cold is scarcely tolerable; whence the use of these for cooling liquors, preserving meat, &c.

16
Lambert and De Luc's reasons for the cold on the tops of mountains.

The coldness of the atmosphere on the tops of mountains has been ascribed by M. Lambert and De Luc, to the igneous fluid, or elementary fire, being more rare in those elevated situations than on the plains. M. Lambert is of opinion that it is rarefied above by the action of the air, and that below it is condensed by its own proper weight. He considers fire as a fluid in motion, the parts of which are separable, and which is rarefied when its velocity is accelerated. He does not decide with regard to the identity of fire and light, though he seems inclined to believe it. M. de Luc compares elementary fire to a continuous fluid, whose parts are condensed by being mutually compressed. He denies that fire and light are the same; and maintains that the latter is incapable, by itself, of setting fire to bodies, thought it does so by putting in motion the igneous fluid they contain; and that it acts with more force near the earth than at a distance from its surface, by reason of this fluid, which he calls a *heavy* and *elastic* one, being more condensed there than at a greater height.

17
M. Saussure's account.

M. Saussure, in treating of this subject in his account of the Alps, does not consider fire as a fluid so free and detached as to be able either to ascend with rapidity by its specific levity, or to condense itself sensibly by its proper weight. He supposes it to be united to bodies by so strict an affinity, that all its motions are determined, or at least powerfully modified, by that affinity. As soon therefore as fire, disengaged by combustion or by any other cause, endeavours to diffuse itself, all the bodies that come within the sphere of its activity endeavour to attract it; and they absorb such quantities of it as are in the direct ratio of their affinities with it, or in the inverse ratio of what is necessary for their equilibrium with the surrounding bodies. Now it does not appear that in this distribution the situation of places, with regard to the horizon, has any other influence than what they receive from the different currents produced by the dilatation of the air, and by the levity which that dilatation produces. The ascent of flame, smoke, &c. or of air heated in any way, persuaded the ancients that fire is possessed of absolute levity, by which it had a tendency to mount upwards. "But these effects (says he) are owing either to the levity of the fluid which constitutes flame, or to that of air dilated by heat; and not to the levity of the igneous fluid. I am, however, sufficiently convinced, that this fluid is incomparably lighter than air, though I do not believe that it possesses the power of ascending in our atmosphere by virtue of its levity alone.

18
Mr Bouguer's reasons for the cold on the top of the Andes.

"The celebrated Bouguer has demonstrated, by principles the most simple, and most universally adopted, that it is not necessary, in order to account for the diminution of heat on mountains, to have recourse to hypotheses that are at best doubtful. The following is his explanation of what was felt on the mountains of Peru.

"It was proper, in order to explain this subject, to insist on the short duration of the sun's rays, which cannot strike the different sides of mountains but for a few hours, and even this not always. A horizontal plain, when the sun is clear, is exposed at mid-day to the perpendicular and undiminished action of these rays, while they fall but obliquely on a plain not much inclined, or on the sides of a high pile of steep rocks. But let us conceive for a moment an insulated point, half the height of the atmosphere, at a distance from all mountains, as well as from the clouds which float in the air. The more a medium is transparent, the less heat it ought to receive by the immediate action of the sun. The free passage which a very transparent body allows to the rays of light, shows that its small particles are hardly touched by them. Indeed what impression could they make on it, when they pass through almost without obstruction? Light, when it consists of parallel rays, does not by passing through a foot of free atmospheric air, near the earth, lose an hundred thousandth part of its force. From this we may judge how few rays are weakened, or can act on this fluid, in their passage through a stratum of the diameter not of an inch or a line, but of a particle. Yet the subtility and transparency are still greater at great heights, as was obvious on the Cordilleras, when we looked at distant objects. Lastly, the grosser air is heated below by the contact or neighbourhood of bodies of greater density than itself, which it surrounds, and

Digitized by Google

and on which it rests; and the heat may be communicated by little and little to a certain distance. The inferior parts of the atmosphere by this means contract daily a very considerable degree of heat, and may receive it in proportion to its density or bulk. But it is evident that the same thing cannot happen at the distance of a league and a half or two leagues above the surface of the earth, although the light there may be something more active. The air and the wind therefore must at this height be extremely cold, and colder in proportion to the elevation.

"Besides, the heat necessary to life is not merely that which we receive every instant from the sun. The momentary degree of this heat corresponds to a very small part of that which all the bodies around us have imbibed, and by which ours is chiefly regulated. The action of the sun only serves to maintain nearly in the same state the sum of the total heat, by repairing through the day the loss it sustains through the night, and at all times. If the addition be greater than the loss, the total heat will increase, as it happens in summer, and it will continue to accumulate in a certain degree; but for the reasons already given, this accumulation cannot be very great on the top of a mountain, where the summit, which rises high, is never of great bulk. The lowest state of the thermometer in every place is always in proportion to the heat acquired by the soil; and that being very small on the top of a mountain, the quantity added to it by the sun during the day must be comparatively greater; and the accumulated heat will be more in a condition to receive increase in proportion to its distance from the degree which it cannot pass.

"Another particular observable on all the high places of the Cordilleras, and which depends on the same cause, is, that when we leave the shade, and expose ourselves to the sunshine, we feel a much greater difference than we do here in our fine days when the weather is temperate. Every thing contributes at Quito to make the sun exceedingly powerful: a single step from an exposed place to the shade gives the sensation of cold: this would not be the case if the quantity of heat acquired by the soil were more considerable. We now also see why the same thermometer, put first into the shade and then in the sun, does not undergo the same changes at all times and in all places. In the morning, upon Pichincha, this instrument is generally a few degrees below the freezing point, which may be reckoned the natural temperature of the place; but when during the day we expose it to the sun, it is easy to imagine that the effect must be great, and much more than double in whatever way it is measured."

This theory is adopted by M. Saussure, who adds the following fact to prove that the action of the sun's rays, considered abstractedly and independent of any extrinsic source of cold, is as great on mountains as on plains; viz. that the power of burning lenses and mirrors is the same at all heights. To ascertain this fact, our author procured a burning-glass so weak that at Geneva it would just set fire to tinder. This he carried, with some of the same tinder, to the top of the mountain Saleve (a height of 3000 feet); where it not only produced the same effect, but apparently with greater facility than on the plain. Being persuaded, then, that the principal source of cold on the tops of high mountains is their being continually surrounded with an atmosphere which cannot be much heated either by the rays of the sun on account of its transparency, or by the reflection of them from the earth by reason of its distance, he wished to know, whether the direct solar rays on the top of a high mountain had the same power as on the plain, while the body on which they acted was placed in such a manner as to be unaffected by the surrounding air. For this purpose he instituted a set of experiments, from which he drew the following conclusions, viz. that a difference of 777 toises in height diminishes the heat which the rays of the sun are able to communicate to a body exposed to the external air, 14° of the thermometer; that it diminishes the heat of a body partially exposed, only 6°; and that it augments by 1° the heat of a third body completely defended from the air.

19 Burning-glasses equally powerful on the tops of mountains as on plains.

20 Atmosphere every where counteracts the heat of the sun.

Hence it appears that the atmosphere, though so essentially necessary to the support of fire, is somehow or other the greatest antagonist of heat, and most effectually counteracts the operation of the solar rays in producing it. This power it seems to exert at all distances, at the surface as well as in the higher regions. From some experiments made by M. Pictet it appears, that even in places exposed to the rays of the sun, the heat, at five feet distance from the ground, is greater only by one or two degrees than at 50 feet above the surface, though the ground was at that time 15 or 20° warmer than the air immediately in contact with it. Inconsiderable as this difference is, however, it does not hold as we go higher up; for if it did, the cold on the top of the mountain of Saleve, which is 3000 feet above the level of the lake of Geneva, would be 60° greater than at the foot of it; whereas in reality it is only 10°. In the night-time the case is reversed; for the stratum of air at five feet from the ground, was found by M. Pictet to be colder than at 50. Besides this, different strata of the atmosphere are found to possess very different and variable degrees of cold, without any regard to their situation high up or low down. In the year 1780, Dr Wilson of Glasgow found a very remarkable cold existing close to the surface of the ground; so that the thermometer, when laid on the surface of the snow, sunk many degrees lower than one suspended 24 feet above it. It has been likewise observed, that in clear weather, though the surface of the earth be then most liable to be heated by the sun, yet after that is set, and during the night, the air is coldest near the ground, and particularly in the valleys. Experiments on this subject were made for a whole year by Mr James Sex, who has given an account of them in the 78th volume of the Philosophical Transactions. He suspended thermometers (constructed in such a manner as to show the true maximum and minimum of heat that might take place in the observer's absence) in a shady northerly aspect, and at different heights in the open air. One of these was placed at the height of 9 feet, and the other at that of 220 from the ground; and the observations were continued, with only a few days omission, from July 1784 to July 1785. The greatest variations of heat were in the months of October and June; in the former the thermometers generally differed most in the night, and in the latter mostly in the day. From the 25th to the

21 Is colder very near the surface of the ground than at some distance.

22 Mr Sex's experiments on this subject.

28th

28th of October, the heat below, in the night-time, exceeded in a small degree the heat above; at which time there was frequent rain mingled with hail. From the 11th to the 14th, and also on the 31st, there was no variation at all; during which time likewise the weather was rainy; all the rest of the month proving clear, the air below was found colder than that above, sometimes by nine or ten degrees. In the month of June, the greatest variations took place from the 11th to the 15th, and from the 25th to the 30th; and at both these times there appeared to be two currents of wind, the upper from the south-west and the lower from the north-east. Sometimes these were rendered visible by clouds, in different strata, moving in different directions; and sometimes by clouds moving in a contrary direction to a very sensible current of air below. On cloudy nights the lowest thermometer sometimes showed the heat to be a degree or two greater than the upper one; but in the day-time the heat below constantly exceeded that above more than in the month of October.

To determine whether the nocturnal refrigeration was augmented by a nearer approach to the earth, two thermometers were placed in the midst of an open meadow, on the bank of the river near Canterbury. One was placed on the ground, and the other only six feet above it. The thermometer, at six feet distance from the ground, agreed nearly with the former at nine feet; but the nocturnal variations were found to correspond entirely with the clearness or the cloudiness of the sky; and though they did not always happen in proportion to their respective altitudes, yet when the thermometers differed in any respect, that on the ground always indicated the greatest degree of cold.

The difference between these two thermometers, at the small distance of six feet from each other, being found no less than three degrees and a half, the number of thermometers in the meadow was augmented to four. One was sunk in the ground, another placed just upon it, and the third suspended at three feet above it. Three others were placed on a rising ground where the land was level with the cathedral tower, and about a mile distance from it. One of these was likewise sunk in the ground, another placed just upon it, and a third suspended six feet above it. With these seven thermometers, and the two first mentioned, which were placed in the city, he continued his observations for 20 days; but as the weather happened to be cloudy during the whole of that space, excepting for seven or eight days, no considerable variation happened excepting on these days. The result of the experiments was, that the cold was generally greater in the valley than on the hill; but the variations between the thermometers on the ground and those six feet above them, were often as great on the hill as in the valley.

Thus it was perceived that a difference of temperature took place at the distance of only three feet from the ground; but the length of the thermometers hitherto made use of rendered it impossible to make any experiment at a smaller distance. Two new ones, therefore, were formed by bending down the large tube, the body or bulb of the thermometer, to a horizontal position, while the stem remained in a vertical one; by which method the temperature might be observed to the distance of a single inch. Sometimes, in clear weather, these two horizontal thermometers were placed in the open air, one within an inch of the ground, and the other nine inches above it. When the variation among the other thermometers was considerable, a difference was likewise perceived between these; the lower one sometimes indicating more than two degrees less heat than the upper one, though placed so near each other.

23 His conclusions from these experiments.

From these experiments, Mr Sex concludes, that a greater diminution of heat frequently takes place near the earth in the night-time than at any altitude in the atmosphere within the limits of his inquiry, that is, 220 feet from the ground; and at such times the greatest degrees of cold are always met with nearest the surface of the earth.

This is a constant and regular operation of nature under certain circumstances and dispositions of the atmosphere, and takes place at all seasons of the year; and this difference never happens in any considerable degree but when the air is still, and the sky perfectly unclouded. The moistest vapour, as dews and fogs, did not at all impede, but rather promote, the refrigeration. In very severe frosts, when the air frequently deposites a quantity of frozen vapour, it is commonly found greatest; but the excess of heat which in the day-time was found at the lowest station in summer, diminished in winter almost to nothing.

24 Mr Darwin's experiments on cold produced by the rarefaction of air.

It has been observed, that a thermometer, included in a receiver, always sinks when the air begins to be rarefied. This has been thought to arise, not from any degree of cold thus produced, but from the sudden expansion of the bulb of the thermometer, in consequence of the removal of the atmospherical pressure: But from some late experiments related, Phil. Trans. vol. lxxviii. by Mr Darwin, it appears that the atmosphere always becomes warm by compression, and cold by dilatation from a compressed state. These experiments were,

1. The blast from an air-gun was repeatedly thrown upon the bulb of a thermometer, and it uniformly sunk it about two degrees. In making this experiment, the thermometer was firmly fixed against a wall, and the air-gun, after being charged, was left for an hour in its vicinity, that it might previously lose the heat it had acquired in the act of charging; the air was then discharged in a continued stream on the bulb of the thermometer, with the effect already mentioned.

2. A thermometer was fixed in a wooden tube, and so applied to the receiver of an air-gun, that, on discharging the air by means of a screw pressing on the valve of the receiver, a continued stream of air, at the very time of its expansion, passed over the bulb of the thermometer. This experiment was four times repeated, and the thermometer uniformly sunk from five to seven degrees. During the time of condensation there was a great difference in the heat, as perceived by the hand, at the two ends of the condensing syringe: that next the air-globe was almost painful to touch; and the globe itself became hotter than could have been expected from its contact with the syringe. "Add to this (says Mr Darwin), that in exploding an air-gun the stream of air always becomes visible, which is owing

Digitized by Google

owing to the cold then produced, precipitating the vapour it contained; and if this stream of air had been previously more condensed, or in greater quantity, so as not instantly to acquire heat from the common atmosphere in its vicinity, it would probably have fallen in snow.

3. A thermometer was placed in the receiver of an air-pump, and the air being hastily exhausted, it sunk two or three degrees; but after some minutes regained its former station. The experiment was repeated with a thermometer open at the top, so that the bulb could not be affected by any diminution of the external pressure; but the result was the same. Both during exhaustion and re-admission of the air into the receiver, a steam was regularly observed to be condensed on the sides of the glass; which, in both cases, was in a few minutes re-absorbed, and which appeared to be precipitated by being deprived of its heat by the expanded air.

4. A hole, above the size of a crow-quill, was bored into a large air-vessel placed at the commencement of the principal pipe of the water-works of Derby. There are four pumps worked by a water-wheel, the water of which is first thrown into the lower part of this air-vessel, and rises from thence to a reservoir about 35 or 40 feet above the level; so that the water in this vessel is constantly in a state of compression. Two thermometers were previously suspended on the leaden air-vessel, that they might assume the temperature of it, and as soon as the hole above mentioned was opened, had their bulbs applied to the stream of air which issued out; the consequence of which was, that the mercury sunk some degrees in each. This sinking of the mercury could not be ascribed to any evaporation of moisture from their surfaces, as it was seen both in exhausting and admitting the air into the exhausted receiver mentioned in the last experiment, that the vapour which it previously contained was deposited during its expansion.

5. There is a curious phenomenon observed in the fountain of Hiero, constructed on a very large scale, in the Chemniscensian mines in Hungary. In this machine the air, in a large vessel, is compressed by a column of water 260 feet high: a stop-cock is then opened: and, as the air issues with great vehemence, and in consequence of its previous condensation becomes immediately much expanded, the moisture it contains is not only precipitated, as in the exhausted receiver above mentioned, but falls down in a shower of snow, with icicles adhering to the nose of the cock. See Phil. Trans. vol. lii.

25
His conclusions with regard to cold on the tops of mountains.

From this phenomenon, as well as the four experiments above related, Mr Darwin thinks "there is good reason to conclude, that in all circumstances where air is mechanically expanded, it becomes capable of attracting the fluid matter of heat from other bodies in contact with it.

"Now (continues he), as the vast region of air which surrounds our globe is perpetually moving along its surface, climbing up the sides of mountains, and descending into the valleys; as it passes along, it must be perpetually varying the degree of heat according to the elevations of the country it traverses: for in rising to the summits of mountains, it becomes expanded, having so much of the pressure of the superincumbent atmosphere taken away; and when thus expanded, it attracts or absorbs heat from the mountains in contiguity with it; and, when it descends into the valleys, and is compressed into less compass, it again gives out the heat it has acquired to the bodies it comes in contact with. The same thing must happen to the higher regions of the atmosphere, which are regions of perpetual frost, as has lately been discovered by the aerial navigators. When large districts of air, from the lower parts of the atmosphere, are raised two or three miles high, they become so much expanded by the great diminution of the pressure over them, and thence become so cold, that hail or snow is produced by the precipitation of the vapour: and as there is, in these high regions of the atmosphere, nothing else for the expanded air to acquire heat from after it has parted with its vapour, the same degree of cold continues, till the air, on descending to the earth, acquires its former state of condensation and of warmth.

"The Andes, almost under the line, rests its base on burning sands; about its middle height is a most pleasant and temperate climate covering an extensive plain, on which is built the city of Quito; while its forehead is encircled with eternal snow, perhaps coeval with the mountain. Yet, according to the accounts of Don Ulloa, these three discordant climates seldom encroach much upon each other's territories. The hot winds below, if they ascend, become cooled by their expansion; and hence they cannot affect the snow upon the summit; and the cold winds that sweep the summit, become condensed as they descend, and of temperate warmth before they reach the fertile plains of Quito."

26
Difficulties still remain on the subject.

Notwithstanding all these explanations, however, several very considerable difficulties remain with regard to the heat and cold of the atmosphere. That warm air should always ascend; and thus, when the source of heat is taken away by the absence of the sun, that the stratum of atmosphere lying immediately next to the earth should be somewhat colder than that which lies a little farther up; is not at all to be wondered at. We have an example somewhat similar to this in the potter's kiln; where, after the vessels have been intensely heated for some time, and the fire is then withdrawn, the cooling always begins at bottom, and those which stand lowermost will often be quite black, while all the upper part of the furnace and the vessels next to it are of a bright red. It doth not, however, appear why such degrees of cold should take place at the surface of the earth as we sometimes meet with. It is, besides, no uncommon thing to meet with large strata in the upper regions of the atmosphere, remarkable for their cold, while others are warmer than those at the surface; as we have been assured by the testimony of several aerial navigators. It is also difficult to see why the air which has once ascended, and become rarefied to an extreme degree, should afterwards descend among a denser fluid of superior gravity, though indeed the atmospherical currents by which this fluid is continually agitated may have considerable effect in this way. See the article WINDS.

pour, &c. For the cause of the elasticity of the atmosphere, see Elasticity; and for an explanation of its various operations, see Meteorology. See also the articles Atmometer, Climate, Dew, and Meteorology, in the Supplement.

The uses of the atmosphere are so various, that it is impossible to enumerate them. One of the most essential is its power of giving life to vegetables, and supporting that of all animated beings. For the latter purpose, however, it is not in all places equally proper: we shall therefore conclude this article with some remarks on

27 Of the salubrity of the atmosphere.

The Salubrity of the Atmosphere.—The air on the tops of mountains is generally more salubrious than that in pits. Dense air indeed is always more proper for respiration than such as is more rare; yet the air on mountains, though much more rare, is more free from phlogistic vapours than that of pits. Hence it has been found, that people can live very well on the tops of mountains where the barometer sinks to 15 or 16 inches. M. de Saussure, in his journey upon the Alps, having observed the air at the foot, on the middle, and on the summits of various mountains, observes, that the air of the very low plains seems to be the least salubrious; that the air of very high mountains is neither very pure, nor, upon the whole, seems so fit for the lives of men, as that of a certain height above the level of the sea, which he estimates to be about 200 or 300 toises, that is, about 430 or 650 yards.

Dr White, in the 68th volume of the Phil. Trans. giving an account of his experiments on air made at York, says, that the atmospherical air was in a very bad state, and indeed in the worst he had ever observed it, the 13th of September 1777; when the barometer stood at 30.30, the thermometer at 69°; the weather being calm, clear, and the air dry and sultry, no rain having fallen for above a fortnight. A slight shock of an earthquake was perceived that day.

The air of a bed-room at various times, viz. at night, and in the morning after sleeping in it, has been examined by various persons; and it has been generally found, that after sleeping in it the air is less pure than at any other time. The air of privies, even in calm weather, has not been found to be so much phlogisticated as might have been expected, notwithstanding its disagreeable smell.

From this and other observations, it is thought that the exhalations of human excrements are very little if at all injurious, except when they become putrid, or proceed from a diseased body; in which case they infect the air very quickly.

28 Dr Ingenhousz's experiments.

Dr Ingenhousz, soon after he left London, sent an account of his experiments made in the year 1779 upon the purity of the air at sea and other parts; which account was read at the Royal Society the 24th of April 1780, and inserted in the 70th vol. of the Phil. Trans. His first observations were made on board a vessel in the mouth of the Thames, between Sheerness and Margate, where he found that the air was purer than any other sort of common air he had met with before. He found that the sea-air taken farther from the land, viz. between the English coast and Ostend, was not so pure as that tried before; yet this inferior purity seems not to take place always. The Doctor's general observations, deduced from his numerous experiments, are, "That the air at sea and close to it, is in general purer, and fitter for animal life, than the air on the land, though it seems to be subject to some inconsistency in its degree of purity with that of the land: That probably the air will be found in general much purer far from the land than near the shore, the former being never subject to be mixed with land air."

The Doctor in the same paper transcribes a journal of experiments, showing the degree of purity of the atmosphere in various places, and under different circumstances; which we shall insert here in an abridged manner.

The method used in those experiments was to introduce one measure of common air into the eudiometer tube, and then one measure of nitrous air. The moment that these two sorts of elastic fluids came into contact, he agitated the tube in the water-trough, and then measured the diminution, expressing it by hundredth parts of a measure; thus, when he says, that such air was found to be 130, it signifies, that after mixing one measure of it with one of nitrous air, the whole mixed and diminished quantity was 130 hundredths of a measure, viz. one measure and 30 hundredths of a measure more. 29 His journal of the purity of the air in different places.

"The different degrees of salubrity of the atmosphere, as I found it in general in my country house at Southal-Green, ten miles from London, from June to September, lay between 103 and 109. I was surprised when, upon my return to town to my former lodgings in Pall Mall Court, I found the common air purer in general in October than I used to find it in the middle of summer in the country; for on the 22d of October, at nine o'clock in the morning, the weather being fair and frosty, I found that one measure of common air, and one of nitrous air, occupied 100 subdivisions in the glass-tube, or exactly one measure. That very day, at two o'clock in the afternoon (it being then rainy weather), the air was somewhat altered for the worse. It gave 102. October the 23d, it being rainy weather, the air gave 102. October the 24th, the weather being serene, the air at nine o'clock in the morning gave 100. October the 25th, the sky being cloudy at 11 o'clock in the morning, the air gave 102. At 11 o'clock at night, from five different trials, it gave 105. October the 26th, the weather being very dark and rainy, the air gave 105, as before."

The air at Ostend was found by the Doctor to be generally very good, giving between 94 and 98. At Bruges, the air taken at seven o'clock at night gave 103. November the 8th, the air at Ghent at three in the afternoon gave 103.

November the 12th, the air of Brussels at seven o'clock P. M. gave $105\frac{1}{2}$. The next day, the air of the lower part of the same city gave 106; that of the highest appeared to be purer, as it gave 104: which agrees with the common popular observation. November the 14th, both the air of the highest and that of the lowest part of the city appeared to be of the same goodness, giving 103. The weather was frosty.

November the 22d, the air of Antwerp in the evening gave $109\frac{1}{2}$; the weather being rainy, damp, and cold. November the 23d, the air of Breda gave 106. The next day about 11 o'clock the air gave 102; the weather being fair, cold, and inclining to frost. At seven

Atmosphere.

seven o'clock it gave 103. Next day, being the 25th, the air gave 104; the weather being cold and rainy. The 26th it gave 103; the weather being very rainy, cold, and stormy. November the 27th, the air at the Moordyke close to the water gave $101\frac{1}{2}$; the weather being fair and cold, but not frosty. This spot is reckoned very healthy. November the 28th, the air of Rotterdam gave 103; the weather being rainy and cold. November the 29th, the air of Delft gave 103; the weather being stormy and rainy.

November the 30th, the air of the Hague gave 104; the weather being cold, and the wind northerly. The first of December the weather underwent a sudden change; the wind becoming southerly and stormy, and the atmosphere becoming very hot. The day after, Fahrenheit's thermometer stood at 54°; and the common air being repeatedly and accurately tried gave 116; and that preserved in a glass phial from the preceding day gave 117; and that gathered close to the sea gave 115.

December the 4th, the air of Amsterdam gave 103; the weather being rainy, windy, and cold. The day after, the weather continuing nearly the same, the air gave 102. December the 10th, the air of Rotterdam gave 101; the weather being rainy. December the 12th, being in the middle of the water between Dort and the Moordyke, the air gave 109; the weather being remarkably dark, rainy, and windy. December the 13th, the air of Breda in the morning gave 109; the weather continuing as the day before. And in the afternoon, the air gave $106\frac{1}{2}$; the weather having cleared up. December the 16th, the air of the lower part of the city of Antwerp gave 105, that of the higher part 104; the weather being rainy and temperate. December the 17th, the air of Antwerp gave 107; the weather continuing nearly as in the preceding day. December the 10th, the air of Brussels gave 109; the weather being rainy, windy, and rather warm. December the 21st, the air of Brussels gave 106; the weather being dry and cold. The next day the air and the weather continued the same. December the 23d, the air of Mons gave 104; the weather being rainy and cold. December the 24th, the air near Bouchain gave $104\frac{1}{2}$; the weather being cloudy and cold. December the 25th, the air of Peronne gave $102\frac{1}{2}$; the weather being frosty. December the 26th, the air of Cuvilli gave 103; the weather frosty. December the 27th, the air of Senlis gave $102\frac{1}{2}$; the weather frosty. December the 29th, the air of Paris gave 103; the weather frosty. 1780, January the 8th, the air of Paris gave 100; the weather frosty. January the 13th, the air of Paris gave 98; hard frost.

30 Apparatus with which his experiments were made.

Thus far with Dr Ingenhousz's observations. His apparatus was a very portable one, made by Mr Martin, which in reality is the eudiometer-tube and measure as used by Mr Fontana before he made his last improvement. "The whole of this apparatus (says Dr Ingenhousz) was packed up in a box about ten inches long, five broad, and three and a half high. The glass-tube or great measure, which was 16 inches long, and divided into two separate pieces, lay in a small compass, and could be put together by brass screws adapted to the divided extremities. Instead of a water trough, such as is used commonly, I made use of a small round wooden tub," &c.

31 Fontana's opinions on the subject.

The abbé Fontana, who has made a great number of very accurate experiments upon this subject, gives his opinion in the following words: "I have not the least hesitation in asserting, that the experiments made to ascertain the salubrity of the atmospherical air in various places in different countries and situations, mentioned by several authors, are not to be depended upon; because the method they used was far from being exact (A), the elements or ingredients for the experiment were unknown and uncertain, and the results very different from one another.

"When all the errors are corrected, it will be found that the difference between the air of one country and that of another, at different times, is much less than what is commonly believed; and that the great differences found by various observers are owing to the fallacious effects of uncertain methods. This I advance from experience; for I was in the same error. I found very great differences between the results of the experiments of this nature which ought to have been similar; which diversities I attributed to myself, rather than to the method I then used. At Paris I examined the air of different places at the same time, and especially of those situations where it was most probable to meet with infected air, because those places abounded with putrid substances and impure exhalations; but the differences I observed were very small, and much less than what could have been suspected, for they hardly arrived at one-fiftieth of the air in the tube. Having taken the air of the hill called *Mount Valerian*, at the height of about 500 feet above the level of Paris, and compared it with the air of Paris taken at the same time, and treated alike, I found the former to be hardly one-thirtieth better than the latter.

"In London I have observed almost the same. The air of Islington and that of London suffered an equal diminution by the mixture of nitrous air; yet the air of Islington is esteemed to be much better. I have examined the air of London taken at different heights (for instance, in the street, at the second floor, and at the top of the adjoining houses), and have found it to be of the same quality. Having taken the air at the iron gallery of St Paul's cupola, at the height of 313 feet above the ground, and likewise the air of the stone gallery, which is 202 feet below the other; and having compared these two quantities of air with that of the street adjoining, I found that there was scarce any sensible difference between them, although taken at such different heights.

"In this experiment a circumstance is to be considered, which must have contributed to render the above-mentioned differences more sensible: that is, the agitation of the air of the cupola; for there was felt a pretty brisk wind upon it, which I observed to be stronger and stronger the higher I ascended; whereas in

(A) It is plain that Dr Ingenhousz's method is not implied in this remark; since the Doctor's experiments were made long after, and the method used by him was properly that of Mr Fontana.

Digitized by Google

in the street, and indeed in all the streets I passed through, there was no sensible wind to be felt. This experiment was made at four in the afternoon, the weather being clear. The quicksilver in the barometer at that time was 28,6 inches high, and Fahrenheit's thermometer stood at 54°."

A few lines after, Mr Fontana proceeds thus:—— "From this we clearly see, how little the experiments hitherto published about the differences of common air are to be depended upon. In general, I find that the air changes from one time to another: so that the differences between them are far greater than those of the airs of different countries or different heights. For instance, I have found that the air of London in the months of September, October, and November, 1778, when treated with the nitrous air, gave II, I, 1,90, and II, II, 2,25, which is a mean result of many experiments which differed very little from each other. The 26th day of November last, I found the air, for the first time, much better; for it gave II, I, 1,80, and II, II, 2,20; but the 14th of February 1779, the air gave II, I, 1,69 and II, II, 2,21; from whence it appears, that the air of this 14th of February was better than it had been six months before. There can be no doubt of the accuracy of the experiments, because I compared the air taken at different times with that which I had first used in the month of September, and which I had preserved in dry glass bottles accurately stopped."

This difference in the purity of the air at different times, Mr Fontana farther remarks, is much greater than the difference between the air of the different places observed by him: notwithstanding this great change, as he observed, and as he was informed by various persons, no particular change of health in the generality of people, or facility of breathing, was perceived.

Mr Fontana lastly concludes with observing, that "Nature is not so partial as we commonly believe. She has not only given us an air almost equally good everywhere at every time, but has allowed us a certain latitude, or a power of living and being in health in qualities of air which differ to a certain degree. By this I do not mean to deny the existence of certain kinds of noxious air in some particular places; but only say, that in general the air is good everywhere, and that the small differences are not to be feared so much as some people would make us believe. Nor do I mean to speak here of some vapours and other bodies which are accidentally joined to the common air in particular places, but do not change its nature and intrinsical property. This state of the air cannot be known by the test of nitrous air; and those vapours are to be considered in the same manner as we should consider so many particles of arsenic swimming in the atmosphere. In this case it is the arsenic, and not the degenerated air, that would kill the animals who ventured to breathe it."

ATOCK, the capital of a province of the same name in the north-western part of Hindostan. It is supposed to be the Taxila of the Greeks, and the place where Alexander, Tamerlane, and Nadir Shah crossed the Indus. Formerly nobody was permitted to enter the fortress without a passport from the Mogul himself. E. Long. 71. 55. N. Lat. 33. 59.

ATOM, in *Philosophy*, a particle of matter, so minute, as to admit of no division. Atoms are the *minima naturæ*, and are conceived as the first principles or component parts of all physical magnitude.

ATOMICAL PHILOSOPHY, or the doctrine of atoms, a system which, from the hypothesis that atoms are endued with gravity and motion, accounted for the origin and formation of things. This philosophy was first broached by Moschus, some time before the Trojan war; but was much cultivated and improved by Epicurus; whence it is denominated the *Epicurean Philosophy*. See EPICUREAN.

ATOMIC THEORY, a new species of philosophy, lately introduced into chemistry, to explain the combinations of bodies. See ATOMIC THEORY, SUPPLEMENT.

ATONEMENT. See EXPIATION.

ATONY, in *Medicine*, a defect of tone or tension, or a laxity or debility of the solids of the body.

ATOOI, one of the Sandwich islands, situated in W. Long. 160. 20. N. Lat. 21. 57. Towards the north-east and north-west, the face of the country is rugged and broken; but to the southward it is more even. The hills rise from the sea-side with a gentle acclivity, and at a little distance back are covered with wood. Its produce is the same with that of the other islands of this cluster; but its inhabitants greatly excel the people of all the neighbouring islands in the management of their plantations. In the low grounds, contiguous to the bay wherein our navigators * anchored, these plantations were regularly divided by deep ditches; the fences were formed with a neatness approaching to elegance; and the roads through them were finished in such a manner as would have reflected credit even on an European engineer.

* *Cook's Voyage.*

The island is about 30 miles in length. The road, or anchoring place, which our vessels occupied, is on the south-west side of the island, about two leagues from the west end, before a village named *Wymoa*. This road is somewhat exposed to the trade wind; notwithstanding which defect, it is far from being a bad station, and greatly superior to those which necessity continually obliges ships to use, in countries where the winds are not only more variable but more boisterous; as at Madeira, Teneriffe, the Azores, &c. The landing too is not so difficult as at most of those places; and, unless in very bad weather, is always practicable. The water in the neighbourhood is excellent, and may be conveyed with ease to the boats. But no wood can be cut at any convenient distance, unless the islanders could be prevailed upon to part with the few etooa trees (*cordia sebestina*) that grow about their villages, or a species called *dooe dooe*, which grows farther up the country. The ground from the wooded part to the sea, is covered with an excellent kind of grass, about two feet in height, which sometimes grows in tufts, and appeared capable of being converted into abundant crops of fine hay. But on this extensive space not even a shrub grows naturally.

Besides taro, the sweet potato, and other similar vegetables used by our crews as refreshments, among which were at least five or six varieties of plantains, the island produces bread fruit; which, however, seems to be scarce. There are also a few cocoa palms; some yams; the kappe of the Friendly islands, or Virginian arum; the etooa tree, and odoriferous gardenia, or cape

Digitized by Google

cape jasmine. Our people also met with several trees of the dooe dooe, that bear the oily nuts, which are stuck upon a kind of skewer and made use of as candles. There is a species of sida, or Indian mallow; also the morinda citrifolia, which is here called *none;* a species of convolvulus; the ava or intoxicating pepper, besides great quantities of gourds. These last grow to a very large size, and are of a remarkable variety of shapes, which are perhaps the effect of art.

The scarlet birds, which were brought for sale, were never met with alive; but one small one was seen, about the size of a canary bird, of a deep crimson colour; also a large owl, two brown hawks or kites, and a wild duck. Other birds were mentioned by the natives; among which were the otoo or bluish heron, and the torata, a sort of whimbrel. It is probable that the species of birds are numerous, if we may judge by the quantity of fine yellow, green, and small velvet-like blackish feathers, used upon the cloaks and other ornaments worn by these people. Fish, and other productions of the sea, were, to appearance, not various. The only tame or domestic animals found here were hogs, dogs, and fowls, which were all of the same kind that had been met with at the islands of the South Pacific. There were also small lizards, and some rats.

The inhabitants of Atooi are of the middle size, and in general stoutly made, They are neither remarkable for a beautiful shape nor for striking features. Their visage, particularly that of the women, is sometimes round, but others have it long; nor can it justly be said, that they are distinguished as a nation by any general cast of countenance. Their complexion is nearly of a nut-brown; but some individuals are of a darker hue. They are far from being ugly, and have to all appearance few natural deformities of any kind. Their skin is not very soft nor shining; but their eyes and teeth are, for the most part, pretty good. Their hair in general is straight; and though its natural colour is usually black, they stain it, as at the Friendly and other islands. They are active, vigorous, and most expert swimmers; leaving their canoes upon the most frivolous occasion, diving under them, and swimming to others, though at a considerable distance. Women, with infants at their breast, when the surf was so high as to prevent their landing in the canoes, frequently leaped overboard, and swam to the shore, frequently endangering their little ones. They appeared to be of a frank, cheerful disposition; and are equally free from the fickle levity which characterizes the inhabitants of Otaheite, and the sedate cast which is observable among many of those of Tongataboo. They seem to cultivate a sociable intercourse with each other; and except the propensity to thieving, which is as it were innate in most of the people in those seas, they appeared extremely friendly. It was pleasing to observe with what affection the women managed their infants, and with what alacrity the men contributed their assistance in such a tender office; thus distinguishing themselves from those savages who consider a wife and child as things rather necessary than desirable or worthy of their regard and esteem. From the numbers that were seen assembled at every village in coasting along, it was conjectured that the inhabitants of this island are pretty numerous. Including the straggling houses, it was computed that there might perhaps be, in the whole island, sixty such villages as that near which our ships anchored; and allowing five persons to each house, there would be in every village, five hundred, or thirty thousand upon the island. This number is by no means exaggerated; for there were sometimes three thousand people at least collected upon the beach, when it could not be supposed that above a tenth part of the natives were present.

ATRA Bilis, Black Bile, or Melancholy. According to the ancients it hath a twofold origin: 1st, From the grosser parts of the blood, and this they called the *melancholy humour*. 2d, From yellow bile being highly concocted. Dr Perceival, in his Essays Med. and Exp. suggests, that it is the gall rendered acrid by a stagnation in the gall-bladder, and rendered viscid by the absorption of its fluid parts. Bile in this state discharged into the duodenum, occasions universal disturbance and disorder until it is evacuated: it occasions violent vomiting, or purging, or both; and previous to this the pulse is quick, the head aches, a delirium comes on, a hiccough, intense thirst, inward heat, and a fetid breath. Some describe this kind of bile as being acid, harsh, corroding, and when poured on the ground, bubbling up and raising the earth after the manner of a ferment. Dr Percival says, that by the use of the *infus. senæ limon.* warmed with the *tinct. columb.* he had checked the vomitings occasioned by this matter.

Atra Dies, in antiquity, denotes *a fatal day* whereon the Romans received some memorable defeat. The word literally imports *a black day;* a denomination taken from the colour which is the emblem of death and mourning. Whence the Thracians had a custom of marking all their happy days with white stones or calculi, and their unhappy days with black ones; which they cast, at the close of each day, into an urn. At the person's death the stones were taken out; and from a comparison of the numbers of each complexion, a judgment was made of the felicity or infelicity of his course of life. The *dies atræ* or *atri* were afterwards denominated *nefasti* and *posteri*. Such in particular was the day when the tribunes were defeated by the Gauls at the river Allia, and lost the city; also that whereon the battle of Cannæ was fought; and several others marked in the Roman calendar, as *atræ* or unfortunate.

ATRACTYLIS, Distaff Thistle. See Botany *Index*.

ATRÆTI, in *Medicine*, infants having no perforation in the anus, or persons imperforated in the vagina or urethra.

ATRAGENE. See Botany *Index*.

ATRAPHAXIS. See Botany *Index*.

ATREBATII, a people of Britain, seated next to the Bibroci, in part of Berkshire and part of Oxfordshire. This was one of those Belgic colonies which had come out of Gaul into Britain, and there retained their ancient name. For the Atrebatii were a tribe of the Belgæ, who inhabited the country which is now called Artois. They are mentioned by Cæsar among the nations which composed the Belgic confederacy against him: and the quota of troops which they engaged to furnish on that occasion was 15,000. Comius of Arras was a king or chieftain among the Atrebatii in Gaul in Cæsar's time: and he seems to

Digitized by Google

have possessed some authority, or at least some influence, over our Atrebatii in Britain; for he was sent by Cæsar to persuade them to submission. This circumstance makes it probable that this colony of the Atrebatii had not been settled in Britain very long before that time. The Atrebatii were among those British tribes which submitted to Cæsar: nor do we hear of any remarkable resistance they made against the Romans at their next invasion under Claudius. It is indeed probable, that before the time of this second invasion they had been subdued by some of the neighbouring states, perhaps by the powerful nation of the Cattivellauni, which may be the reason they are so little mentioned in history. Calliva Atrebatum, mentioned in the seventh, twelfth, thirteenth, and fourteenth Itinera of Antoninus, and called by Ptolemy *Calcula*, seems to have been the capital of the Atrebatii; though our antiquaries differ in their sentiments about the situation of this ancient city, some of them placing it at Wallingford, and others at Ilchester.

ATREUS, in fabulous history, the son of Pelops and Hippodamia, and the father of Agamemnon and Menelaus, is supposed to have been king of Mycenæ and Argos about 1228 years before the Christian era. He drove his brother Thyestes from court, for having a criminal commerce with Ærope his wife: but understanding that he had had two children by her, he sent for him again, and made him eat them; at which horrid action, the sun, it is said, withdrew his light.

ATRI, a town of Italy, in the farther Abruzzo, in the kingdom of Naples, with the title of a duchy; it is the see of a bishop, and is seated on a craggy mountain, four miles from the Adriatic sea. E. Long. 13. 8. N. Lat. 42. 45.

ATRIENSES, in antiquity, a kind of servants or officers in the great families at Rome, who had the care and inspection of the atriæ and the things lodged therein.

These are otherwise called atriarii, though some make a distinction between *atrienses* and *atriarii*; suggesting that the latter were an inferior order of servants, perhaps assistants of the atrienses, and employed in the more servile offices of the atrium, as to attend at the door, sweep the area, &c.

The atrienses are represented as servants of authority and command over the rest: they acted as procurators, or agents, of their master, in selling his goods, &c. To their care were committed the statues and images of the master's ancestors, &c. which were placed round the atrium; and which they carried in procession at funerals, &c.

In the villas, or country houses, the atrienses had the care of the other furniture and utensils, particularly those of metal, which they were to keep bright from rust. Other things they were to hang from time to time in the sun, to keep them dry, &c. They were clothed in a short white linen habit, to distinguish them, and prevent their loitering from home.

ATRIP, in nautical language, is applied either to the anchor or sails. The anchor is atrip, when it is drawn out of the ground in a perpendicular direction, either by the cable or buoy-rope. The topsails are atrip, when they are hoisted up to the mast-head, or to their utmost extent.

ATRIPLEX, ORACH, or ARACH. See BOTANY *Index*.

ATRIUM, in ecclesiastical antiquity, denotes an open place or court before a church, making part of what was called the *narthex* or *antetemple*.

The atrium in the ancient churches was a large area or square plat of ground, surrounded with a portico or cloyster, situated between the porch or vestibule of the church and the body of the church.

Some have mistakenly confounded the atrium with the porch or vestibule, from which it was distinct; others with the narthex, of which it was only a part.

The atrium was the mansion of those who were not suffered to enter farther into the church. More particularly, it was the place where the first class of penitents stood to beg the prayers of the faithful as they went into the church.

ATRIUM is also used in the canon law, for the cemetry or churchyard. In this sense we find a law prohibiting buildings to be raised *in atrio ecclesiæ*, except for the clergy: which the glossary explains thus, *id est in cemeterio*, which includes the space of forty paces around a large church, or thirty round a little church or chapel.

ATROPA, DEADLY NIGHTSHADE. See BOTANY *Index*.

Buchanan gives an account of the destruction of the army of Sweno the Dane, when he invaded Scotland, by mixing a quantity of the belladonna berries with the drink which the Scots were, according to a treaty of truce, to supply them with. This so intoxicated the Danes, that the Scots fell upon them in their sleep, and killed the greatest part of them, so that there were scarcely men enough left to carry off their king. There have also been many instances in Britain of children being killed by eating berries of a fine black colour, and about the size of a small cherry, which are no other than those of belladonna. When an accident of this kind is discovered in time, a glass of warm vinegar will prevent the bad effects.

Naturalists tell strange stories of this plant: but setting aside its soporiferous virtue, the modern botanists will scarce warrant any of them, nor even that human figure ordinarily ascribed to its roots, especially since the discovery of the artifice of charlatans in fashioning it, to surprise the credulity of the people.

Moses informs us (Gen. xxx. 14.) that Reuben the son of Leah, being in the field, happened to find mandrakes, which he brought home to his mother. Rachel had a mind to them, and obtained them from Leah, upon condition that she should consent that Jacob should be Leah's bedfellow the night following. The term דודאים, *dudaim*, here made use of by Moses, is one of those words of which the Jews at this day do not understand the true signification. Some translate it *violets*, others *lilies*, or *jessamine*. Junius calls it *agreeable flowers*; Codurquus makes it *truffle*, or *mushroom*; and Calmet will have it to be the *citron*. Those that would support the translation of *mandrakes* plead, that Rachel being barren, and having a great desire to conceive, coveted Leah's mandrakes, it may be presumed, with a view to its prolific virtues. The ancients have given to mandrakes the name of the apples

apples of love, and to Venus the name of *Mandragoritis;* and the emperor Julian, in his epistle to Calixenes, says, that he drinks the juice of mandrakes to excite amorous inclinations.

ATROPHY, in *Medicine*, a disease, wherein the body or some of its parts, does not receive the necessary nutriment, but wastes and decays incessantly. See MEDICINE *Index*.

ATROPOS, in fabulous history, the name of the third of the Parcæ, or Fates, whose business it was to cut the thread of life.

ATTACHMENT, in the *Law of England*, implies the taking or apprehending a person by virtue of a writ or precept. It is distinguished from an *arrest*, by proceeding out of a higher court by precept or writ; whereas the latter proceeds out of an inferior court by precept only. An arrest lies only on the body of a man; whereas an attachment lies often on the goods only, and sometimes on the body and goods. An attachment by writ differs from *distress*, in not extending to lands, as the latter does; nor does a distress touch the body, as an attachment does.

ATTACHMENT out of the Chancery, is obtained upon an affidavit made, that the defendant was served with a subpœna, and made no appearance; or it issues upon not performing some order or decree. Upon the return of this attachment by the sheriff, *quod non est inventus in balliva sua*, another attachment, with a proclamation, issues; and if he still refuses to appear, a commission of rebellion.

ATTACHMENT of the Forest, is one of the three courts held in the forest. The lowest court is called the *court of attachment*, or *wood-mote court;* the mean, *swanmote*, and the highest, the *justice in eyre's seat*. The court of attachments has its name from the verdurers of the forest having no other authority in it, but to receive the attachments of offenders against vert and venison taken by the foresters, and to enroll them, that they may be presented or punished at the next justice in eyre's seat. This attachment is by three means: by goods and chattels; by body, pledges, or mainprize; or by the body only. This court is held every 40 days throughout the year; and is thence called *forty days court*.

Foreign ATTACHMENT, is an attachment of money or goods found within a liberty or city, to satisfy some creditor within such liberty or city. By the custom of London, and several other places, a man can attach money or goods in the hands of a stranger, to satisfy himself.

ATTACK, a violent attempt upon any person or thing, an assault, or the act of beginning a combat or dispute.

ATTACK, in the military art, is an effort made to force a post, break a body of troops, &c.

ATTACK of a Siege, is a furious assault made by the besiegers with trenches, covers, mines, &c. in order to make themselves masters of a fortress, by storming one of its sides. If there are two or three attacks made at the same time, there should be a communication betwixt them. See WAR.

ATTACOTTI, an ancient people of Britain, mentioned by Ammianus Marcellinus and St Jerome, as well as in the *Notitia Imperii*. They are represented as allies and confederates of the Scots and Picts, and therefore probably their neighbours: though their precise situation has not been determined by antiquaries.

ATTAINDER, in *Law*. When sentence of death, the most terrible and highest judgment in our laws, is pronounced, the immediate inseparable consequence by the common law is attainder. For when it is now clear beyond all dispute, that the criminal is no longer fit to live upon the earth, but is to be exterminated as a monster and a bane to human society, the law sets a note of infamy upon him, puts him out of its protection, and takes no farther care of him than barely to see him executed. He is then called *attaint*, *attinctus*, *stained* or *blackened*. He is no longer of any credit or reputation; he cannot be a witness in any court; neither is he capable of performing the functions of another man: for by an anticipation of his punishment, he is already dead in law. This is after judgment: for there is a great difference between a man *convicted* and *attainted;* though they are frequently through inaccuracy confounded together. After conviction only, a man is liable to none of these disabilities: for there is still in contemplation of law a possibility of his innocence. Something may be offered in arrest of judgement: the indictment may be erroneous, which will render his guilt uncertain, and thereupon the present conviction may be quashed: he may obtain a pardon, or be allowed the benefit of clergy; both which suppose some latent sparks of merit, which plead in extenuation of his fault. But when judgment is once pronounced, both law and fact conspire to prove him completely guilty; and there is not the remotest possibility left of any thing to be said in his favour. Upon judgement, therefore, of death, and not before, the attainder of a criminal commences: or upon such circumstances as are equivalent to judgment of death; as judgment of outlawry on a capital crime, pronounced for absconding or fleeing from justice, which tacitly confesses the guilt; and therefore, upon judgment either of outlawry, or of death, for treason or felony, a man shall be said to be attainted.

A person attainted of high treason forfeits all his lands, tenements, and hereditaments; his blood is corrupted, and he and his posterity rendered base; and this corruption of blood cannot be taken off but by act of parliament. *

* See the articles *Forfeiture* and *Corruption* of Blood.

Attainders may be reversed or falsified (i. e. proved to be false) by writ of error, or by plea. If by writ of error, it must be by the king's leave, &c.; and when by plea, it must be by denying the treason, pleading a pardon by act of parliament, &c.

Persons may be attainted by act of parliament.—Acts of attainder of criminals have been passed in several reigns, on the discovery of plots and rebellions, from the reign of King Charles II. when an act was made for the attainder of several persons guilty of the murder of King Charles I. Among acts of this nature, that for attainting Sir John Fenwick, for conspiring against King William, is the most remarkable; it being made to attaint and convict him of high treason on the oath of one witness, just after a law had been enacted, "That no person should be tried or attainted of high treason where corruption of blood is incurred, but by the oath of two lawful witnesses, unless the party confess, stand mute, &c." Stat. 7 and 8 W. III.

Digitized by Google

W. III. cap. 3. But in the case of Sir John Fenwick there was something extraordinary; for he was indicted of treason on the oaths of two witnesses, though but only one could be produced against him on his trial.

ATTAINT, is a writ that lies after judgment against a jury of twelve men that have given false verdict in any court of record, in an action real or personal, where the debt or damages amounted to above 40s. stat. 5 and 34 Edw. III. c. 7. It is called *attaint*, because the party that obtains it endeavours thereby to stain or taint the credit of the jury with perjury, by whose verdict he is grieved.

The jury who are to try this false verdict must be twenty-four, and are called *the grand jury*; for the law wills not that the oath of one jury of twelve men should be attainted or set aside by an equal number, nor by less indeed than double the former. And he that brings the attaint can give no other evidence to the grand jury, than what was originally given to the petit. For as their verdict is now trying, and the question is whether or no they did right upon the evidence that appeared to them, the law adjudged it the highest absurdity to produce any subsequent proof upon such trial, and to condemn the prior jurisdiction for not believing evidence which they never knew. But those against whom it is brought are allowed, in the affirmance of the first verdict, to produce new matter: because the petit jury may have formed their verdict upon evidence of their own knowledge, which never appeared in court; and because very terrible was the judgment which the common law inflicted upon them, if the grand jury found their verdict a false one. The judgment was, 1. That they should lose their *liberam legem*, and become for ever infamous. 2. That they should forfeit all their goods and chattels. 3. That their lands and tenements should be seized into the king's hands. 4. That their wives and children should be thrown out of doors. 5. That their houses should be razed and thrown down. 6. That their trees should be rooted up. 7. That their meadows should be ploughed. 8. That their bodies should be cast into jail. 9. That the party should be restored to all that he lost by reason of the unjust verdict. But as the severity of this punishment had its usual effect, in preventing the law from being executed, therefore by the statute 11 Hen. VII. c. 24. revived by 23 Hen. VIII. c. 3. and made perpetual by 13 Eliz. c. 25. it is allowed to be brought after the death of the party, and a more moderate punishment was inflicted upon attainted jurors: viz. perpetual infamy, and if the cause of action were above 40l. value, a forfeiture of 20l. a-piece by the jurors; or, if under 40l. then 5l. a-piece; to be divided between the king and the party injured. So that a man may now bring an attaint either upon the statute or at common law, at his election; and in both of them may reverse the former judgment. But the practice of setting aside verdicts upon motion, and granting new trials, has so superseded the use of both sorts of attaints, that there is hardly any instance of an attaint later than the 16th century.

ATTAINT, among farriers, a knock or hurt in a horse's leg, proceeding either from a blow with another horse's foot, or from an over-reach in frosty weather, when a horse, being rough shod, or having shoes with long caulkers, strikes his hinder feet against his fore leg.

ATTAINTED, in *Law*, is applied to a person's being under attainder. See ATTAINDER.

ATTALICÆ VESTES, in antiquity, garments made of a kind of cloth of gold. They took the denomination from Attalus, surnamed Philomater, a wealthy king of Pergamus, who was the first, according to Pliny, who procured gold to be wove into cloth.

ATTALUS, the name of several kings of Pergamus. See PERGAMUS.

ATTELABUS. See ENTOMOLOGY *Index*.

ATTENTION, a due application of the ear, or the mind, to any thing said or done, in order to acquire a knowledge thereof. The word is compounded of *ad*, "to," and *tendo*, "I stretch."

Attention of mind is not properly an act of the understanding, but rather of the will, by which it calls the understanding from the consideration of other objects, and directs it to the thing in hand. Nevertheless, our attention is not always voluntary: an interesting object seizes and fixes it beyond the power of controul.

Attention, in respect of hearing, is the stretching or straining of the *membrana tympani*, so as to make it more susceptible of sounds, and better prepared to catch even a feeble agitation of the air. Or it is the adjusting the tension of that membrane to the degree of loudness or lowness of the sound to which we are attentive.

According to the degree of attention, objects make a stronger or weaker impression (A). Attention is requisite even to the simple act of seeing: the eye can take in a considerable field at one look; but no object in the field is seen distinctly but that singly which fixes the attention: in a profound reverie that totally occupies the attention, we scarce see what is directly before us. In a train of perceptions, no particular object makes such a figure as it would do singly and apart; for when the attention is divided among many objects, no particular object is entitled to a large share. Hence the stillness of night contributes to terror, there being nothing to divert the attention.

Horror ubique animos, simul ipsa silentia terrent. Æn.

Zara. Silence and solitude are ev'rywhere!
Through all the gloomy ways and iron doors
That hither lead, nor human face nor voice

Is

(A) Bacon, in his natural history, makes the following observations. "Sounds are meliorated by the intension of the sense, where the common sense is collected most to the particular sense of hearing, and the sight suspended. Therefore sounds are sweeter, as well as greater, in the night than in the day; and I suppose they are sweeter to blind men than to others; and it is manifest, that between sleeping and waking, when all the senses are bound and suspended, music is far sweeter than when one is fully waking."

Digitized by Google

Is seen or heard. A dreadful din was wont
To grate the sense, when enter'd here, from groans
And howls of slaves condemn'd, from clink of chains,
And crash of rusty bars and creaking hinges;
And ever and and anon the sight was dash'd
With frightful faces, and the meagre looks
Of grim and ghastly executioners.
Yet more this stillness terrifies my soul,
Than did that scene of complicated horrors.

Mourning Bride, act v. sc. 3.

In matters of slight importance, attention is mostly directed by will; and for that reason, it is our own fault if trifling objects make any deep impression. Had we power equally to withhold our attention from matters of importance, we might be proof against any deep impression. But our power fails us here: an interesting object seizes and fixes the attention beyond the possibility of controul; and while our attention is thus forcibly attached to one object, others may solicit for admittance; but in vain, for they will not be regarded. Thus a small misfortune is scarcely felt in presence of a greater:

Lear. Thou think'st 'tis much, that this contentious storm
Invades us to the skin: so 'tis to thee:
But where the greater malady is fix'd,
The lesser is scarce felt. Thou'dst shun a bear;
But if thy flight lay tow'rd the roaring sea,
Thou'dst meet the bear i' th' mouth. When the mind's free,
The body's delicate: the tempest in my mind
Doth from my senses take all feeling else,
Save what beats there.

King Lear, act iii. sc. 5.

ATTENUANTS, or ATTENUATING *Medicines*, are such as were supposed to subtilize and break the humours into finer parts; and thus dispose them for motion, circulation, excretion, &c.

ATTENUATION, the act of attenuating; that is, of making any fluid thinner, and less consistent, than it was before. The word is compounded of *ad*, 'to,' and *tenuis*, 'thin.' Attenuation is defined more generally by Chavin, the dividing or separating of the minute parts of any body, which before, by their mutual *nexus* or implication, formed a more continuous mass. Accordingly, among alchemists, we sometimes find the word used for pulverization, or the act of reducing a body into an impalpable powder, by grinding, pounding, the like.

ATTERBURY, DR FRANCIS, son of Dr Lewis Atterbury, was born at Milton in Buckinghamshire, 1662; educated at Westminster; and from thence elected to Christ-church in Oxford, where he soon distinguished himself by his fine genius and turn for polite literature. The year he was made M. A. 1687, he exerted himself in the controversy with the Papists, vindicated Luther in the strongest manner, and showed an uncommon fund of learning, enlivened with great vivacity. In 1690 he married Miss Osborn, a distant relation of the duke of Leeds; a lady of great beauty, but with little or no fortune, who lived at or in the neighbourhood of Oxford.

In Feb. 1690–1, we find him resolved to "bestir himself in his office in the house;" that of censor probably, an officer (peculiar to Christ-church) who presides over the classical exercises; he then also held the catechetical lecture founded by Dr Busby.

About this period it must have been that he took orders, and entered into another scene, and another sort of conversation: for in 1691 he was elected lecturer of St Bride's church in London, and preacher at Bridewell chapel. An academic life, indeed must have been irksome and insipid to a person of his active and aspiring temper. It was hardly possible that a clergyman of his fine genius, improved by study, with a spirit to exert his talents, should remain long unnoticed; and we find that he was soon appointed chaplain to King William and Queen Mary.

The share he took in the controversy against Bentley (about the genuineness of Phalaris's Epistles) is now very clearly ascertained. In one of the letters to his noble pupil, dated "Chelsea 1698 (he says), the matter had cost him some time and trouble. In laying the design of the book, in writing above half of it, in reviewing a good part of the rest, in transcribing the whole, and attending the press (he adds), half a year of my life went away."

"In 1700, a still larger field of activity opened, in which Atterbury was engaged four years with Dr Wake (afterwards archbishop of Canterbury) and others, concerning "the Rights, Powers, and Privileges of Convocations:" in which, however the truth of the question may be supposed to lie, he displayed so much learning and ingenuity, as well as zeal for the interests of his order, that the lower house of convocation returned him their thanks, and the university of Oxford complimented him with the degree of D. D. January 29. 1700, he was installed archdeacon of Totness, being promoted to that dignity by Sir Jonathan Trelawney, then bishop of Exeter. The same year he was engaged, with some other learned divines, in revising an intended edition of the "Greek Testament," with Greek "Scholia," collected chiefly from the fathers, by Mr Archdeacon Gregory. At this period he was popular as preacher at the Rolls chapel; an office which had been conferred on him by Sir John Trevor, a great discerner of abilities, in 1698, when he resigned Bridewell, which he had obtained in 1693. Upon the accession of Queen Anne in 1702, Dr Atterbury was appointed one of her majesty's chaplains in ordinary; and, in October 1704, was advanced to the deanery of Carlisle. About two years after this, he was engaged in a dispute with Mr Hoadly, concerning the advantages of virtue with regard to the present life; occasioned by his sermon, preached August 30. 1706, at the funeral of Mr Thomas Bennet a bookseller. In 1707, Sir Jonathan Trelawney, then bishop of Exeter, appointed him one of the canons residentiaries of that church. In 1709, he was engaged in a fresh dispute with Mr Hoadly, concerning "Passive Obedience;" occasioned by his Latin Sermon, entitled "Concio ad Clerum Londinensem, habita in Ecclesia S. Elphegi." In 1710, came on the famous trial of Dr Sacheverell, whose remarkable speech on that occasion was generally supposed to have been drawn up by our author, in conjunction with Dr Smalridge and Dr Freind. The same year Dr Atterbury was unanimously chosen prolocutor of the lower house of convocation, and had the chief management of

Digitized by Google

Atterbury. of affairs in that house. May 11. 1711, he was appointed by the convocation, one of the committee for comparing Mr Whiston's doctrines with those of the church of England; and in June following, he had the chief hand in drawing up "A Representation of the Present State of Religion." In 1712, Dr Atterbury was made dean of Christ-church, notwithstanding the strong interest and warm applications of several great men in behalf of his competitor Dr Smalridge. The next year saw him at the top of his preferment, as well as of his reputation: for, in the beginning of June 1713, the queen, at the recommendation of Lord Chancellor Harcourt, advanced him to the bishopric of Rochester, with the deanery of Westminster, in commendam; he was confirmed July 4. and consecrated at Lambeth next day.

At the beginning of the succeeding reign, his tide of prosperity began to turn; and he received a sensible mortification presently after the coronation of King George I. when, upon his offering to present his majesty (with a view, no doubt, of standing better in his favour) with the chair of state or royal canopy, his own perquisites as dean of Westminster, the offer was rejected, not without some evident marks of dislike to his person.

During the rebellion in Scotland, when the Pretender's declaration was dispersed, the archbishop of Canterbury, and the bishops in or near London, had published a *Declaration of their abhorrence of the present Rebellion, and an Exhortation to the Clergy and People to be zealous in the discharge of their duties to his majesty King George*: but the bishop of Rochester refused to sign it; and engaged Bishop Smalridge in the same refusal, on account of some reflections it contained against the high church party. He appeared generally among the protestors against the measures of the ministry under the king, and drew up the reasons of the protests with his own hand.

In 1716, we find him advising Dean Swift in the management of a refractory chapter. April 26. 1722, he sustained a severe trial in the loss of his lady; by whom he had four children; Francis, who died an infant; Osborn, student of Christ-church; Elizabeth, who died September 29. 1716, aged 17; and Mary, who had been then seven years married to Mr Morice.

In this memorable year, on a suspicion of his being concerned in a plot in favour of the Pretender, he was apprehended August 24. and committed prisoner to the Tower.

Two officers, the under secretary, and a messenger, went about two o'clock in the afternoon to the bishop's house at Westminster, where he then was, with orders to bring him and his papers before the council. He happened to be in his nightgown when they came in; and being made acquainted with their business, he desired time to dress himself. In the mean time his secretary came in; and the officers went to search for his papers; in the sealing of which the messenger brought a paper, which he pretended to have found in his close stool, and desired it might be sealed up with the rest. His Lordship observing it, and believing it to be a forged one of his own, desired the officers not to do it, and to bear witness that the paper was not found with him. Nevertheless they did it; and though they behaved themselves with some respect to him, they suffered the messengers to treat him in a very rough manner, threatening him, if he did not make haste to dress himself, they would carry him away undrest as he was. Upon which he ordered his secretary to see his papers all sealed up, and went himself directly to the Cock-pit, where the council waited for him. The behaviour of the messengers, upon this occasion, seems to have been very unwarrantable, if what the author of "A Letter to the Clergy of the Church of England," &c. tells us be true, that the persons, directed by order of the king and council to seize his lordship and his papers, received a strict command to treat him with great respect and reverence. However this was, when he came before the council, he behaved with a great deal of calmness, and they with much civility towards him. He had liberty to speak for himself as much as he pleased, and they listened to his defence with a great deal of attention; and, what is more unusual, after he was withdrawn, he had twice liberty to re-enter the council chamber, to make for himself such representations and requests as he thought proper. It is said, that, while he was under examination, he made use of our Saviour's answer to the Jewish council, while he stood before them; "If I tell you, ye will not believe me; and if I also ask you, ye will not answer me, nor let me go." After three quarters of an hour's stay at the Cock-pit, he was sent to the Tower privately, in his own coach, without any manner of noise or observation.

This commitment of a bishop upon a suspicion of high treason, as it was a thing rarely practised since the Reformation, so it occasioned various speculations among the people. Those who were the bishop's friends, and pretended to the greatest intimacy with him, laid the whole odium of the matter upon the ministry. They knew the bishop so well, they said, his love to the constitution, and attachment to the Protestant succession, his professed abhorrence of Popery, and settled contempt of the Pretender, and his caution, prudence, and circumspection, to be such, as would never allow him to engage in an attempt of subverting the government, so hazardous in itself, and so repugnant to his principles; and therefore they imputed all to the malice and management of a great minister of state or two, who were resolved to remove him, on account of some personal prejudices, as well as the constant molestation he gave them in parliament, and the particular influence and activity he had shown in the late election. The friends to the ministry, on the other hand, were strongly of opinion, that the bishop was secretly a favourer of the Pretender's cause, and had formerly been tampering with things of that nature, even in the queen's time, and while his party was excluded from power; but upon their re-admission, had relinquished that pursuit, and his confederates therein, and became a good subject again. They urged, that the influence which the late duke of Ormond had over him, assisted by his own private ambition and revenge, might prompt him to many things contrary to his declared sentiments, and inconsistent with that cunning and caution which in other cases he was master of. And to obviate the difficulty, arising from the bishop's aversion to Popery, and the Pretender's bigotry to that religion, they talked of a new

Digitized by Google

new invented scheme of his, not to receive the Pretender, whose principles were not to be changed, but his son only, who was to be educated a Protestant in the church of England, and the bishop to be his guardian, and lord protector of the kingdom, during his minority. These, and many more speculations, amused the nation at that time; and men, as usual, judged of things by the measure of their own affections and prejudices.

March 23. 1722 3, a bill was brought into the house of commons, for "inflicting certain pains and penalties on Francis Lord Bishop of Rochester;" a copy of which was sent to him, with notice that he had liberty of counsel and solicitors for making his defence. Under these circumstances, the bishop applied by petition, to the house of lords, for their direction and advice as to his conduct in this conjuncture; and April 4. he acquainted the speaker of the house of commons, by a letter, that he was determined to give that house no trouble in relation to the bill depending therein; but should be ready to make his defence against it when it should be argued in another house, of which he had the honour to be a member. On the 9th the bill passed the house of commons, and was the same day sent up to the house of lords for their concurrence.

May 6th being the day appointed by the lords for the first reading of the bill, Bishop Atterbury was brought to Westminster to make his defence. The counsel for the bishop were, Sir Constantine Phipps and William Wyne, Esq.; for the king, Mr Reeve and Mr Wearg. The proceedings continued above a week; and on Saturday May 11th, the bishop was permitted to plead for himself. This he did in a very eloquent speech: which he feelingly opens by complaining of the uncommon severity he had experienced in the Tower; which was carried to so great a length, that not even his son-in-law Mr Morice was permitted to speak to him in any nearer mode than standing in an open area, whilst the bishop looked out of a two-pair-of-stairs window. In the course of his defence he observes, "Here is a plot of a year or two standing, to subvert the government with an armed force; an invasion from abroad, an insurrection at home: just when ripe for execution, it is discovered; and twelve months after the contrivance of this scheme, no consultation appears, no men corresponding together, no provision made, no arms, no officers provided, not a man in arms; and yet the poor bishop has done all this. What could tempt me to step thus out of my way? Was it ambition, and a desire of climbing into a higher station in the church? There is not a man in my office farther removed from this than I am. Was money my aim? I always despised it too much, considering what occasion I am now like to have for it; for out of a poor bishopric of 500l. per annum, I have laid out no less than 1000l. towards the repairs of the church and episcopal palace; nor did I take one shilling for dilapidations. The rest of my little income has been spent, as is necessary, as I am a bishop. Was I influenced by any dislike of the established religion, and secretly inclined towards a church of greater pomp and power? I have, my lords, ever since I knew what Popery was, opposed it; and the better I knew it, the more I opposed it. I began my study in divinity, when the Popish controversy grew hot, with that immortal book of Tillotson's, when he undertook the Protestant cause in general; and as such, I esteemed him above all. You will pardon me, my lords, if I mention one thing: Thirty years ago, I writ in defence of Martin Luther; and have preached, expressed, and wrote to that purpose from my infancy; and whatever happens to me, I will suffer any thing, and by God's grace, burn at the stake, rather than depart from any material point of the Protestant religion as professed in the church of England. Once more: Can I be supposed to favour arbitrary power? The whole tenor of my life has been otherwise: I was always a friend to the liberty of the subject; and, to the best of my power, constantly maintained it. I may have been thought mistaken in the measures I took to support it; but it matters not by what party I was called, so my actions are uniform." Afterwards, speaking of the method of proceeding against him as unconstitutional, he says: "My ruin is not of that moment to any number of men, to make it worth their while to violate, or even to seem to violate, the constitution in any degree, which they ought to preserve against any attempts whatsoever. Though I am worthy of no regard, though whatsoever is done to me may for that reason be looked upon to be just; yet your lordships will have some regard to your own lasting interests and that of posterity. This is a proceeding with which the constitution is unacquainted; which, under the pretence of supporting it, will at last effectually destroy it. For God's sake, lay aside these extraordinary proceedings; set not up these new and dangerous precedents. I, for my part, will voluntarily and cheerfully go into perpetual banishment, and please myself that I am in some measure the occasion of putting a stop to such precedents, and doing some good to my country: I will live, wherever I am, praying for its prosperity; and do, in the words of Father Paul to the state of Venice, say, *esto perpetua*. It is not my departing from it I am concerned for. Let me depart, and let my country be fixed upon the immoveable foundation of law and justice, and stand for ever." After a solemn protestation of his innocence, and an appeal to the Searcher of Hearts for the truth of what he had said, he concludes thus: If, on any account, there shall still be thought by your lordships to be any seeming strength in the proofs against me; if, by your lordships judgments, springing from unknown motives, I shall be thought to be guilty; if, for any reasons or necessity of state, of the wisdom and justice of which I am no competent judge, your lordships shall proceed to pass this bill against me; I shall dispose myself quietly and tacitly to submit to what you do; God's will be done: Naked came I out of my mother's womb, and naked shall I return; and, whether he gives or takes away, blessed be the name of the Lord!"

On Monday the 13th he was carried for the last time from the Tower to hear the reply of the king's counsel to his defence. These were both men of great knowledge and sagacity in law, but of different talents in point of eloquence. Their speeches on this occasion were made public; and they seemed to have formed their "Replies," designedly, in a different way. The former sticks close to the matter in evidence, and enforces the charge against the bishop with great strength

 and

and perspicuity: The latter answers all his objections, and refutes the arguments brought in his defence, in an easy soft manner, and with great simplicity of reasoning. Mr Reeve is wholly employed in facts, in comparing and uniting together circumstances, in order to corroborate the proofs of the bishop's guilt: Mr Wearg is chiefly taken up in silencing the complaints of the bishop and his counsel, and replying to every thing they advance, in order to invalidate the allegations of his innocence. The one, in short, possesses the minds of the lords with strong convictions against the bishop: The other dispossesses them of any favourable impression that might possibly be made upon them by the artifice of his defence. And accordingly Mr Reeve is strong, nervous, and enforcing; but Mr Wearg, smooth, easy, and insinuating, both in the manner of his expression and the turn of his periods. Mr Wearg pays the highest compliments to the bishop's eloquence: but, at the same time, represents it as employed to impose upon the reason, and misguide the judgment of his hearers in proportion as it affected their passions; and he endeavours to strip the bishop's defence of all its ornaments and colour of rhetoric.

On the 15th the bill was read the third time; and after a long and warm debate, passed on the 16th, by a majority of 83 to 43. On the 27th, the king came to the house, and confirmed it by his royal assent. June 18. 1723, this eminent prelate, having the day before taken leave of his friends, who, from the time of passing the bill against him to the day of his departure, had free access to him in the Tower (B), embarked on board the Aldborough man of war, and landed

(B) The following anecdote was first communicated to the public by the late Dr Maty, on the credit of Lord Chesterfield: "I went (said Lord Chesterfield) to Mr Pope, one morning, at Twickenham, and found a large folio bible, with gilt clasps, lying before him upon his table; and, as I knew his way of thinking upon that book, I asked him, jocosely, if he was going to write an answer to it? It is a present, said he, or rather a legacy, from my old friend the Bishop of Rochester. I went to take my leave of him yesterday in the Tower, where I saw this bible upon his table. After the first compliments, the Bishop said to me, 'My friend Pope, considering your infirmities, and my age and exile, it is not likely that we should ever meet again; and therefore I give you this legacy to remember me by it. Take it home with you: and let me advise you to abide by it.'—'Does your Lordship abide by it yourself?'—'I do.' 'If you do, my Lord, it is but lately. May I beg to know what new light or arguments have prevailed upon you now, to entertain an opinion so contrary to that which you entertained of that book all the former part of your life?'—The Bishop replied, 'We have not time to talk of these things; but take home the book; I will abide by it, and I recommend you to do so too; and so God bless you."

These anecdotes Mr Nichols has inserted in the "Epistolary Correspondence," vol. ii. p. 79. with the professed view of vindicating Atterbury, in the following words of an ingenious correspondent:

"Dr Warton has revived this story, which he justly calls an 'uncommon' one, in his last 'Essay on the Genius and Writings of Pope.' It was indeed very uncommon; and I have my reasons for thinking it equally groundless and invidious. Dr Warton, though he retails the story from 'Maty's Memoirs,' yet candidly acknowledges, that it ought not to be implicitly relied on. That this caution was not unnecessary, will, I apprehend, be sufficiently obvious, from the following comparison between the date of the story itself and Mr Pope's letters to the bishop.

"According to Lord Chesterfield's account, this remarkable piece of conversation took place but a few days before the Bishop went into exile: and it is insinuated, that Mr Pope, till that period, had not even entertained the slightest suspicion of his friend's reverence for the bible: Nay, it is asserted, that the very recommendation of it from a quarter so unexpected, staggered Mr Pope to such a degree, that in a mingled vein of raillery and seriousness, he was very eager to know the grounds and reasons of the Bishop's change of sentiment.

"Unfortunately for the credit of Lord Chesterfield and his story, there is a letter on record, that was written nine months before this pretended dialogue took place, in which Mr Pope seriously acknowledged the Bishop's piety and generosity, in interesting himself so zealously and affectionately in matters which immediately related to his improvement in the knowledge of the holy scriptures. The passage I refer to is a very remarkable one; and you will find it in a letter, dated July 27. 1722. It appears undeniably from this letter, that the Bishop had earnestly recommended to Mr Pope the study of the bible; and had softened his zeal with an unusual urbanity and courtesy, in order to avoid the imputation of ill-breeding, and remove all occasion of disgust from a mind so 'tremblingly alive as Mr Pope's.' I will transcribe the passage at large. 'I ought first to prepare my mind for a better knowledge even of good profane writers, especially the moralists, &c. before I can be worthy of tasting the Supreme of books, and Sublime of all writings, in which, as in all the intermediate ones, you may (if your friendship and charity towards me continue so far) be the best guide to Yours, A. POPE.'

"The last letter of Mr Pope to the Bishop, previous to his going into exile, was written very early in June 1723. It must have been about this time that Pope paid his farewel visit to the Bishop in the Tower. But whether such a conversation as that which hath been pretended actually took place, may be left to the determination of every man of common sense, after comparing Lord Chesterfield's anecdote with Mr Pope's letter.

"There must have been a mistake, or a wilful misrepresentation, somewhere. To determine its origin, or to mark minutely the various degrees of its progress, till it issued forth into calumny and falsehood, is impossible.

landed the Friday following at Calais. When he went on shore, having been informed that Lord Bolingbroke, who had, after the rising of the parliament, received the king's pardon, was arrived at the same place on his return to England, he said, with an air of pleasantry, "Then I am exchanged?" And it was, in the opinion of Mr Pope on the same occasion, "a sign of the nation's being cursedly afraid of being overrun with too much politeness, when it could not regain one great man but at the expence of another." But the severity of his treatment did not cease even with his banishment. The same vindictive spirit pursued him in foreign climes. No British subject was even permitted to visit him without the king's sign manual, which Mr Morice was always obliged to solicit, not only for himself, but for every one of his family whom he carried abroad with him, for which the fees of office were very high.

When Bishop Atterbury first entered upon his banishment, Brussels was the place destined for his residence; but, by the arts and instigations of the British ministers, he was compelled to leave that place, and retire to Paris. There being solicited by the friends of the Pretender to enter into their negociations, he changed his abode for Montpelier in 1728; and, after residing there about two years, returned to Paris, where he died Feb. 15. 1731-2. The affliction which he sustained by the death of his daughter in 1729, was thought to have hastened his own dissolution. The former event he hath himself related in a very affecting manner, in a letter to Mr Pope: "The earnest desire of meeting one I dearly loved, called me abruptly to Montpelier; where, after continuing two months under the cruel torture of a sad and fruitless expectation, I was forced at last to take a long journey to Toulouse; and even there I had missed the person I sought, had she not, with great spirit and courage, ventured all night up the Garonne to see me, which she above all things desired to do before she died. By that means she was brought where I was, between seven and eight in the morning, and lived 20 hours afterwards; which time was not lost on either side, but passed in such a manner as gave great satisfaction to both, and such as, on her part, every way became her circumstances and character: For she had her senses to the very last gasp, and exerted them to give me, in those few hours, greater marks of duty and love than she had done in all her lifetime, though she had never been wanting in either. The last words she said to me were the kindest of all; a reflection on the goodness of God, which had allowed us in this manner to meet once more, before we parted for ever. Not many minutes after that, she laid herself on her pillow, in a sleeping posture,

Placidaque ibi demum morte quievit.

Judge you, Sir, what I felt, and still feel, on this occasion, and spare me the trouble of describing it. At my age, under my infirmities, among utter strangers, how shall I find out proper reliefs and supports? I can have none, but those with which reason and religion furnish me; and those I laid hold on, and grasp as fast as I can. I hope that He who laid the burden upon me (for wise and good purposes no doubt) will enable me to bear it in like manner, as I have borne others, with some degree of fortitude and firmness."

How far the bishop might have been attached in his inclinations to the Stuart family, to which he might be led by early prejudices of education, and the divided opinions of the times, it is not necessary here to inquire: But that he should have been weak enough to engage in a plot so inconsistent with his station, and so clumsily devised (to say the least of it, and without entering into his solemn asseveration of innocence), is utterly inconsistent with that cunning which his enemies allowed him. The duke of Wharton, it is well known, was violent against him, till convinced by his unanswerable reasoning.

It has been said that Atterbury's wishes reached to the bishopric of London, or even to York or Canterbury. But those who were better acquainted with his views, knew that Winchester would have been much more desirable to him than either of the others. And there are those now living, who have been told from respectable authority, that that bishopric was offered to him whenever it should become vacant (and till that event should happen, a pension of 5000l. a-year, besides an ample provision for Mr Morice), if he would cease to give the opposition he did to Sir Robert Walpole's administration, by his speeches and protests in the house of lords. When that offer was rejected by the bishop, then the contrivance for his ruin was determined on.

In his speech in the house of lords, the bishop mentions his being "engaged in a correspondence with two learned men (Bishop Potter and Dr Wall) on settling the times of writing the four gospels." Part of this correspondence is still in being, and will soon be published. The same subject the bishop pursued during his exile, having consulted the learned of all nations, and had nearly brought the whole to a conclusion when he died. These laudable labours are an ample confutation of Bishop Newton's assertion, that Atterbury "wrote little whilst in exile but a few criticisms on French authors."

His body was brought over to England, and interred on the 12th of May following in Westminster abbey, in a vault which in the year 1722 had been prepared by his directions. There is no memorial over his grave; nor could there well be any, unless his friends would have consented (which it is most probable they refused to do) that the words implying him to have died bishop of Rochester should have been omitted on his tomb.

Some

I have simply stated matters of fact as they are recorded; and leave it to your readers to settle other points not quite so obvious and indisputable, as they may think fit. My motives in this very plain narration arose from an honest wish to remove unmerited obloquy from the dead. I should sincerely rejoice if the cloud which in other respects still shades the character of this ingenious prelate could be removed with equal facility and success. I am, dear Sir, your faithful humble servant, SAMUEL BADCOCK."

Atterbury.

Some time before his death, he published a vindication of himself, Bishop Smalridge, and Dr Aldrich, from a charge brought against them by Mr Oldmixon, of having altered and interpolated the copy of Lord Clarendon's "History of the Rebellion." Bishop Atterbury's "Sermons" are extant in four volumes in octavo: those contained in the two first were published by himself, and dedicated to his great patron Sir Jonathan Trelawney bishop of Winchester; those in the two last were published after his death by Dr Thomas Moore, his lordship's chaplain. Four admirable "Visitation Charges" accompany his "Epistolary Correspondence."

As to Bishop Atterbury's character, however the moral and political part of it may have been differently represented by the opposite parties, it is universally agreed, that he was a man of great learning and uncommon abilities, a fine writer, and a most excellent preacher. His learned friend Smalridge, in the speech he made when he presented him to the upper house of convocation, as prolocutor, styles him *Vir in nullo literarum genere hospes, in plerisque artibus et studiis diu et feliciter exercitatus, in maxime perfectis literarum disciplinis perfectissimus.* In his controversial writings, he was sometimes too severe upon his adversary, and dealt rather too much in satire and invective; but this his panegyrist imputes more to the natural fervour of his wit than to any bitterness of temper or prepense malice. In his sermons, however, he is not only every way unexceptionable, but highly to be commended. The truth is, his talent as a preacher was so excellent and remarkable, that it may not properly be said, that he owed his preferment to the pulpit. "He has," says an author in the Tatler, "so particular a regard to his congregation, that he commits to his memory what he has to say to them; and has so soft and graceful a behaviour, that it must attract your attention. His person, it is to be confessed, is no small recommendation; but he is to be highly commended for not losing that advantage, and adding to propriety of speech (which might pass the criticism of Longinus) an action which would have been approved by Demosthenes. He never attempts your passions, till he has convinced your reason. All the objections which you can form are laid open and dispersed before he uses the least vehemence in his sermon; but when he thinks he has your head, he very soon wins your heart, and never pretends to show the beauty of holiness, till he has convinced you of the truth of it."—In his letters to Pope, &c. Bishop Atterbury appears in a pleasing light, both as a writer and as a man.

Atterbury ‖ Attica.

ATTESTATION, the act of affirming or witnessing the truth of something, more especially in writing.

ATTIC, any thing relating to Attica, or to the city of Athens: thus Attic salt, in philology, is a delicate poignant sort of wit and humour peculiar to the Athenian writers; Attic witness, a witness incapable of corruption, &c.

Attic Order. See Architecture.

Attic Base, a peculiar kind of base used by the ancient architects in the Ionic order; and by Palladio, and some others in the Doric.

Attic Story, in *Architecture;* a story in the upper part of a house, where the windows are usually square.

ATTICA.

Attica.

1 Boundaries, extent, &c.

ATTICA, an ancient kingdom of Greece, situated along the north coast of the gulf of Saron; bounded on the west by Megara, Mount Cithæron, and part of Bœotia; on the north by the strait of Euripus, now *Stretto di negro ponte*, and Bœotia; and on the east by the Euripus. It extends in length from north-west to south-west about 60 miles; its breadth from north to south was 56, decreasing as it approached the sea.

2 Inhabitants thought to be produced from the soil.

The soil of this country was naturally barren and craggy, though by the industry of its inhabitants it produced all the necessaries of life. On this account Attica was less exposed to invasions than other more fertile countries; and hence it preserved its ancient inhabitants beyond all the other kingdoms in its neighbourhood: so that they were reputed to be the spontaneous productions of the soil; and as a badge of this, Thucydides tells us, they wore golden grasshoppers in their hair.

3 Cities.

The chief cities in the kingdom of Attica were Athens the capital; next to it Eleusis, situated on the same gulf, near the coast of Megara; and next to that Rhamnus, famed for the temple of Amphiaraus and the statue of the goddess Nemesis.

4 Cecrops the first king.

The first king of this country, of whom we have any distinct account, was Cecrops. Others indeed are said to have reigned before him, particularly one Actæus, whose daughter Cecrops married, and in her right laid the foundation of his new monarchy. Cecrops is said to have been the first who deified Jupiter, set up altars and idols, and instituted marriage among the Greeks. He is likewise affirmed to have taught his subjects navigation; and for the better administration of justice, and promoting intercourse among them, to have divided them into the first four tribes, called *Cecropis*, *Autochthon*, *Actea* and *Paralia;* and he is also by some said to be the founder of the Areopagus. From this monarch the Athenians affected to call themselves *Cecropidæ* till the reign of Erectheus their sixth king, after whom they took the name of *Erecthydæ*.

Attica.

5 Cranaus.

Cecrops dying after a reign of 50 years, left three daughters; by marrying one of whom, probably, Cranaus a wealthy citizen ascended the throne. He enjoyed his crown peaceably for ten years; till, having married one of his daughters named *Attis*, to Amphictyon the son of Deucalion, he was by him dethroned, and forced to lead a private life to the last. From this daughter, the country, which before had been called *Actea*, took the name of *Attica*.

6 Whence the country was called Attica.

After

Digitized by Google

After a reign of 10 or 12 years, Amphictyon was himself deposed by Ericthonius, said to be the son of Vulcan and Tethys. Being lame of both his feet, he is said to have invented coaches, or, as others will have it, instituted horse and chariot races, in honour of Minerva. He is also reported to have been the first who stamped silver coin. He reigned 50 years, and was succeeded by his son Pandion, the father of Progne and Philomela; whose hard fate, so famous among the poets, is supposed to have broke his heart, after a reign of about 40 years. In his time Triptolemus taught the Athenians agriculture, which he had learned from Ceres.

7 Ericthonius. 8 Pandion.

9 Erectheus.

Pandion was succeeded by his son Erectheus, who being reckoned the most powerful prince of his time, Boreas king of Thrace demanded his daughter Orithia in marriage, and on being refused carried her off by force. After a reign of 50 years, Erectheus being killed in a battle with the Eleusinians, was succeeded by his son Cecrops II. who is generally allowed to have been the first who gathered the people into towns; they having till then lived in houses and cottages scattered here and there, without order or regular distance. After a reign of 40 years he was driven out by his brethren Metion and Pandorus, who forced him to fly into Ægialea, where he died.

10 Cecrops II.

11 Pandion II.

Cecrops II. was succeeded by his son Pandion II. and he was likewise driven out by Metion, who assumed the government. Pandion in the mean time fled into Megara, where he married Pelia the daughter of Pylas king of that place, and was appointed successor to the kingdom. Here he had four sons, who returning to Athens, whether with or without their father is uncertain, expelled the sons of Metion, and after the decease of Pandion their father, divided the government among themselves; notwithstanding which, the royal dignity did in effect remain with Ægeus the eldest.

12 Ægeus.

Ægeus, when he ascended the throne, finding himself despised by his subjects because he had no sons, and sometimes insulted by his brother Pallas, who had no less than fifty, consulted the oracle of Apollo at Delphi. Receiving here, as was commonly the case, an answer which could not be understood without a commentator, he applied to Pittheus king of Troezen, famous for his skill in expounding oracles. This prince easily prevailed with him to lie with his daughter Æthra, who proved with child; and as none but these three were privy to the secret, Ægeus, before his return to Athens, hid a sword and a pair of shoes under a stone, leaving orders with the princess, that if the child proved a boy, she should send him to Athens with these tokens as soon as he was able to lift up that stone. He charged her moreover to use all imaginable secrecy, lest the sons of his brother Pallas should waylay and murder him.

13 Theseus born.

Æthra being delivered of a son, Pittheus gave out that Neptune was the father of it. This child was named *Theseus*, and proved one of the most famous heroes of antiquity. Being arrived at the age of 16, his mother brought him to the stone above mentioned; and he having lifted it with ease, was desired to take up the sword and shoes and prepare himself to go to his father. He was advised to go by sea rather than by land, as, ever since the departure of Hercules, the roads had been exceedingly infested by banditti. Theseus, however, who had already begun to discover marks of uncommon strength and courage, no sooner heard the name of Hercules mentioned, than he became desirous of imitating so great a pattern; and after performing a number of glorious exploits, for which see the article THESEUS, he arrived safe at his father's capital.

The great atchievements of our young hero procured him a welcome reception at the court of Ægeus, though his birth was unknown to all except Medea, to whom the king had lately been married. This queen being a sorceress, it is not to be supposed any thing could be concealed from her: she therefore, by her diabolical penetration, quickly found out that Theseus was the king's son; after which she became so jealous of him on account of his valour, that she persuaded her old husband to invite the young stranger to a banquet, and poison him in a glass of wine. The poison was accordingly prepared, and Theseus invited; but the prince suddenly drawing his sword, it was immediately recognised by Ægeus to be the same he had formerly buried below the stone. Upon this he stepped forward to Theseus, throwing down the poisoned draught in his way; and, embracing him with much tenderness, owned him for his son before all the court.

14 Is made known to his father.

At this time the king of Athens had great occasion for such a champion as Theseus. The sons of Pallas, who had all along behaved with great insolence, upon Theseus being discovered to be the king's son, and heir apparent to the crown, broke out in open rebellion. They were soon discomfited; but Ægeus and the whole country of Attica were still in great distress on the following account. Some years before, Androgeus, the son of Minos king of Crete, came to Athens to be present at one of their feasts. During this visit he contracted such an intimacy with the fifty sons of Pallas, that Ægeus, fearing some fatal consequences, caused him to be privately murdered. According to others, Androgeus having undertaken to encounter the Marathonian bull, was killed by it. Be this as it will, Minos having received news of his son's death, imputed it to the people of Attica; and therefore, after several unsuccessful attempts to revenge his own quarrel, prayed to the gods to do it for him. The Athenians, in consequence of this prayer, were visited with earthquakes, famine, and pestilence; on account of which they applied to the oracle. Here they were informed, that no relief was to be had till they were reconciled to the Cretan king. Minos resolving to make them pay dear for their deliverance, imposed upon them a tribute of seven young men and as many virgins, whom he condemned to be devoured by the Minotaur, a monster feigned by the poets to have been half man and half bull. This bloody tribute had been twice paid, and Minos had already sent his messengers the third time, when Theseus willingly offered himself to be one of the unhappy victims; and embarking with them in one ship, he gave the pilot two sails, the one black to sail with, and the other white to be hoisted up at his return in case he came off victorious. Our hero had all the success he could wish: he killed the Minotaur, prevailed with Minos to remit the tribute, and his daughter Ariadne to run away with him; but her he left with child in the isle of Naxos. Unfortunately, however, for Ægeus, the joy of Theseus and his

his company was so great, that at their return they forgot to hoist the white flag in token of their victory:
16 Death of Ægeus. upon which the old king, taking for granted that his son was killed, threw himself into the sea, which ever
17 Theseus king of Attica. since has from him been called the *Ægean Sea*.

Theseus being thus left in possession of the kingdom of Attica, began immediately to think of indulging his
18 New models the government. warlike genius, and rendering the civil affairs of his kingdom as little troublesome as possible. To accomplish this purpose, he began with gathering most of the people of Attica into the old and new town, which he incorporated into one city. After this he divested himself of all his regal power, except the title of king, the command of the army, and the guardianship of the laws. The rest he committed to proper magistrates chosen out of three different orders of the people, whom he divided into nobles, husbandmen, and artificers. The first he invested with the power of interpreting and executing the laws, and regulating whatever related to religion. The other two chose their inferior magistrates from among themselves, to take care of whatever related to their separate orders: so that the kingdom was in some measure reduced to a commonwealth, in which the king had the greatest post, the nobles were next to him in honour and authority, the husbandmen had the greatest profit, and the artists exceeded them in number. He likewise abolished all their distinct courts of judicature, and built one common council hall called *Prytaneum*, which stood for many ages afterwards.

Having thus new-modelled the government, his next care was to join to his dominions the kingdom of Megara, in right of his grandfather Pandion II. who had married the daughter of Pylas, as above mentioned. On this occasion he erected the famous pillar in the isthmus, which showed the limits of the two countries that met there. On the one side of this pillar was inscribed, "This is not Peloponnesus, but Ionia;" and on the other, "This is Peloponnesus, not Ionia." After this
19 Defeats the Amazons, kills the Centaurs, and carries off Helena. he undertook an expedition against the Amazons, whom he overcame, took their queen Hippolita, and afterwards married her. Soon after this, Theseus contracted an intimacy with Perithous the son of Ixion: and being invited to his nuptials, assisted him in killing a number of Centaurs, or rather Thessalian horsemen (who in their cups had offered violence to their female guests), and drove the rest out of the country. Our two associates then proceeded to Sparta, where Theseus fell in love with the famed Helena, at that time not above nine years old, while he himself was upwards of fifty. Her they carried off: and of the rape there are various accounts; but the following one, which is given by Plutarch, is generally allowed to be the most authentic.

According to that historian, they stole this beauty, the greatest in the world at that time, out of the temple of Diana Ortia, where Helena happened to be dancing. They were pursued as far as Tegea, but made their escape out of Peloponnesus; and thinking themselves now secure of their prey, they agreed to cast lots for her, upon condition that he to whose lot she fell should assist the other in procuring some celebrated beauty. Fortune having declared for Theseus, he assisted his companion in the like attempt upon Proserpina daughter of Aidonius king of the Mollossi in Epirus; who, being the next beauty to Helena, was guarded by the dog Cerberus, which had three heads, and was consequently a very formidable enemy. Her father, however, understanding that they designed to steal away his daughter, threw Perithous to be torn in
pieces by Cerberus, and put Theseus in prison, from 20 Imprisoned by the king of Epirus.
whence he was afterwards relieved at the intercession of Hercules.

After this misfortune, Theseus at length returned to Athens, but found himself very coolly received by his subjects. Mnestheus, the son of Pteus, and great-grandson of Erectheus, had made use of the king's absence to ingratiate himself with the people; and, upon the commencement of a war with Castor and Pollux, the two brothers of Helena, he persuaded the people of
Athens to open their gates to the two brothers. Up- 21 Driven out of Athens.
pon this, Theseus was under the necessity of conveying away himself and family with all possible privacy. This he luckily accomplished; and designed to have sailed to Crete, to have obtained assistance from Deucalion son of Minos, and now brother-in-law to Theseus himself, he having lately married Phædra sister to Deucalion. Unfortunately, however, our hero was shipwrecked on the island of Scyros. Here he was at first kindly re-
ceived by Lycomedes the king of that island; but was 22 His death.
soon after killed by a fall from a high rock, over which some say he was pushed by Lycomedes himself, who had been prevailed on to destroy Theseus in that manner by Mnestheus, that he might with the more security enjoy the kingdom of Athens.

Mnestheus reigned 24 years, but lost his life at the 23 Mnestheus, Demophon, &c.
siege of Troy; and was succeeded by Demophon one of the sons of Theseus by Phædra, who was likewise at the siege of Troy, but had the good fortune to return in safety. In his reign was erected the famous court of the Ephetæ; consisting originally of 50 Athenians and as many Argives, for trying of wilful murders. By this court the king himself afterwards submitted to be tried for having accidentally killed one of his subjects. He reigned 33 years, and was succeeded by his son, according to some, or according to others his brother, Oxyntes, who reigned 12 years. Oxyntes was succeeded by his son Aphydes, who was murdered by Thymætes the bastard son of Oxyntes.

This king discovered many base qualities unworthy 24 Thymætes deposed.
of his dignity; and at last was deposed by his subjects on the following occasion. Xanthus king of Bœotia had a contest with the Athenians about one of their frontier towns. He offered to decide the matter by single combat with the king; but this was declined by Thymætes. It happened, that at that time one Melanthus a Messenian, who had been driven out of his country by the Heraclidæ, was come to Athens; who accepted the king of Bœotia's challenge. At the first onset, Melanthus asked his adversary, why he had, contrary to the articles, brought a second into the field with him? and as Xanthus immediately looked about to see who was behind him, Melanthus run him through with his lance. This victory, though it did little honour to him who gained it, was so agreeable to the Athenians, that they deposed their cowardly king Thymætes, af-
ter he had reigned 8 years; and appointed Melanthus 25 Melanthus.
in his stead, who after a reign of 37 years left the kingdom to his son Codrus.

This prince reigned about 21 years; during which time the Dores and Heraclidæ had regained all Peloponnesus, Attica. ponnesus, and were upon the point of entering into Attica. Codrus, being informed that the oracle had

26 Codrus the last king sacrifices himself for his country.

promised them victory provided they did not kill the king of the Athenians, came immediately to a resolution of dying for his country. Disguising himself, therefore, like a peasant, he went into the enemy's camp, and quarrelling with some of the soldiers, was killed by them. On the morrow, the Athenians knowing what was done, sent to demand the body of their king; at which the invaders were so terrified, that they decamped without striking a blow.

27 Republican government introduced.

Upon the death of Codrus, a dispute which happened among his sons concerning the succession, furnished the Athenians with a pretence for ridding themselves of their kings altogether, and changing the monarchical form of government into a republican one. It was improbable, they said, that they should ever have so good a king as Codrus; and to prevent their having a worse, they resolved to have no king but Jupiter. That they might not, however, seem ungrateful to the family of Codrus, they made his son Medon their supreme magistrate, with the title of *archon*. They afterwards rendered that office decennial, but continued it still in the family of Codrus. The extinction of the Medontidæ at last left them without restraint; upon which they not only made this office annual, but created nine archons. By the latter invention they provided against the too great power of a single person, as by the former they took away all apprehension of the archons having time to establish themselves, so as to change the constitution. In a word, they now attained what they had long sought, viz. the making the supreme magistrates dependant on the people.

We have a list of these archons for upwards of 600 years, beginning with Creon, who lived about 684 years before Christ, to Herodes, who lived only 60 years before that time. The first archon of whom we

28 Draco legislator of Athens.

hear any thing worth notice, is named *Draco*. He reigned in the second, or, as others say, in the last year of the 39th Olympiad, when it is supposed he published his laws: but though his name is very frequently mentioned in history, yet no connected account can be found either of him or his institutions; only, in general, his laws were exceedingly severe, inflicting death for the smallest faults; which gave occasion to one Demades an orator to observe, that the laws of Draco were written with blood, and not with ink. For this extraordinary severity he gave no other reason, than that small faults seemed to him to be worthy of death, and he could find no higher punishment for the greatest. He was far advanced in years when he gave laws to Athens; and to give his institutions the greater weight, he would not suffer them to be called *nomoi*, or laws, but *thesmoi*, or sanctions proceeding from more than human wisdom. The extreme severity of these

29 Expelled the city.

laws, however, soon made the Athenians weary both of them and the author of them; upon which Draco was obliged to retire to Ægina. Here he was received with the highest honours: but the favour of the inhabitants of this place proved more fatal to him than the hatred of the Athenians; for coming one day into the theatre, the audience, to show their regard, threw, as the

30 His death.

custom then was, their cloaks upon him; and the multitude of these being very great, they stifled the old man, who was too weak to disengage himself from their load.

After the expulsion of Draco, nothing remarkable happened at Athens till the year before Christ 606 when we find the republic engaged in a war with the Mitylenians about the city Sigæum, situated near the mouth of the river Scamander. The Athenian army

31 Mitylenian war.

was commanded by Phrynon, a person equally remarkable for the comeliness of his person and the generosity of his mind. The Mitylenians were commanded by Pittacus, one of the celebrated sages of Greece. As these commanders looked upon the honour of their respective countries to be concerned, they exerted themselves to the utmost. At last they met in single combat; wherein Phrynon depended on his valour only: but Pittacus concealed behind his shield a net, wherewith he suddenly entangled his antagonist, and easily slew him. This, however, not putting an end to the war, Periander tyrant of Corinth interposed; and both parties having submitted to his arbitration, he decreed that Sigæum should belong to the Athenians.

32 Cylon's conspiracy.

About seven years after this war, a conspiracy was formed by Cylon son-in-law to Theagenes tyrant of Megara, who, having by his affable behaviour procured many friends, formed a design of seizing the sovereignty of Athens. Having consulted the oracle as to the most proper time, he was directed to make the attempt when the citizens of Athens were employed in celebrating their highest feasts to Jupiter. When many of the citizens therefore were gone to the Olympic games, Cylon and his associates made themselves masters of the citadel. Here they were instantly besieged by Megacles at that time archon, and soon reduced to great distress for want of water. The chief, together with his brother, found means to make their escape, but the meaner sort were left to shift for themselves. In this extremity they fled to the temple of Minerva; from whence Megacles with much ado prevailed upon them to come down and submit themselves to the mercy of their country. Having at last assented to this, they tied a cord to the image of the goddess, and carried the clue with them, to demonstrate, that though they were out of the temple they were still under Minerva's protection. Unfortunately for them, however, as they passed the temple of the Furies, the line snapt of itself; which Megacles construing into a renunciation by the goddess, caused his men to fall upon them and despatch

33 Conspirators massacred by Megacles;

as many as they could find. Such as were without the temple were immediately massacred, and those who fled thither again were murdered in their sanctuary. In short, none escaped but such as bribed the wives of the officers of justice. This carnage, however, did not put an end to the sedition. The remains of Cylon's faction created great disturbances, by insinuating that the violation of Minerva's sanctuary had drawn down

34 who is execrated by the people.

the anger of the gods; and these discourses had such an effect, that Megacles and his officers were styled *execrable*, and held to be persons under the displeasure of heaven.

35 Unsuccessful war with Megara.

During the time of this confusion, the Megarensians attacked Nisea, which they took, as well as Salamis; and so completely routed the Athenians in every attempt to recover the latter, that a law was at last passed, by which it should be capital for any one to propose the recovery of Salamis. About the same time the city was disturbed by reports of frightful appearances, and filled with superstitious fears; the oracle at

Attica.

Delphi was therefore consulted, and an answer returned that the city behoved to be expiated. Upon this, Epimenides the Phestian was sent for from Crete, to perform the necessary ceremonies, he being reputed a holy man, and one that was deeply skilled in all the mysteries of religion. His expiation consisted in taking some black, and some white sheep, turning them all loose, and directing some persons to follow them to those places where they couched, and there to sacrifice them to the local deity. He caused also many temples and chapels to be erected, two of which have been particularly noted, viz. the chapel of *Contumely* and that of *Impudence*. This man is said to have looked wistfully on the port of Munychia for a long time, and then to have spoke as follows to those that were near him: "How blind is man to future things! for did the Athenians know what mischief will one day be derived to them from this place, they would eat it with their teeth." This prediction was thought to be accomplished 270 years after, when Antipater constrained the Athenians to admit a Macedonian garrison into that place.

36 Epimenides's expiation and prophecy.

37 Solon the wise legislator.

About 597 years before Christ, Solon the famed Athenian legislator began to show himself to his countrymen. He is said to have been lineally descended from Codrus; but left by his father in circumstances rather necessitous, which obliged him to apply to merchandise; it is plain, however, both from his words and writings, that he was a disinterested patriot. The shameful decree, that none under pain of death should propose the recovery of Salamis, grieved him so much, that having composed an elegy of 100 verses, such as he thought would be most proper to inflame the minds of the people, he ran into the market-place as if he had been mad, with his night-cap on his head, repeating his elegy. A crowd being gathered round the pretended madman, his kinsman Pisistratus mingled among the rest, and observing the people moved with Solon's words, he also seconded him with all the eloquence he was master of; and between them they prevailed so far as to have the law repealed, and a war was immediately commenced against the people of Megara. Who was commander in this expedition is not certain; but the city was recovered, according to the most general account, by the following stratagem. Solon coming with Pisistratus to Colias, and finding there the women busy in celebrating, according to custom, the feast of Ceres, sent a confidant of his to Salamis, who pretended to be no friend to the people of Attica, telling the inhabitants of Salamis, that if they had a mind to seize the fairest of the Athenian ladies, they might now do it by passing over to Colias. The Megarensians giving easy credit to what the man said, immediately fitted out a ship; which Solon perceiving from the opposite shore, dismissed the women, and having dressed a number of beardless youths in female habits, under which they concealed every one a dagger, he sent them to the sea-side to dance and divert themselves as the women were wont to do. When those who came from Salamis saw these young persons skipping up and down, they strove who should be first on shore; but were every one of them killed, and their vessel seized; aboard which the Athenians embarking, sailed immediately to Salamis and took it.

38 Salamis recovered by his means.

On the return of Solon to Athens, he was greatly honoured by the people, to whom another occasion of admiring his wisdom was quickly afforded. The inhabitants of Cirrha, a town situated in the bay of Corinth, after having by repeated incursions wasted the territory of Delphi, at last besieged the capital itself, with a view of making themselves masters of the treasures contained in the temple of Apollo. Advice of this intended sacrilege being sent to the Amphictyons, who were the states-general of Greece, Solon advised that the matter should be universally resented, and that all the states should join in punishing the Cirrhæans, and saving the Delphic oracle. This advice was complied with, and a general war against Cirrha declared. Clysthenes, tyrant of Sicyon, commanded in chief, and Alcmæon was general of the Athenian quota. Solon went as assistant or counsellor to Clysthenes, and by following his advice the war was conducted to a prosperous issue. For when the Greek army had besieged Cirrha for some time without any appearance of success, the oracle at Delphi was consulted, from whence the following answer was returned:

39 Cirrha likewise reduced by Solon's wisdom.

"In vain you hope to take the place before
"The sea's blue waves roll o'er the hallowed shore."

This answer struck the whole army with surprise, till Solon advised Clysthenes to consecrate solemnly the whole territory of Cirrha to the Delphic Apollo; so as that was a maritime country, the sea must then wash the sacred coast. According to Pausanias, the city was reduced by the following stratagem, likewise invented by Solon. He caused the river Plistus, which run through Cirrha, to be turned into another channel, hoping thereby to have distressed the inhabitants for want of water: but finding they had many wells within the city, and were not to be reduced by that means, he caused a vast quantity of roots of hellebore to be thrown into the river, which was then suffered to return into its former bed. The inhabitants, overjoyed at the sight of running water, came in troops to drink of it: whereupon an epidemic flux ensued, and the citizens being no longer able to defend the walls, the town was easily taken.

On the return of Solon to Athens he found things again in the utmost confusion. The remnant of Cylon's faction gave out, that all sorts of misfortunes had befallen the republic on account of the impiety of Megacles and his followers; which clamour was heightened by the retaking of Salamis about this time by the Megarensians. Solon interposed, and persuaded those who were styled *execrable* to abide a trial, and 300 persons were chosen to judge them. The event was, that 300 of Megacles's party who were alive were sent into perpetual banishment, and the bones of such as were dead were dug up and sent without the limits of their country.

40 Athens in great confusion.

41 Megacles's party banished.

Though this decision restored the public quiet for the present, it was not long before the people were divided into three factions, contending about the proper form of government. These were called the *Diacrii*, *Pediæi*, and *Parali*; the first of these were the inhabitants of the hilly country, who declared positively for democracy; the second, dwelling in the lower parts, and who were far more opulent than the former, declared for an oligarchy, as supposing the government would fall mostly into their hands; the third party, who lived on

42 Three factions start up.

Digitized by Google

 on the sea-coast, were people of moderate principles, and therefore were for a mixed government. Besides the disturbances raised on this account, others were occasioned by the rich oppressing the poor. According to Plutarch, the poor being indebted to the rich, either tilled their grounds and paid them the sixth part of the produce, or engaged their bodies for their debts, so that many were made slaves at home, and many sold into other countries; nay, some were obliged to sell their children to pay their debts, and others in despair quitted Attica altogether. The greatest part, however, were for throwing off the yoke, and began to look about for a leader, openly declaring that they intended to change the form of government, and make a repartition of lands. In this extremity, the eyes of all the citizens were cast upon Solon. The most prudent were for offering him the sovereignty; but he perceiving their intentions, behaved in such a manner as to cheat both parties, and showed a spirit of patriotism perhaps never equalled. He refused the sovereignty as far as it might have benefited himself; and yet took upon himself all the care and trouble of a prince, for the sake of his people.

43 Solon chosen archon. He was chosen archon without having recourse to lots, and after his election disappointed the hopes of both parties. It was Solon's fundamental maxim, That those laws will be best observed which power and justice equally support. Wherever, therefore, he found the old constitution consonant to justice in any tolerable degree, he refused to make any alteration at all, and was at extraordinary pains to show the reason of the changes he did make. In short, being a perfect judge of human nature, he sought to rule only by showing his subjects that it was their interest to obey, and not by forcing upon them what he himself esteemed best. Therefore, to a person who asked whether he had given the Athenians the best laws in his power, he replied, "I have established the best they could receive."

44 Settles all disorders. As to the main cause of sedition, viz. the oppressed state of the meaner sort, Solon removed it by a contrivance which he called *sisachthia*, i. e. *discharge*; but what this was, authors are not agreed upon. Some say that he released all debts then in being, and prohibited the taking any man's person for payment of a debt for the future. According to others, the poor were eased, not by cancelling the debts, but by lowering the interest, and increasing the value of money; a mina, which before was made equal to 73 drachms only, being by him made equal to 100; which was of great advantage to the debtor, and did the creditor no hurt. It is, however, most probable that the sisachthia was a general remittance of all debts whatever, otherwise Solon could not have boasted in his verses that he had removed so many marks of mortgages (B) as were everywhere frequent; that he had freed from apprehension such as were driven to despair, &c.

45 Infamous behaviour of his three friends. But in the midst of all Solon's glory, an accident befel him, which, for a time, hurt his reputation, and had almost entirely ruined his schemes. He had consulted Conon, Clinias, and Hipponicus, his three friends, on an oration prepared with a view to engage the people's consent to the discharge; and these three men, thus knowing there was to be a general discharge of debts, basely took the opportunity of borrowing vast sums before the law was promulgated, in consequence of which they were never obliged to return them.

This was thought at first to have been done with Solon's consent, and that he had shared in the money; but this aspersion was quickly wiped off when it appeared that the lawgiver himself was a very considerable loser by his own law. His friends, however, could never recover their credit, but were ever afterwards stigmatized with the opprobrious appellation of *chreocopidæ*, or *debt-sinkers*.

46 Solon blamed at first, but afterwards applauded and chosen legislator. The Athenians were as little pleased with Solon's management as with their former condition; the rich thinking he had done too much in cancelling the money-debts due to them, and the poor that he had done too little, because he had not divided the lands of Attica equally. In a short time, however, they acquiesced in the new institutions, and gave a more public token of their repentance than they had before shown of their displeasure, instituting a solemn sacrifice under the name of *Sisachthia*, at the same time that Solon was unanimously elected legislator of Athens, with full power to make laws, and alter or new-model the constitution as he thought fit.

47 Compiles a new body of laws. Solon being now invested with unlimited authority, set about the arduous task of compiling new laws for the turbulent people of Attica; which having at last completed in the best manner he was able, or in the best manner the nature of the people would admit, he procured them to be ratified for 100 years. Such as related to private actions were preserved on parallelograms of wood, with cases which reached from the ground, and turned about upon a pin like a wheel. These were thence called *axones*; and were placed first in the citadel, and afterwards in the prytaneum, that all the subjects might have access to them when they pleased. Such as concerned public institutions and sacrifices were contained in triangular tables of stone called *cyrbes*. The Athenian magistrates were sworn to observe both; and in process of time these monuments of Solon's wisdom became so famous, that all public acts were from them named *Axones* and *Cyrbes*.

48 He goes abroad for ten years. After the promulgation of the laws, Solon found himself obliged to leave Athens, to prevent his being continually teazed for explanations and alterations of them. He therefore pretended an inclination to merchandise, and obtained leave to absent himself for 10 years, during which time he hoped the laws would be grown familiar. From Athens Solon travelled into Egypt, where he conversed with Psenophis the Heliopolitan, and Sonchis the Saite, the most learned priests of that age. From these he learned the situation of the island Atlantis, of which he wrote an account in verse, which Plato afterwards continued *.

* See *Atlantis*.

 From

(B) The Athenians had a custom of hanging up billets to show that houses were engaged for such and such sums of money.

Digitized by Google

From Egypt he went to Cyprus, where he was extremely well received by one of the petty kings. This prince lived in a city called *Apeia*, built by Demophon the son of Theseus, on an eminence near the river Clarius, but in a soil craggy and barren. Solon observing a very pleasant plain below, engaged the king to remove thither; assisted in executing the scheme he had formed; and succeeded so well, that a new city was formed, which soon became populous, and out of gratitude to the Athenian legislator was called *Solos*.

49 Things fall into disorder in his absence.

But while Solon was thus travelling in quest of wisdom, and with a view to benefit those among whom he came, his countrymen, who seem to have resolved on being dissatisfied at all events, had again divided themselves into three factions. Lycurgus put himself at the head of the country people; Megacles the son of Alcmæon was at the head of those who lived on the sea coast; and Pisistratus put himself at the head of the poorer sort, to protect them, as he pretended, from tyranny, but in reality to seize on the sovereignty for himself. All the factions pretended to have a vast regard for Solon and his laws, at the same time that they were very desirous of a change; but how they were to be bettered, none of them knew, or pretended to know.

50 He returns to Athens, but refuses to resume his office.

In the midst of this confusion the legislator returned. Each of the factions paid their court to him, and affected to receive him with the deepest reverence and respect; beseeching him to reassume his authority, and compose the disorders which they themselves kept up. This Solon declined on account of his age, which, he said, rendered him unable to speak and act for the good of his country as formerly; however, he sent for the chiefs of each party, beseeching them in the most pathetic manner not to ruin their common parent, but to prefer the public good to their own private interest.

Pisistratus, who of all the three had perhaps the least intention to follow Solon's advice, seemed to be the most affected with his discourses; but as Solon perceived he affected popularity by all possible methods, he easily penetrated into his designs of assuming the sovereign power. This he spoke of to Pisistratus himself, at first privately; but as he saw that his admonitions in this way had no effect, he then said the same things to others, that the public might be on their guard against him.

51 Pisistratus assumes the sovereignty.

All the wise discourses of Solon, however, were lost upon the Athenians. Pisistratus had got the meaner sort entirely at his devotion, and therefore resolved to cheat them out of the liberty which they certainly deserved to lose. With this view he wounded himself, and, as Herodotus says, the mules that drew his chariot; then he drove into the market-place, and there showed his bleeding body, imploring the protection of the people from those whom his kindness to them had rendered his implacable enemies. A concourse of people being instantly formed, Solon came among the rest, and suspecting the deceit, openly taxed Pisistratus with his perfidious conduct; but to no purpose. A general assembly of the people was called, wherein it was moved by one Ariston, that Pisistratus should have a guard. Solon was the only person present who had resolution enough to oppose this measure; the richer Athenians, perceiving that the multitude implicitly followed Pisistratus, and applauded every thing he said, remaining silent through fear. Solon himself, when he saw he could prevail nothing, left the assembly, saying he was *wiser* than some, and *stouter* than others. A guard of 400 men was now unanimously decreed to Pisistratus, as we are told by Solon himself. This inconsiderable body he made use of to enslave the people, but in what manner he accomplished his purpose is not agreed. Certain it is, that with his guard he seized the citadel; but Polyænus hath given an account of a very singular method which he took to put it out of the power of the Athenians to defend themselves even against such a small number. He summoned an assembly to be held at the Anacium, and directed that the people should come thither armed. They accordingly came; and Pisistratus harangued them, but in a voice so low that they could not tell what he said. The people complaining of this, Pisistratus told them that they were hindered from hearing him by the clangour of their arms; but if they would lay them down in the portico, he would then be heard distinctly. This they did; and while they listened very attentively to a long and eloquent oration, Pisistratus's guard conveyed away their arms, so that they found themselves deprived of all power of resistance. During the confusion which followed this event, another assembly was held, wherein Solon inveighed bitterly against the meanness of his countrymen, inviting them to take up arms in defence of their liberty. When he saw that nothing would do, he laid down his own arms, saying, that he had done his utmost for his country and his laws. According to Plutarch, he refused to quit the city; but the most probable opinion is, that he immediately retired from the dominion of Athens, and refused to return, even at the solicitation of Pisistratus himself.

52 Solon leaves Athens.

53 Pisistratus governs with great moderation.

Pisistratus having thus obtained the sovereignty, did not overturn the laws of Solon, but used his power with the greatest moderation. It is not to be expected, however, that so turbulent a people as the Athenians could be satisfied by any method of government he could lay down. At the beginning of his administration, Megacles and his family retired out of Athens to save their own lives, yet without despairing of being able some time or other to return. With this view Megacles and his associates entered into a treaty with Lycurgus; and having brought him and his party into a scheme for deposing Pisistratus, they concerted matters so well, that Pisistratus was soon obliged to seek for shelter somewhere else, and, on his departure, the Athenians ordered his goods to be sold. Nobody, however, except one person (*Callias*) would venture to buy any of them, from an apprehension, no doubt, that they would soon be restored to their proper owner, which accordingly happened in a very short time.

54 Driven out by Megacles.

55 Who soon after reinstates him.

As Megacles and his party had negociated with Lycurgus to turn out Pisistratus, so they now entered into a treaty with Pisistratus to reinstate him in his principality, as soon as they found Lycurgus would not be implicitly governed by them. To accomplish this, they fell upon a very ridiculous project; which, however, was attended with the desired success. They found out a woman whose name was *Phya*, of a mean family and fortune, but of a great stature, and very handsome. Her

Digitized by Google

Attica.

Her they dressed in armour, placed her in a chariot, and having disposed things so as to make her appear with all possible advantage, they conducted her towards the city, sending heralds before, with orders to speak to the people in the following terms: "Give a kind reception, O Athenians, to Pisistratus, who is so much honoured by Minerva above all other men, that she herself condescends to bring him back to the citadel." The report being universally spread that Minerva was bringing home Pisistratus, and the ignorant multitude believing this woman to be the goddess, addressed their prayers to her, and received Pisistratus with the utmost joy. When he had recovered the sovereignty, Pisistratus married the daughter of Megacles as he had promised, and gave the pretended goddess to his son Hipparchus.

56 Driven out a second time;

Pisistratus did not long enjoy the kingdom to which he had been restored in so strange a manner. He had married the daughter of Megacles, as already observed; but having children by a former wife, and remembering that the whole family of Megacles was reprobated by the Athenians, he thought proper to let his new spouse remain in a state of perpetual widowhood. This she patiently bore for some time, but at last acquainted her mother. An affront so grievous could not fail to be highly resented. Megacles instantly entered into a treaty with the maleconteuts, of whom there were always great plenty at Athens whatever was the form of government. This Pisistratus being apprized of, and perceiving a new storm gathering, he voluntarily quitted Athens, and retired to Eretria. Here having consulted with his sons, it was resolved to reduce Athens by force. With this view he applied to several of the Greek states, who furnished him with the troops he desired, but the Thebans exceeded all the rest in their liberality; and with this army he returned to Attica, according to Herodotus, in the 11th year of his banishment. They first reduced Marathon, the inhabitants of which had taken no measures for their defence, though they knew that Pisistratus was preparing to attack them. The republican forces in the mean time marched out of Athens to attack him; but behaving in a secure and careless manner, they were surprised by Pisistratus, and totally routed. While they were endeavouring to make their escape, he caused his two sons to ride before him with all speed, and tell those they came up with that nobody had any thing to fear, but that they might every one return to his own home. This stratagem so effectually dispersed the republican army, that it was impossible to rally them, and Pisistratus became a third time absolute master of Attica.

57 but returns with an army.

58 He takes possession of the city.

59 His subjects still discontented notwithstanding his moderation.

Pisistratus being once more in possession of the sovereignty, took a method of establishing himself on the throne directly opposite to what Theseus had done. Instead of collecting the inhabitants from the country into cities, Pisistratus made them retire from the cities into the country, in order to apply themselves to agriculture. This prevented their meeting together, and caballing against him in such bodies as they had been accustomed to do. By this means also the territory of Athens was greatly meliorated, and great plantations of olives were made over all Attica, which had before not only been destitute of corn, but also bare of trees. He also commanded, that, in the city, men should wear a kind of sheep-skin vest, reaching to the knees; but so intolerable were the laws of Pisistratus to his subjects, that this kind of garment in succeeding times became proverbially the habit of slavery.

As prince of Athens, Pisistratus received the tenth part of every man's revenues, and even of the fruits of the earth; and this also, though for the service of the state, seemed to the Athenians a most grievous burden. In short, though Pisistratus behaved in all respects as a most excellent prince, his subjects fancied themselves oppressed by tyranny, and were perpetually grumbling from the time he first ascended the throne to the day of his death, which happened about 33 years after he had first assumed the sovereignty, of which time, according to Aristotle, he reigned 17 years.

60 Hipparchus and Hippias.

Pisistratus left behind him two sons named *Hipparchus* and *Hippias*, both men of great abilities, who shared the government between them, and behaved with lenity and moderation. But though by the mildness of their government the family of the Pisistratidæ seemed to be fully established on the throne of Athens, a conspiracy was unexpectedly formed against both the brothers, by which Hipparchus was taken off, and Hippias narrowly escaped. The most material facts relating to this conspiracy are what follow.

61 Conspiracy of Harmodius and Aristogiton.

There were at that time in Athens two young men, called *Harmodius* and *Aristogiton;* the former of these was exquisitely beautiful in his person, and on that account, according to the infamous custom of the Greeks, violently beloved of the other. This Harmodius was also beloved of Hipparchus; who, if we may believe Thucydides, forced him. This was grievously resented, and revenge determined on; to hasten which, another accident concurred. Hipparchus, finding that Harmodius endeavoured to avoid him, publicly affronted him, by not suffering his sister to carry the offering of Minerva, as if she was a person unworthy of that office. The two young men, not daring to show any public signs of resentment, consulted privately with their friends; among whom it was resolved, that at the approaching festival of Panathenæa, when the citizens were allowed to appear in arms, they should attempt to restore Athens to its former liberty. In this they imagined that they should find themselves seconded by the whole body of the people. But when the day appointed was come, they perceived one of their number talking very familiarly with Hippias; and fearing that they were discovered, they immediately fell upon Hipparchus, and despatched him with a multitude of wounds. In this exploit the people were so far from seconding them, as they expected, that they suffered Harmodius to be killed by Hipparchus's guards, and seizing Aristogiton themselves, delivered him up to Hippias. Some time afterwards, however, the respect they paid to these two young men exceeded all bounds. They caused their praises to be sung at the Panathenæa, forbade any citizen to call a slave by either of their names, and erected brazen statues to them in the forum; which statues were afterwards carried into Persia by Xerxes, and sent back from thence by Alexander the Great, Antiochus, or Seleucus, for authors are not agreed by which. Several immunities and privileges were also granted to the descendants of these

62 Hipparchus killed.

63 The conspirators extravagantly honoured.

these two patriots, and all possible means were taken to render their memory venerable and respected by posterity.

64 Cruelty of Hippias.

Hippias being now sole master of Athens, and probably exasperated by the murder of his brother, began to alter his conduct greatly, and treat his subjects in an oppressive and cruel manner. He began with torturing Aristogiton, in order to make him confess his accomplices: but this proved fatal to his own friends: for Aristogiton impeaching such as he knew to be best affected to Hippias, they were immediately put to death; and when he had destroyed all those he knew, at last told Hippias, that now he knew of none that deserved to suffer death except the tyrant himself. Hippias next vented his rage on a woman named *Leæna*, who was kept by Aristogiton. She endured the torture as long as she could; but finding herself unable to bear it any longer, she at last bit off her tongue, that she might not have it in her power to make any discovery. To her the Athenians erected the statue of a lioness, alluding to her name, without a tongue, on which was engraved a suitable inscription.

After the conspiracy was, as Hippias thought, thoroughly quashed, he set himself about strengthening his government by all the means he could think of. He contracted leagues with foreign princes, increased his revenues by various methods, &c. But these precautions were of little avail; the lenity of Pisistratus's government had alone supported it; and Hippias pursuing contrary methods, was deprived of his sovereignty in less than four years after the death of his brother.

65 He is driven out of Athens;

This revolution was likewise owing to the family of Megacles, who were styled *Alcmæonidæ*, and had settled at Lipsydrum. In times of discontent, which at Athens were very frequent, this family was the common refuge of all who fled from that city; and at last they thought of a method of expelling the Pisistratidæ altogether. The method they took to accomplish their purpose was as follows. The agreed with the Amphictyons to rebuild the temple at Delphi; and being possessed of immense riches, they performed their engagement in a much more magnificent manner than they were bound to do; for having agreed only to build the front of common stone, they built it of Parian marble. At the same time they corrupted the prophetess Pythia, engaging her to exhort all the Lacedæmonians that came to consult the oracle either in behalf of the state, or their own private affairs, to attempt the delivery of Athens. This had the desired effect: the Lacedæmonians, surprised at hearing this admonition incessantly repeated, at last resolved to obey the divine command, as they imagined it to be; and sent Anchimolius, a man of great quality, at the head of an army, into Attica, though they were at that time in league with Hippias, and accounted by him his good friends and alies. Hippias demanding assistance from the Thessalians, they readily sent him 1000 horse, under the command of one of their princes named *Sineas*. The Lacedæmonians being landed, Hippias fell upon them so suddenly, that he defeated them with great slaughter, killed their general, and forced the shattered remains of their army to fly to their ships. The Spartans, incensed at this unfortunate expedition, determined to send another army into Attica; which they accordingly did soon after under their king Cleomenes: and he having, at his entrance into the Athenian territories, defeated the Thessalian horse, obliged Hippias to shut himself up in the city of Athens, which he was soon after forced to abandon altogether. He was, however, in no want of a place of refuge; the Thessalian princes inviting him into their country, and the king of Macedon offering his family a city and territory, if they choose to retire into his dominions. 66
But Hippias chose rather to go to the city of Sigeum, and retires
which Pisistratus had conquered, and left to his own to Sigeum.
family.

After the expulsion of the Pisistratidæ, the Athenians did not long enjoy the quiet they had proposed to themselves. 67 They were quickly divided into two factions; at the head of one was Clysthenes, one of the chief of the Alcmæonidæ; and of the other, Isagoras, a man of great quality, and highly in favour with the Athenian nobility. Clysthenes applied himself to the people, and endeavoured to gain their affection by increasing their power as much as possible. Isagoras perceiving that by this means his rival would get the better, applied to the Lacedæmonians for assistance, reviving at the same time the old story of Megacles's sacrilege, and insisting that Clysthenes ought to be banished as being of the family of Megacles. 68 Cleomenes king of Sparta readily came into his measures, and suddenly despatched a herald to Athens with a declaration of war in case all the Alcmæonidæ were not immediately banished. The Athenians did not hesitate to banish their benefactor Clysthenes, and all his relations; but this piece of ingratitude did not answer their purpose. Cleomenes entered Attica at the head of a Spartan army; and, arriving at Athens, condemned to banishment 700 families more than what had been sent into exile before. Not content with this, he would have dissolved the senate, and vested the government in 300 of the chief of Isagoras's faction. This the Athenians would by no means submit to; and therefore took up arms, and drove Cleomenes and his troops into the citadel, where they were besieged for two days. On the third day Cleomenes surrendered on condition that all those who were in the citadel should retire unmolested. This, though agreed to, was not performed by the Athenians. They fell upon such as were separated from the army, and put them to death without mercy. Among the number of those slain on this occasion was Timesitheus the brother of Cleomenes himself.

Two factions in Athens.

The Spartans support Isagoras;

The Spartan king was no sooner withdrawn from Athens, than he formed a strong combination in favour of Isagoras. 69 He engaged the Bœotians to attack Attica on the one side, and the Chalcidians on the other, while he at the head of a powerful Spartan army entered the territories of Eleusina. In this distress, the Athenians, not being able to cope with so many enemies at once, resolved to suffer their territories to be ravaged by the Chalcidians and Bœotians, contenting themselves with opposing the army commanded by Cleomenes in person. But this powerful confederacy was quickly dissolved: the Corinthians, who were allied with Cleomenes, doubting the justice of their cause, returned home; his other allies likewise beginning to waver, and his colleague Ariston the other king of Sparta, differing in sentiments, Cleomenes

but without success.

Digitized by Google

menes was obliged to abandon the enterprise. The Spartans and their allies being withdrawn, the Athenians took a severe revenge of the Bœotians and Chalcidians, totally routing their forces, and carrying off a great number of prisoners. The prisoners taken in this war were put in irons, but afterwards set at liberty on paying a ransom of two minæ per head. Their fetters were, however, hung up in the citadel; and the Athenians consecrating the tenth of what they had received for ransom, purchased a statue, representing a chariot and four horses, which they set up in the portico of the citadel, with a triumphant inscription in token of their victory.

70
Bœotians and Chalcidians defeated.

These indignities rousing the Bœotians, they immediately vowed revenge, and engaged on their side the people of Ægina, who had an hereditary hatred at the Athenians; and while the latter bent all their attention to the Bœotian war, the Æginetans landing a considerable army, ravaged the coasts of Attica.

71
Attempt of the Spartans to restore Hippias.

But while the Athenians were thus employed against the Bœotians and Æginetans, a jealousy sprung up on the part of Lacedæmon, which was never afterwards eradicated. Cleomenes, after his unsuccessful expedition against Attica, produced at Sparta certain oracles which he said he had found in the citadel of Athens while he was besieged therein: the purport of these oracles was, that Athens would in time become a rival to Sparta. At the same time it was discovered, that Clysthenes had bribed the priestess of Apollo to cause the Lacedæmonians to expel the Pisistratidæ from Athens; which was sacrificing their best friends to those whom interest obliged to be their enemies. This had such an effect, that the Spartans, repenting their folly in expelling Hippias, sent for him from Sigeum, in order to restore him to his principality: but this not being agreed to by the rest of the states, they were forced to abandon the enterprise, and Hippias returned to Sigeum as he came.

72
Cause of the war with Persia.

About this time, too, Aristagoras the Milesian having set on foot a revolt in Ionia against the Persian king, applied to the Spartans for assistance; but they declining to have any hand in the matter, he next applied to the Athenians, and was by them furnished with 20 ships under the command of Melanthus, a nobleman universally esteemed. This rash action cost the Greeks very dear, as it brought upon them the whole power of the Persian empire; for no sooner did the king of Persia hear of the assistance sent from Athens to his rebellious subjects, than he declared himself the sworn enemy of that city, and solemnly besought God that he might one day have it in his power to be revenged on them.

The Ionian war being ended, by the reduction of that country again under the Persian government, the king of Persia sent to demand earth and water as tokens of submission from the Greeks. Most of the islanders yielded to this command out of fear, and among the rest the people of Ægina; upon which the Athenians accused the inhabitants of this island of treachery towards Greece, and a war was carried on with them for a long time. How it ended we are not informed; but its continuance was fortunate for Greece in general, as, by inuring them to war, and sea-affairs in particular, it prevented the whole of the Grecian states from being swallowed up by the Persians, who were now about to invade them.

Besides the displeasure which Darius had conceived against the Athenians on account of the assistance they had afforded the Ionians, he was further engaged to an expedition against Greece by the intrigues of Hippias. Immediately on his returning unsuccessfully from Lacedæmon, as above related, Hippias passed over into Asia, went to Artaphernes, governor of the adjacent provinces belonging to the Persian king, and excited him to make war upon his country, promising to be obedient to the Persian monarch provided he was restored to the principality of Athens. Of this the Athenians being apprised, sent ambassadors to Artaphernes, desiring leave to enjoy their liberty in quiet: but that nobleman returned for answer, that if they would have peace with the great king, they must immediately receive Hippias; upon which answer the Athenians resolved to assist the enemies of Darius as much as possible. The consequence of this resolution was, that Darius commissioned Mardonius to revenge him of the insults he thought the Greeks had offered him. But Mardonius having met with a storm at sea, and other accidents which rendered him unable to do any thing, Datis and Artaphernes the son of Artaphernes above mentioned, were commissioned to do what he was to have done.

73
Hippias applies to the Persians.

The Persian commanders, fearing again to attempt to double the promontory of Athos, where their fleet had formerly suffered, drew their forces into the plains of Cilicia: and passing from thence through the Cyclades to Eubœa, directed their course to Athens. Their charge from Darius was to destroy both Eretria and Athens; and to bring away the inhabitants, that they might be at his disposal. Their first attempt was on Eretria, the inhabitants of which sent to Athens for assistance on the first approach of the Persian fleet. The Athenians, with a magnanimity almost unparalleled at such a juncture, sent 4000 men to their assistance; but the Eretrians were so much divided amongst themselves, that nothing could be resolved on. One party among them was for receiving the Athenian succours into the city; another, for abandoning the city and retiring into the mountains of Eubœa; while a third sought to betray their country to the Persians for their own private interest. Seeing things in this situation, therefore, and that no good could possibly be done, one Æschines, a man of great authority among the Eretrians, generously informed the Athenian commanders that they might return home. They accordingly retired to Oropus, by which means they escaped destruction: for Eretria being soon after betrayed to the Persians, was pillaged, burnt, and its inhabitants sold for slaves.

74
They invade Greece.

75
Eretria destroyed.

On the news of this disaster the Athenians immediately drew together all the forces they were able, which after all amounted to no more than 9000 men. These, with 1000 Platæans who afterwards joined them, were commanded by ten general officers, who had equal power; among whom were Miltiades, Aristides, and Themistocles, men of distinguished valour and great abilities. But it being generally imagined that so small a body of troops would be unable to resist the formidable power of the Persians, a messenger was despatched

Digitized by Google

Attica. patched to Sparta to entreat the immediate assistance of that state. He communicated his business to the senate in the following terms: "Men of Lacedæmon, the Athenians desire you to assist them, and not to suffer the most ancient of all the Grecian cities to be enslaved by the barbarians. Eretria is already destroyed, and Greece consequently weakened by the loss of so considerable a place." The assistance was readily granted; but at the same time the succours arrived so slowly, that the Athenians were forced to fight without them. In this memorable engagement in the plains of Marathon, whither Hippias had conducted the Persians, the latter were defeated with the loss of 6300 men, while the Greeks lost only 192. The Persians being thus driven to their ships, endeavoured to double Cape Sunium, in order to surprise Athens itself before the army could return: but in this they were prevented by Miltiades; who, leaving Aristides with 1000 men to guard the prisoners, returned so expeditiously with the other 9000, that he was at the temple of Hercules, which was but a small way distant, before the barbarians could attack the city.

76 Persians defeated at Marathon.

77 Integrity of Aristides.

After the battle, Aristides discharged the trust reposed in him with the greatest integrity. Though there was much gold and silver in the Persian camp, and the tents and ships they had taken were filled with all sorts of riches, he not only forbore touching any thing himself, but to the utmost of his power prevented others from doing it. Some, however, found means to enrich themselves; among the rest, one Callias, cousin-german to Aristides himself. This man being a torch-bearer, and, in virtue of his office, having a fillet on his head, one of the Persians took him for a king, and, falling down at his feet, discovered to him a vast quantity of gold hid in a well. Callias not only seized, and applied it to his own use, but had the cruelty to kill the poor man who dicovered it to him, that he might not mention it to others; by which infamous action he entailed on his posterity the name of *Laccopluti*, or *enriched by the well.*

78 Miltiades ungratefully treated by the Athenians.

After the battle of Marathon, all the inhabitants of Platæa were declared free citizens of Athens, and Miltiades, Themistocles, and Aristides were treated with all possible marks of gratitude and respect. This, however, was but very short-lived; Miltiades proposed an expedition against the island of Paros, in which having been unsuccessful, through what cause is not well known, he was, on his return, accused and condemned to pay 50 talents, the whole expence of the scheme; and, being unable to pay the debt, was thrown into prison, where he soon died of a wound received at Paros.

79 As likewise Aristides.

If any thing can exceed the enormity of such a proceeding as this, it was the treatment Aristides next received. Miltiades had proposed an expedition, which had not proved successful, and in which he might possibly have had bad designs; but against Aristides not so much as a shadow of guilt was pretended. On the contrary, his extraordinary virtue had procured him the title of *Just*, and he had never been found to swerve from the maxims of equity. His downfal was occasioned by the intrigues of Themistocles; who being a man of great abilities, and hating Aristides on account of the character he deservedly bore among his countrymen, took all opportunities of insinuating, that his rival had in fact made himself master of Athens without the parade of guards and royalty. "He gives laws to the people (said he); and what constitutes a tyrant, but giving laws?" In consequence of this strange argument, a strong party was formed against the virtuous Aristides, and it was resolved to banish him for 10 years by the ostracism. In this case, the name of the person to be banished was written upon a shell by every one who desired his exile, and carried to a certain place within the forum enclosed with rails. If the number of shells so collected exceeded 6000, the sentence was inflicted; if not, it was otherwise. When the agents of Themistocles had sufficiently accomplished their purpose, on a sudden the people flocked to the forum, desiring the ostracism. One of the clowns who had come from a borough in the country, bringing a shell to Aristides, said to him, "Write me Aristides upon this." Aristides, surprised, asked him if he knew any ill of that Athenian, or if he had ever done him any hurt? "Me hurt! (said the fellow), no, I don't so much as know him; but I am weary and sick at heart on hearing him everywhere called *the just*." Aristides, thereupon, took the shell, and wrote his own name upon it; and when informed that the ostracism fell upon him, modestly retired out of the forum, saying, "I beseech the gods that the Athenians may never see that day which shall force them to remember Aristides."

After the battle of Marathon, the war with Ægina was revived with great vigour; but the Æginetans generally had the superiority, on account of their great naval power. Themistocles observing this, was continually exhorting his countrymen to build a fleet, not only to make them an equal match for the Æginetans, but also because he was of opinion that the Persians would soon pay them another visit. At last, he had the boldness to propose, that the money produced by the silver mines, which the Athenians had hitherto divided among themselves, should be applied to the building of a fleet: which proposal being complied with, 100 galleys were immediately put upon the stocks; and this sudden increase of their maritime power proved the means of saving all Greece from slavery.

80 Themistocles advises the building of a fleet.

About three years after the banishment of Aristides, Xerxes king of Persia sent to demand earth and water: but Themistocles desiring to make the breach with that monarch still wider, put to death the interpreter for publishing the decree of the king of Persia in the language of the Greeks; and having prevailed upon the several states to lay aside their animosities and provide for their common safety, got himself elected general of the Athenian army.

81 Xerxes invades Greece.

When the news arrived that the Persians were advancing to invade Greece by the straits of Thermopylæ, and that they were for this purpose transporting their forces by sea, Themistocles advised his countrymen to quit the city, embark on board their galleys, and meet their enemies while yet at a distance. This they would by no means comply with; for which reason Themistocles put himself at the head of the army, and having joined the Lacedæmonians, marched towards Tempe. Here, having received advice that the straits of Thermopylæ were forced, and that both Bœotia and Thessaly

Digitized by Google

Thessaly had submitted to the Persians, the army returned without doing any thing.

In this distress the Athenians applied to the oracle at Delphi: from whence they received at first a very severe answer, threatening them with total destruction; but after much humiliation, a more favourable one was delivered, in which, probably by the direction of Themistocles, they were promised safety in *walls of wood.* This was by Themistocles and the greatest part of the

82 Athens abandoned by its inhabitants,

citizens interpreted as a command to abandon Athens, and put all their hopes of safety in their fleet. Upon this, the opinion of Themistocles prevailing, the greatest part began to prepare for this embarkation; and had money distributed among them by the council of the Areopagus, to the amount of eight drachms per man: but this not proving sufficient, Themistocles gave out that somebody had stolen the shield of Minerva; under pretence of searching for which, he seized on all the money he could find. Some, however, there were who refused to embark with the rest, but raised to themselves fortifications of wood; understanding the oracle in its literal sense, and resolving to wait the arrival of the Persians, and defend themselves to the last. In the mean time Aristides was recalled, when the Athenians saw it their interest, lest he should have gone over to the Persians and assisted them with his advice.

83 and destroyed by the Persians.

The Persians having advanced to Athens soon after the inhabitants had deserted it, met with no opposition except from a few just now mentioned; who, as they would hearken to no terms of accommodation, were all

84 They are totally defeated at Salamis.

cut in pieces, and the city utterly destroyed. Xerxes, however, being defeated in a sea fight at Salamis, was forced to fly with prodigious loss. See SALAMIS. Themistocles was for pursuing him, and breaking down the bridge he had cast over the Hellespont; but this advice being rejected, he sent a trusty messenger to Xerxes, acquainting him that the Greeks intended to break down his bridge, and therefore desired him to make all the haste he could, lest by that means he should be shut up in Europe. According to Herodotus, he also advised the Athenians to quit the pursuit and return home, in order to rebuild their ruined houses. This advice, though misinterpreted by some, was certainly a very prudent one, as Xerxes, though once defeated, was still at the head of an army capable of destroying all Greece; and had he been driven to despair by finding himself shut up or warmly pursued, it was impossible to say what might have been the event. After this, Themistocles formed a scheme for the aggrandisement of Athens indeed, but a most unjust and infamous one. It was, in short, to make Athens mistress of the sea, by burning all the ships except those belonging to that republic. He told his countrymen, that he had something to propose of great consequence, but which could not be spoken publicly: whereupon he was desired to communicate it to Aristides, by whom the proposal was rejected; and Aristides having informed the Athenians that what Themistocles had said was very advantageous but very unjust, they desired him to think no more of it.

85 Themistocles honoured by the Lacedæmonians.

When the fleet returned to Salamis, extraordinary honours were paid to Themistocles by the Lacedæmonians. On his entering that city, they decreed him a wreath of olives as the prize of prudence; presented him with the most magnificent chariot in Sparta: and when he returned to Athens, he was escorted by 500 horse, an honour never paid to any stranger but himself. On his arrival at Athens, however, there were not wanting some who insinuated that the receiving such honours from the Lacedæmonians was injurious to the republic; but Themistocles, confiding in his innocence, treated these clamours with contempt, and exhorted his countrymen to entertain no doubts of their allies, but rather endeavour to preserve the great reputation they had acquired throughout all Greece.

The defeat of Xerxes at Salamis made Mardonius, who was left to carry on the war by land, more ready to treat with the Athenians than to fight them; and with this view he sent Alexander king of Macedon to Athens to make proposals of alliance with that republic, exclusively of all the other Grecian states. This

86 Athens a second time destroyed.

proposal, however, was rejected; and the consequence was, that Athens was a second time destroyed, the Spartans sending assistance so slowly, that the Athenians were forced to retire to Salamis; but they were soon

87 The Persians defeated at Platæa and Mycale.

freed from all apprehensions by the total defeat and death of Mardonius at Platæa; where Aristides, and the body of troops under his command, distinguished themselves in a most extraordinary manner.

The same day that the battle of Platæa was fought, the Persians were defeated in a sea-fight at Mycale in Ionia, wherein it was allowed that the Athenians who were there behaved better than any of the other Greeks; but when it was proposed to transport the Ionians into Europe, that they might be in perfect safety, and give them the territories of such Grecian states as had sided with the Persians, the Athenians refused to comply, fearing the Ionians would rival them in trade, or refuse the obedience they used to pay them; besides which, they would then lose the opportunity of plundering the Persians in case of any quarrel with Ionia. Before they returned home, however, the Athenians crossed over to the Chersonesus, and besieged Sestos. The siege was

88 Sestos taken by the Athenians.

long and troublesome: but at last the garrison, being pressed with hunger, and having no hopes of relief, divided themselves into two bodies, and endeavoured to make their escape; but were pursued, and all either killed or taken. *Oibazus*, one of their commanders, was sacrificed to a Thracian god; and the other, called *Artyactes*, impaled alive, and his son stoned before his face, because he had rifled the sepulchre of Protesilaus.

89 They rebuild their city.

After the victories at Platæa and Mycale, the Athenians returned without any apprehension, and began to rebuild their city in a more magnificent manner than before. Here they were no sooner arrived than a dispute was ready to be commenced about the form of government. The commons, with Themistocles at their head, were for a democracy; to which Aristides, rather than hazard the raising disturbances, consented. It was therefore proposed, that every citizen should have an equal right to the government; and that the archons should be chosen out of the body of the people, without preference or distinction: and this proposal being agreed to, put an end to all discontents for the present.

At this time also Themistocles proposed that the city of Athens should be fortified in the best manner possible, that it might not be liable to be again destroyed,

Digitized by Google

Attica when the Persians should take it into their heads to invade Greece. At this proposal the Lacedæmonians were exceedingly alarmed; and therefore remonstrated,

90 Themistocles advises to fortify Athens, and deceives the Spartans who oppose it.

that should Athens once be strongly fortified, and the Persians become possessed of it, it would be impossible to get them out of it again. At last, seeing these arguments had no effect, they absolutely forbade the Athenians to carry their walls any higher. This command gave great offence; but Themistocles, considering the power of Sparta at that time, advised the Athenians to temporize; and to assure the ambassadors that they should proceed no farther in their work, till, by an embassy of their own, satisfaction should be given to their allies. Being named ambassador at his own desire to Sparta, with some other Athenians, Themistocles set out alone, telling the senate that it would be for the interest of the state to delay sending the other ambassadors as long as possible. When arrived at Sparta, he put off from time to time receiving an audience, on account of his colleagues not being arrived: but in the mean time the walls of Athens were building with the utmost expedition; neither houses nor sepulchres being spared for materials; and men, women, children, strangers, citizens, and servants, working without intermission. Of this the Lacedæmonians having notice, and the rest of the Athenian ambassadors being arrived, Themistocles and his colleagues were summoned before the ephori, who immediately began to exclaim against the Athenians for their breach of promise. Themistocles denied the charge: he said his colleagues assured him of the contrary: that it did not become a great state to give heed to vague reports, but that deputies ought to be sent from Sparta to inquire into the truth of the matter, and that he himself would remain as a hostage, to be answerable for the event. This being agreed to, he engaged his associates to advise the Athenians to commit the Spartan ambassadors to safe custody till he should be released; after which he publicly avowed the whole transaction, took the scheme upon himself, and told the Lacedæmonians that "all things are lawful for our country." The Spartans, seeing no remedy, concealed their resentment, and sent Themistocles home in safety.

91 Makes the Pyræus the port of Athens.

The next year, being the last of the 75th Olympiad, Themistocles observing the inconvenience of the port Phalerum, thought of making the *Pyræus* the port of Athens. This he did not at first think proper to mention publicly; but having signified to the people that he had something of importance to communicate, they appointed Xanthippus and Aristides to judge of his proposal. They readily came into his measures, and told the people that what Themistocles proposed would be of the utmost advantage to the state, at the same time that it might be performed with ease. Upon this they were desired to lay the matter before the senate; who coming unanimously into their measures, ambassadors were depatched to Sparta to insinuate there how proper it would be for the Greeks to have some great port, where a fleet might always watch the designs of the Persians; and thus having prevented any umbrage from their first undertakings, the work was set about with such expedition, that it was finished before the Lacedæmonians knew well what they were about.

At this time also the sovereignty of the sea was transferred from Sparta to Athens, through the haughty behaviour of Pausanias the Lacedæmonian. He had commanded at Platæa, and still enjoyed the supreme authority in the war which was all this time carrying on against the Persians; but being elated with his success at Platæa, and having entered into a treasonable correspondence with the enemy, he treated the captains under his command with the greatest haughtiness, giving the preference to the Spartans in such a manner that the rest of the Greeks could no longer bear his insolence. On the contrary, Aristides, and Cimon the son of Miltiades, who commanded the Athenians, by their obliging behaviour gained the favour of every body; so that the allies, having publicly affronted Pausanias, put themselves under the protection of the Athenian republic; and thenceforward the Athenians, and not the Lacedæmonians, had the supreme command.

92 Sovereignty of the sea transferred to Athens.

93 Aristides taxes Greece with extraordinary applause.

The Greeks being now sensible that they would always have occasion to be on their guard against the Persians, and that it was necessary to establish a fund by a common taxation of all the states, Aristides was pitched upon as the only person that could be trusted with the power of allotting to each of the states its proper quota. This difficult task he undertook, and executed in a manner unparalleled in the annals of history. All parties were pleased, and his taxation was styled *the happy lot of Greece*. The gross amount of it was 450 talents.

94 Themistocles banished.

It now came to the turn of Themistocles to experience the ingratitude of his countrymen. His services had been so essential, that the treatment he received may perhaps be a sufficient excuse for modern patriots when they connect their own interest with the service of their country. Themistocles had plainly saved the state from ruin by his advice; he had distinguished himself by his valour; had rendered Athens, by his policy, superior to the other states of Greece; and entirely subverted the Lacedæmonian scheme of power. Yet, notwithstanding all this, he was banished by the ostracism, without the smallest crime pretended, unless that he was hated by the Lacedæmonians, and that he had erected a temple, near his own house, dedicated to *Diana, the giver of the best counsel;* intimating that he himself had given the best counsel for the safety both of Athens and of all Greece, which was no more than the truth. Nay, he was not only driven out of Athens, but out of all Greece; so that he was forced to seek shelter from the king of Persia, against whom he had fought with so much valour. That monarch gave him a gracious reception; and he was never recalled, because the Greeks had no occasion for his services.

95 Success of Cimon against the Persians.

The war with Persia was not yet discontinued; the Greeks found their advantage in plundering and enriching themselves with the spoils of the king of Persia's subjects. For this reason, in the end of the 77th Olympiad, they equipped a navy, under a pretence of relieving such of the Greek cities in Asia as were subject to the Persians. Of this fleet Cimon, the son of Miltiades by the daughter of the king of Thrace, was appointed commander in chief. He had already tasted the justice and generosity of his countrymen, having been thrown into prison for his father's fine, from which he was released by *Callias*, whom his sister Elpinice married on account of his great wealth procured by no very honourable means. He accepted of the command, however,

Digitized by Google

Attica. however, and gained such immense booty in this expedition, that the Athenians were thereby enabled to lay the foundation of those long-extended walls which united the port to the city. The foundation was laid in a moorish ground; so that they were forced to sink it very deep, and at a great expence; but to this Cimon himself contributed out of his own share of the spoils, which was very considerable. He also adorned the forum with palm trees, and beautified the academy with delightful walks and fountains.

96 He subdues the Chersonesus. The Persians having soon after this expedition invaded the Chersonesus, and with the assistance of the Thracians made themselves masters of it, Cimon was sent against them in a great hurry. He had only four ships; but nevertheless with these he took 13 of the Persian galleys, and reduced the whole of the Chersonesus. After this he marched against the Thracians, who revolting against the Athenians, had made themselves masters of the gold mines lying between the rivers Nyssus and Strymon. The Thracians were quickly obliged to yield; after which the Athenians sent a great colony to Amphipolis, a city of Thrace, which for some time made a considerable figure, but afterwards attempting to penetrate into the country of the *Edones*, great part of them were destroyed.

97 Makes Athens irresistible at sea. Cimon also fell upon the following expedient to make Athens irresistible at sea by the other states of Greece. Many of the Greek states, by virtue of Aristides's taxation, were bound to furnish men and galleys as well as to pay the tax for their support. But when they saw themselves out of danger from the Persians, most of them were very unwilling to furnish their quota of men. This the Athenian generals being offended with, were for having recourse to force; but Cimon permitted such as were desirous of staying at home to do so, and accepted a sum of money in lieu of a galley completely manned. By this means he inured the Athenians, whom he took on board his galleys, to hardship and discipline; while the allies who remained at home became enervated through idleness, and from being confederates, dwindled into tributaries, and almost slaves. In the last year of the 77th Olympiad, Cimon was sent to assist the Lacedæmonians against their Helotes, who had revolted from them. In this he was attended with his usual success; but, some time after, the Lacedæmonians being engaged in the siege of Ithome, sent again to the Athenians for succour, and Cimon was a second time sent to their relief; but the Spartans having received a sufficient support of troops from other quarters before the arrival of the Athenian general, he and his men were dismissed without doing any thing. This grievously offended the people of Athens, who thenceforward hated not only the Lacedæmonians, but all their own citizens who were thought to be friends to that state.

98 He is banished. It was not possible, however, that any person who had served the state should escape banishment at Athens. Cimon had gained great wealth both to the public and to himself. In his public character he had behaved with unimpeached honesty, and as a private citizen he dedicated his wealth to the most excellent purposes. He demolished the enclosures about his grounds and gardens, permitting every one to enter and take what fruits they pleased; he kept an open table, where both rich and poor were plentifully entertained. If he met a citizen in a tattered suit of clothes, he made some of his attendants exchange with him; or if the quality of the person rendered that kindness unsuitable, he caused a sum of money to be privately given him. All this, however, was not sufficient: he did not concur with every measure of the commonalty; and therefore the popular party determined not to banish him, but to put him to death. The crime laid to his charge was, that by presents from the Macedonians he was prevailed upon to let slip a manifest opportunity of enlarging his conquests, after taking from the Persians the gold mines of Thrace. To this accusation Cimon replied, that to the utmost of his power he had prosecuted the war against the Thracians, and other enemies of the state of Athens; but that, it was true, he had not made any inroads into Macedonia, because he did not imagine he was to act as a public enemy of mankind, and because he was struck with respect for a nation modest in their carriage, just in their dealings, and strictly honourable in their behaviour towards him and the Athenians: that if his countrymen looked upon this as a crime, he must abide their judgment; but, for his part, he could never be brought to think such conduct amiss. Elpinice, Cimon's sister, used all her interest in his behalf, and amongst others spoke to Pericles the celebrated statesman and orator. He was indeed Cimon's rival, and had no doubt assisted in stirring up the prosecution against him; but he did not desire his death; and therefore, though appointed to accuse him, Pericles spoke in such a manner that it plainly appeared he did not think him guilty; and, in consequence of this lenity, Cimon was only banished by the ostracism.

The Athenian power was now risen to such a height, that all the other states of Peloponnesus looked upon this republic with a jealous eye, and were continually watching every opportunity of making war upon it when the state was engaged in troublesome affairs, and seemed to be less able to resist. These attempts, however, so far from lessening, generally contributed to increase, the power of the Athenians; but in the year before Christ 458, the republic entered into a war with Sparta, which was scarcely put an end to but by the destruction of the city of Athens. For this war, there was no recent provocation on the part of the Spartans. They had sent a great army to assist the Dorians against the Phocians, and the Athenians took this opportunity to revenge themselves of former quarrels. Having therefore drawn in the Argives and Thessalians to be their confederates, they posted themselves on the isthmus, so that the Spartan army could not return without engaging them. The Athenians and their confederates amounted to 14,000, and the Spartans to 11,500. The Spartan general, however, not very willing to hazard a battle, turned aside to Tanagra, a city in Bœotia, where some of the Athenians who inclined to aristocracy entered into a correspondence with him. But before their designs were ripe for execution, the Athenian army marched with great expedition to Tanagra, so that a battle became inevitable. When the armies were drawn up in order of battle, Cimon presented himself before his countrymen in complete armour, and went to take post among those of his own tribe; but the popular party raised such a clamour against him, that he was forced to retire. Before he departed, however, he exhorted Euthippus and the rest of his friends to behave in such a manner that they

99 War between Athens and Sparta.

100 Athenians defeated.

might wipe off the aspersion thrown upon him, as if he had designed to betray his country's cause to the Lacedæmonians. Euthippus desired him to leave his armour, which he did; and a battle ensuing, the Athenians were defeated with great loss, and Euthippus with the rest of Cimon's friends were all killed in defence of his armour which they had surrounded. Another engagement soon followed, wherein both armies suffered so much, that they were glad to conclude a short truce, that each might have time to recruit their shattered forces.

101 They gain great advantages over the Spartans.

The scale of fortune now seemed to turn in favour of the Athenians. The Thebans, who had been deprived of the command of Bœotia on account of their having sided with Xerxes, were now restored to it by the Lacedæmonians. At this the Athenians were so displeased, that they sent an army under Myronides the son of Callias into Bœotia to overturn all that had been done. That general was met by the Thebans and their allies, who composed a numerous and well-disciplined army. Nevertheless, though the Athenian army was but a handful in comparison of their enemies, Myronides gained a complete victory over the allies, in some sense more glorious than either that of Marathon or Platæa. In these battles they had fought against effeminate and ill-disciplined Persians, but now they encountered and defeated a superior army composed of the bravest Greeks. After this victory, Myronides marched to Tanagra, which he took by storm, and razed to the ground: he then plundered Bœotia; defeated another army which the Bœotians had drawn together to oppose him; then fell upon the Locrians; and having penetrated into Thessaly, chastised the inhabitants of that country for having revolted from the Athenians; and from thence returned to Athens laden with riches and glory.

The next year Tolmides the Athenian admiral invaded Laconia, where he made himself master of several places; and on the back of this, Pericles invaded Peloponnesus with great success, burning, spoiling, or

102 Cimon recalled.

taking, whatever places he attempted. On his return he found the people greatly out of humour on account of Cimon's banishment; so he was immediately recalled.

Cimon was no sooner returned than he fell to his old employment of plundering the Persians; and, according to Plutarch, he had now nothing less in view than the conquest of the whole Persian empire. The Persian monarch finding he could have no rest, at last sent orders to Artabazus and Megabizus, his commanders, to conclude a treaty; which was done on the following conditions: 1. That the Greek cities in Asia should be free, and governed by their own laws. 2. That the Persians should send no army within three days journey of the sea. 3. That no Persian ship of war should sail between Thesalis and Cyrene, the former a city of Pamphylia, and the latter of Lycia.

103 His death.

While this treaty was going on, Cimon died, whether of sickness or of a wound he had received is not known; and after his death the Athenian affairs began to fall into confusion. It was now the misfortune of this state to be alike hated by her enemies and allies; the consequence of which was, that the latter were perpetually revolting whenever they thought they had an opportunity of doing so with impunity. The Megarians, at this time, who had been long under the protection or dominion of Athens, thought proper for some reason or other to disclaim all dependence on their former protectors, and have recourse to Sparta, with which state they entered into a strict alliance. This the Athenians revenged by ravaging the country of the Megarians; which soon brought on a renewal of the Lacedæmonian war that had been for a little time suspended. Pericles, however, procured the return of the first Lacedæmonian army, without bloodshed, by bribing Chandrides the young king of Sparta's tutor. In the winter, Tolmides resolved to undertake an expedition into Bœotia with a small body of troops: which design he put in execution contrary to the advice of Pericles; and his rashness was soon punished by his own death and the total defeat of his army. Notwithstanding this misfortune, however, Pericles soon after invaded and reduced Eubœa; and the Lacedæmonians, finding it was not for their interest to carry on the war, concluded a truce with the Athenians for 30 years.

104 A thirty years truce with the Lacedæmonians.

About this time Psammiticus, king of Egypt, sent by way of present to the people of Athens 40,000 bushels of wheat; which proved a great misfortune to the city: for Pericles, out of spite to Cimon, who had children by an Arcadian woman, had preferred a law whereby the Athenians of the half blood were disfranchised; and this law, on account of the distribution of the corn above mentioned, was prosecuted with such severity, that no less than 5000 persons, who till then had been considered as free men, were sold for slaves. This piece of cruelty has been of great service to the critics, as by means of it we know exactly the number of Athenian citizens, which at this time amounted to no more than 14,040 persons, though Athens was now aiming at no less than erecting an universal monarchy.

105 Cruelty of Pericles.

106 Number of the Athenian citizens.

Six years after the conclusion of the peace between Athens and Sparta, a war broke out between the Samians and Milesians about the city of Priene, seated under Mount Mycale in Ionia. How this war came to affect the Athenians is not certainly known; but, somehow or other, this republic was induced to take the part of the Milesians; and the island of Samos was reduced by Pericles, who established there a democracy, and left an Athenian garrison. He was no sooner gone, however, than the Samians disliking their new form of government, drove out the garrison he had left; but Pericles quickly returning, besieged and took their city, demolished their walls, and fined them of the whole expence of the war; part of which he obliged them to pay down, and took hostages for the remainder. When Pericles returned, he procured himself to be appointed to pronounce the public oration in honour of those who fell: which he did with such eloquence, that when he came down from the pulpit the women gathered about him, took him by the hand, and crowned him with garlands.

107 Samos reduced by Pericles.

A little after this commenced the war between the Corcyrians and Corinthians, which by degrees brought the Athenians into those engagements that proved the ruin of their state. The causes of this war were the following. An intestine war breaking out in the little territory of Epidamnum, a city of Macedonia, founded by the Corcyrians, one party called in to their assistance

108 War between the Corcyrians and Corinthians.

Digitized by Google

sistance the Illyrians, and the other the Corcyrians. The latter neglecting the matter, Corinth was applied to, as the Corcyrians were a colony from that place. The Corinthians, partly out of pity to the Epidamnians, and partly out of spleen to the Corcyrians, sent a very great fleet to the assistance of the former, by which means that party which had applied to Corinth was thoroughly established. This being resented by the Corcyrians, they sent a fleet to Epidamnum to support the exiles; and accordingly this fleet began to act offensively on its entering the port, the chief commanders having instructions to propose terms of accommodation, to which the Corinthians would by no means agree. The next year the Corcyrians defeated at sea the Corinthians and their allies, and took Epidamnum by storm; after which they wasted the territories of the allies of the Corinthians, which greatly exasperated the latter. At Corinth, therefore, they began to make great preparations for carrying on the war, and pressed their confederates to do the same, that they might be in a condition to retrieve the honour they had lost, and humble this ungrateful colony which had thus insulted her mother city.

The Corcyrians were no sooner acquainted with these proceedings, than they despatched ambassadors to Athens with their complaints; and these were quickly followed by others from Corinth on the same errand.

109 Athens sides with the Corcyrians.

At first the people of Athens inclined to favour the Corinthians: but they soon changed their minds, and took part with the Corcyrians: they contented themselves, however, with entering into a defensive alliance with that little state, whereby they promised to assist each other, in case either party should be attacked; and in consequence of this treaty, they furnished the Corcyrians with ten galleys, under Lacedæmonius the son of Cimon, with whom were joined Diotenes and Proteus as colleagues.

As soon as the season of the year permitted, the Corinthians sailed for the coast of Corcyra with a fleet of 150 ships, under the command of Xenoclides, assisted by four other Corinthian admirals; each squadron of their allies being commanded by a chief of their own. The Corcyrian and Athenian fleet amounted to 120, but the Athenians had orders to give as little assistance as possible. The action was very brisk for some time: the Corcyrian right wing broke the left of the Corinthian fleet; and forcing some of the ships on shore, landed, pillaged their camp, and made a great number of them prisoners; on the other hand, the Corinthian ships in the right wing beat the Corcyrian ships there, they being but very faintly assisted by the Athenians, till the latter were at last obliged to defend themselves, which they did so well, that the Corinthians were glad to retire. The next day preparations were made on both sides for another engagement; but 20 ships coming from Athens to the assistance of the Corcyrians; the Corinthians declined the combat.

110 Potidæa besieged by the Athenians.

As soon as the Corcyrian war broke out, the Athenians sent orders to the citizens of Potidæa to demolish a part of their wall, to send back the magistrates they had received from Corinth, and to give hostages for their own behaviour. Potidæa was a town in Macedonia, founded by the Corinthians, but at that time in alliance with the Athenians.—Perdiccas king of Macedon, who hated the Athenians, took this opportunity to persuade the Potidæans to revolt. Accordingly they sent ambassadors to Athens to entreat the revocation of these orders; but at the same time sent deputies to Sparta, to join with the Corinthians and Megarians in their complaints against the Athenians. The Athenians upon this sent a considerable fleet against Potidæa, under the command of Callias, a nobleman of great courage. The Corinthians on their part despatched one Aristeus with a considerable body of troops to the assistance of that city. An engagement following, the Athenians were victors, but with the loss of their general. Phormio, who succeeded in the command, invested the city in form, and shut up its port with his fleet; but the Potidæans dreading to fall into the hands of the Athenians, made a most obstinate defence, while in the mean time they warmly solicited the Corinthians to perform their promises, and engage the rest of the states of Peloponnesus in their quarrel.

111 The Spartans demand reparation for the injuries offered to the states of Greece.

The Lacedæmonians having heard what the Corinthians and other little states of Greece had to say against the Athenians, sent ambassadors to the latter, demanding reparation for the injuries, with orders, in case of a refusal, to declare war. The terms demanded were, in the first place, the expulsion of those Athenians who were allied to the family of Megacles so often mentioned. This article was on account of Pericles; for he was the son of Xanthippus the Athenian commander at Mycale by Agariste niece to the famous Clysthenes, who corrupted the priestess of Apollo in order to procure the expulsion of the Pisistratidæ. They next insisted that the siege of Potidæa should be raised; thirdly, that the inhabitants of Ægina should be left free; and lastly, that a decree made against the Megarians, whereby they were forbid the ports and markets of Athens, should be revoked, and all the Grecian states under the dominion of Athens set at liberty.

112 Their terms rejected by advice of Pericles.

These terms the Athenians were persuaded by Pericles to reject. The arguments used by him were in substance as follows: That whatever the Lacedæmonians might pretend as to the injustice of the complaints of the allies, the true ground of this resentment was the prosperity of the Athenian republic, which the Spartans always hated, and now sought an opportunity of humbling: that it must be owing to the Athenians themselves if this design succeeded, because for many reasons Athens was better able to engage in a long and expensive war than the Peloponnesians. He then laid before the people an exact account of their circumstances; putting them in mind, that the treasure brought from Delos amounted to 10,000 talents; and that though 4000 of these had been expended on the stately gate of their citadel, yet that 6000 were still in hand; that they were also entitled to the subsidies paid by the confederate states; that the statues of their gods, the Persian spoils, &c. were worth immense sums; that private men were arrived at vast fortunes; and that, considering their trade by sea, they had a certain annual increase of wealth; that they had on foot an army of 12,000 men, and in their colonies and garrisons 17,000; that their fleet consisted of 300 sail; whereas the Peloponnesians had no such advantages. For these reasons he proposed as the most feasible and likewise

Digitized by Google

Attica. likewise the most equitable satisfaction that could be given, that they would reverse their decree against Megara, if the Lacedæmonians would allow free egress and regress in their city to the Athenians and their allies; that they would leave all those states free who were free at the making of the last peace with Sparta, provided the Spartans would also leave all states free who were under their dominion; and that future disputes should be submitted to arbitration. In case these offers should be rejected, he advised them to hazard a war; telling them, that they should not think they ran that hazard for a trifle, or retain a scruple in their minds as if a small matter moved them to it, because on this small matter depended their safety, and the reputation of their constancy and resolution; whereas, if they yielded in this, the next demand of the Lacedæmonians would be of a higher nature; for having once discovered that the Athenians were subject to fear, they would thence conclude that nothing could be denied to Sparta; whereas a stiff denial in this case would teach them to treat Athens for the future on terms of equality. He enforced these reasons by showing that their ancestors had always acted on the like principles, and in all cases preferred their glory to their ease, and their liberty to their possessions.

113 Attempt of the Thebans on Platæa.

This was the origin of the Peloponnesian war, which makes so great a figure in ancient history. The immediate preliminary to general hostilities was an attempt of the Thebans to surprise Platæa. With this view they sent Eurymachus with 300 Thebans to assist such of the Platæans as they had drawn over to their interest, in making themselves masters of the place. In this design, they succeeded very well at first, the Platæans, who had promised to open the gates, keeping their words exactly, so that they were instantly in possession of the city. The other party, however, perceiving how small a number they had to contend with, unanimously rose upon them, killed a great many, and forced the rest to surrender themselves prisoners of war. Another party came from Thebes to assist their countrymen; but they arrived too late: the Platæans, however, foreseeing that they would waste their country, promised to release their prisoners if they would forbear to spoil their lands. On this the Thebans withdrew; and the Platæans cruelly put to death all their prisoners, to the number of 180, with Eurymachus their chief, alleging that they had not promised their release but in case of peace. The Athenians, as soon as they had notice of this attempt of the Thebans, caused all the Bœotians in their territory to be arrested; and when they understood how the Platæans had delivered themselves, they sent a great convoy of provisions to that city, and a numerous body of troops to escort their wives and children to Athens.

114 They are massacred.

115 Account of the allies on both sides.

Both parties now prepared in earnest for war, both sent ambassadors to the Persians, and both sought to rouse their allies. Most of the Greek states inclined to favour the Spartans, because they acted on this occasion as the deliverers of Greece, and because they either had been, or feared that they would be, oppressed by the Athenians. With the Spartans joined all the Peloponnesians, except the Argives and part of the Achæans; without Peloponnesus, the Megarians, Phocians, Locrians, Bœotians, Ambraciots, Leucadians, and Anactorians, declared themselves on their side. On the other hand, the Chians, Lesbians, Platæans, Messenians, Acarnanians, Corcyrians, Zacynthians, Carians, Dorians, Thracians, most part of the islands, and all the Cyclades excepting Melos and Thera, with Eubœa and Samos, joined the Athenians.

116 First year of the war.

The Peloponnesian war commenced 431 years before Christ. The Lacedæmonian army was assembled at the isthmus, and consisted of no less than 60,000 men; but before Archidamus king of Sparta, who commanded in chief, would enter Attica, he despatched a herald to Athens. The herald was sent back without any answer, by which all hopes of peace were cut off. As Archidamus was a friend to Pericles, the latter apprehended that he might forbear plundering his estates. With this he immediately acquainted the people; telling them at the same time, that in such a case he made a present of his lands to the public. He then advised the citizens to take no care of defending their country-seats, but to attend only to the city, busy themselves in the equipping of ships, and settle a thorough resolution not to be intimidated with the first evils of war. This proposal the Athenians readily complied with, and appointed Pericles commander in chief, with nine more generals to assist him.

The first year, the Spartan army committed great ravages in Attica, Pericles having no force capable of opposing it, and refusing to engage on disadvantageous terms, notwithstanding prodigious clamours were raised against him by his countrymen. The allies, however, had no great reason to boast of the advantages they gained this year: an Athenian fleet ravaged the coasts of Peloponnesus; another infested the Locrians, drove out the inhabitants of Ægina, and repeopled the island from Athens. They likewise reduced Cephalenia, and some towns in Acarnania and Leucas which had declared for the Lacedæmonians; and in the autumn, when the Peloponnesians were retired, Pericles entering the Megarian territory, did all the mischief that could be expected from a provoked enemy.

117 Second year. A dreadful plague at Athens.

The spring of the second year was very fatal to Athens, by a dreadful plague which destroyed great numbers of the citizens, while the Peloponnesians under Archidamus wasted every thing abroad. In the midst of these distresses, however, Pericles retained his courage, and would suffer none of his countrymen to stir without the city either to escape the plague or infest the enemy. He caused a great fleet to be equipped, on board which he embarked 4000 foot and 300 horse, with which he sailed to Epidaurus. Upon this the enemy withdrew their forces out of Attica; but Pericles was able to do no great matter on account of the plague, which made so great havock among his men, that he brought back to Athens only 1500 of the 4000 he carried out. By this misfortune the Athenians were thrown into despair; they immediately sued for peace, which the Spartans were now too proud to grant; then turning their rage upon Pericles, they dismissed and fined him. Soon after, Pericles's children and almost all his relations died of the plague; so that this great statesman was overwhelmed with melancholy, and for some time shut himself up from public view: at last, through the persuasion of Alcibiades and some others, he showed himself to the people. They received him with acclamations, and at his request repealed the unjust

118 Athenians sue for peace.

just law he had made, whereby all Athenians of the half blood were disfranchised, and then reinstated him in all

119 Pericles requests the repeal of his law.

his former honours. Hereupon he inrolled the only son he had left, who before had been counted a bastard on account of his mother being a Milesian.

This year also the island of Zacynthus was wasted by the Peloponnesians; and the city of Potidæa submitted to the Athenians, after the inhabitants had been driven to such extremity as to feed upon human flesh. The Athenians permitted the men to depart with one garment, and the women with two; after which, the town was repeopled by a colony from Athens.

120 Third year. Pericles dies.

The third year of the Peloponnesian war was remarkable for the death of the great Pericles, who was taken off by the plague. Platæa also was besieged by

121 Platæa besieged.

Archidamus; but without success, even though the greatest part of it was set on fire; the Platæans resolving to submit to every kind of misery rather than abandon the Athenian cause. In the end, therefore, the king of Sparta was obliged to turn the siege into a blockade; and having thrown up an intrenchment fortified with a deep ditch, he left a sufficient number of men to guard his lines, and then returned back to Peloponnesus.

122 Fourth year. Desperate attempt of the Platæans.

The following summer, the Peloponnesians under the command of Archidamus invaded Attica, where they wasted every thing with fire and sword; at the same time the whole island of Lesbos, except the district of Methymna, revolted from the Athenians, who hereupon invested the city of Mitylene. All this time the city of Platæa was blocked up by the Peloponnesians; and its inhabitants being now greatly distressed for want of provisions, the garrison, consisting of 400 natives and 80 Athenians, came to the desperate resolution of forcing a passage through the enemy's lines. When they came to attempt this, however, many of them were intimidated: but 300 persisted in their resolution; and of these 212 got safe through and marched to Athens, but the rest were compelled to retire.

123 Fifth year. Mitylene, &c. taken by the Athenians.

In the beginning of the fifth year, the Peloponnesians sent 40 ships to the relief of Mitylene; but without effect, for the place had surrendered before the fleet could come to its assistance. Paches, the Athenian commander, likewise chased away the Peloponnesian fleet upon its arrival; and returning to Lesbos sent the Lacedæmonian minister, whom he found in Mitylene, together with a deputations, to Athens. On their arrival, the Lacedæmonian was immediately put to death; and in a general assembly of the people, it was resolved, that all the Mitylenians who were arrived at man's estate should be put to death, and the women and children sold for slaves. The next day, however, this cruel decree was reversed, and a galley sent with all expedition to countermand the bloody orders. This last vessel, however, could not get before the other: but Paches, being a man of great humanity, had taken a day to consider on the orders he had received; during which time the last-mentioned galley arrived; in consequence of which, only about 1000 of the most forward rebels were put to death; the walls of the city were also demolished, their ships taken away, and their lands divided among the Athenians, who let them again to their old masters at very high rents. The same summer the Athenians seized the island of Minoas, lying over against the territory of Megara; and likewise the port of Nisæa, which last they fortified, and it proved afterwards a place of the utmost importance to them. At this time also the Platæans, driven to the last extremity, surrendered to the Lacedæmonians, by whom they were, to the number of 208, including 25 Athenians, put to death, and their women sold for slaves. Their city was soon after razed by their implacable enemies the Thebans, who left only an inn to show where it stood. The fame of Platæa, however, induced Alexander the Great afterwards to rebuild it.

124 Platæa taken and razed.

125 Sedition of Corcyra.

In this year happened the famous sedition of Corcyra, whence other seditions, when their effects rendered them terrible, have been called *Corcyrian*. It hath been already observed, that the war between the Corcyrians and Corinthians brought on the general war throughout Peloponnesus. A great number of Corcyrians were in the beginning of this war carried away prisoners into Peloponnesus, where the chief of them were very well treated, but the rest sold for slaves. The reason of this conduct of the Corinthians was a design they had formed of engaging these Corcyrians to influence their countrymen to side with them and their allies. With this view they treated them with all imaginable lenity and tenderness, instilling into them by degrees a hatred of democratic government; after which they were told, that they might obtain their liberty upon condition of using all their influence at home in favour of the allies, and to the prejudice of Athens. This the Corcyrians readily promised and endeavoured to perform. At first, those who were for an aristocracy prevailed, and murdered all those of the opposite party that fell into their hands, in which they were assisted by a fleet of Peloponnesians: but the Athenians sending first one fleet and then another to the assistance of the distressed party, the Peloponnesians were forced to withdraw; after which the democratic party sufficiently revenged themselves, and destroyed their antagonists without mercy. The worst of all was, that this example once set, the several states of Greece felt in their turns the like commotions, which were always heightened by agents from Sparta and Athens; the former endeavouring to settle aristocracy, and the latter democracy, wherever they came.

126 Athenians engage in a war with Sicily.

While the Athenians were thus engaged in a war wherein they were already overmatched, they foolishly engaged in a new one, which in the end proved more fatal than all the rest. The inhabitants of Sicily were split into two factions; the one called the *Doric*, at the head of which was the city of Syracuse; the other the *Ionic*, which owned the Leontines for their chiefs: the latter perceiving themselves too weak without foreign aid, sent one Gorgias, a celebrated orator, to apply to Athens for relief; and he by his fine speeches so captivated the giddy and inconstant Athenians, that they ran headlong into a war which they were unable to maintain while engaged with all the Peloponnesians. Enticed by this new prospect, therefore, and grasping at the conquest of Sicily, as well as of all Greece, they sent a fleet to the assistance of the Leontines, under the command of Lachetes and Chabrias; and they were no sooner sailed than another fleet for the same purpose was begun to be fitted out. All this time the plague continued to rage with great violence at Athens, cutting off this year 4090 citizens, besides

Digitized by Google

sides a much greater number of the meaner sort of people.

127 Sixth year. The sixth year of the Peloponnesian war was remarkable for no great exploit: Agis the son of Archidamus, king of Sparta, assembled an army in order to invade Attica, but was prevented from so doing by many great earthquakes which happened throughout Greece.

128 Seventh year. Pylus fortified by the Athenians. The next year, however, he entered Attica with his army, while the Athenians on their part sent a fleet under the command of Demosthenes, to infest the coasts of Peloponnesus. As this fleet passed by Laconia, the commander took notice that the promontory of Pylus, which was joined to the continent by a narrow neck of land, had before it a barren island about two miles in circumference, in which, however, there was a good and safe port, all winds being kept off by the headland, or by the isle. These advantages made him apprehend, that a garrrison left here would give the Peloponnesians so much trouble, that they would find it more advisable to protect their own country than to invade that of their neighbours. Accordingly, having raised a strong fortification, he himself with five ships staid to defend it, while the rest of the fleet proceeded on their intended expedition.

129 Besieged. On the news of this event, the Peloponnesian army immediately returned to besiege Pylus. When they arrived before the place they took possession of the harbour, and then caused a chosen body of Spartans take possession of the island of Sphacteria, after which they attacked the fort with great vigour. Demosthenes and his garrison defended themselves with great valour;

130 Spartan fleet destroyed. and an Athenian fleet arriving very seasonably, offered battle to the Peloponnesian fleet. This being refused, the Athenians boldly sailed into the harbour, broke and sunk most of the vessels therein, after which they besieged the Spartans in Sphacteria. The Peloponnesians now began to treat with their enemies, and a truce was concluded during the time that negociations were carried on at Athens. One of the articles of this truce was, that the Peloponnesians should deliver up all their ships, on condition of having them punctually returned in case the treaty did not take effect. The Athenians having heard the Spartan ambassadors, were inclined to put an end to this destructive war: but Cleon, one of their orators, a warm and obstinate man, persuaded his countrymen to insist on very unreasonable terms; upon which the ambassadors

131 Treachery of the Athenians. returned, and by doing so put an end to the truce. The Peloponnesians then demanded their vessels; but the Athenians refused to deliver them, under pretence of their having broke the truce.

132 They attack Sphacteria. Hostilities being thus recommenced on both sides, the Lacedæmonians attacked the Athenians at Pylus, while the latter attacked the Spartans at Sphacteria. The Spartans, though but a handful of men, and under every imaginable discouragement, behaved with such

133 Cleon the orator appointed general. bravery, that the siege proceeded very slowly, so that the people of Athens became very uneasy. They began then to wish they had embraced the offers of the Spartans, and to rail vehemently against Cleon, who, to excuse himself, said it would be easy for the general of the forces they were at that time sending to attack the Spartans in the isle, and reduce them at once. Nicias, who had been appointed to this command, replied that if Cleon believed he could do such great things he would do well to go thither in person: the latter imagining this only meant to try him, said he was ready to go with all his heart; whereby Nicias catched him, and declared that he had relinquished his charge. Cleon thereupon said, that he was no general; but Nicias told him that he might become one; and the people, pleased with the controversy, held the orator to his word. Cleon then advancing, told them he was so little afraid of the enemy, that, with a very inconsiderable force, he would undertake, in conjunction with those already at Pylus, to bring to Athens the Spartans who gave them so much trouble in 20 days. The people laughed at these promises: however, 134

they furnished him with the troops he desired; and to He takes

their surprise, Cleon brought the Spartans prisoners to the place.

Athens within the time appointed.

This summer, likewise, an Athenian fleet was sent 135 End of the Corcyrian sedition.

to Sicily, with instructions to put in at Corcyra, and assist the government against the Lacedæmonian faction which still subsisted in that island. This they effectually performed; for by their means the exiles fell into the hands of the other party: these they imprisoned; and then drew them out by 20 at a time, to suffer death, which was inflicted with all the circumstances of cruelty that party-rage could suggest. When only 60 remained, they entreated the Athenians to put them to death, and not to deliver them up to their countrymen; but upon this the Corcyrians surrounded the place where they were confined, endeavouring to bury them under their darts; upon which the unhappy captives all put an end to their own lives.

In the eighth year Nicias reduced the isle of Cythe- 136 Eighth year. Success of the Athenians.

ra on the coast of Laconia; as likewise Thyræa, on the confines of that country. The latter had been given to the Æginetans when expelled from their own country by the Athenians: and they were now condemned to death, as inveterate enemies of the Athenian state and nation.—In Sicily, one Hermocrates of Syracuse persuaded all the inhabitants of the island to adjust their differences among themselves; upon which the Athenian generals returned home, and for so doing two of them were banished, and the third sentenced to pay a heavy fine.

The Athenians next laid siege to Megara under the conduct of Hippocrates and Demosthenes; but Brasidas a Spartan general coming to its relief, a battle ensued, by which, though neither party got the better, 137

the Lacedæmonian faction prevailed in Megara, and Spartan party prevails in Megara.

many who favoured the Athenians were forced to withdraw. After this, such as had been banished for adhering to the Lacedæmonians were allowed to return, on their taking an oath to forget what was past, and attempt nothing that might disturb their country. As soon as they were settled, however, they forgot their oath; and causing 100 of those who were most obnoxious to be apprehended, forced the people to condemn them to death. They then changed the whole form of government, introduced an oligarchy, and possessed themselves of the supreme power.

In Bœotia some commotions were raised in favour of 138 Athenians lose their power in Bœotia.

the Athenians; but their generals Hippocrates and Demosthenes being defeated by the opposite party, all hopes ceased of the Athenian power being established in Bœotia. In the mean time Brasidas reduced the city of Amphipolis, which greatly alarmed the Athenians,

ans, who thereupon sent new supplies of men, money, and ships to the Macedonian coast; but all their care could not prevent a great desertion from their interest in those parts, where the conduct and valour of Brasidas carried all before him.

139 Ninth year. A truce concluded and broken.

In the ninth year, the Spartans made new proposals of peace, which the Athenians were now more inclined to accept than formerly; and finding their affairs very much unsettled by the loss of Amphipolis, a truce for a year was quickly agreed on, while negociations were in the mean time carrying on for a general peace. This pacific scheme, however, was very soon overthrown by the following accident in Thrace. The city of Scione, and that of Menda, revolted to Brasidas; who, knowing nothing of the truce, sought to draw over Potidæa also. The Athenians, pretending that Scione revolted two days after the truce was concluded, made heavy complaints, asserting that this was a breach of the truce, and that both it and Menda should be restored to them. This not being effected by negociations, an army was sent against the two cities by which Menda was reduced; but Scione making an obstinate defence, the siege was turned into a blockade.

140 Cleon defeated and killed by Brasidas.

In the tenth year Brasidas made an attempt upon Potidæa; which having failed, the Athenians began to recover some courage. The truce expiring on the day of the Pythian games, Cleon persuaded the Athenians to send an army into Thrace under his own command. It consisted of 1200 foot and 300 horse, all Athenian citizens, who embarked on board 30 galleys. Brasidas had an army much inferior; but observing that the Athenian general was become careless, and neglected discipline, he attacked him. In this engagement Cleon was killed, and the Athenians were defeated with the loss of 600 men, while the Spartans lost only seven; but among these was their brave commander Brasidas, whose death affected them almost as much as the loss of their army did the Athenians.

141 A fifty years peace.

As the death of Cleon deprived the Athenians of one of their best speakers, and one who had been very industrious in promoting the war, they were now much more disposed than formerly to hearken to terms of accommodation. Amongst the Spartans, too, there was a party, at the head of whom was Plistonax their king, who earnestly wished for peace; and as Nicias laboured no less assiduously at Athens to bring about this desirable event, a peace was at last concluded for fifty years between the two nations. The conditions were, that a restitution of places and prisoners should be made on both sides; excepting that Nisæa should remain to the Athenians, who had taken it from the Megarians, and that Platæa should continue with the Thebans, because they absolutely would not give it up. The Bœotians, Corinthians, and Megarians, refused to be included in this peace: but the rest of the allies yielded to it; and it was accordingly ratified, receiving the name of the *Nician* peace, from Nicias who had so vigorously promoted it.

142 New discontents.

By this means, however, tranquillity was far from being restored. Such of the states of Peloponnesus as were dissatisfied, began immediately to league among themselves, and to set on foot a new confederacy, the head of which was to be the state of Argos. The Lacedæmonians, too, found it impossible to perform exactly the articles of agreement; the city of Amphipolis, in particular, absolutely refused to return under the Athenian government; for which reason the Athenians refused to evacute Pylus. In the winter, new negociations were entered into on all sides, but nothing determined, and universal murmuring and discontent took place. These discontents were not a little heightened by Alcibiades, who now began to rival Nicias, and, perceiving the Lacedæmonians paid their court mostly to his rival, took all opportunities to incense his countrymen against that nation. Nicias, on the other hand, who wished for nothing so much as peace, used all his endeavours to bring about a reconciliation. The artifices of Alcibiades, however, added to the turbulent and haughty disposition of both nations, rendered this impossible; so that though Nicias went on purpose to Sparta, he returned without doing any thing.

143 Heightened by Alcibiades.

144 His measures for the safety of Attica.

Alcibiades having thus disposed every thing according to his wishes, and a war being inevitable, he began to take the most prudent methods for preserving his country in safety. With this view he entered into a league for 100 years with the Argives, which he hoped would keep the war at a distance; he next passed over into the territories of Argos, at the head of a considerable army; and laboured, both at that city and at Patræ, to persuade the people to build walls to the sea, that so they might the more easily receive assistance from the Athenians. But though great preparations for war were now made, nothing was undertaken this year; only the Argives thought to have made themselves masters of Epidaurus, but were hindered by the Lacedæmonians putting a garrison into it.

145 Fourteenth year. War renewed.

The next year (the 14th after the Peloponnesian war was first begun) a Spartan army, under the command of Agis, entered the territory of Argos, where the confederate army lay; but just as the engagement was about to begin, a truce was suddenly concluded by two of the Argive generals and the king of Sparta. With this neither party was pleased, and both the king and generals were very ill treated by their citizens. On the arrival of some fresh troops from Athens, therefore, the Argives immediately broke the truce; but the allied army was soon after defeated with great slaughter by Agis; notwithstanding which, however, the Eleans and Athenians invested Epidaurus. In the winter a strong party in Argos joined the Lacedæmonians; in consequence of which that city renounced her alliance with Athens, and concluded one with Sparta for 50 years. In compliment to their new allies, also, the Argives abolished democracy in their city, establishing an aristocracy in its place, and assisted the Lacedæmonians with a considerable body of troops to force the Sicyonians to do the same.

146 Athenians, &c. defeated at Mantinea.

147 Fifteenth year.

In the beginning of the 15th year, the Argives, with a levity seemingly natural to all the Greeks, renounced their alliance with Sparta, abolished aristocracy, drove all the Lacedæmonians out of the city, and renewed their league with Athens. The Athenians, in the mean time, being convinced of the treachery of Perdiccas king of Macedon, renounced their alliance with him, and declared war against him.

148 Sixteenth year. Melos reduced by the Athenians.

Next year Alcibiades terminated the disputes in the city of Argos, by the banishment of the Spartan faction; after which he sailed to the island of Melos, whose inhabitants had acted with the greatest invete-

Attica. racy against his countrymen: perceiving, however, that the reduction of the island would be a work of time, he left a considerable body of forces there, and returned to Athens. In his absence the capital of Melos surrendered at discretion, and the inhabitants were treated with the utmost cruelty: all the men capable of bearing arms being slaughtered, and the women and children carried into captivity.

149 Seventeenth year. Athenian army in Sicily lost, and Alcibiades flies to Sparta.

In the beginning of the 17th year, Nicias was appointed commander of an expedition against the Syracusans, along with Alcibiades and Lamachus as colleagues. But while the necessary preparations were making, all things were thrown into confusion by the defacing of the Hermæ, or statues of Mercury, of which there was a great number in the city. The authors of this sacrilege could by no means be discovered, though rewards were offered for this purpose: at last the suspicion fell upon Alcibiades; and for this weighty reason he was commanded to return from Sicily to take his trial. Alcibiades, however, knew the temper of his countrymen too well to trust himself to their mercy; and therefore, instead of returning to Athens, he fled immediately to Sparta, where he met with a gracious reception; while the infatuated Athenians were severely punished by the loss of their army, generals, and fleet, in Sicily, which the superior abilities of Alcibiades would in all probability have prevented.

150 Nineteenth and twentieth years, &c.

The 19th and 20th years of the war were spent by the Athenians in equipping a new fleet in order to repair their vast losses; but Alcibiades hurt their interests very much, by persuading Tissaphernes the Persian to league with the Spartans against them: at the same time he persuaded several of the Ionian states to revolt from Athens, but they were in a short time obliged again to submit. Notwithstanding all these services, however, Alcibiades had rendered himself so hateful to Agis, by debauching his wife, that he soon found himself obliged to fly to the Persians, where Tissaphernes gave him a very favourable reception, and profited much by his advice, which was, to let the Greeks weaken one another by their mutual wars, and that the Persians ought never to see one state totally destroyed, but always to support the weaker party.

151 Alcibiades flies to Persia.

152 Proposes the abolition of democracy at Athens.

When Tissaphernes had acquiesced with these counsels, Alcibiades privately wrote to some of the officers in the Athenian army at Samos, that he had been treating with the Persians in behalf of his countrymen, but did not choose to return till the democracy should be abolished; and to incline the citizens to comply with this measure, he told them that the Persian king disliked a democracy, but would immediately assist them if that was abolished, and an oligarchy erected in its stead.

On the arrival of Pisander and other deputies from the army, with the proposals of Alcibiades, the Athenians without hesitation resolved to overturn that democracy which they had all along so strenuously defended. The issue of their present debate was, that Pisander with ten deputies should return to Alcibiades, in order to know on what terms the king of Persia would make an alliance with them: but that cunning Athenian having perceived that Tissaphernes was by no means disposed to assist the Athenians on account of their having been lately successful, he set up such high demands in the king of Persia's name, that the Athenians of themselves broke off the treaty, and thus Alcibiades preserved the friendship of both parties.

Pisander having engaged the army at Samos in his scheme of overturning democracy, that form of government was abolished first in the cities subject to Athens, and lastly in the capital itself. Pisander's new scheme was, That the old form of government should be totally dissolved: that five prytanes should be elected: that these five should choose 100: and that each of the hundred should choose three: that the 400 thus elected should become a senate with full power; but should occasionally consult with 5000 of the most wealthy citizens, who should thenceforward be esteemed only *the people;* and that no authority should remain with the lowest class. Though the people were not very fond of this change, those who conducted it, being men of great parts, found means to establish it by force; for when the people were gone out of the city to their ordinary employments, the 400, having each a dagger concealed under his vest, attended by a guard of 120 men, entered the senate house, dissolved the old senate, and without ceremony turned them out; after which the commons, not knowing whom to submit to, or to whom to apply, made no opposition.

153 New form of government established.

The first step of the new governors was to destroy all their enemies; who, however, were not very numerous, so that little blood was shed. They next sent ambassadors to Agis to sue for peace; but he, taking for granted that the Athenians would never defend an oligarchy, gave no answer to the ambassadors, but immediately marched towards the capital with a design to attack it. On his arrival, however, he was quickly convinced of his mistake, being repulsed with loss, and obliged to retire to his old post.

154 The army declare for a democracy, and recal Alcibiades.

In the mean time the Athenian army declared again for a democracy; and having recalled Alcibiades, invested him with full power, and insisted on his immediate return to Athens to restore the ancient government. This measure he refused to comply with, and persuaded them to stay where they were, in order to save Ionia: he also prevailed on them to allow some deputies, who had been sent from the new governors of Athens, to come and deliver their message. To these deputies Alcibiades replied, that they should immediately return to Athens, and acquaint the 400, that they were commanded immediately to resign their power and restore the senate; but that the 5000 might retain theirs, provided they used it with moderation.

155 Great confusion at Athens.

By this answer the city was thrown into the utmost confusion; but the new government party prevailing, ambassadors were despatched to Sparta with orders to procure peace on any terms. This, however, was not to be effected; and Phrynicus, the head of the embassy, and likewise of the new government party, was murdered on his return. After his death, Theramenes, the head of the other party, seized the chiefs of the 400; upon which a tumult ensued that had almost proved fatal to the city itself. The mob, however, being at last dispersed, the 400 assembled, though in great fear, and sent deputies to the people, promising to set all things to rights. In consequence of this deputation,

Attica.

tion, a day was appointed for convoking a general assembly, and settling the state; but when that day came, news was brought that the Lacedæmonian fleet appeared in view, and steered directly for Salamis. Thus all was again thrown into confusion; for the people, instead of deliberating on the subject proposed, ran in crowds down to the port, and perceiving the Spartans made towards Eubœa, a fleet of 36 ships was immediately despatched under the command of Thymochares, to engage the enemy. This fleet was utterly defeated, 22 of the Athenian ships being taken, and most of the others sunk or disabled; but what was worse, this defeat was followed by the revolt of all the country of Eubœa except Orcus.

156 Athenian fleet destroyed by the Spartans.

When these dismal tidings arrived at Athens, every thing was given up for lost; and had the Lacedæmonians taken this opportunity of attacking the city, they had undoubtedly succeeded, and thus put an end to the war: but being at all times slow, especially in naval affairs, they gave the Athenians time to equip a new fleet, and to retrieve their affairs. One good effect of this disaster, however, was the putting an end for a time to the internal dissensions of this turbulent people; insomuch that Thucydides the historian is of opinion, that the republic never enjoyed so much quiet as at this time.

157 Exploits of Alcibiades.

Alcibiades now showed his abilities and inclination to serve his country in an eminent manner. By his intrigues he so effectually embroiled the Persians and Peloponnesians with each other, that neither party knew whom to trust. Thrasybulus, with 55 ships, gained a victory over the Peloponnesian fleet consisting of 73: after which he took eight galleys coming from Byzantium; which city had revolted from the Athenians, but was soon after taken, and the inhabitants severely fined. The fleet being afterwards joined by Alcibiades, nine more of the Peloponnesian galleys were taken, the Halicarnassians were constrained to pay a large sum of money, and Cos was strongly fortified: which transactions ended the 21st year of the Peloponnesian war.

In the succeeding years of this famous war, the Athenians had at first great advantages. Thrasybulus gained a signal victory at sea; and Alcibiades gained two victories, one by sea and another by land, in one day; took the whole Peloponnesian fleet, and more spoil than his men could carry away. The Spartans were now humbled in their turn, and sued for peace; but the Athenians were so intoxicated with their success, that they sent back the ambassadors without an answer: which they soon had sufficient reason to repent of. The beginning of the Athenian misfortunes was the taking of Pylus by the Spartans. The Athenians had sent a fleet under the command of one Anytus to its defence: but he was driven back by contrary winds; upon which he was condemned to death, because he could not cause the wind blow from what quarter he pleased: this sentence, however, was remitted on his paying a vast sum of money. This misfortune was quickly followed by another. The Megarians surprised Nysæa; which enraged the Athenians so much, that they immediately sent an army into that country, who defeated the Megarians who opposed them with great slaughter, and committed horrid devastations.

158 The Spartans sue for peace.

159 They take Pylus.

These misfortunes as yet, however, were overbalanced by the great actions of Alcibiades, Thrasybulus, and Theramenes. When Alcibiades returned, he brought with him a fleet of 200 ships, and such a load of spoils as had never been seen in Athens since the conclusion of the Persian war. The people left their city destitute, that they might crowd to the port, to behold Alcibiades as he landed; old and young blessed him as he passed; and next day when he made a harangue to the assembly, they directed the record of his banishment to be thrown into the sea, absolved him from the curses he lay under, and created him general with full power. Nor did he seem inclined to indulge himself in ease, but soon put to sea again with a fleet of 100 ships. He had not been long gone, however, before all this was forgot. Alcibiades sailed to the Hellespont with part of his fleet, leaving the rest under the command of Antiochus his pilot, but with strict orders to attempt nothing before his return. This command the pilot paid no regard to, but provoked Lysander the Lacedæmonian admiral to an engagement, and in consequence of his temerity was defeated with the loss of 15 ships, himself being killed in the engagement. On the news of this defeat Alcibiades returned, and endeavoured to provoke the Lacedæmonians to a second battle; but this Lysander prudently declined; and in the mean time, the Athenians, with unparalleled ingratitude and inconstancy, deprived Alcibiades of his command, naming ten new generals in his room.

160 Alcibiades enters Athens in triumph.

161 He is disgraced.

162 The Athenians gain a great victory, and put six of their generals to death.

This was the last step the Athenians had to take for perfecting their ruin. Conon, who succeeded to the command, was defeated by Callicratides, Lysander's successor; but being afterwards strongly reinforced, the Lacedæmonians were entirely defeated with the loss of 77 ships. Such a victory might at this time have inspired the Athenians with some kind of gratitude towards the generals who gained it; but instead of this, on pretence of their not having assisted the wounded during the engagement, eight of them were recalled; two were wise enough not to return; and the six who trusted to the justice of their country were all put to death.

163 They are utterly defeated by Lysander;

The next year Lysander was appointed commander of what fleet the Peloponnesians had left, with which he took Thasus and Lampsacus. Conon was despatched against him with 180 ships, which being greatly superior to Lysander's fleet, that general refused to come to an engagement, and was blocked up in the river Ægos. While the Athenians lay there, they grew quite idle and careless; insomuch that Alcibiades, who had built a castle for himself in the the neighbourhood, entreated them to be more on their guard, as he well knew Lysander's abilities. They answered, that they wondered at his assurance, who was an exile and a vagabond, to come and give laws to them; telling him, that if he gave them any farther trouble, they would seize and send him to Athens. At the same time they looked on victory as so certain, that they consulted what they should do with their prisoners; which, by the advice of Philocles their general, was to cut off all their right hands, or, according to Plutarch, their right thumbs; and Adiamantus, one of their officers, rendered himself very obnoxious by saying, that such idle discourse did not become Athenians. The

Digitized by Google

consequences of such conduct may be easily imagined. Lysander fell unexpectedly upon them, and gained a most complete victory; Conon, with eight galleys only, escaping to Cyprus; after which Lysander returned to Lampsacus, where he put to death Philocles with 3000 of his soldiers, and all the officers except Adiamantus. This execution being over, he reduced all the cities subject to Athens; and with great civility sent home their garrisons, that so the city might be overstocked with inhabitants, and destitute of provisions, when he came to besiege it; which he did soon after by sea, while Agis, with a great army, invested it by land. 164

who takes Athens.

For a long time the Athenians did not so much as desire a peace; but at last were forced to send deputies to Agis, who sent them to Sparta, where no terms could be granted except they consented to demolish their walls. They next sent to Lysander, who after a long attendance referred them to Sparta; and thither Theramenes with some other deputies was immediately sent. On their arrival, they found the council of the confederates sitting, who all except the Spartans gave their votes that Athens should be utterly destroyed; but they would not consent to the ruin of that city, which had deserved so well of Greece. On the return of Theramenes, peace was concluded, on condition that the long walls and the fortifications of the port should be demolished; that they should give up all their ships but 12, receive all they had banished, and follow the fortune of the Lacedæmonians. These severe terms were punctually executed. Lysander caused the walls to be pulled down, all the music in his army playing, on that very day of the year on which they had beat the Persians at Salamis. He likewise established an oligarchy expressly against the will of the people; and thus the ruin of Athens ended the 27th year of the Peloponnesian war, and the 404th before Christ.

165 *Terms of peace.*

166 *The thirty tyrants.*

As soon as Lysander had demolished the long walls, and the fortifications of the Piræus, he constituted a council of thirty, with power, as was pretended, to make laws, but in truth to subjugate the state. These are the persons so famous in history, under the title of *the thirty tyrants*. They were all the creatures of Lysander; who, as they derived their rise from conquest and the law of the sword, exercised their offices in a suitable manner; that is, with the highest testimonies of pride, insolence, and cruelty. Instead of making laws, they governed without them; appointed a senate and magistrates at their will; and, that they might do all things without danger of controul, they sent for a garrison from Lacedæmon; which was accordingly granted them, under the command of Callidius, upon their promise to pay the soldiers regularly. One of the first steps they took was to punish all informers; which, though severe, was popular; but when, through flattery and bribes, they had wholly drawn over Callidius to their party, they suffered bad men to live in quiet, and turned their rage against the good.

167 *Critias and Theramenes, their opposite characters.*

Critias and Theramenes were at the head of the thirty, men of the greatest power and abilities in Athens. The former was ambitious and cruel without measure; the latter was somewhat more merciful: the former pushed on all the bloody schemes framed by his confederates; and carried into execution many of his own; the latter always opposed them, at first with moderation, at last with vehemence. He said, that power was given them to rule, and not to spoil, the commonwealth; that it became them to act like shepherds, not like wolves; and that they ought to beware of rendering themselves at once odious and ridiculous, by attempting to domineer over all, being such a handful of men as they were. The rest, disliking much the former part of his discourse, catched hold of the latter, and immediately chose out 3000, whom they made the representatives of the people, and to whom they granted this notable privilege, that none of them should be put to death but by judgment of the senate, thereby openly assuming a power of putting any other of the Athenian citizens to death by their own authority. A glorious use they made of this new-assumed privilege; for as many as they conjectured to be no friends to the government in general, or to any of themselves in particular, they put to death, without cause, and without mercy. Theramenes openly opposing this, and absolutely refusing to concur in such measures, Critias accused him to the senate as a man of unsteady principles, sometimes for the people, sometimes against them, always for new things and state-revolutions. Theramenes owned, that he had sometimes changed his measures, but alleged that he had always done it to serve the people. He said that it was solely with this view he made the peace with Sparta, and accepted the office of one of the thirty: that he had never opposed their measures while they cut off the wicked; but when they began to destroy men of fortune and family, then he owned he had differed with them, which he conceived to be no crime against the state. 168

Theramenes put to death.

While Theramenes was speaking, Critias withdrew, perceiving that the senate were thoroughly convinced of the truth of what Theramenes had said: but he quickly returned with a guard, crying out, that he had struck Theramenes's name out of the list of the 3000; that the senate had, therefore, no longer cognizance of the cause, when the thirty had already judged and condemned him to death. Theramenes perceiving that they intended to seize him, fled to the altar, which was in the midst of the senate-house, and laying his hands thereon, said, "I do not seek refuge here because I expect to escape death, or desire it; but that, tearing me from the altar, the impious authors of my murder may interest the gods in bringing them to speedy judgment, and thereby restore freedom to my country." The guards then dragged him from the altar, and carried him to the place of execution, where he drank the poison with undaunted courage, putting the people in mind with his last breath, that as they had struck his name out of the 3000, they might also strike out any of theirs. His death was followed by a train of murders, so that, in a short time, 60 of the worthiest and most eminent citizens of Athens fell by the cruelty of the thirty. Among these, the most pitied was Niceratus the son of Nicias; a man universally beloved for his goodness, and universally admired for his virtues. As for the Spartans, they, losing their former generosity, were extremely pleased with these things, and, by a public decree, commanded that such as fled from the thirty tyrants should be carried back bound to Athens: which extraordinary proceeding frightened all Greece; but the Argives and Thebans only had courage

courage to oppose it: the former received the Athenian exiles with humanity and kindness, the latter punished with a mulct such of their citizens as did not rise and rescue the Athenian prisoners, who in pursuance of the Lacedæmonian decree were carried bound through their territories.

Thrasybulus, and such as with him had taken shelter in the Theban territory, resolved to hazard every thing, rather than remain perpetual exiles from their country; and though he had but 30 men on whom he could depend, yet considering the victories he had heretofore obtained in the cause of his country, he made an irruption

169 Thrasybulus seizes Phyla.

into Attica, where he seized Phyla, a castle at a very small distance from Athens, where in a very short space his forces were augmented to 700 men; and though the tyrants made use of the Spartan garrison in their endeavours to reduce him and his party, yet Thrasybulus prevailed in various skirmishes, and at last obliged them to break up the blockade of Phyla, which they had formed. The thirty and their party conceiving it very advantageous for them to have the possession of Eleusina, marched thither, and having persuaded the people to go unarmed out of their city, that they might number them, took this opportunity most inhumanly to murder them. The forces of Thrasybulus increasing daily, he at length possessed himself of the Piræus, which he fortified in the best manner he could; but the tyrants being determined to drive him from thence, came down against him with the utmost force they could raise. Thrasybulus defended himself with great obstinacy; and in the end they were forced to retreat, having lost before the place not only a great number

170 Critias killed.

of their men, but Critias the president of the thirty, another of the same body, and one who had been a captain of the Piræus.

When they came to demand the dead from Thrasybulus, in order for their interment, he caused a crier he had with him to make a short speech in a very loud voice to the people, entreating them to consider, that as they were citizens of Athens without, so those against whom they fought, and those who sought to preserve themselves within the fort, were Athenian citizens also; wherefore, instead of thinking how to ruin and destroy their brethren, they ought rather to consult how all differences might be composed, and especially ought to rid themselves of those bloody tyrants, who, in the short time they had had the administration in their hands, had destroyed more than had fallen in the Peloponnesian war. The people, though moved by these discourses, differed among themselves; the consequence of

171 The tyrants expelled

which was, that they expelled the thirty, and chose ten men out of each tribe to govern in their stead, whereupon the tyrants retired to Eleusina. The citizens, however, though they changed the government, made no agreement with those in the Piræus; but sent away deputies to Sparta, as did all the tyrants from Eleusina, complaining, that the Athenians had revolted,

172 Attempt of the Spartans to reduce Athens a second time.

and desiring their assistance to reduce them. The Spartans sent thereupon a large sum of money to encourage their confederates, and appointed Lysander commander in chief, and his brother to be admiral; resolving to send sea and land forces to reduce Athens a second time; intending, as most of the Greek states suspected, to add it now to their own dominions. It is very probable that this design of theirs would have taken effect, if Pausanias king of Sparta, envying Lysander, had not resolved to obstruct it. With this view, he procured another army to be raised against the Athenians, of which himself had the command, and with which he marched immediately to besiege the Piræus. While he lay before the place, and pretended to attack it, he entered into a private correspondence with Thrasybulus, informing him what propositions he should make in order to force the Lacedæmonians, who were suspected by their allies, to grant them peace.

173 How frustrated.

The intrigues of Pausanias had all the success he could wish. The Ephori who were with him in the camp concurred in his measures, so that in a short space a treaty was concluded on the following terms: That all the citizens of Athens should be restored to their houses and privileges, excepting the thirty, the ten which had succeeded them and who had acted no less tyrannically than they, and the eleven who during the time of the oligarchy had been constituted governors or keepers of the Piræus: that all should remain quiet for the future in the city; and that, if any were afraid to trust to this agreement, they should have free leave to retire to Eleusina. Pausanias then marched away with the Spartan army, and Thrasybulus at the head of his forces marched into Athens, where having laid down their arms, they sacrificed with the rest of the citizens in the temple of Minerva, after which the popular government was restored. Yet quiet was not thoroughly established. The exiles at Eleusina having endeavoured by the help of money to raise an army of foreigners, by whose aid they might recover the authority they had lost: but first depending on their friends in the city, they sent some of the principal persons amongst them as deputies, to treat with the citizens; but strictly instructed them to sow jealousies and excite discords among them. This the latter quickly perceiving, put these persons to death: and then remonstrating to those at Eleusina, that these contentions would undoubtedly end either in their own or the destruction of their country, they offered immediately to pass an act of oblivion, which they would confirm with an oath.

This being accepted, those who had withdrawn returned to the city, where all differences were adjusted, and both parties most religiously observed the agreement they had made, and thereby thoroughly resettled the state. In this whole transaction, the virtue of Thrasybulus deserves chiefly to be admired.

174 Virtue of Thrasybulus.

When he first seized the castle of Phyla, the tyrants privately offered to receive him into their number instead of Theramenes, and to pardon at his request any 12 persons he should name: but he generously answered, That his exile was far more honourable than any authority could be, purchased on such terms; and by persisting in his design, accomplished, as we have seen, the deliverance of his country. A glorious deliverance it was; since, as Isocrates informs us, they had put 1400 citizens to death contrary to and without any form of law, and driven 5000 more into banishment; procuring also the death of Alcibiades, as many think, though at a great distance from them.

From this time to the reign of Philip of Macedon, the Athenians continued in a pretty prosperous situation, though they never performed any such great exploits

Digitized by Google

as formerly. By that monarch and his son Alexander all Greece was in effect subdued, and the history of all the Grecian states from that time becomes much less interesting. Of the history of Athens from that time to the present, the following elegant abridgement is given by Dr Chandler *. "On the death of Alexander, the Athenians revolted, but were defeated by Antipater, who garrisoned Munychia. They rebelled again, but the garrison and oligarchy were reinstated. Demetrius the Phalerean, who was made governor, beautified the city, and they erected to him 360 statues; which on his expulsion they demolished, except one in the Acropolis. Demetrius Poliocertes withdrew the garrison, and restored the democracy; when they deified him, and lodged him in the Opisthodomos or the back part of the Parthenon, as a guest to be entertained by their goddess Minerva. Afterwards they decreed, that the Piræus, with Munychia, should be at his disposal; and he took the Museum. They expelled his garrison, and he was persuaded by Craterus a philosopher to leave them free. Antigonus Gonatas, the next king, maintained a garrison in Athens: but on the death of his son Demetrius, the people, with the assistance of Aratus, regained their liberty; and the Piræus, Munychia, Salamis, and Sunium, on paying a sum of money.

* *Travels into Greece*, p. 28. &c.

175 History of Athens from the time of Alexander the Great to the present.

"Philip, son of Demetrius, encamping near the city, destroying and burning the sepulchres and temples in the villages, and laying their territory waste, the Athenians were reduced to solicit protection from the Romans, and to receive a garrison, which remained until the war with Mithridates king of Pontus, when the tyrant Aristion made them revolt.

176 Athens besieged and taken by Sylla.

"Archelaus the Athenian general, unable to withstand the Roman fury, relinquished the *long walls*, and retreated into the Piræus and Munychia. Sylla laid siege to the Piræus and to the city, in which Aristion commanded. He was informed that some persons had been overheard talking in the Ceramicus, and blaming Aristion for his neglect of the avenues about the Heptachalcos, where the wall was accessible. Sylla resolved to storm there, and about midnight entered the town at the gate called *Dypylon* or *the Piræan*; having levelled all obstacles in the way between it and the gate of the Piræus. Aristion fled to the Acropolis, but was compelled to surrender by the want of water; when he was dragged from the temple of Minerva, and put to death. Sylla burned the Piræus and Munychia, and defaced the city and suburbs, not sparing even the sepulchres.

"The civil war between Cæsar and Pompey soon followed, and their natural love of liberty made them side with Pompey. Here again they were unfortunate, for Cæsar conquered. But Cæsar did not treat them like Sylla. With that clemency which made so amiable a part of his character, he dismissed them by a fine allusion to their illustrious ancestors, saying, that he spared the living for the sake of the dead.

"Another storm followed soon after this; the wars of Brutus and Cassius with Augustus and Antony. Their partiality for liberty did not here forsake them: they took part in the contest with the two patriot Romans, and erected their statues near their own ancient deliverers Harmodius and Aristogiton, who had slain Hipparchus. But they were still unhappy, for their enemies triumphed.

"They next joined Antony, who gave them Ægina and Cea, with other islands. Augustus was unkind to them; and they revolted four years before he died. Under Tiberius the city was declining, but free, and regarded as an ally of the Romans. The high privilege of having a lictor to precede the magistrates was conferred on it by Germanicus; but he was censured as treating with too much condescension a mixture of nations, instead of genuine Athenians, which race was then considered as extinct.

"The emperor Vespasian reduced Achaia to a province paying tribute and governed by a proconsul. Nerva was more propitious to the Athenians; and Pliny, under Trajan his successor, exhorts Maximus to be mindful whither he was sent, to rule genuine Greece, a state composed of free cities. 'You will revere the gods and heroes their founders. You will respect their pristine glory, and even their age. You will honour them for the famous deeds, which are truly, nay for those which are fabulously, recorded of them. Remember, it is Athens you approach.' This city was now entirely dependent on Rome, and was reduced to sell Delos and the islands in its possession.

"Hadrian, who was at once emperor and an archon of Athens, gave the city laws, compiled from Draco, Solon, and the codes of other legislators; and displayed his affection for it by unbounded liberality. Athens reflourished, and its beauty was renewed. Antoninus Pius who succeeded, and Antoninus the Philosopher, were both benefactors.

"The barbarians of the north, in the reign of Valerian, besieging Thessalonica, all Greece was terrified, and the Athenians restored their city wall, which had been dismantled by Sylla, and afterwards neglected.

"Under the next emperor, who was the archon Gallienus, Athens was besieged, the archontic office ceased; and the stratægus or general, who had before acted as overseer of the agora or market, then became the supreme magistrate. Under Claudius his successor, the city was taken, but soon recovered.

"It is related, that Constantine, when emperor, gloried in the title of *general of Athens*; and rejoiced exceedingly on obtaining from the people the honour of a statue with an inscription, which he acknowledged by an yearly gratuity of many bushels of grain. He conferred on the governor of Attica and Athens the title of *grand duke*, μεγας δουξ. That office was at first annual, but afterwards hereditary. His son Constans bestowed several islands on the city, to supply it with corn.

"In the time of Theodosius I. 380 years after Christ, the Goths laid waste Thessaly and Epirus; but Theodore, general of the Achæans, by his prudent conduct preserved the cities of Greece from pillage, and the inhabitants from being led into captivity. A statue of marble was erected to him at Athens by order of the city; and afterwards one of brass, by command of the emperor, as appears by an inscription in a church dedicated to a saint of the same name, not far from the French convent. It is on a round pedestal, which supports a flat stone serving for the holy table. Eudocia the wife of Theodosius II. was an Athenian.

177 By Alaric the Goth.

"The fatal period now approached, and Athens was about to experience a conqueror more savage even than

than Sylla. This was Alaric king of the Goths: who, under the emperors Arcadius and Honorius, overran Greece and Italy, sacking, pillaging, and destroying. Then the Peloponnesian towns were overturned, Arcadia and Lacedæmon were laid waste, the two seas by the isthmus were burnished with the flames of Corinth, and the Athenian matrons were dragged in chains by barbarians. The invaluable treasures of antiquity, it is related, were removed; the stately and magnificent structures converted into piles of ruin; and Athens was stripped of every thing splendid or remarkable. Synesius, a writer of that age, compares the city to a victim of which the body had been consumed, and the hide only remained.

"After this event, Athens became an unimportant place, and as obscure as it once had been famous. We read that the cities of Hellas were put into a state of defence by Justinian, who repaired the walls, which at Corinth had been subverted by an earthquake, and at Athens and in Bœotia were impaired by age; and here we take a long farewell of this city. A chasm of near 700 years ensues in its history, except that, about the year 1130, it furnished Roger the first king of Sicily with a number of artificers, whom he settled at Palermo, where they introduced the culture of silk, which then passed into Italy. The worms had been brought from India to Constantinople in the reign of Justinian.

"Athens, as it were, re-emerges from oblivion in the 13th century, under Baldwin, but besieged by a general of Theodorus Lascaris, the Greek emperor. It was taken in 1427 by Sultan Morat. Boniface, marquis of Montferrat, possessed it with a garrison; after whom it was governed by Delves of the house of Arragon. On his death, it was seized, with Macedonia, Thessaly, Bœotia, Phocis, and the Peloponnesus, by Bajazet; and then, with the island Zante, by the Spaniards of Catalonia in the reign of the Greek emperor Andronicus Palæologus the elder. These were dispossessed by Reinerius Acciaioli, a Florentine; who, leaving no legitimate male issue, bequeathed it to the state of Venice. His natural son, Antony, to whom he had given Thebes with Bœotia, expelled the Venetians. He was succeeded in the dukedom by his kinsman Nerius, who was displaced by his own brother named *Antony*, but recovered the government when he died. Nerius, leaving only an infant son, was succeeded by his wife. She was ejected by Mahomet on a complaint from Francus son of the second Antony, who confined her at Megara, and made away with her; but her son accusing him to Mahomet the Second, the Turkish army under Omar advanced, and he surrendered the citadel in 1455; the Latins refusing to succour him unless the Athenians would embrace their religious tenets. Mahomet, it is related, when he had finished the war with the despot of the Morea, four years after, surveyed the city and Acropolis with admiration. The janizaries informed him of a conspiracy; and Francus Acciaioli, who remained lord of Bœotia, was put to death. In 1464 the Venetians landed at the Piræus, surprised the city, and carried off their plunder and captives to Eubœa.

178 By the Turks.

"It is remarkable, that after these events Athens was again in a manner forgotten. So lately as about the middle of the 16th century, the city was commonly believed to have been utterly destroyed, and not to exist, except a few huts of poor fishermen. Crusius, a learned and inquisitive German, procured more authentic information from his Greek correspondents residing in Turkey, which he published in 1584, to awaken curiosity and to prompt farther discoveries. One of these letters is from a native of Nauplia, a town near Argos in the Morea. This writer says that he had been often at Athens, and that it still contained many things worthy to be seen, some of which he enumerates, and then subjoins; "But why do I dwell on this place? It is as the skin of an animal which has been long dead."

It now remains to give some idea of the character, government, and religion of this once so famous people.

179 Character of the ancient Athenians.

The Athenians, says Plutarch, are very subject to violent anger; but they are soon pacified. They are likewise easily impressed with humanity and compassion. That this was their temper, is proved by many historical examples. We shall produce a few. The sentence of death pronounced against the inhabitants of Mitylene, and revoked the next day: The condemnation of Socrates, and that of the ten chiefs, each followed by quick repentance and most pungent grief.

The minds of the same people, adds Plutarch, are not formed for laborious researches. They seize a subject, as it were, by intuition; they have not patience and phlegm enough to examine it gradually and minutely. This part of their character may seem surprising and incredible. Artisans, and other people of their rank, are in general slow of comprehension. But the Athenians of every degree were endowed with an inconceivable vivacity, penetration, and delicacy of taste. Even the Athenian soldiers could repeat the fine passages of the tragedies of Euripides. Those artisans and those soldiers assisted at public debates, were bred to political affairs, and were equally acute in apprehension and in judgment. We may infer the understanding of the hearers of Demosthenes from the genius of his orations, which were laconic and poignant.

As their inclination, continues Plutarch, leads them to assist and support people of low condition, they like discourse seasoned with pleasantry, and productive of mirth. The Athenians patronize people of low degree; because from them their liberty is in no danger, and because such patronage tends to support a democratical constitution. They love pleasantry; which turn of mind proves that they are a humane social people, who have a taste for raillery and wit, and are not soured with that reserve which marks the despot or the slave.

They take pleasure in hearing themselves praised; but they can likewise patiently bear raillery and censure. We know with what art and success Aristophanes and Demosthenes applied their praise and their irony to the Athenian people. When the republic enjoyed peace, says the same Plutarch in another place, it encouraged the adulation of its orators: but when it had important affairs to discuss, when the state was in danger, it became serious; and preferred to its eloquent sycophants, the honest orators who opposed its follies and its vices; such ingenious and bold patriots as a Pericles, a Phocion, and a Demosthenes.

The Athenians, continues Plutarch, often make their governors tremble, and show great humanity to their

their enemies. They were very attentive to the information and instruction of those citizens who were most eminent for their policy and eloquence; but they were on their guard against the superiority of their talents; they often checked their boldness, and repressed their exuberant reputation and glory. That this was their temper, we are convinced by the ostracism: which was established to restrain the ambition of those who had great talents and influence, and which spared neither the greatest nor the best men. The detestation of tyranny and of tyrants, which was inherent in the Athenians, rendered them extremely jealous of their privileges, made them zealous and active in defence of their liberty, whenever they thought it was violated by men in power.

As to their enemies, they did not treat them with rigour. They did not abuse victory by a brutal inhumanity to the vanquished. The act of amnesty, which they passed after the usurpation of the 30 tyrants, proves that they could easily forgive injuries. It was this mildness, this humanity of disposition, which made the Athenians so attentive to the rules of politeness and decorum. In their war with Philip, having seized one of his courtiers, they read all the letters he bore, except one from Olympias to her husband, which they sent back unopened. Such was their veneration of love and conjugal secrecy; those sacred rights, which no enmity, no hostility, warrants us to violate!

The views of conquest cherished by a small republic, were extensive and astonishing; but this people, so great, so ambitious in their projects, were, in other respects, of a different character. In the expences of the table, in dress, in furniture, in houses, in short, in private life, they were frugal, simple, modest, poor; but sumptuous and magnificent whenever the honour of the state was concerned. Their conquests, their victories, their riches, their connections with the inhabitants of Asia Minor, never reduced them to luxury, to riot, to pomp, to profusion. Xenophon remarks, that a citizen was not distinguished from a slave by his dress. The wealthiest citizen, the most renowned general, was not ashamed to go himself to market.

The taste of the Athenians, for all the arts and sciences, is well known. When they had delivered themselves from the tyranny of Pisistratus, and after this had defeated the vast efforts of the Persians, they may be considered as at the summit of their national glory. For more than half a century afterwards they maintained, without controul, the sovereignty of Greece; and that ascendant produced a security, which left their minds at ease, and gave them leisure to cultivate every thing liberal or elegant. It was then that Pericles adorned the city with temples, theatres, and other beautiful public buildings. Phidias, the great sculptor, was employed as his architect, who, when he had erected edifices, adorned them himself, and added statues and basso-relievos, the admiration of every beholder. It was then that Polignotus and Myro painted; that Sophocles and Euripides wrote; and not long after, that they saw the divine Socrates.

Human affairs are, by nature, prone to change; and states, as well as individuals, are born to decay. Jealousy and ambition insensibly fomented wars, and success in these wars, as in others, was often various. The military strength of the Athenians was first impaired by the Lacedæmonians; after that it was again humiliated, under Epaminondas, by the Thebans: and last of all it was wholly crushed by the Macedonian Philip.

Nor, when their political sovereignty was lost, did their love of literature and the arts sink along with it. Just at the close of their golden days of empire flourished Xenophon and Plato, the disciples of Socrates; and from Plato descended that race of philosophers called the *Old Academy*. Aristotle, who was Plato's disciple, may be said not to have invented a new philosophy, but rather to have tempered the sublime and rapturous mysteries of his master with method, order, and a stricter mode of reasoning. Zeno, who was himself also educated in the principles of Platonism, only differed from Plato in the comparative estimate of things, allowing nothing to be intrinsically good but virtue, nothing intrinsically bad but vice, and considering all other things to be in themselves indifferent. He too and Aristotle accurately cultivated logic, but in different ways; for Aristotle chiefly dwelt upon the simple syllogism; Zeno upon that which is derived out of it, the compound or hypothetic. Both too, as well as other philosophers, cultivated rhetoric along with logic; holding a knowledge in both to be requisite for those who think of addressing mankind with all the efficacy of persuasion. Zeno elegantly illustrated the force of these two powers by a simile taken from the hand: the close power of logic he compared to the fist, or hand comprest: the diffuse power of logic, to the palm, or hand open.

The new academy was founded by Arcesilas, and ably maintained by Carneades. From a mistaken imitation of the great parent of philosophy Socrates (particularly as he appears in the dialogues of Plato), because Socrates doubted some things, therefore Arcesilas and Carneades doubted all.—Epicurus drew from another source; Democritus had taught him atoms and a void: by the fortuitous concourse of atoms he fancied he could form a world; while by a feigned veneration he complimented away his gods, and totally denied their providential care, lest the trouble of it should impair their uninterrupted state of bliss. Virtue he recommended, though not for the sake of virtue, but pleasure; pleasure, according to him, being our chief and sovereign good. See Aristotle, Epicurus, Plato, Socrates, &c.

We have already mentioned the alliance between philosophy and rhetoric. This cannot be thought wonderful, if rhetoric be the art by which men are persuaded, and if men cannot be persuaded without a knowledge of human nature: for what but philosophy can procure us this knowledge? It was for this reason the ablest Greek philosophers not only taught, but wrote also treatises upon rhetoric. They had a farther inducement, and that was the intrinsic beauty of their language as it was then spoken among the learned and polite. They would have been ashamed to have delivered philosophy, as it has been too often delivered since, in compositions as clumsy as the common dialect of the mere vulgar.

The same love of elegance, which made them attend to their style, made them attend even to the places

Digitized by Google

Attica.

ces where their philosophy was taught. Plato delivered his lectures in a place shaded with groves, on the banks of the river Ilissus; and which, as it once belonged to a person called *Academus*, was called after his name, the ACADEMY. Aristotle chose another spot of a similar character, where there were trees and shade; a spot called the LYCEUM. Zeno taught in a portico or colonnade, distinguished from other buildings of that sort (of which the Athenians had many) by the name of the *Variegated Portico*, the walls being decorated with various paintings of Polygnotus and Myro, two capital masters of that transcendant period. Epicurus addressed his hearers in those well known gardens, called, after his own name, *The gardens of Epicurus*.

These places of public institution were called among the Greeks by the name of *Gymnasia;* in which, whatever that word might have originally meant, were taught all those exercises, and all those arts, which tended to cultivate not only the body but the mind. As man was a being consisting of both, the Greeks could not consider that education as complete, in which both were not regarded, and both properly formed. Hence their Gymnasia, with reference to this double end, were adorned with two statues, those of Mercury and of Hercules, the corporeal accomplishments being patronized (as they supposed) by the god of strength, the mental accomplishments by the god of ingenuity.

It was for the cultivation of every liberal accomplishment that Athens was celebrated (as we have said) during many centuries, long after her political influence was lost and at an end.

She was the place of education, not only for Greeks but for Romans. It was hither that Horace was sent by his father; it was here that Cicero put his son Marcus under Cratippus, one of the ablest philosophers then belonging to that city. The sects of philosophers which we have already described, were still existing when St Paul came thither. We cannot enough admire the superior eloquence of that apostle, in his manner of addressing so intelligent an audience. We cannot enough admire the sublimity of his exordium; the propriety of his mentioning an altar which he had found there; and his quotation from Aratus, one of their well known poets. Nor was Athens only celebrated for the residence of philosophers, and the institution of youth: men of rank and fortune found pleasure in a retreat, which contributed so much to their liberal enjoyment.

We shall finish this picture of the Athenians by the addition of one object more, to which every one will admit they have a right; an object which was prominent and striking, in all their actions and in all their enterprises: We mean their ardent love of liberty. This was their predominant quality; the main spring of their government. From the beginning of the Persian war, they sacrificed every thing to the liberty of Greece. They left, without hesitation, their cities, their houses, to fight at sea the common enemy, from whom they were in danger of servitude. What a glorious day was it for Athens, when all her allies, growing flexible to the advantageous offers which were made to them by the king of Persia, she replied by Aristides, to the ambassadors of that monarch,—"That it was impossible for all the gold in the world to tempt the republic of Athens: to prevail with her to sell her liberty, and that of Greece." It was by these generous sentiments that the Athenians not only became the bulwark of Greece, but likewise guarded the rest of Europe from a Persian invasion.

These great qualities were blended with great failings, seemingly incompatible with patriotism. For the Athenians, notwithstanding their tenacious jealousy of the rights of their country, were a volatile, inconstant, capricious people.

180 Religion.

There never was a people more attentive to the worship of the gods than the Athenians. The worship of their principal deities was diffused over all Greece, and even beyond its limits.

Each temple had its particular religious rites: the pomp, the ceremonies, the duration, and the succession of the solemn feasts were all appointed by fixed rules. The worship paid to each divinity, whether public or private, was founded on traditions, or on laws constantly obeyed. The feast of Bacchus, the Panathenæa, the feast of the mysteries of Eleusis, were celebrated according to established rules, most of which were as ancient as the feasts themselves. The old customs, of which the priests were the guardians, were observed in the temples. It is probable that the priests were consulted on affairs in which the worship of a deity was interested, and that their answer was decisive. We are certain that the Eumolpidæ had this authority. They were the interpreters of the ancient laws on which the worship of Ceres was founded, its magnificence, and its mode—laws which were not written, as Lysias informs us, but were perpetuated by a constant observation. The abuses which had gradually crept into the celebration of those feasts, had given rise to several new regulations; to that of the orator Lycurgus, for example, and to the law of Solon, which enjoined the senate to repair to Eleusis on the second day of the feast: but neither these, nor the other particular regulations which we find in Samuel Petit's collection of Attic laws, could make a religious code. There was no general system which comprehended all the branches of their religion, which, by combining all its articles, might regulate their belief and conduct, and direct the judges in their decisions.

181 Crimes against religion, why sometimes punished with severity.

Crimes against religion were only punished as they affected the state; and consequently they were tried by the magistrate. Mere raillery, though somewhat profane, was thought productive of no worse consequence than offending the ministers of the gods. The Athenians acknowledged no other religion than the hereditary public worship; no other gods than those they had received from their ancestors; no other ceremonies but those which had been established by the laws of the state, and practised by their country from time immemorial. They were only solicitous to preserve this worship, which was closely interwoven with their government, and made a part of its policy. They were likewise attentive to the ceremonial pomp; because order, the regular vigour of legislation, depends greatly on the awe impressed by externals. But as to the inconsistent and monstrous romance of fable, foreign opinions, popular traditions, and poetical fictions, which formed a religion quite different from that of the state —in it they were very little interested, and allowed every one to think of it as he pleased.

This explanation will reconcile a seeming contradic-

Digitized by Google

Attica. tion in the conduct of the Athenians, who gave great license to their poets, and severely punished the citizens who were guilty of impiety. Aristophanes, who made as free with the gods as with the great, was applauded by the Athenians. They condemned Socrates to death, who revered the Deity, but disapproved the public manner of worshipping him. The life of Æschylus was in danger, from a suspicion that he had revealed some of the secrets of Eleusis in one of his pieces. The wit of Aristophanes's drama was unpunished.

182 Priests, their duty

The priests were not confined to the care of the altars; they who were vested with the sacerdotal dignity, which was only incompatible with professions merely useful and lucrative, might likewise hold the most important offices of the commonwealth. This we could prove by a great number of examples; we shall cite that of Xenophon the illustrious historian and philosopher: he was likewise a famous general, and he was a priest. He was performing the sacerdotal function when he received the news of his son's death, who was killed at the battle of Mantinea.

The sacred ministry was not only compatible with civil offices, but likewise with the profession of arms. The priest and the soldier were often blended. Callias, the priest of Ceres, fought at Platæa. This custom was not peculiar to the Athenians. The Lacedæmonians, after the battle which we have just mentioned, made three graves for their slain; one for the priests, one for the other Spartans, and one for the Helots.

183 Sacred revenues, &c.

As the ordinary business of life was incompatible with the sacerdotal dignity, the priests had a revenue fixed to their office. We know that a part of the victims was their right, and that apartments were assigned them near the temples. But, besides these advantages, they had a salary proportioned to the dignity of their functions, and to the rank of the deities whom they served. Their salary was probably paid from the revenue of the temples. Those revenues, which kept the temples in repair, and defrayed the sacrificial expences, were very considerable. They were of many different kinds.

A great part of the sacred revenues arose from fines, which individuals were condemned to pay for various offences; fines, of which the tenth part was appropriated to Minerva Polias, and the fiftieth to the other gods, and to the heroes whose names their tribes bore. Besides, if the Prytanes did not hold the assemblies conformably with the laws, they were obliged to pay a fine of 1000 drachms to the goddess. If the Proedri, i. e. the senators whose office it was to lay before the assembly the matters on which they were to deliberate, did not discharge that duty according to the rules prescribed to them, they were likewise condemned to pay a fine, which, as the former, was applied to the use of Minerva. By these fines her temple must have been greatly enriched.

Besides this revenue, which was the common property of the gods, and which varied according to the number and degrees of the misdemeanours, the temples had their permanent revenues: We mean the produce of the lands which were consecrated to the deities. We do not here allude to the lands consecrated to the gods, which were never to be cultivated: such as the territory of Cirrha, proscribed by a solemn decree of the Amphictyons; the land betwixt Megara and Attica, which was consecrated to the goddesses of Eleusis, and many others. We would speak only of those which were cultivated, the fruits of which enriched the temples.

There were likewise lands belonging to the state, the produce of which was destined to defray the expence of the sacrifices which were offered in the name of the republic. There were likewise first fruits which the public officers levied on all lands, for the use of the gods. All these emoluments made a part of the revenue of the temples.

The gods, besides the revenues immediately appertaining to their temples, had certain rights which were granted them by particular compact. The Lepreatæ, for instance, were obliged to pay every year a talent to Olympian Jupiter, on account of a treaty of alliance which they made with the Eleans in one of their wars. The inhabitants of Epidaurus, to obtain leave from the Athenians to cut down olive-trees for statues, which the Pythian priestess had commanded them to make, engaged to send deputies every year to Athens, to offer sacrifices in their name to Minerva and to Neptune. But this prerogative was rather honorary than lucrative.

The tenth part of the spoils taken in war was likewise the property of Minerva. Sacred vessels were bought with the effects of the 30 tyrants. In short, the gods were profited by almost every public accident. But what contributed most to enrich the famous temples of Greece, was the money which was constantly brought to them by individuals, in consequence of vows they had made, or to pay for sacrifices which were offered in their names. The credulity of the people was an inexhaustible fund. That credulity enriched the temples of Delos and Eleusis, and supported the magnificence of Delphi. And those immense treasures which were the fruit of superstition, were often a prey to avarice.

These revenues were not deposited with the priests; nor did they expend them. A moderate salary was all their gain; and to offer sacrifices to the deities whose ministers they were, was all their employment.

It is very probable that all the sacred revenues were paid into the hands of officers who were appointed to receive them, and who were to give an account of the discharge of their trust. Nay, we cannot doubt of this, after reading a passage in Aristotle, who, speaking of the officers of the temples, expressly mentions those who are intrusted with the money appertaining to the gods. Citizens, without doubt, of approved integrity, were chosen to this office; and their duty must have been, to keep the temples in repair and order, and to disburse and keep an account of the ordinary sacred expences.

As to the solemn feasts, which were incredibly magnificent, such as the feast of Bacchus, and the Panathenæa, they were celebrated at the expence of the choregus; i. e. of the chief of the choir of each tribe; for each tribe had its poet and its musicians, who sung, emulating each other, hymns in honour of the deity. The richest citizens were appointed chiefs of the different choirs; and as their office was very expensive, to indemnify them in some degree, the choregus of the

Digitized by Google

Attica.

the victorious tribe had the privilege of engraving his name on the tripod which that tribe suspended to the roof of the temple. This office, though ruinous, was eagerly solicited; and naturally, in a republican state. It led to honours, like the curule dignity at Rome; and it greatly tended to ingratiate its possessor with a people who were more affected with pleasures than with essential services, and who, consequently, would more highly esteem a profuse choregus than a victorious general.

With regard to the fines, which were in the whole, or in part, the property of Minerva and of the other deities, there were at Athens public treasurers appointed to receive them. They were ten in number, and they were nominated by lot. They were called *Treasurers of the goddess*, or *Receivers of the sacred money*. That money they received in the presence of the senate; and they were empowered to diminish or to annihilate the fine, if they thought it unjust. The statue of Minerva, that of the Victories, and the other invaluable pledges of the duration of the state, were deposited with them.

The treasury in which the money consecrated to the gods was kept, was in the citadel, behind the temple of Minerva Polias; and from its situation it was termed *Opisthodomus*. It was surrounded with a double wall. It had but one door, the key of which was kept by the Epistates, or chief of the Prytanes: his dignity was very considerable; but it lasted only one day. In this treasury a register was kept, in which were written the names of all those who were indebted to the state; he who owed the smallest fine was not omitted. If the debtors proved insolvent, they were prosecuted with extreme rigour, and often punished with a cruelty which religion could not excuse; though the interest of the gods was the motive, or rather the pretext. The sacred treasurers held a considerable rank among the magistrates who received the public finances. Of these magistrates there were many kinds, as there were many sorts of revenues.

The Athenian priests did not compose an order distinct and separate from the other orders of the state. They did not form a body united by particular laws, under a chief whose authority extended to all his inferiors. The dignity of sovereign pontiff was unknown at Athens; and each of the priests served his particular temple, unconnected with his brethren. The temples, indeed, of the principal deities; those of Minerva, for instance, of Neptune, of Ceres, and of Proserpine, had many ministers; and in each of them a chief presided, who had the title of *High Priest*. The number of subaltern ministers was in proportion to the rank of the deity; but the priests of one temple were altogether a separate society from those of another. Thus at Athens there was a great number of high priests, because many deities were worshipped there, whose service required many ministers. The power of each priest was confined to his temple; and there was no sovereign pontiff, the minister general of the gods, and the president at all the feasts.

It naturally follows from this account, that the ministers of the gods at Athens were not judges in matters of religion. They were neither authorized to take cognizance of crimes committed against the deity, nor to punish them. Their function was to offer sacrifices to the gods, and to entreat their acceptance of the adorations of the people. But the punishment of impiety, of sacrilege, of the profanation of mysteries, and of other irreligious crimes, was not entrusted to their zeal.

The priests were not only incapable of avenging crimes against religion by a criminal process; they even could not, without an express order either from the senate or the people, exercise their right of devoting criminals to the infernal gods. It was in consequence of a civil sentence pronounced against Alcibiades, that the Eumolpidæ launched their anathema against him. It was in virtue of another decree that they revoked their imprecations, when his countrymen wanted his service, and therefore restored him to their favour.

Religious causes, according to M. de Bougainville, fell under the jurisdiction of the Heliastæ.

The government, though often altered, continued pretty much on the plan established by Solon. 184

People divided into different tribes, &c.

The people of Athens were freemen, sojourners, or slaves. The citizens, called in Greek *Politai*, were very numerous; but what may seem strange, were as many in the time of Cecrops as in the most flourishing state of the commonwealth, hardly ever exceeding 20,000. It was Solon who decreed that none should be accounted free but such as were Athenians both by father and mother. After his time it fell into desuetude, till revived by Pericles; and was again at his instance repealed. After the expulsion of the 30 tyrants, Solon's law was restored. A person born of a stranger was styled *Nothos*, a bastard; whereas the son of a free woman was called *Cnesios*, i. e. *legitimate*. There was in Cynosarges a court of judicature, to which causes of illegitimacy properly belonged; and the utmost care was taken to prevent any from being enrolled Athenian citizens, who had not a clear title thereto. The citizens were divided by Cecrops into four tribes: the first called *Cecropes*, from Cecrops; the second, *Antochthon*, from a king of that name; the third, *Actai*, from Acteus, another king of Athens, or rather from *Acte*, which signifies a *shore;* the fourth, *Puralia:* these names were altered by Cranaus, and again by Ericthonius. In the reign of Erictheus, they were again changed; the soldiers were called *Oblitai*, the craftsmen *Ergatai*, the farmers *Georgoi*, the graziers and shepherds *Aigicorai:* in this state they were when Solon settled the commonwealth, and appointed the senate to be composed of 400, 100 out of each tribe. Clysthenes increased the number of the tribes to ten; and made the senate consist of 500, taking 50 out of each tribe. In succeeding times, two other tribes were added. Each tribe was subdivided into its *Demoi* or wards: and with respect to these it was that Solon instituted the public feasts before-mentioned, at which sometimes the whole tribe assembled, sometimes several wards, and sometimes only the inhabitants of one ward.

The second sort of inhabitants we mentioned were called *Metoicoi*, i. e. *sojourners;* these were persons who lived always at Athens, yet were not admitted free denizens: as for such as did not constantly reside in Athens, they were styled *Xenoi;* i. e. *strangers*. The sojourners were obliged to choose out of the citizens protectors, who were styled *Patrons;* they paid services to the state, and besides these an annual tribute of 12 drachms for every man, and six for every woman; but such as had sons, and paid for them, were

exempted.

exempted. If people fell to poverty, and were not able to pay the tribute, they were seized by the tax-masters, and actually sold for slaves; which, as Diogenes Laertius tells us, was the fate of Xenocrates the philosopher. The sojourners in Attica were under the same law as those in Athens. As to servants, they were freemen, who through indigency were driven to receive wages, and while they were in this state had no vote in the assembly. As to slaves, they were absolutely the property of their masters, and as such were used as they thought fit: They were forbidden to wear clothes, or to cut their hair like their masters; and, which is indeed amazing, Solon prohibited them to love boys, as if that had been honourable: They were likewise debarred from anointing or perfuming themselves, and from worshipping certain deities: They were not allowed to be called by honourable names; and in most other respects were used like dogs. They stigmatized them at their pleasure, that is, branded them with letters in the forehead and elsewhere. However, Theseus's temple was allowed them as a sanctuary, whither, if they were exceedingly ill used, they might fly, and thereby oblige their owners to let them be transferred to another master. In this and many other respects the Athenian slaves were in a much better condition than those throughout the rest of Greece: they were permitted to get estates for themselves, giving a small premium to their masters, who were obliged to make them free if they could pay their ransom; they likewise obtained the same favour from the kindness of their masters, or for having rendered military services to the states. When they were made free, they were obliged to choose patrons; and had likewise the privilege of choosing a curator, who, in case their patrons injured them, was bound to defend them.

185 General assembly of the people.

The general assembly of the people, which Solon made the dernier resort, was called the *Ecclesia;* and consisted of all the freemen of Athens, excepting such as were *atimoi* or infamous. The meetings of these assemblies were either ordinary or extraordinary. The ordinary were such as were appointed by law, the extraordinary such as necessity required. Of the first there were four in 35 days. In the first assembly they approved or rejected magistrates, heard proposals for the public good, and certain causes. In the second they received petitions, and heard every man's judgement on the matters that were before them. In the third they gave audience to foreign ambassadors. The fourth was employed altogether in affairs relating to the gods and their worship. The extraordinary meetings were appointed by the magistrates when occasion required, whereas to the ordinary assemblies the people came of their own accord. The first were held either in the market-place, in the Pnyx a place near the citadel, or in the theatre of Bacchus: as to the latter, the magistrates who appointed the extraordinary meeting appointed also the place where it should be held. If any sudden tempest rose, or any earthquake happened, or any sign notoriously inauspicious appeared, the assembly was immediately adjourned, to prevent the people from apprehending unhappy consequences from their deliberations. But if the weather was fair and serene, and nothing happened out of the ordinary course of things, they proceeded to purify the place where the assembly was held, which was done by sprinkling it round with the blood of young pigs; then the crier made a solemn prayer for the prosperity of the republic, and that heaven would bestow a happy issue on their counsels and undertakings: he then pronounced a bitter execration against any who should in that assembly propound what might be disadvantageous to the state. Those ceremonies being over, they proceeded to business.

186 Method of giving their opinions.

There were several magistrates who had the overseeing and regulating these assemblies. These were, first, the Epistate, or president of the assembly, who was chosen by lot out of the Proedri: his office was to give the signal for the people's voting. Next to him were the Prytanes, i. e. a committee of the senate, who of course were present on this occasion: by their order a programma, or scheme of the business to be proposed at the assembly, was previously set up in some public place, that every man might know what business to apply his thoughts to. The Proedri were nine in number, appointed by lots out of all the tribes to which the Prytanes did not belong: they had the right of proposing to the people what they were to deliberate upon, and their office ended with the assembly; there sat with them assessors, who were to take care that nothing they proposed was detrimental to the commonwealth. The first step to business was the crier's reading the decree of the senate whereon the assembly was to deliberate; when he had finished this, he made proclamation in these words: *Who of the men above 50 will make an oration?* When the old men had done speaking, the crier made proclamation again that any Athenian might then offer his sentiments, whom the law allowed so to do; that is, all such as were above 30 years old, and were not infamous. If such a one rose up to speak, the Prytanes interposed, and bid him be silent; and if he did not obey them, the lictors pulled him down by force. When the debates were over, the president permitted the people to vote; which they did by casting first beans, but in after times pebbles, into certain vessels: these were counted, and then it was declared that the decree of the senate was either rejected or approved: after which, the Prytanes dismissed the assembly.

187 The senate.

The senate was instituted by Solon to prevent the dangerous consequences of leaving the supreme power in the people. At the time of his institution, it was to consist of 400, 100 out of each tribe; it was increased to 500, when the tribes were augmented to 10; and when they came to 12, it was also swelled to 600. They were elected by lots after this manner: At a day appointed, towards the close of the year, the president of each tribe gave in a list of such persons belonging thereto, as were fit for and desired to appear for this dignity: these names were engraven on tables of brass, and a number of beans equal to the number of the amount of them, among which were 100 white ones, put into a vessel; and then the names of the candidates and the beans were drawn one by one, and such as were drawn by the white beans were received into the senate. After the senate was elected, they proceeded to appoint the officers who were to preside in the senate: these were the Prytanes before mentioned; and they were elected thus: The names of the ten tribes were thrown into one vessel, and nine black beans and a white one into another vessel. Then the names of the tribes

Digitized by Google

Attica. tribes were drawn with the beans. The tribe to which the white bean answered, presided first; and the rest according to the order in which they were drawn.

188 Prytanes. The Prytanes, while the senate consisted of 500, were 50 in number. For the farther avoiding of confusion, therefore, 10 of these presided a week, during which space they were called *Proedri*; and out of these an Epistate or president was chosen, whose office lasted but one day, and by law no man could hold it more than once: the reason of this was, that he had in his custody the public seal, the keys of the citadel, and the charge of the exchequer. The reader must distinguish between the Epistates and Proedri last mentioned, and those spoken of in the former paragraph, because, though their titles were the same, their offices were perfectly distinct. The senate assembled by direction of the Prytanes once every day, excepting festivals, and sometimes oftener, in the senate-house, which was thence called *Prytaneum*.

189 Laws how established, &c. When a member of the senate made a motion for a new law, it was immediately engraven on tablets, that the members when they came next might be prepared to speak to it. At the subsequent assembly the Epistates opened the matter; after which every senator that pleased delivered his sentiments; then any of the Prytanes drew up the decree, and repeated it aloud: after which they proceeded to vote; and if there was a majority of white beans, then it became *psephisma*, and was afterwards propounded to the people: if they approved it, it became a law; otherwise it was of no force longer than the senate who decreed it subsisted. The power of the senate was very great; for they took the account of magistrates at the expiration of their offices; they directed the provisions made for poor citizens out of the public treasure; they had the superintendency of public prisons, and a power of punishing such as committed acts morally evil, though not prohibited by any law; they had the care likewise of the fleet; and besides all these they had many other branches of authority, which it is not necessary for us to mention. Before they took their seats, they were constrained to undergo a very strict examination, wherein the whole course of their lives was inquired into; and if the least slur on their reputation appeared, they were set aside. When this examination was over, they took an oath, whereby they bound themselves to promote in all their counsels the public good, to advise nothing contrary to the laws, and to execute their functions exactly. The highest fine the senate could impose was 500 drachms: if they thought the offender deserved a heavier mulct, they then transmitted the cause to the Thesmothetæ, who punished them as they thought fit. The senators, when their year was out, gave an account of their management to the people: but that they might have the less to do, they always punished such of their number as they found had offended by expulsion; and in this they were mighty exact. Yet an expelled senator was notwithstanding eligible to any other office, the most trivial omission being sufficient to occasion a dismission from the senatorial dignity; and therefore, when the tribes chose their senators, they also chose a certain number of subsidiaries, out of which, when a senator was expelled, another was substituted in his place. Each senator was allowed a drachm every day: for it was a constant rule with the Athenians, that the public ought to pay for every man's time; and therefore such of the poor Athenians as thought fit to demand it, had three oboli for going to the assembly. If during their administration any ships of war were built, the senators had crowns decreed them; but if not, they were forbid to sue for them.

Next to the senate was the court of AREOPAGUS; for a description of which see that article.

190 Archons, Nomophylaces, &c. The chief magistrates of Athens were Archons, and inferior to them there were many others; of whom it will be necessary to mention some. In the first place they had Nomophylaces, who were also styled *the eleven*, because they were so many in number, one chosen out of each tribe, and a clerk or secretary who made up the eleventh. Their duty it was to look to the execution of the laws: they had authority to seize robbers and other capital offenders; and if they confessed, to put them to death. Dr Potter thinks they resembled our sheriffs. The Phylarchi were the presidents of the Athenian tribes; but in time this became a military title. The Philobasileus was an officer in each tribe, who did the same things within his jurisdiction as the Basileus did with respect to the state. The Demarchi were the principal magistrates in wards. The Lexarchi were six in number, and were bound to take care that the people came duly to the assemblies; in their custody was the public register of the citizens names. They had under them Toxotæ, who were lictors or bailifs; they were sometimes 1000 in number: these men were necessary: but, like most of their sort, were in a manner infamous, as may be gathered from the comedies of Aristophanes; they were generally Scythians, raw-boned, brawny fellows, ready to execute any thing they were commanded. The Nomothetæ were 1000 in number; their business was to watch over and inspect into the laws. There were two sorts of orators in the service of the state. Some were appointed to defend an old law, when a motion was made to repeal it; these had their fee from the state, but the same man was incapable of being elected twice. Besides these, there were 10 settled orators called *Rhetores*, elected by lot; their business was to plead public causes in the senate house. For this they had their stated fees; and with respect to their qualifications, the

191 Laws regarding orators. law run thus: "Let no one be a public orator who hath struck his parents, denied them maintenance, or shut them out of his doors; who hath refused to serve in the army; who hath thrown away his shield; who hath been addicted to lewd women, notoriously effeminate, or has run out his patrimony. If any man who has been guilty of these crimes dare to deliver an oration, let him be brought to trial upon the spot. Let an orator have children lawfully begotten, and an estate within Attica; if in his oration he talks impertinently, makes idle repetitions, affects an unbecoming raillery, digresses from the point in question, or, after the assembly is over, abuses the president, let the Proedri fine him 50 drachms; and if that is not thought enough, let him be brought before the next assembly and fined again."

192 Courts of justice. We shall conclude this draught of the Athenian government with an account of their courts of justice, which, exclusive of the Areopagus, were 10 in number; four had cognizance of criminal, and six of civil causes. These 10 courts were numbered with the 10 first

Attica.

first letters of the alphabet, and were thence styled, *Alpha*, *Beta*, *Gamma*, &c. When an Athenian was at leisure to hear causes, he wrote his own name, that of his father, and the ward to which he belonged, upon a tablet; this he presented to the Thesmothetæ, who returned it again to him with another tablet, with the letter which fell to his lot; then he went to the crier of the court, who presented him a sceptre, and gave him admission. When the causes were over, every judge went and delivered his sceptre to the Prytanes, and received a stated fee for every cause that was tried. But this was intended only to compensate their loss of time; so that there might be no appearance of covetousness, a man was forbid to sit in two courts on the same day. The first criminal court after the Areopagus was that of the *Ephetæ*. It consisted of 51 members, all upwards of 51 years old. Draco gave it a very extensive jurisdiction; but Solon took away from them the power of judging in any other causes than those of manslaughter, accidental killing, and lying in wait to destroy: the Basileus entered all causes in this court. The second criminal court was called *Delphinium*, because it was held in the temple of Apollo Delphinius; it had cognizance of such murders as were confessed by the criminal, but at the same time justified under some pretence or other. The *Prytaneum* was the third criminal court. It held plea of such cases where death ensued from inanimate things; causes were heard here with the same solemnity as in other courts; and on judgment given, the thing, whatever it was, that had occasioned the death of a man, was thrown out of the territory of Athens. The last criminal court was styled *Phreatum*. It sat in a place near the sea shore; and such persons were brought before this court as had committed murders in their own country and fled to Attica; the proceedings of this court were so severe, that they did not permit the criminal to come on shore, but obliged him to plead his cause in his vessel; and if he was found guilty, he was committed to the mercy of the winds and seas.

Of the judicatures for hearing civil causes, the first was the *Parabaston*, so called, as some think, because in it no matter could be heard if the cause of action was above one drachm. The *Cainon*, or new court, was the second tribunal. The third was styled the *court of Lycus*, because it assembled in a temple dedicated to that hero, whose statue, represented with the face of a wolf, was set up in all courts of justice. The *Trigonon* was so called, because it was triangular in its form. The court *Metidius* derived its appellation from the architect who built it. The sixth and last court was called *Heliæa*; it was by far the greatest, and is generally believed to have derived its name from the judges sitting in the open air exposed to the sun. All the Athenians who were free citizens were allowed by law to sit in these courts as judges; but before they took their seats were sworn by Apollo Patrius, Ceres, and Jupiter the king, that they would decide all things righteously and according to law, where there was any law to guide them; and by the rules of natural equity, where there was none. The Helæastic court consisted at least of 50, but its usual number was 500, judges; when causes of very great consequence were to be tried, 1000 sat therein; and now and then the judges were increased to 1500, and even to 2000.

Atticus, Attila.

ATTICUS, Titus Pomponius, one of the most honourable men in ancient Rome. He understood the art of managing himself with such address, that without leaving his state of neutrality, he preserved the esteem and affection of all parties. His strict friendship with Cicero did not hinder him from having great intimacy with Hortensius. The contests at Rome between Cinna's party and that of Marius induced him to go to Athens, where he continued for a long time. He was very fond of polite learning, and kept at his house several librarians and readers. He might have obtained the most considerable posts in the government; but chose rather not to meddle, because in the corruption and faction which then prevailed he could not discharge them according to the laws. He wrote Annals. He married his daughter to Agrippa; and attained to the age of 77.

ATTILA, king of the Huns, surnamed *the scourge of God*, lived in the fifth century. He may be ranked amongst the greatest conquerors, since there was scarcely any province of Europe which did not feel the weight of his victorious arms.

Gibbon's Rome, vol. iii. p. 357.

Attila deduced his noble, perhaps his regal, descent from the ancient Huns, who had formerly contended with the monarchs of China. His features, according to the observation of a Gothic historian, bore the stamp of his national origin: and the portrait of Attila exhibits the genuine deformity of a modern Calmuck; a large head, a swarthy complexion, small deep-seated eyes, a flat nose, a few hairs in the place of a beard, broad shoulders, and a short square body, of nervous strength, though of a disproportioned form. The haughty step and demeanour of the king of the Huns expressed the consciousness of his superiority above the rest of mankind; and he had a custom of fiercing rolling his eyes, as if he wished to enjoy the terror which he inspired. Yet this savage hero was not inaccessible to pity; his suppliant enemies might confide in the assurance of peace or pardon; and Attila was considered by his subjects as a just and indulgent master. He delighted in war: but after he had ascended the throne in a mature age, his head, rather than his hand, achieved the conquest of the north; and the fame of an adventurous soldier was usefully exchanged for that of a prudent and successful general. The effects of personal valour are so inconsiderable, except in poetry or romance, that victory, even among barbarians, must depend on the degree of skill, with which the passions of the multitude are combined and guided for the service of a single man. The arts of Attila were skilfully adapted to the character of his age and country. It was natural enough, that the Scythians should adore with peculiar devotion, the god of war; but as they were incapable of forming either an abstract idea, or a corporeal representation, they worshipped their tutelar deity under the symbol of an iron scimitar. One of the shepherds of the Huns perceived, that a heifer, who was grazing, had wounded herself in the foot; and curiously followed the track of the blood, till he discovered, among the long grass, the

Digitized by Google

the point of an ancient sword; which he dug out of the ground, and presented to Attila. That magnanimous, or rather that artful, prince, accepted with pious gratitude, this celestial favour; and, as the rightful possessor of the *sword of Mars*, asserted his divine and indefeasible claim to the dominion of the earth. If the rites of Scythia were practised on this solemn occasion, a lofty altar, or rather pile of faggots, 300 yards in length and in breadth, was raised in a spacious plain; and the sword of Mars was placed erect on the summit of this rustic altar, which was annually consecrated by the blood of sheep, horses, and of the hundredth captive. Whether human sacrifices formed any part of the worship of Attila, or whether he propitiated the god of war with the victims which he continually offered in the field of battle, the favourite of Mars soon acquired a sacred character, which rendered his conquests more easy and more permanent; and the barbarian princes confessed, in the language of devotion or flattery, that they could not presume to gaze with a steady eye on the divine majesty of the king of the Huns. His brother Bleda, who reigned over a considerable part of the nation, was compelled to resign his sceptre and his life. Yet even this cruel act was attributed to a supernatural impulse; and the vigour with which Attila wielded the sword of Mars, convinced the world that it had been reserved alone for his invincible arm. But the extent of his empire affords the only remaining evidence of the number and importance of his victories; and the Scythian monarch, however ignorant of the value of science and philosophy, might perhaps lament that his illiterate subjects were destitute of the art which could perpetuate the memory of his exploits.

If a line of separation were drawn between the civilized and the savage climates of the globe; between the inhabitants of cities who cultivated the earth, and the hunters and shepherds who dwelt in tents; Attila might aspire to the title of supreme and sole monarch of the Barbarians. He alone, among the conquerors of ancient and modern times, united the two mighty kingdoms of Germany and Scythia: and those vague appellations, when they are applied to his reign, may be understood with an extensive latitude. Thuringia, which stretched beyond its actual limits as far as the Danube, was in the number of his provinces: he interposed, with the weight of a powerful neighbour, in the domestic affairs of the Franks; and one of his lieutenants chastised, and almost exterminated, the Burgundians of the Rhine. He subdued the islands of the ocean, the kingdoms of Scandinavia, encompassed and divided by the waters of the Baltic; and the Huns might derive a tribute of furs from that northern region, which has been protected from all other conquerors by the severity of the climate, and the courage of the natives. Towards the east, it is difficult to circumscribe the dominion of Attila over the Scythian deserts: yet we may be assured, that he reigned on the banks of the Volga; that the king of the Huns was dreaded not only as a warrior but as a magician; that he insulted and vanquished the khan of the formidable Geougen; and that he sent ambassadors to negociate an equal alliance with the empire of China. In the proud review of the nations who acknowledged the sovereignty of Attila, and who never entertained during his lifetime the thought of a revolt, the Gepidæ and the Ostrogoths were distinguished by their numbers, their bravery, and the personal merit of their chiefs. The renowned Ardaric king of the Gepidæ, was the faithful and sagacious counsellor of the monarch; who esteemed his intrepid genius, whilst he loved the mild and discreet virtues of the noble Walamir king of the Ostrogoths. The crowd of the vulgar kings, the leaders of so many martial tribes, who served under the standard of Attila, were ranged in the submissive order of guards and domestics round the person of their master. They watched his nod; they trembled at his frown: and at the first signal of his will, they executed without murmur or hesitation his stern and absolute commands. In time of peace, the dependent princes, with their national troops, attended the royal camp in regular succession; but when Attila collected his military force, he was able to bring into the field an army of five, or, according to another account, of seven hundred thousand Barbarians.

The death of Attila was attended with singular circumstances. He had married a new wife, a beautiful virgin named *Ildico*. His nuptials were celebrated with great festivity, at his palace beyond the Danube, and he retired late to bed oppressed with wine. In the night, a blood-vessel burst in his lungs, which suffocated him. The bride was found in the morning sitting by the bedside, lamenting his death and her own danger. The body of Attila was exposed in the plain, while the Huns, singing funeral songs to his praise, marched round it in martial order. The body, enclosed in three coffins, of gold, silver, and iron, was privately interred during the night; and to prevent the violation of his remains by the discovery of the place where he was buried, all the captive slaves who were employed in the solemnity were barbarously massacred. This happened about the year 453. With Attila ended the empire of the Huns. His sons, by dissension and civil war, mutually destroyed each other, or were dispossessed by more powerful and independent chieftains.

For a farther account of his exploits, see the article Huns.

ATTIRE, in hunting, signifies the head or horns of a deer. The attire of a stag, if perfect, consist of bur, pearls, beam, gutters, antler, sur-antler, royal, surroyal, and crotchets; of a buck, of the bur, beam, brow-antler, advancer, palm, and spellers.

ATTITUDE, in *Painting* and *Sculpture*, the gesture of a figure or statue; or it is such a disposition of their parts as serves to express the action and sentiments of the person represented.

ATTIUM, in *Ancient Geography*, a promontory on the north-west of Corsica, (Ptolemy). It still retains some traces of its ancient name, being now called *Punta di Acciuolo* (Cluverius).

ATTLEBURY, a town in the county of Norfolk in England. E. Long. 0. 40. N. Lat. 52. 23.

ATTOLLENS, in *Anatomy*, an appellation given to several muscles, otherwise called *levatores* and *elevatores*. See Anatomy, *Tables of the Muscles*.

ATTORNEY at law, answers to the Procurator or Proctor of the civilians and canonists: And he is one who is put in the place, stead, or turn, of another, to manage his matters of law. Formerly every suitor

suitor was obliged to appear in person, to prosecute or defend his suit (according to the old Gothic constitution), unless by special license under the king's letters patent. This is still the law in criminal cases. And an idiot cannot to this day appear by attorney, but in person; for he hath not discretion to enable him to appoint a proper substitute: and upon his being brought before the court in so defenceless a condition, the judges are bound to take care of his interests, and they shall admit the best plea in his behalf that any one present can suggest. But, as in the Roman law, *cum olim in usu fuisset, alterius nomine agi non posse, sed quia hoc non minimam incommoditatem habebat, cœperunt homines per procuratores litigare;* so, with us, on the same principle of convenience, it is now permitted in general, by divers ancient statutes, whereof the first is statute West. 2. c. 10. that attorneys may be made to prosecute or defend any action in the absence of the parties to the suit. These attorneys are now formed into a regular corps; they are admitted to the execution of their office by the superior courts of Westminster hall; and are in all points officers of the respective courts in which they are admitted; and as they have many privileges on account of their attendance there, so they are peculiarly subject to the censure and animadversion of the judges. No man can practise as an attorney in any of those courts, but such as is admitted and sworn an attorney of that particular court: an attorney of the court of king's bench cannot practise in the court of common pleas; nor *vice versa.* To practise in the court of chancery, it is also necessary to be admitted a solicitor therein: and by the statute 22 Geo. II. c. 46. no person shall act as an attorney at the court of quarter-sessions, but such as has been regularly admitted in some superior court of record. So early as the statute 4 Hen. IV. c. 18. it was enacted, that attorneys should be examined by the judges, and none admitted but such as were virtuous, learned, and sworn to do their duty. And many subsequent statutes have laid them under farther regulations.

Letter of attorney pays by different acts, 6s. By 25 Geo. III. c. 80. the following duties are to be paid by every solicitor, attorney, notary, proctor, agent, or procurator, viz. for every warrant to prosecute for a debt of 40s. or to defend, a stamp duty of 2s. 6d. And they are to take out certificates annually; and if resident in London, Westminster, the bills of mortality, or Edinburgh, they are now obliged to pay 5l. for the same; and in every other part of Great Britain, 3l. The duties are under the management of the commissioners of stamps: and every acting solicitor, and other persons as above, shall annually deliver in a note of his name and residence, to the proper officer of the court in which he practises; the entering officers are to certify notes delivered, and issue annual certificates, stamped as above, which must be renewed ten days before the expiration. Refusing to issue, or improperly issuing certificates, is a penalty of 50l. and damages to the party aggrieved. Acting without a certificate, or giving in a false place of residence, is a penalty of 50l. and incapacity to sue for fees due. A stamped memorandum shall be given to the proper officer, of the names of the parties in every action; and in such cases as used to require precipes. Officers who receive stamped memorandums, are to file the same, on penalty of 50l. and persons not acting conformable to this act forfeit 5l.

Attorney-General, is a great officer under the king, made by letters patent. It is his place to exhibit informations, and prosecute for the crown, in matters criminal; and to file bills in the exchequer, for any thing concerning the king in inheritance or profits; and others may bring bills against the king's attorney. His proper place in court, upon any special matters of a criminal nature, wherein his attendance is required, is under the judges on the left hand of the clerk of the crown: but this is only upon solemn and extraordinary occasions; for usually he does not sit here, but within the bar in the face of the court.

ATTOURNMENT, or Attornment, in *Law*, a transfer from one lord to another of the homage and service a tenant makes; or that acknowledgment of duty to a new lord.

ATTRACTION, in *Natural Philosophy*, a general term used to denote the cause by which bodies tend towards each other, and cohere till separated by some other power.

The principle of attraction, in the Newtonian sense of it, seems to have been first surmised by Copernicus, "As for gravity," says Copernicus, "I consider it as nothing more than a certain natural appetence (*appetentia*) that the Creator has impressed upon all the parts of matter, in order to their uniting or coalescing into a globular form, for their better preservation; and it is credible that the same power is also inherent in the sun and moon, and planets, that those bodies may constantly retain that round figure in which we behold them." *De Rev. Orb. Cœlest.* lib. i. cap. 9. And Kepler calls gravity a corporeal and mutual affection between similar bodies, in order to their union. *Ast. Nov. in Introd.* And he pronounces more positively, that no bodies whatsoever were absolutely light, but only relatively so; and consequently, that all matter was subjected to the law of gravitation. *Ibid.*

The first in this country who adopted the notion of attraction was Dr Gilbert in his book *De Magnete;* and the next was the celebrated Lord Bacon, *Nov. Organ.* lib. ii. aphor. 36. 45. 48. *Sylv.* cent. i. exp. 33. In France it was received by Fermat and Roberval; and in Italy by Galileo and Borelli. But till Sir Isaac Newton appeared, this principle was very imperfectly defined and applied.

It must be observed, that though this great author makes use of the word attraction, in common with the school philosophers; yet he very studiously distinguishes between the ideas. The ancient attraction was supposed a kind of quality, inherent in certain bodies themselves, and arising from their particular or specific forms. The Newtonian attraction is a more indefinite principle; denoting not any particular kind or manner of action, nor the physical cause of such action; but only a tendency in the general, a *conatus accedendi*, to whatever cause, physical or metaphysical, such effect be owing, whether to a power inherent in the bodies themselves, or to the impulse of an external agent. Accordingly, that author, in his *Philosoph. Nat. Prin. Math.* notes, "that he uses the words *attraction*, *impulse*, and *propension* to the centre, indifferently; and cautions the reader not to imagine that by

Digitized by Google

Attraction. by attraction he expresses the modus of the action, or the efficient cause thereof, as if there were any proper powers in the centres, which in reality are only mathematical points; or as if centres could attract." Lib. i. p. 5. So he "considers centripetal powers as attractions, though, physically speaking, it were perhaps more just to call them impulses." *Ib.* p. 147. He adds, "that what he calls attraction may possibly be effected by impulse, though not a common or corporeal impulse, or after some other manner unknown to us." *Optic.* p. 322.

Attraction, if considered as a quality arising from the specific forms of bodies, ought, together with sympathy, antipathy, and the whole tribe of occult qualities, to be exploded. But when we have set these aside, there will remain innumerable phenomena of nature, and particularly the gravity or weight of bodies, or their tendency to a centre, which argue a principle of action seemingly distinct from impulse, where at least there is no sensible impulsion concerned. Nay, what is more, this action in some respects differs from all impulsion we know of; impulse being always found to act in proportion to the surfaces of bodies, whereas gravity acts according to their solid content, and consequently must arise from some cause that penetrates or pervades the whole substance thereof. This unknown principle, unknown we mean in respect of its cause, for its phenomena and effects are most obvious, with all the species and modifications thereof, we call *attraction;* which is a general name, under which all mutual tendencies, where no physical impulse appears, and which cannot therefore be accounted for from any known laws of nature, may be ranged.

And hence arise divers particular kinds of attraction; as, *Gravity*, *Magnetism*, *Electricity*, &c. which are so many different principles acting by different laws, and only agreeing in this, that we do not see any physical causes thereof; but that, as to our senses, they may really arise from some power or efficacy in such bodies, whereby they are enabled to act even upon distant bodies, though our reason absolutely disallows of any such action.

Attraction may be divided, with respect to the law it observes, into two kinds.

1. That which extends to a sensible distance. Such are the attraction of gravity, found in all bodies; and the attraction of magnetism and electricity, found in particular bodies. The several laws and phenomena of each, see under their respective articles.

The attraction of gravity, called also among mathematicians the *centripetal force*, is one of the greatest and most universal principles in all nature. We see and feel it operate on bodies near the earth, and find by observation that the same power (i. e. a power which acts in the same manner, and by the same rules, viz. always proportionably to the quantities of matter, and as the squares of the distances reciprocally) does also obtain in the moon, and the other planets primary and secondary, as well as in the comets; and even that this is the very power whereby they are all retained in their orbits, &c. And hence, as gravity is found in all the bodies which come under our observation, it is easily inferred, by one of the settled rules of philosophizing, that it obtains in all others: and as it is found to be as the quantity of matter in each body, it must be in every particle thereof; and hence every particle in nature is proved to attract every other particle, &c. See ATTRACTION, ASTRONOMY *Index*. Attraction.

From this attraction arises all the motion, and consequently all the mutation, in the material world. By this heavy bodies descend, and light ones ascend; by this projectiles are directed, vapours and exhalations rise, and rains, &c. fall. By this rivers glide, the air presses, the ocean swells, &c. In effect, the motions arising from this principle make the subject of that extensive branch of mathematics, called *mechanics* or *statics*, with the parts or appendages thereof, hydrostatics, pneumatics, &c.

2. That which does not extend to sensible distances. Such is found to obtain in the minute particles whereof bodies are composed, which attract each other at or extremely near the point of contact, with a force much superior to that of gravity, but which at any distance from it decreases much faster than the power of gravity. This power a late ingenious author chooses to call the *attraction of cohesion*, as being that whereby the atoms or insensible particles of bodies are united into sensible masses.

This latter kind of attraction owns Sir Isaac Newton for its discoverer; as the former does for its improver. The laws of motion, percussion, &c. in sensible bodies under various circumstances, as falling, projected, &c. ascertained by the later philosophers, do not reach to those more remote intestine motions of the component particles of the same bodies, whereon the changes of the texture, colour, properties, &c. of bodies depend: so that our philosophy, if it were only founded on the principle of gravitation, and carried so far as that would lead us, would necessarily be very deficient.

But beside the common laws of sensible masses, the minute parts they are composed of are found subject to some others, which have been but lately taken notice of, and are even yet imperfectly known. Sir Isaac Newton, to whose happy penetration we owe the hint, contents himself to establish that there are such motions in the *minima naturæ*, and that they flow from certain powers or forces, not reducible to any of those in the great world. In virtue of these powers, he shows, "That the small particles act on one another even at a distance; and that many of the phenomena of nature are the result thereof. Sensible bodies, we have already observed, act on one another divers ways: and as we thus perceive the tenor and course of nature, it appears highly probable that there may be other powers of the like kind; nature being very uniform and consistent with herself. Those just mentioned reach to sensible distances, and so have been observed by vulgar eyes; but there may be others which reach to such small distances as have hitherto escaped observation; and it is probable electricity may reach to such distances, even without being excited by friction.

The great author just mentioned proceeds to confirm the reality of these suspicions from a great number of phenomena and experiments, which plainly argue such powers and actions between the particles, e. g. of salts and water, sulphuric acid and water, nitric acid and iron, sulphuric acid and nitre. He also shows, that these powers, &c. are unequally strong between diffe-

Digitized by Google

rent bodies; stronger, e. g. between the particles of potash and those of nitric acid than those of silver, between nitric acid and zinc than iron, between iron and copper than silver or mercury. So sulphuric acid acts on water, but more on iron or copper, &c.

The other experiments which countenance the existence of such principle of attraction in the particles of matter are innumerable.

These actions, in virtue whereof the particles of the bodies above mentioned tend towards each other, the author calls by a general indefinite name *attraction;* which is equally applicable to all actions whereby distant bodies tend towards one another, whether by impulse or by any other more latent power: and from hence he accounts for an infinity of phenomena, otherwise inexplicable, to which the principle of gravity is inadequate.

"Thus (adds our author) will nature be found very conformable to herself and very simple; performing all the great motions of the heavenly bodies by the attraction of gravity, which intercides those bodies, and almost all the small ones of their parts, by some other attractive power diffused through the particles thereof. Without such principles, there never would have been any motion in the world; and without the continuance thereof, motion would soon perish, there being otherwise a great decrease or diminution thereof, which is only supplied by these active principles.

We need not say how unjust it is in the generality of foreign philosophers to declare against a principle which furnishes so beautiful a view, for no other reason but because they cannot conceive how one body should act on another at a distance. It is certain, philosophy allows of no action but what is by immediate contact and impulsion (for how can a body exert any active power there where it does not exist? to suppose this of any thing, even the Supreme Being himself, would perhaps imply a contradiction): yet we see effects without seeing any such impulse; and where there are effects, we can easily infer there are causes, whether we see them or not. But a man may consider such effects without entering into the consideration of the causes, as indeed it seems the business of a philosopher to do: for to exclude a number of phenomena which we do see, will be to leave a great chasm in the history of nature; and to argue about actions which we do not see, will be to build castles in the air.—It follows, therefore, that the phenomena of attraction are matter of physical consideration, and as such entitled to a share in the system of physics; but that the causes thereof will only become so when they become sensible, i. e. when they appear to be the effect of some other higher causes (for a cause is no otherwise seen than as itself is an effect, so that the first cause must from the nature of things be invisible): we are therefore at liberty to suppose the causes of attraction what we please, without any injury to the effects.—The illustrious author himself seems a little irresolute as to the causes; inclining sometimes to attribute gravity to the action of an immaterial cause (*Optics*, p. 343, &c.) and sometimes to that of a material one (Ib. p. 325.).

In his philosophy, the research into causes is the last thing, and never comes under consideration till the laws and phenomena of the effect be settled; it being to these phenomena that the cause is to be accommodated. The cause even of any, the grossest and most sensible action, is not adequately known. How impulse or percussion itself produces its effects, i. e. how motion is communicated by body to body, confounds the deepest philosophers; yet is impulse received not only into philosophy, but into mathematics: and accordingly the laws and phenomena of its effects make the greatest part of common mechanics.

The other species of attraction, therefore, in which no impulse is remarkable, when their phenomena are sufficiently ascertained, have the same title to be promoted from physical to mathematical consideration; and this without any previous inquiry into their causes, which our conceptions may not be proportionate to: let their causes be occult, as all causes strictly speaking are, so that their effects, which alone immediately concern us, be but apparent.

Our great philosopher, then, far from adulterating science with any thing foreign or metaphysical, as many have reproached him with doing, has the glory of having thrown every thing of this kind out of his system, and of having opened a new source of sublimer mechanics, which duly cultivated might be of infinitely greater extent than all the mechanics yet known. It is hence alone we must expect to learn the manner of the changes, productions, generations, corruptions, &c. of natural things; with all that scene of wonders opened to us by the operations of chemistry.

Some of our own countrymen have prosecuted the discovery with laudable zeal: Dr Keill particularly has endeavoured to deduce some of the laws of this new action, and applied them to solve divers of the more general phenomena of bodies, as cohesion, fluidity, elasticity, softness, fermentation, coagulation, &c.; and Dr Freind, seconding him, has made a further application of the same principles, to account at once for almost all the phenomena that chemistry presents: so that some philosophers are inclined to think that the new mechanics should seem already raised to a complete science, and that nothing now can occur but what we have an immediate solution of from the attractive force.

But this seems a little too precipitate: A principle so fertile should have been further explored. Attraction in the gross is so complex a thing, that it may solve a thousand different phenomena alike. The notion is but one degree more simple and precise than action itself; and, till more of its properties are ascertained, it were better to apply it less and study it more. It may be added, that some of Sir Isaac Newton's followers have been charged with falling into that error which he industriously avoided, viz. of considering attraction as a cause or active property in bodies, not merely as a phenomenon or effect.

For an account of the mathematical laws of attraction, see ATTRACTION, SUPPLEMENT.

ATTRACTION of Mountains. See MOUNTAINS.

Elective ATTRACTION. See CHEMISTRY *Index.*

ATTREBATII. See ATREBATII.

ATTRIBUTE, in a general sense, that which agrees with some person or thing; or a quality determining something to be after a certain manner. Thus understanding is an attribute of mind, and extension an attribute of body. That attribute which the mind conceives

Digitized by Google

conceives as the foundation of all the rest, is called its *essential attribute;* thus extension is by some, and solidity by others, esteemed the essential attribute of body or matter.

ATTRIBUTES, in *Theology*, the several qualities or perfections of the Divine nature.

ATTRIBUTES, in *Logic*, are the predicates of any subject, or what may be affirmed or denied of any thing.

ATTRIBUTES, in *Painting* and *Sculpture*, are symbols added to several figures, to intimate their particular office and character. Thus the eagle is an attribute of Jupiter; a peacock, of Juno; a caduce, of Mercury; a club, of Hercules; and a palm, of Victory.

ATTRIBUTIVES, in *Grammar*, are words which are significant of attributes; and thus include adjectives; verbs, and particles, which are attributes of substances; and adverbs, which denote the attributes only of attributes. Mr Harris, who has introduced this distribution of words, denominates the former *attributives of the first order*, and the latter *attributives of the second order*.

ATTRITION, the rubbing or striking of bodies one against another, so as to throw off some of their superficial particles.

ATURÆ, an ancient town in the district of Novempopulana in Aquitania, on the river Aturus; now Aire in Gascony, on the Adour. E. Long. 0. 3. N. Lat. 43. 40.

ATWOOD, GEORGE, a mathematician and mechanician. See SUPPLEMENT.

AVA, a kingdom of Asia, in the peninsula beyond the Ganges. The king is very powerful, his dominions being bounded by Bengal and the sea on the west, Siam on the south, Tonquin and Cochin China on the east, and by Tibet and China on the north. Several large rivers run through this country, which annually overflow their banks like the Nile, and thus render it extremely fertile. Here are mines of lead and copper, together with some of gold and silver, besides large quantities of the finest oriental rubies, sapphires, emeralds, &c. See ASIA, N° 81, &c.

AVA, formerly the metropolis of the kingdom of the same name, is situated in E. Long. 96. 30. N. Lat. 21. 0. It is pretty large; the houses built with timber or bamboo canes, with thatched roofs, and floors made of teak plank or split bamboo. The streets are very straight, with rows of trees planted on each side. The king's palace is an exact quadrangle, each side of which is 800 paces, and is surrounded with a brick wall; but the palace itself is of stone. It has four gates: the golden gate, through which all ambassadors enter; the gate of justice, through which the people bring petitions, accusations, or complaints; the gate of grace, through which those pass who have received any favours, or have been acquitted of crimes laid to their charge; and the gate of state, through which his majesty himself passes when he shows himself to the people.

AVA AVA, a plant so called by the inhabitants of Otaheite, in the South sea, from the leaves of which they express an intoxicating juice. It is drunk very freely by the chiefs and other considerable persons, who vie with each other in drinking the greatest number of draughts.

AVADOUTAS, a sect of Indian Bramins, who in austerity surpass all the rest. The other sects retain earthen vessels for holding their provisions, and a stick to lean on; but none of these are used by the Avadoutas; they only cover their nakedness with a piece of cloth; and some of them lay even that aside, and go stark naked, besmearing their bodies with cow-dung. When hungry, some go into houses, and, without speaking, hold out their hand; eating on the spot whatever is given them. Others retire to the sides of holy rivers, and there expect the peasants to bring them provisions, which they generally do very liberally.

AVAIL OF MARRIAGE, in *Scots Law*, that casualty in wardholding, by which the superior was entitled to a certain sum from his vassal, upon his attaining the age of puberty, as the value or avail of his tocher.

AVALANCHES, a name given to prodigious snowballs that frequently roll down the mountains in Savoy, particularly Mount Blanc, to the extreme danger of such adventurous travellers as attempt to ascend those stupendous heights. Some of the avalanches are about 200 feet diameter; being fragments of the ice-rocks which break by their own weight from the tops of the precipices. See *Mount* BLANC.

AVALON, a small but ancient city of France, in the department of the Yonne, and containing 4200 inhabitants in 1815. E. Long. 3. 50. N. Lat. 47. 48.

AVANIA, in the Turkish legislature, a fine for crimes and on deaths, paid to the governor of the place. In the places wherein several nations live together under a Turkish governor, he takes this profitable method of punishing all crimes among the Christians or Jews, unless it be the murder of a Turk.

AVARICUM, an ancient town of the Bituriges in Gallia Celtica, situated on the rivulet Avara, in a very fertile soil (Cæsar.) Now *Bourges*, in Berry. E. Long. 2. 30. N. Lat. 47. 10.

AVAST, in the sea language, a term requiring to stop or to stay.

AVAUNCHERS, among hunters, the second branches of a deer's horns.

AUBAGNE, a town of Provence in France, situated on the river Veaune, on the road from Marseilles to Toulon. The states formerly held their session at this place. E. Long. 5. 52. N. Lat. 43. 17.

AUBAINE, in the old customs of France, a right vested in the king, by virtue of which he claimed the inheritance of all foreigners that died within his dominions, notwithstanding of any testament the deceased could make. An ambassador was not subject to the right of aubaine; and the Swiss, Savoyards, Scots, and Portuguese were also exempted. This ancient privilege of the crown was abolished in 1819.

AUBE, a department in the east of France, comprehending part of the ancient Champagne. It contains 305 square leagues, and had a population of 238,819 in 1815. Troyes is the chief town.

AUBENAS, a town of France, in the department of Ardeche, situated on the river Ardeche, at the foot of the mountains called the *Cevennes*. E. Long. 4. 32. N. Lat. 44. 40.

AUBENTON, a town of France, in the department of Aisne, situated on the river Aube. E. Long. 4. 25. N. Lat. 49. 51.

Digitized by Google

AUBETERRE, a town of France, in the Angumois, on the river Dronne. E. Long. 0. 10. N. Lat. 45. 15.

AUBIGNE, a town of France, in the department of Cher, situated on the river Verre, in a flat and agreeable country. It is surrounded with high strong walls, wide ditches, and high counterscarps. The castle is within the town, and is very handsome. E. Long. 2. 20. N. Lat. 47. 29.

AUBIN DU COMIER, a town of Erance, in the department of Isle and Vilaine. W. Long. 1. 15. N. Lat. 48. 15.

AUBIN, in *Horsemanship*, a broken kind of gait, between an amble and a gallop, accounted a defect.

AUBONNE, a town of Switzerland, in the canton of Bern. E. Long. 5. 54. N. Lat. 46. 30. It is situated near a river of the same name, seven miles north of the lake of Geneva, upon an eminence which has a gentle declivity, at the foot of which runs the river with an impetuous torrent. The town is built in the form of an amphitheatre; on the upper part of which stands a very handsome castle with a fine court, and a portico supported by pillars of a single stone each; above there is a covered gallery that runs round the court; and as the castle stands high, there is a most delightful prospect, not only of the town and neighbouring fields, but of the whole lake of Geneva and the land that surrounds it. At Thonen, in Savoy, on the other side of the lake, is a town covered with tin, which makes a glittering appearance when the sun is in a certain position; and the castle of Aubonne has likewise a tower of the same kind, which at certain hours makes a similar appearance to the Savoyards. The bailiage of Aubonne contains several villages, which are mostly at the foot of the mountain Jura. In one part of this mountain there is a very deep cave, wherein those that go down find a natural and perpetual icehouse. At the bottom is heard a great noise like that of a subterraneous river, which is supposed to be that of the river Aubonne, because it first appears, with several sources, about 100 paces from the foot of that mountain.

AUBREY, JOHN, a famous English antiquary, descended from an ancient family in Wiltshire, was born in 1626. He made the history and antiquities of England his peculiar study and delight; and contributed considerable assistance to the famous *Monasticon Anglicanum*. He succeeded to several good estates; but law-suits and other misfortunes consumed them all, so that he was reduced to absolute want. In this extremity he found a valuable benefactress in the Lady Long of Draycot in Wilts, who gave him an apartment in her house, and supported him to his death, which happened about the year 1700. He was a man of considerable ability, learning, and application, a good Latin poet, an excellent naturalist, but somewhat credulous, and tinctured with superstition. He left many works behind him. He wrote, 1. Miscellanies. 2. A Perambulation of the county of Surry, in five volumes, octavo. 3. The Life of Mr Hobbes of Malmsbury. 4. *Monumenta Britannica*, or a discourse concerning Stonehenge, and Roll Rich stones in Oxfordshire. 5. *Architectonica Sacra*; and several other works still in manuscript.

AUBURN, a market-town of Wiltshire, in England. W. Long. 1. 20. N. Lat. 53. 20.

AUBUSSON, a small town of France, in the province of La Marche, and the government of the Lyonnois, now the department of Creuse. Its situation is very irregular, on the river Creuse, in a bottom surrounded with rocks and mountains. A manufacture of tapestry is carried on here, and the town contained a population of 3520 souls in 1815. E. Long. 2. 15. N. Lat. 45. 58.

AUCAUGREL, the capital of the kingdom of Adel in Africa, seated on a mountain. E. Long. 44. 25. N. Lat. 9. 10.

AUCH, a city of France, the capital of the county of Armagnac, now the department of Gers, and the metropolis of all Gascony. The archbishop formerly assumed the title of primate of Aquitain. It lies on the summit and declivity of a very steep hill, which is surrounded by other hills that rise at a small distance; and through the vale below runs a rivulet, called the *Gers*. The inhabitants amount to 8800; the buildings are modern and elegant; the streets, though in general narrow, yet are clean and well paved. In the centre of the city stands the cathedral, which is one of the most magnificent in France, both as to its construction and the internal decorations. The painted windows are only inferior to those of Gouda in Holland. The chapels are of equal beauty, and ornamented at a prodigious expence. The revenues of the see of Auch amounted formerly to three hundred thousand livres per annum. It contains manufactures of serge and the coarse woollens called *barat*; there are also tanneries, and the environs are noted for producing the excellent pear called *bon chretien*.

AUCTION, a kind of public sale, very much in use for household goods, books, plate, &c. By this method of sale the highest bidder is always the buyer. This was originally a kind of sale among the ancient Romans, performed by the public crier *sub hasta*, i. e. under a spear stuck up on that occasion, and by some magistrate, who made good the sale by delivery of the goods.

AUDEANISM, the same with anthropomorphism. See ANTHROPOMORPHITES.

AUDEUS, the chief of the Audeans, obtained the name of a heretic, and the punishment of banishment, for celebrating Easter in the manner of the Jews, and attributing a human form to the Deity. He died in the country of the Goths, about the year 370.

AUDIENCE given to ambassadors, a ceremony observed in courts at the admission of ambassadors or public ministers to a hearing.

In England, audience is given to ambassadors in the presence chambers; to envoys and residents, in a gallery, closet, or in any place where the king happens to be. Upon being admitted, as is the custom of all courts, they make three bows; after which they cover and sit down; but not before the king is covered and sat down, and has given them the sign to put on their hats. When the king does not care to have them covered, and sit, he himself stands uncovered; which is taken as a slight. At Constantinople, ministers usually have audience of the prime vizier.

AUDIENCE

Audience is also the name of a court of justice established in the West Indies by the Spaniards, answering in effect to the parliament in France. These courts take in several provinces, called also *audiences*, from the name of the tribunal to which they belong.

Audience is also the name of an ecclesiastical court held by the archbishop of Canterbury, wherein differences upon elections, consecrations, institutions, marriages, &c. are heard.

AUDIENDO & terminando, a writ, or rather a commission to certain persons, when any insurrection or great riot is committed in any place, for the appeasing and punishment thereof.

AUDIENTES, or Auditores, in church history, an order of catechumens; consisting of those newly instructed in the mysteries of the Christian religion, and not yet admitted to baptism.

AUDIT, a regular hearing and examination of an account by some proper officers, appointed for that purpose.

AUDITOR, in a general sense, a hearer, or one who listens or attends to any thing.

Auditor, according to our *Law*, is an officer of the king, or some other great person, who, by examining yearly the accounts of the under officers, makes up a general book, with the difference between their receipts and charges, and their allowances to allocations.

Auditor of the Receipts, is an officer of the exchequer who files the tellers bills, makes an entry of them, and gives the lord treasurer a certificate of the money received the week before. He also makes debentures to every teller, before they receive any money, and takes their accounts. He keeps the black book of receipts, and the treasurer's key of the treasury, and sees every teller's money locked up in the new treasury.

Auditors of the Revenue, or of the exchequer, officers who take the accounts of those who collect the revenues and taxes raised by parliament, and take the accounts of the sheriffs, escheators, collectors, tenants, and customers, and set them down in a book, and perfect them.

Auditors of the Prest and Imprest, officers of the exchequer, who take and make up the accounts of Ireland, Berwick, the mint, and of any money impressed to any man for the king's service. They received poundage on all accounts passed by them, which amounted to a prodigious sum, especially in time of war. But the office is now abolished, and 7000l. a-year given to the incumbents.

Auditors Collegiate, *Conventual*, &c. officers formerly appointed in colleges, &c. to examine and pass their accounts.

AUDITORES, in church history. See Audientes.

The auditores formed one branch of the Manichean sect, which was divided into *elect* and *auditors;* corresponding, according to some writers, to *clergy* and *laity;* and, according to others, to the *faithful* and *catechumens* among the Catholics. By the Manichean rule, a different course of life was prescribed to the elect from that of the auditors. The latter might eat flesh, drink wine, bathe, marry, traffic, possess estates, bear magistracy, and the like; all which things were forbidden to the elect. The auditors were obliged to maintain the elect, and kneeled down to ask their blessing. Beausobre observes, that the elect were ecclesiastics, and in general, such as made profession of observing certain counsels, called *evangelic;* such as the clergy and monks; and they were called the *perfect* by Theodoret. The auditors were the laity, and so denominated, because they heard in the church, whilst others taught and instructed.

AUDITORIUM, in the ancient churches, was that part of the church where the audientes stood to hear and be instructed.

The auditorium was that part now called *navis ecclesiæ**. In the primitive times, the church was so strict in keeping the people together in that place, that the person who went from thence in sermon-time, was ordered by the council of Carthage to be excommunicated.

* See Nave.

AUDITORY, something relating to the sense of hearing.

Auditory, or Audience, an assembly of people who attend to hear a person who speaks in public.

Auditory is also used for the bench whereon a magistrate or judge hears causes.

Auditory, in ancient churches. See Auditorium.

Auditory Passage, (*meatus auditorius*), in *Anatomy;* the entrance of the ear. See Anatomy *Index*.

Auditory Nerves. See Anatomy *Index*.

AUDRAN, Claude, a French engraver, the first of the celebrated artists of that name, was the son of Lewis Audran, an officer belonging to the wolf-hunters, in the reign of Henry IV. of France; and was born at Paris in 1592. He never made any great progress in that art; so that his prints are held in little or no estimation. Yet though he acquired no great reputation by his own works, it was no small honour to him to be the father of three great artists, Germain, Claude, and Girard; the last of whom has immortalized the name of the family. Claude Audran retired from Paris to Lyons, where he resided, and died in 1677.

Audran, *Carl*, a very eminent engraver, was brother to the preceding, though some assert he was only his cousin-german; and was born at Paris in 1594. In his infancy he discovered much taste, and a great disposition for the arts; and to perfect himself in engraving, which he appears to have been chiefly fond of, he went to Rome, where he produced several prints that did him great honour. At his return, he adopted that species of engraving which is performed with the graver only. He settled at Paris, where he died in 1674, without having ever been married. The Abbé Marolles, who always speaks of this artist with great praise, attributes 130 prints to him: amongst which, the *annunciation*, a middle-sized plate, upright, from Hannibal Carracci; and the *assumption*, in a circle, from Domenichino, are the most esteemed. In the early part of his life he marked his prints with C, or the name of Carl, till his brother Claude published some plates with the initial only of his baptismal

Audran.

tismal name; when, for distinction's sake, he used the letter K, or wrote his name Karl, with the K instead of the C.

AUDRAN, *Germaine*, the eldest son of Claude, mentioned in the preceding article but one, was born in 1631 at Lyons, where his parents then resided. Not content with the instructions of his father, he went to Paris, and perfected himself under his uncle Carl; so that, upon his return to Lyons, he published several prints which did great honour to his graver. His merit was in such estimation, that he was made a member of the academy established in that town, and chosen a professor. He died at Lyons in 1710, and left behind him four sons, all artists; namely, Claude, Benoist, John, and Louis.

AUDRAN, *Claude*, the second of this name, and second son to Claude above mentioned, was born at Lyons in 1639, and went to Rome to study painting; where he succeeded so well, that at his return he was employed by Le Brun to assist him in the battles of Alexander, which he was then painting for the king of France. He was received into the Royal Academy in the year 1675, and died unmarried at Paris in 1684. His virtues (says Abbe Fontenai) were as praiseworthy as his talents were great. M. Heineken mentions this artist as an engraver, without specifying any of his works in that line.

AUDRAN, *Girard*, or *Gerard*, the most celebrated artist of the whole family of the Audrans, was the third son of Claude Audran mentioned in a preceding article, and born at Lyons in 1640. He learned from his father the first principles of design and engraving; and following the example of his brother, he left Lyons and went to Paris, where his genius soon began to manifest itself. His reputation there brought him to the knowledge of Le Brun, who employed him to engrave the *battles of Constantine*, and the *triumph* of that emperor; and for these works he obtained apartments at the Gobelins. At Rome, whither he went for improvement, he is said to have studied under Carlo Maratti, in order to perfect himself in drawing; and in that city, where he resided three years, he engraved several fine plates. M. Colbert, that great encourager of the arts, was so struck with the beauty of Audran's works whilst he resided at Rome, that he persuaded Louis XIV. to recal him. On his return, he applied himself assiduously to engraving; and was appointed engraver to the king, from whom he received great encouragement. In the year 1681 he was named counsellor of the Royal Academy; and died at Paris in 1703. He had been married; but left no male issue behind him.

Strutt's Dictionary.

The great excellency of this artist above that of any other engraver was, that though he drew admirably himself, yet he contracted no manner of his own; but transcribed on copper simply, with great truth and spirit, the style of the master whose pictures he copied. On viewing his prints you lose sight of the engraver, and naturally say, it is Le Brun, it is Poussin, it is Mignard, or it is Le Sueur, &c. as you turn to the prints which he engraved from those masters. Let any one examine the *battles* above-mentioned from Le Brun, the *preservation of the young Pyrrhus* from Nicholas Poussin, the *pest* from Mignard, and the *martyrdom of St Lawrence* from Le Sueur, and then judge candidly of the truth of this observation. The following judicious observations by the abbé Fontenai, taken chiefly from M. Basan, with some small variation and additions, will fully illustrate the merits of Gerard Audran. "This sublime artist, far from conceiving that a servile arrangement of strokes, and the too frequently cold and affected clearness of the graver, were the great essentials of historical engraving, gave worth to his works by a bold mixture of free hatchings and dots, placed together apparently without order, but with an inimitable degree of taste; and has left to posterity most admirable examples of the style in which grand compositions ought to be treated. His greatest works, which have not a very flattering appearance to the ignorant eye, are the admiration of true connoisseurs and persons of fine taste. He acquired the most profound knowledge of the art by the constant attention and study which he bestowed upon the science of design, and the frequent use he made of painting from nature. This great man always knew how to penetrate into the genius of the painter he copied from; often improved upon, and sometimes even surpassed him. Without exception, he was the most celebrated engraver that ever existed in the historical line. We have several subjects which he engraved from his own designs, that manifested as much taste as character and facility. But, in the *battles of Alexander*, he surpassed even the expectations of Le Brun himself." These consist of three very large prints, lengthwise, each consisting of four plates, which join together, from Le Brun; namely, *the passage of the Granicus; the battle of Arbela; Porus brought to Alexander*, after his defeat. To this set are added two more large prints lengthwise, on two plates each, also from Le Brun, as follow: *Alexander entering the tent of Darius;* and *The triumphal entry of Alexander into Babylon*. The former was engraved by Gerard Edelink, and the latter by Gerard Audran. It is to be remarked of all these plates, that those impressions are generally most esteemed which have the name of Goyton the printer marked upon them. The *Pest*, from Peter Mignard, a large plate, lengthwise, also deserves particular notice. In the first impressions, the figure in the clouds is Juno with her peacock behind her; in the latter, the peacock is obliterated, and the wings of an angel are added to the figure.

AUDRAN, *Benoit*, the second son of Germain Audran, was born at Lyons in 1661, where he learned the first principles of design and engraving under the instruction of his father. But soon after going to Paris, his uncle Gerard Audran took him under his tuition; and Benoit so greatly profited by his instructions, that though he never equalled the sublime style of his tutor, yet he deservedly acquired great reputation. Nay, the abbé Fontenai adds this eulogium: "We admire in his works a share of those beauties which we find in the engravings of the illustrious Gerard." He was honoured with the appellation of the king's engraver, and received the royal pension. He was made an academician, and admitted into the council in 1715. He died unmarried at Louzouer, where he had an estate, in 1721. His manner was founded upon the bold clear style of his uncle. His outlines were firm and determined; his drawing correct; the heads of his figures are in general very expressive; and the

Digitized by Google

the other extremities well marked. His works, when compared with those of his uncle, appear to want that mellowness and harmony which are so conspicuous in the latter; they are more dry; and the round dots with which he finished his flesh upon the lights are often too predominant. In his most finished plates, we find the mechanical part of the engraving extremely neat, and managed with great taste and judgment. Among his neatest prints may be reckoned that which represents *Alexander sick*, drinking from the cup which his physician presents to him: a circular plate, from Le Sueur.

AUDRAN, *John*, the third son of Germain Audran, was born at Lyons in 1667; and, after having received instructions from his father, went to Paris to perfect himself in the art of engraving under his uncle Gerard Audran. At the age of 20 years, the genius of this great artist began to display itself in a surprising manner; and his future success was such, that in 1707, he obtained the title of engraver to the king, and had a pension allowed him by his majesty, with apartments in the Gobelins; and the following year he was made a member of the Royal Academy. He was 80 years of age before he quitted the graver: and near 90 when he died at his apartments assigned him by the king. He left three sons behind him; one of whom was also an engraver, as we shall see below. "The most masterly and best prints of this artist (in Mr Strutt's opinion) are those which are not so pleasing to the eye at first sight. In these the etching constitutes a great part; and he has finished them in a bold rough style. The scientific hand of the master appears in them on examination. The drawing of the human figure, where it is shown, is correct. The heads are expressive and finely finished; the other extremities well marked. He has not, however, equalled his uncle. He wants that harmony in the effect; his lights are too much and too equally covered; and there is not sufficient difference between the style in which he has engraved his back grounds and his draperies. This observation refers to a fine print by him of Athaliah, and such as he engraved in that style. At other times he seems almost to have quitted the point, and substituted the graver. But here I think he has not so well succeeded. The effect is cold and silvery: see, for example, the *Andromache* from Sylvestre. One of his best finished prints, in this neat style, seems to me to be *Cupid* and *Psyche* from Ant. Coypel."

AUDRAN, *Louis*, the last son of Germain Audran, was born at Lyons in 1670; from whence he went to Paris, after the example of his brothers, to complete his studies in the school of his uncle Gerard. He died suddenly at Paris in 1712, before he had produced any great number of prints by his own hand. He assisted, it is presumed, his brothers in their more extensive works. Among the most esteemed prints by this artist are *the seven acts of mercy*, on seven middling sized plates, lengthwise, from Sebastian Bourdon.

AUDRAN, *Benoit*, the second engraver of that name, was the son of John Audran, and nephew to the former Benoit: and was also established at Paris. He engraved but a few plates. It is necessary, however, to be careful not to confound him with his uncle. But a little attention will easily prevent this mistake; for the second Benoit is vastly inferior to the first in point of merit. We have some few portraits by this artist: and among other plates, the *descent from the cross*, from a picture of Poussin.

AVEIRO, a considerable city of Portugal, seated near the head of a small gulf formed by the tide at the mouth of the river Vouga. This river forms a small haven with a bar, over which vessels may pass that do not draw above eight or nine feet water. The city stands in a long plain well watered, and very fertile. This plain is nine miles broad, from Porto to Coimbra; and is bounded on the east by a chain of mountains called *Sara d'Alcoba*, which reach from the one town to the other. Near this city there is salt made in sufficient quantity to serve two or three provinces. Here is a remarkable nunnery, where none are received but the daughters of the ancient nobility. The inhabitants of Aveiro have the singular privilege, that no stranger whatever can pass a night there without leave of the magistrate. W. Long. 8. 34. N. Lat. 40. 30.

AVELLANE, in *Heraldry*, a cross, the quarters of which somewhat resemble a filbert-nut. Sylvanus Morgan says, that it is the cross which ensigns the mound of authority, or the sovereign's globe.

AVELLINO, a city of Italy, in the kingdom of Naples, with a bishop's see. It was almost ruined by an earthquake in 1694. It is, however, at present a pretty considerable place, extending a mile in length down the declivity of a hill, with ugly streets, but tolerable houses. The churches have nothing to recommend them, being crowded with monstrous ornaments, in a barbarous style, which the Neapolitans seem to have borrowed from the Spaniards. The cathedral is a poor building, in a wretched situation, with little to attract the eye. The good people here need not run to Naples to see the blood of St Januarius: for they have a statue of St Lawrence, with a phial of his blood, which for eight days in August entertains them with a similar miraculous liquefaction. Their only edifice of note is a public granary, of the Composite order, adorned with antique statues, and a very elegant bronze one of Charles II. of Spain, while a boy, cast by Cavalier Cosimo. The number of inhabitants amounts to 8000, some say 10,000. The bishop's revenue is about 6000 ducats (1125l.) a-year. The magistracy consists of a syndic and four eletti, all annual; which offices are engrossed by a certain number of families of some distinction, that neither intermarry nor associate with the rest of the burghers. There is a considerable manufacture of cloth here of various qualities and colours, but chiefly blue. Many wealthy merchants have a concern in this business, some with a capital of eighty thousand ducats (15,000l.). The poor women who spin the wool must work very hard to earn above four grana a-day. The second article of trade is maccaroni and paste of many kinds, which being of an excellent quality, are in high repute all over the country. Wooden chairs are also made and sold here in great quantities. Avellino abounds with provisions of every sort; each street is supplied with wholesome water; the wine is but indifferent. The soil of this district, which consists chiefly of volcanic substances, produces little corn, but fruit in abundance, of which the apple is deservedly held in great esteem. The most profitable, however, of all its fruit-trees is the hazel. Nut bushes cover the face of the valley, and in

Digitized by Google

good years bring in a profit of sixty thousand ducats (11,250l.). The nuts are mostly of the large round species of filbert, which we call *Spanish*. These bushes were originally imported into Italy from Pontus, and known among the Romans by the appellation of *Nux Pontica*, which in process of time was changed into that of *Nux Avellana*, from the place where they had been propagated with the greatest success. The proprietors plant them in rows, and by dressing, form them into large bushes of many stems. Every year they refresh the roots with new earth, and prune off the straggling shoots with great attention.

AVE-MARIA, the angel Gabriel's salutation of the Virgin Mary, when he brought her the tidings of the incarnation.—It is become a prayer or form of devotion in the Romish church. The chaplets and rosaries are divided into so many ave-marias, and so many pater-nosters, to which the Papists ascribe a wonderful efficacy.

AVENA, OATS. See BOTANY *Index*.

AVENACEOUS, something belonging to or partaking of the nature of oats.

AVENAGE, in *Law*, a certain quantity of oats paid by a tenant to a landlord, instead of rent or some other duties.

AVENCHE, an ancient city of Switzerland, in the canton of Bern, formerly the capital of all Switzerland, but now shows its former greatness only by its ruins. E. Long. 7. 7. N. Lat. 46. 50.

AVENES, a small but strong town in French Flanders, in the county of Hainault, seated on the river Thespis. It contains about 2700 inhabitants; but the houses are wretchedly built, and the streets irregular. It was fortified by M. Vauban in a strong regular manner. About this place is a prodigious number of white stones proper for building, and used by sculptors for statues: they are known by the name of *Stones of Avenes*. E. Long. 3. 50. N. Lat. 50. 10.

AVENIO, an ancient town of the Cavares, and one of the most opulent in Gallia Narbonensis; now *Avignon*, in Provence. See AVIGNON.

AVENOR, an officer belonging to the king's stables, who provides oats for the horses. He acts by warrant from the master of the horse.

AVENS. See CARIOPHYLLUS, BOTANY *Index*.

AVENTINE, JOHN, author of the Annals of Bavaria, was born of mean parentage, in the year 1466, at Abensperg in the country just named. He studied first at Ingoldstadt, and afterwards in the university of Paris. In 1503, he privately taught eloquence and poetry at Vienna; and in 1507 he publicly taught Greek at Cracow in Poland. In 1509, he read lectures on some of Cicero's works at Ingoldstadt: and in 1512, was appointed to be preceptor to Prince Louis and Prince Ernest, sons of Albert the Wise, duke of Bavaria, and travelled with the latter of these two princes. After this he undertook to write the annals of Bavaria; being encouraged by the dukes of that name, who settled a pension upon him, and gave him hopes that they would defray the charges of the book. This work, which gained its author great reputation, was first published in 1554, by Jerome Zieglerus, professor of poetry in the university of Ingoldstadt; and afterwards at Basil in 1580, by Nicholas Cisner. An affront which Aventine received in the year 1529, stuck by him all the rest of his life: he was forcibly taken out of his sister's house at Abensperg, and hurried to jail; the true cause of which violence was never known: but it would probably have been carried to a much greater length, had not the duke of Bavaria interposed, and taken this learned man into his protection. Mr Bayle remarks, that the incurable melancholy which from this time possessed Aventine, was so far from determining him to lead a life of celibacy, as he had done till he was 64, that it induced him perhaps to think of marrying. The violence of his new passion was not, however, so great, but that it suffered him to advise with two of his friends, and consult certain passages of the Bible relative to marriage. The result was, that it was best for him to marry; and having already lost too much time, considering his age, he took the first woman he met with, who happened to be his own maid, ill-tempered, ugly, and extremely poor. He died in 1534, aged 68; leaving one daughter, who was then but two months old. He had a son, who died before.

AVENTINUS MONS, one of the seven hills on which ancient Rome stood. The origin of the name *Aventinus* is uncertain: but this hill was also called *Murcius*, from Murcia the goddess of sloth, who had a little chapel there; and *Collis Dianæ*, from the temple of Diana; likewise *Remonius*, from Remus, who wanted to build the city, and who was buried there. It was taken within the compass of the city by Ancus Martius. To the east it had the city walls; to the south, the Campus Figulinus; to the west, the Tiber; and to the north, Mons Palatinus: in circuit two miles and a quarter.

AVENTURE, in law books, means a mischance causing the death of a person without felony.

AVENUE, in *Gardening*, a walk planted on each side with trees, and leading to a house, garden-gate, wood, &c. and generally terminated by some distant object.

All avenues that lead to a house ought to be at least as wide as the whole front of the house, if wider they are better still; and avenues to woods, and prospects, ought not to be less than 60 feet wide. The trees should not be planted nearer to one another than 35 feet, especially if they are trees of a spreading kind; and the same ought to be the distance, if they are for a regular grove.

The trees most proper for avenues with us, are the English elm, the lime, the horse-chesnut, the common chesnut, the beech, and the abele. The English elm will do in all grounds, except such as are very wet and shallow; and this is preferred to all other trees, because it will bear cutting, heading, or lopping in any manner, better than most others. The rough or smooth Dutch elm is approved by some, because of its quick growth. This is a tree which will bear removing very well; it is also green almost as soon as any plant whatever in spring, and continues so as long as any, and it makes an incomparable hedge, and is preferable to all other trees for lofty espaliers. The lime is valued for its natural growth and fine shade. The horse-chesnut is proper for all places that are not too much exposed to rough winds. The common chesnut will do very well in a good soil; and rises to a considerable height, when planted somewhat close; though, when it stands single, it is rather inclined to spread than to grow tall.

The

Digitized by Google

The beech is a beautiful tree, and naturally grows well with us in its wild state; but it is less to be chosen for avenues than the before-mentioned, because it does not bear transplanting well, but is very subject to miscarry. Lastly, the abele is fit for any soil, and is the quickest grower of any forest-tree. It seldom fails in transplanting; and succeeds very well in wet soils, in which the others are apt to fail. The oak is but little used for avenues, because of its slow growth.

The old method of planting avenues was with regular rows of trees, and this has been always kept to till of late: but we have now a much more magnificent way of planting avenues; this is by setting the trees in clumps, or platoons, making the opening much wider than before, and placing the clumps of trees at about 300 feet distant from one another. In each of these clumps there should be planted either seven or nine trees; but it is to be observed, that this is only to be practised where the avenue is to be of some considerable length, for in short walks this will not appear so sightly as single rows of trees. The avenues made by clumps are fittest of all for parks. The trees in each clump should be planted about 30 feet asunder; and a trench should be thrown up round the whole clump, to prevent the deer from coming to the trees to bark them.

AVENZOAR, Abu Merwan Abdalmalec ebn Zohr, an eminent Arabian physician, flourished about the end of the eleventh or the beginning of the twelfth century. He was of noble descent, and born at Seville, the capital of Andalusia, where he exercised his profession with great reputation. His grandfather and father were both physicians. The large estate he inherited from his ancesters, set him above practising altogether for gain: he therefore took no fees from the poor, or from artificers, though he refused not the presents of princes and great men. His liberality was extended even to his enemies; for which reason he used to say, that they hated him not for any fault of his, but rather out of envy. Dr Freind writes, that he lived to the age of 135; that he began to practise at 40, or (as others say) at 20; and had the advantage of a longer experience than almost any one ever had, for he enjoyed perfect health to his last hour. He left a son, known also by the name of *Ebn Zohr*, who followed his father's profession, was in great favour with Al Manzur emperor of Morocco, and wrote several treatises of physic.

Avenzoar was cotemporary with Averroes, who, according to Leo Africanus, heard the lectures of the former, and learned physic of him; this seems the more probable, because Averroes more than once gives Avenzoar a very high and deserved encomium, calling him *admirable*, *glorious*, *the treasure of all knowledge*, and *the most supreme in physic from the time of Galen to his own*. Avenzoar, notwithstanding, is by the generality of writers reckoned an empiric: but Dr Freind observes, that this character suits him less than any of the rest of the Arabians. "He was bred," continues that author, "in a physical family, his father and grandfather being both practitioners, whom he always remembers with great gratitude and honour. We have his own testimony that he had a regular education; and that he not only learned what properly belongs to a physician, but, out of a great desire of knowledge, every thing besides which relates to pharmacy or surgery." Dr Freind afterwards observes, "that he was averse to quackery, and rejects the idle superstitions of astrologers; and throughout all his works professes himself so much of the dogmatical or rational sect, which was directly opposite to the empirical, that he has a great deal of reasoning about the causes and symptoms of distempers; and as in his theory he chiefly, if not only, follows Galen, so he quotes him upon all occasions, oftener than the rest of the Arabians do. Notwithstanding he is so Galenical, there are several particulars in him which seldom or ever occur in other authors; and there are some cases which he relates from his own experience, which are worth perusing." He wrote a book entitled, *Tayassir fi'lmâdawât w'altadbîr*, i. e. "The method of preparing medicines and diet;" which is much esteemed. This work was translated into Hebrew, in the year of Christ 1280, and thence into Latin by Paravicius, whose version has had several editions. The author added a supplement to it, under the title of *Jâmé*, or *a Collection*. He also wrote a treatise *Fi'ladwiyat wa'laughdiyat*, i. e. "Of Medicines and Food;" wherein he treats of their qualities.

AVERAGE, in *Commerce*, signifies the accidents and misfortunes which happen to ships and their cargoes, from the time of their loading and sailing to their return and unloading; and is divided into three kinds. 1. The simple or particular average, which consists in the extraordinary expences incurred for the ship alone, or for the merchandises alone. Such is the loss of anchors, masts, and rigging, occasioned by the common accidents at sea; the damages which happen to merchants by storm, prize, shipwreck, wet, or rotting; all which must be borne and paid by the thing which suffered the damage. 2. The large and common average, being those expences incurred, and damages sustained, for the common good and security both of the merchandises and vessels, consequently to be borne by the ship and cargo, and to be regulated upon the whole. Of this number are the goods or money given for the ransom of the ship and cargo, things thrown overboard for the safety of the ship, the expences for unloading, for entering into a river or harbour, and the provisions and hire of the sailors when the ship is put under an embargo. 3. The small averages, which are the expences for towing and piloting the ship out of or into harbours, creeks, or rivers, one third of which must be charged to the ship, and two thirds to the cargo.

Average is more particularly used for a certain contribution that merchants make proportionably to their losses, who have had their goods cast into the sea in the time of a tempest. It also signifies a small duty which those merchants, who send goods in another man's ship, pay to the master for his care of them over and above the freight. Hence it is expressed in the bills of lading, paying so much freight for the said goods, with primage and average accustomed.

AVERDUPOIS. See Avoirdupois.

AVERNUS, a lake of Campania in Italy, near Baiæ, famous among the ancients for its poisonous qualities. It is described by Strabo as lying within the Lucrine bay, deep and darksome, surrounded with steep banks that hang threatening over it, and only accessible

accessible by the narrow passage through which you sail in. Black aged groves stretched their boughs over the watery abyss, and with impenetrable foliage excluded almost every ray of wholesome light; mephitic vapours ascending from the hot bowels of the earth, being denied free passage to the upper atmosphere, floated along the surface in poisonous mists. These circumstances produced horrors fit for such gloomy deities; a colony of Cimmerians, as well suited to the rites as the place itself, cut dwellings in the bosom of the surrounding hills, and officiated as priests of Tartarus. Superstition, always delighting in dark ideas, early and eagerly seized upon this spot, and hither she led her trembling votaries to celebrate her dismal orgies; here she evoked the manes of departed heroes—here she offered sacrifices to the gods of hell, and attempted to dive into the secrets of futurity. Poets enlarged upon the popular theme, and painted its awful scenery with the strongest colours of their art. Homer brings Ulysses to Avernus, as to the mouth of the infernal abodes; and in imitation of the Grecian bard, Virgil conducts his hero to the same ground. Whoever sailed thither, first did sacrifice; and endeavoured to propitiate the infernal powers, with the assistance of some priests who attended upon the place, and directed the mystic performance. Within, a fountain of pure water broke out just over the sea, which was fancied to be a vein of the river Styx; near this fountain was the oracle: and the hot waters frequent in those parts were supposed to be branches of the burning Phlegethon. The poisonous effluvia from this lake were said to be so strong, that they proved fatal to birds endeavouring to fly over it. Virgil ascribes the exhalation not to the lake itself, but to the cavern near it, which was called *Avernus* or *Cave of the Sybil*, and through which the poets feigned a descent to hell. Hence the proper name of the lake is *Lacus Averni*, the "lake near the cavern," as it is called by some ancient authors.

The holiness of these shades remained unimpeached for many ages: Hannibal marched his army to offer incense at this altar; but it may be suspected he was led to this act of devotion rather by the hopes of surprising the garrison of Puteoli, than by his piety. After a long reign of undisturbed gloom and celebrity, a sudden glare of light was let in upon Avernus; the horrors were dispelled, and with them vanished the sanctity of the lake: the axe of Agrippa brought its forest to the ground, disturbed its sleepy waters with ships, and gave room for all its malignant effluvia to escape. The virulence of these exhalations, as described by ancient authors, has appeared so very extraordinary, that modern writers, who know the place in a cleared state only, charge these accounts with exaggeration: but Mr Swinburne thinks them entitled to more respect; for even now he observes the air is feverish and dangerous, as the jaundiced faces of the vine-dressers, who have succeeded the Sibyls and Cimmerians in the possession of the temple, most ruefully testify. Boccacio relates, that during his residence at the Neapolitan court, the surface of this lake was suddenly covered with dead fish, black and singed, as if killed by some subaqueous eruption of fire.

At present the lake abounds with tench; the Lucrine with eels. The change of fortune in these lakes is singular: In the splendid days of imperial Rome the Lucrine was the chosen spot for the brilliant parties of pleasure of a voluptuous court: now, a slimy bed of rushes covers the scattered pools of this once beautiful sheet of water; while the once dusky Avernus is clear and serene, offering a most alluring surface and charming scene for similar amusements. Opposite to the temple is a cave usually styled the Sibyl's grotto; but apparently more likely to have been the mouth of a communication between Cuma and Avernus, than the abode of a prophetess; especially as the Sibyl is positively said by historians to have dwelt in a cavern under the Cumean citadel.

AVERRHOA. See BOTANY *Index*.

AVERROES, one of the most subtile philosophers that ever appeared among the Arabians, flourished at the end of the 11th and beginning of the 12th century. He was the son of the high-priest and chief judge of Corduba in Spain: he was educated in the university of Morocco; and studied natural philosophy, medicine, mathematics, law and divinity. After the death of his father, he enjoyed his posts; but notwithstanding his being exceeding rich, his liberality to men of letters in necessity, whether they were his friends or his enemies, made him always in debt. He was afterwards stripped of all his posts, and thrown into prison, for heresy; but the oppressions of the judge who succeeded him, caused him to be restored to his former employments.

He died at Morocco in the year 1206. He was excessively fat, though he ate but once a-day. He spent all his nights in the study of philosophy; and when he was fatigued, amused himself with reading poetry or history. He was never seen to play at any game, or to partake in any diversion. He was extremely fond of Aristotle's works, and wrote commentaries on them; whence he was styled *the commentator*, by way of eminence. He likewise wrote a work on the whole art of physic, and many amorous verses; but when he grew old, he threw these last into the fire. His other poems are lost, except a small piece, in which he says, "That when he was young, he acted against his reason; but that when he was in years, he followed its dictates:" upon which he utters this wish; "Would to God I had been born old, and that in my youth I had been in a state of perfection!" as to religion, his opinions were, that Christianity is absurd; Judaism, the religion of children; Mahometanism, the religion of swine.

AVERROISTS, a sect of Peripatetic philosophers, who appeared in Italy some time before the restoration of learning, and attacked the immortality of the soul. They took their denomination from AVERROES, the celebrated interpreter of Aristotle (see the preceding article), from whom they borrowed their distinguishing doctrine.

The Averroists, who held the soul was mortal, according to reason or philosophy, yet pretended to submit to the Christian theology, which declares it immortal. But the distinction was held suspicious; and this divorce of faith from reason was rejected by the doctors of that time, and condemned by the last council of the Lateran under Leo X.

AVERRUNCI (DEI)); certain gods, whose business it was, according to the Pagan theology, to avert misfortunes.

Digitized by Google

fortunes. Apollo and Hercules were of the number of these gods among the Greeks; and Castor and Pollux among the Romans.

AVERSA, a town of Italy in the kingdom of Naples, with a bishop's see. It is situated in a very fine plain, in E. Long. 14. 20. N. Lat. 41. 0.

AVERSION, according to Lord Kames, is opposed to *affection*, and not to *desire*, as it commonly is. We have an affection to one person; we have an aversion to another; the former disposes us to do good to its object, the latter to do ill.

AVERTI, in *Horsemanship*, is applied to a regular step or motion enjoined in the lessons. In this sense they say *pas averte*, sometimes *pas ecouté*, and *pas d'ecole*, which all denote the same. The word is mere French, and signifies *advised*.

AVES, one of the Carribbee islands, 451 miles south of Porto Rico, with a good harbour for careening of ships. It is so called from the great number of birds that frequent it. There is another of the same name lying to the northward of this, in N. Lat. 15. 0.; and a third near the eastern coast of Newfoundland, in N. Lat. 50. 5.

Aves, *Birds*, the name of Linnæus's second class of animals. See ORNITHOLOGY.

AVESBURY, ROBERT, an English historian, of whom little more is known than that he was keeper of the registery of the court of Canterbury in the reign of Edward III. and consequently that he lived in the 14th century. He wrote, *Memorabilia gesta magnifici regis Angliæ domini Edwardi tertii post conquestum, procerumque; tactis primitus quibusdam gestis de tempore patris sui domini Edwardi secundi, quæ in regnis Angliæ, Scotiæ, et Franciæ, ac in Aquitania et Britannia, non humana sed Dei potentia, contigerunt, per Robertum de Avesbury.* This history ends with the battle of Poictiers, about the year 1356. It continued in manuscript till the year 1720, when it was printed by the industrious Thomas Hearne at Oxford, from a manuscript belonging to Sir Thomas Seabright. It is now become very scarce.

AVEZZANO, a town of Italy in the kingdom of Naples, in the Farther Abruzzo. It is built on an almost imperceptible declivity, one mile from the lake of Celano, to which an avenue of poplars leads from the baronial castle. This edifice stands at a little distance from the town, is square, and flanked with towers; it was erected by Virginio Orsini, to which family this and many other great lordships belonged, before they were wrested from them in times of civil war, and transferred to the Colonnas. Avezzano was founded in 860, and contains 2700 inhabitants, and two religious communities within its walls, which are indeed in a ruinous condition. The houses are in general mean; but there are some large buildings and opulent families of the class of gentlemen, not possessed of fees held *in capite*.

AUGE, formerly a territory of Normandy in France, which gave title to a viscount. It extends from Falaise and Argenton as far as the sea, between the rivers Dives, Vie, and Tongues. The arable land is stiff, and produces but little good corn: but they sow sainfoin; which succeeds so well that they have five good crops successively; they likewise sow flax and hemp; and have a vast quantity of apples, with which they make cyder. Horses are bred here in great numbers; and the inhabitants fatten the oxen which come from Poictou and Britanny.

AUGEAS, in fabulous history, was king of Elis, and particularly famed for his stable, which contained 3000 oxen, and had not been cleaned for 30 years. Hercules was desired to clear away the filth from this stable in one day; and Augeas promised, if he performed it, to give him a tenth part of the cattle. This task Hercules is said to have executed by turning the course of the river Alpheus through the stable; when Augeas refusing to stand by his engagement, Hercules slew him with his arrows, and gave his kingdom to Phyleus his son, who had shown an abhorrence of his father's insincerity.

AUGMENT, in *Grammar*, an accident of certain tenses of Greek verbs, being either the prefixing of a syllable, or an increase of the quantity of the initial vowels.

AUGMENTATION, in a general sense, is the act of adding or joining something to another with a design to render it large.

AUGMENTATION is also used for the additament or thing added.

AUGMENTATION was also the name of a court erected 27 Hen. VIII. so called from the augmentation of the revenues of the crown, by the suppression of religious houses; and the office still remains, wherein there are many curious records, though the court has been dissolved long since.

AUGMENTATION, in *Heraldry*, are additional charges to a coat-armour, frequently given as particular marks of honour, and generally borne either in the escutcheon or a conton; as have all the baronets of England, who have borne the arms of the province of Ulster in Ireland.

AUGRE, or AWGRE, an instrument used by carpenters and joiners to bore large round holes; and consisting of a wooden handle, and an iron blade terminated at bottom with a steel bit.

AUGSBURG, a city of Germany, in the kingdom of Bavaria, seated near the confluence of the Ardech and Lech, in one of the most beautiful plains that can be imagined. It is one of the largest and handsomest cities of the empire; but the fortifications are after the old manner, and very irregular; the streets are broad and straight; the houses mostly of timber, plastered and whitened without, or adorned with paintings; the rest are of freestone; the churches and fountains are generally ornamented with fine figures of brass. Many of the churches are stately, and adorned within with curious workmanship and paintings. That part of the city erected by the noble family of the Fuggers, who are lords of the adjacent country, consists of several streets crosswise, containing 106 houses: the poor people that inhabit them are maintained by an annual pension. Its magnificent town-house is little inferior to that of Amsterdam, being a vast square stone building, with a marble portico; at the top of the front, within the pediment, is a large spread eagle, holding a sceptre and globe in its talons, of brass gilt, said to weigh 2200 weight; the great portal is of a very beautiful reddish marble, over which is a balcony of the same colour, supported by two pillars of white marble; over the gate there are two large griffins of

Digitized by Google

brass; most of the rooms are wainscotted and ceiled with very fine timber: the great hall is very magnificent, and paved with marble; it is 110 feet long, 58 broad, and 52 high, and its roof is supported by eight columns of red marble: the ceiling of the upper wall is of very curious workmanship of polished ash, consisting of compartments, the squares and pannels of which are enriched with gilded sculptures, and filled with pictures and other ornaments; this is likewise supported by eight pillars, with bases and chapiters of brass: the other rooms are handsomely adorned with very fine paintings.

In the square, near the town-house, is the fountain of Augustus, which is a marble bason, surrounded with iron ballustrades finely wrought: at the four corners are four brass statues, as big as the life, two of which are women and two men; in the middle of the bason is a pedestal, at the foot of which are four large sphinxes squirting water out of their breasts; a little above these are four infants holding four dolphins in their arms, which pour water out of their mouths: and over these infants are festoons and pine-apples all of brass; upon the pedestal, is the statue of Augustus as large as the life. The fountain most remarkable next to this is that of Hercules, which is a hexagon bason with several brass figures, particularly Hercules engaging the hydra. Another curiosity is the secret gate, which was contrived to let in persons safely in time of war: it has so many engines and divisions with gates and keys, and apartments for guards at some distance from each other, where passengers are examined, that it is impossible for the town to be surprised this way; the gates are bolted and unbolted, opened and shut, by unseen operators, insomuch that it looks like enchantment. The water-towers are also very curious, of which there are three seated on a branch of the river Lech, which runs through the city in such a torrent as to drive many mills, which work a number of pumps that raise the water in large leaden pipes to the tops of the towers; one of these sends water to the public fountains, and the rest to near 1000 houses in the city.

The Lutherans have a college here, which is a vast square building, with a fine clock on the top of the front. In this there are seven different classes, a hall for public disputations, and a theatre for dramatic representations. The cathedral is a large, gloomy, Gothic building, with two spire steeples; it is adorned with paintings upon whimsical subjects, and has a great gate all of brass, over which are several scripture passages well represented in basso-relievo. The Jesuits had a splendid college here, with a church full of gilding, painting, and carving; and a fine library. Though half the inhabitants are Lutherans, there are a great many Popish processions. There are no Jews in the town, nor are they suffered to lie there; but they inhabit a village at about a league distance, and pay so much an hour for the liberty of trading in the daytime. The Benedictine abbey is a vast Gothic building, the ceiling of which is said to be the highest in Germany, and overlooks all the rest of the churches; it is adorned with several statues, and has one very grand altar. The church of St Croix is one of the handsomest in Augsburg for architecture, painting, sculpture, gilding, and a fine spire.

The inhabitants look upon Augustus Cæsar as the founder of the town: it is true, that that emperor sent a colony there; but the town was already founded, though he gave it the name of *Augusta Vindelicorum*. Augsburg, indeed, is one of the oldest towns in Germany, and one of the most remarkable of them, as it is there and at Nuremberg that you meet with the oldest marks of German art and industry. In the 14th and 15th centuries, the commerce of this town was the most extensive of any part of south Germany, and contributed much to the civilization of the country, by the works of art and variety of necessaries to the comfort and convenience of life which it was the means of introducing. Many things originated in this town which have had a great influence on the happiness of mankind. Not to mention the many important diets of the empire held here; here, in 952, did a council confirm the order for the celibacy of priests; here, in 1530, was the confession of faith of the Protestants laid before the emperor and other estates of Germany; and here, in 1555, was signed the famous treaty of peace, by which religious liberty was secured to Germany.

Though the Protestants were very powerful at Augsburg, they could not keep their ground: for the Bavarians drove them from thence: but Gustavus Adolphus restored them again in 1632; since which time they have continued there, and share the government with the Catholics. In 1703, the elector of Bavaria took the city after a siege of seven days, and demolished the fortifications: however the battle of Hochstedt restored their liberty, which they enjoyed under the government of their own magistrates, till the French revolution. It was suffered to continue a free city in 1803, but was united to Bavaria in 1807. The chapter is composed of persons of quality, who are to bring proofs of their nobility, and the canons have a right of electing their own bishop.

The police of the place is very good: and though the town has no territory, it has no debts. Augsburg is, however, no longer what it was. It no longer has a Fugger and a Welser in it to lend the emperor millions. In this large and handsome town, formerly one of the greatest trading towns in Germany, there are no merchants at present to be found who have capitals of more than 20,000l. The others, most of whom must have their coaches, go creeping on with capitals of 3000l. or 4000l. and do the business of brokers and commissioners. Some houses, however, carry on a little banking trade; and the way through Tyrol and Graubundten occasions some little exchange between this place and Germany. After these brokers and doers of business by commission, the engravers, statuaries, and painters, are the most reputable of the labouring part of the city. Their productions, like the toys of Nuremberg, go everywhere. There are always some people of genius amongst them; but the small demand for their art affords them so little encouragement, that to prevent starving they are mostly confined to the small religious works which are done elsewhere by Capuchin monks. They furnish all Germany with little pictures for prayer books, and to hang in the citizens houses. There is an academy of arts instituted here under the protection of the magistrates: the principal aim of which is to produce good mechanics, and preserve the manufactures of the city. This

Digitized by Google

This town, which is nine miles and a half in circumference, contains, according to Mr Riesbeck, hardly 30,000 inhabitants: but Mr Nicolai makes them about 35,000.

This city has its drinking water from the river Lech, which runs at some distance from it; and the aqueducts which convey the water are much to be admired. It is a central depositary of the Neckar, Tyrolese, Italian, and Greek wines. Another important branch of traffic here is that of bookselling and publishing, especially in Catholic literature. The Catholics have six churches and eight monasteries here, and the Lutherans six churches; but the former considerably exceed the latter in point of numbers. This city was first constituted the capital of the circle of the Lech, but was joined in 1810 to that of the Iller, of which Kempten is now the chief town. The elector of Treves fixed his residence here after the secularization of his territories. A wooden bridge of ingenious structure was built over the Lech at Augsburg in 1808. In the war of 1756, the citizens were divided into equal parties for the two courts. The Catholics considered the emperor as their god, and the Protestants did the same by the king of Prussia. The flame of religion had almost kindled a bloody civil war amongst them.—The bishop takes his name from this town, but resides at Dillingen. He has an income of about 20,000l. per annum. As a proof of the catholicism of this place, the Pope throughout his whole progress met nowhere with such honours as he did here. This he owed to his friends the Jesuits, who had great influence in this place. E. Long. 10. 58. N. Lat. 48. 24.

Augsburg Confession, denotes a celebrated confession of faith drawn up by Luther and Melancthon, on behalf of themselves and other ancient reformers, and presented in 1530 to the emperor Charles V. at the diet of Augusta or Augsburg, in the name of the evangelic body. This confession contains 28 chapters; of which the greatest part is employed in representing, with perspicuity and truth, the religious opinions of the Protestants, and the rest in pointing out the errors and abuses that occasioned their separation from the church of Rome.

AUGUR, an officer among the Romans appointed to foretel future events, by the chattering, flight, and feeding of birds. There was a college or community of them, consisting originally of three members, with respect to the three tribes, the Luceres, Ramnenses, and Tatienses: afterwards the number was increased to nine, four of whom were patricians and five plebeians. They bore an augural staff or wand, as the ensign of their authority; and their dignity was so much respected, that they were never deposed, or any substituted in their place, though they should be convicted of the most enormous crimes. See Augury.

AUGURAL, something relating to the augurs.—The augural instruments are represented on several ancient medals.

Augural Supper, that given by a priest on his first admission into the order, called also by Varro *Adjicialis*.

Augural Books, those wherein the discipline and rules of augury were laid down.

AUGURALE, the place in a camp where the general took auspicia. This answered to the *Auguratorium* in the city.

Augurale is also used in Seneca for the ensign or badge of an augur, as the *lituus*.

AUGURATORIUM, a building on the Palatine mount, where public auguries were taken.

AUGURY, in its proper sense, the art of foretelling future events by observations taken from the chattering, singing, feeding, and flight, of birds; though it is used by some writers in a more general signification, as comprising all the different kinds of divination.

Augury was a very ancient superstition. We know from Hesiod, that husbandry was in part regulated by the coming or going of birds: and most probably it had been in use long before his time, as astronomy was then in its infancy. In process of time, these animals seem to have attained a greater and very wonderful authority, till at last no affair of consequence, either of private or public concern, was undertaken without consulting them. They were looked upon as the interpreters of the gods; and those who were qualified to understand their oracles were held among the chief men in the Greek and Roman states, and became the assessors of kings, and even of Jupiter himself. However absurd such an institution as a college of augurs may appear in our eyes, yet, like all other extravagant institutions, it had in part its origin from nature. When men considered the wonderful migration of birds, how they disappeared at once, and appeared again at stated times, and could give no guess where they went, it was almost natural to suppose that they retired somewhere out of the sphere of this earth, and perhaps approached the ethereal regions, where they might converse with the gods, and thence be enabled to predict events. It was almost natural for a superstitious people to imagine this; at least to believe it, as soon as some impostor was impudent enough to assert it. Add to this, that the disposition in some birds to imitate the human voice, must contribute much to the confirmation of such a doctrine. This institution of augury seems to have been much more ancient than that of aruspicy; for we find many instances of the former in Homer, but not a single one of the latter, though frequent mention is made of sacrifices in that author. From the whole of what has been observed, it seems probable that natural augury gave rise to religious augury, and this to aruspicy, as the mind of man makes a very easy transition from a little truth to a great deal of error.

A passage in Aristophanes gave the hint for these observations. In the comedy of the Birds, he makes one of them say this: "The greatest blessings which can happen to you mortals, are derived from us. First, we show you the seasons, viz. spring, winter, autumn. The crane points out the time for sowing, when she flies with her warning notes into Egypt; she bids the sailor hang up his rudder and take his rest, and every prudent man provide himself with winter garments. Next the kite appearing, proclaims another season, viz. when it is time to shear his sheep. After that the swallow informs you when it is time to put on summer clothes. We are to you, (adds the chorus), Ammon, Dodona, Apollo: for, after consulting us, you undertake every thing; merchandise, purchases,

marriages,

marriages," &c. Now, it seems not improbable, that the same transition was made in the speculations of men which appears in the poet's words; and that they were easily induced to think, that the surprising foresight of birds, as to the time of migration, indicated something of a divine nature in them; which opinion Virgil, as an Epicurean, thinks fit to enter his protest against, when he says,

Haud equidem credo, quia sit divinitas illis
Ingenium.

But to return to Aristophanes. The first part of the chorus, from whence the fore-cited passage is taken, seems, with all its wildness, to contain the fabulous cant, which the augurs made use of in order to account for their impudent impositions on mankind. It sets out with cosmogony; and says, That in the beginning were Chaos and Night, and Erebus and Tartarus: That there was neither water, nor air, nor sky: That Night laid an egg, from whence, after a time, Love arose: That Love, in conjunction with Erebus, produced a third kind; and that they were the first of the immortal race, &c.

AUGUST, (*augustus*), in a general sense, something majestic, venerable, or sacred. The appellation was first conferred by the Roman senate upon Octavius, after his being confirmed by them in the sovereign power. It was conceived as expressing something divine, or elevated above the pitch of mankind, being derived from the verb *augeo*, "I increase," *tanquam supra humanam sortem auctus*. See AUGUSTUS.

AUGUST, in *Chronology*, the eighth month of our year, containing 31 days. August was dedicated to the honour of Augustus Cæsar, because, in the same month, he was created consul, thrice triumphed in Rome, subdued Egypt to the Roman empire, and made an end of civil wars, being before called *Sextilis*, or the sixth month from March.

AUGUSTA, or AUSTA, an island in the Adriatic sea on the coast of Dalmatia, near Ragusa, subject to Venice. E. Long. 17. 50. N. Lat. 42. 35.

AUGUSTA, a town of Georgia in North America. See GEORGIA.

AUGUSTA *Ausciorum*, a town of Aquitania, so named out of compliment to Augustus, being originally called *Climberrum*, which name it afterwards resumed. In the middle age, it took the name of the people, *Ausci;* and is now called *Auch*, the capital of Gascony.

AUGUSTA *Emerita*, a town of Lusitania, on the river Anas, the capital of the province: a colony of the Emeriti, or such soldiers as had served out their legal time, were men of experience, or had received marks of favour. The colony was founded by Augustus: and is now called *Merida*, a city of Spain, in Estremadura, on the river Guadiana. See MERIDA.

AUGUSTA *Prætoria*, a town and colony of Gallia Cisalpina, and capital of the Salassi; seated at the foot of the Alpes Graiæ on the Duria. Now *Aouste* in Piedmont. See AOUSTE.

AUGUSTA *Rauracorum*, a town of Gallia Belgica; now a small village called *August*, at the bend of the Rhine northward; but from the ruins, which are still to be seen, it appears to have been a considerable colony, at the distance of six miles from Basil to the east.

AUGUSTA *Suessonum*, a town of Gallia Belgica on the Axona; so called from Augustus, and with great probability supposed to be the Noviodunum Suessonum of Cæsar. Now *Soissons*, on the river Aisne, in the Isle of France. See SOISSONS.

AUGUSTA *Taurinorum*, a town of the Taurini at the foot of the Alps, where the Duria Minor falls into the Po; now *Turin*, the capital of Piedmont.

AUGUSTA *Treba*, a town of the Æqui, near the spring of the river Anio in Italy; now *Trevi*, in Umbria, on the east of the Campagna di Roma.

AUGUSTA *Trevirorum*, a town of the Treviri, a people inhabiting between the Rhine and the Meuse, but especially about the Moselle; now *Triers*, or *Treves*, in the circle of the Lower Rhine, on the Moselle.

AUGUSTA *Vindelicorum*, a town of the Licates on the Licus; called by Tacitus a noble colony of *Rhætia;* now *Augsburg*, capital of Suabia.

AUGUSTA *Historia* is the history of the Roman emperors from the time of Adrian to Carinus, that is, from the year of our Lord 157 to 285, composed by six Latin writers, Æl. Spartianus, Julius Capitolinus, Æl. Lampridius, Vulcatius Gallicanus, Trebellius Pollio, and Flavius Vopiscus.

AUGUSTALES, in Roman antiquity, an epithet given to the flamens or priests appointed to sacrifice to Augustus after his deification; and also to the ludi or games celebrated in honour of the same prince on the fourth of the ides of October.

AUGUSTALIA, a festival instituted by the Romans in honour of Augustus Cæsar, on his return to Rome, after having settled peace in Sicily, Greece, Syria, Asia, and Parthia; on which occasion they likewise built an altar to him, inscribed *Fortunæ reduci*.

AUGUSTALIS PRÆFECTUS, a title peculiar to a Roman magistrate who governed Egypt, with a power much like that of a proconsul in other provinces.

AUGUSTAN CONFESSION. See *Augsburg Confession*.

AUGUSTIN, or AUSTIN, ST, the first archbishop of Canterbury, was originally a monk in the convent of St Andrew at Rome, and educated under St Gregory, afterwards Pope Gregory I. by whom he was despatched into Britain with 40 other monks of the same order, about the year 596, to convert the English Saxons to Christianity. They landed in the isle of Thanet; and having sent some French interpreters to King Ethelbert with an account of their errand, the king gave them leave to convert as many of his subjects as they could, and assigned their place of residence, at Durovernum, since called *Canterbury;* to which they were confined till the king himself was converted, whose example had a powerful influence in promoting the conversion of his subjects; but though he was extremely pleased at their becoming Christians, he never attempted to compel them. He despatched a priest and a monk to Rome, to acquaint the pope with the success of his mission, and to desire his resolution of certain questions. These men brought back with them a pall, and several books, vestments, utensils, and ornaments for the churches. His holiness, by the same messengers,

Digitized by Google

Augustin, Augustine. messengers, gave Augustin directions concerning the settling of episcopal sees in Britain; and ordered him not to pull down the idol-temples, but to convert them into Christian churches; only destroying the idols, and sprinkling the place with holy water, that the natives, by frequenting the temples they had been always accustomed to, might be the less shocked at their entrance into Christianity. Augustin resided principally at Canterbury, which thus became the metropolitan church of England; and having established bishops in several of the cities, he died on the 26th May, 607. The Popish writers ascribe several miracles to him. The observation of the festival of St Augustin was first enjoined in a synod held under Cuthbert archbishop of Canterbury, and afterwards by the pope's bull in the reign of King Edward III.

AUGUSTINE, St, an illustrious father of the church, was born at Thagaste, a city of Numidia, on the 13th of November 354. His father, a burgess of that city, was called *Patricius;* and his mother, *Monica*, who being a woman of great virtue, instructed him in the principles of the Christian religion. In his early youth he was in the rank of the catechumens; and falling dangerously ill, earnestly desired to be baptized; but the violence of the distemper ceasing, his baptism was delayed. His father, who was not yet baptized, made him study at Thagaste, Madaura, and afterwards at Carthage. Augustine having read Cicero's books of philosophy, began to entertain a love for wisdom, and applied himself to the study of the Holy Scriptures; nevertheless, he suffered himself to be seduced by the Manicheans. At the age of 19, he returned to Thagaste, and taught grammar, and also frequented the bar: he afterwards taught rhetoric at Carthage with applause. The insolence of the scholars at Carthage made him take a resolution to go to Rome, though against his mother's will. Here also he had many scholars; but disliking them, he quitted Rome, and settled at Milan, and was chosen public professor of rhetoric in that city. Here he had opportunities of hearing the sermons of St Ambrose, which, together with the study of St Paul's epistles, and the conversion of two of his friends, determined him to retract his errors, and quit the sect of the Manicheans; this was in the 32d year of his age. In the vacation of the year 386, he retired to the house of a friend of his, named *Verecundus*, where he seriously applied himself to the study of the Christian religion, in order to prepare himself for baptism, which he received at Easter in the year 387. Soon after this, his mother came to see him at Milan, and invite him back to Carthage; but at Ostia, whither he went to embark in order to his return, she died. He arrived in Africa about the end of the year 388; and having obtained a garden-plot without the walls of the city of Hippo, he associated himself with 11 other persons of eminent sanctity, who distinguished themselves by wearing leathern girdles, and lived there in a monastic way for the space of three years, exercising themselves in fasting, prayer, study, and meditation, day and night: from hence sprung up the Augustine friars, or eremites of St Augustine, being the first order of mendicants; those of St Jerome, the Carmelites, and others, being but branches of this of St Augustine. About this time, or before, Valerius bishop of Hippo, against his will, ordained him priest: nevertheless, he continued to reside in his little monastery, with his brethren, who, renouncing all property, possessed their goods in common. Valerius, who had appointed St Augustine to preach in his place, allowed him to do it in his presence, contrary to the custom of the churches in Africa. He explained the creed, in a general council of Africa, held in 393. Two years after, Valerius, fearing he might be preferred to be bishop of another church, appointed him his coadjutor or colleague, and caused him to be ordained bishop of Hippo, by Megalus bishop of Calame, then primate of Numidia. St Augustine died the 28th day of August, 430, aged 76 years, having had the misfortune to see his country invaded by the Vandals, and the city where he was bishop besieged for seven months.

Augustine, Augustins. The works of St Augustine make ten volumes: the best edition of them is that of Maurin, printed at Antwerp, in 1700. They are but little read at this time, except by the clergy of the Greek church and in the Spanish universities. The booksellers of London receive frequent commissions for them, and indeed for the most of the fathers, from Russia, and also from Spain.

AUGUSTINE, *St*, a fort of North America, on the east coast of Cape Florida, situated in W. Long. 81. 40. N. Lat. 30. 0. This fort was built by the Spaniards; who were scarce well established there when they were attacked by Sir Francis Drake in 1586, who reduced and pillaged the fort and town adjacent. In 1665, it underwent a similar fate, being attacked by Captain Davis at the head of a considerable company of bucaniers. In 1702 an attempt was made by Colonel More to annex St Augustine to the British dominions. He invested it with only 500 English and 700 Indians; but succours having arrived, he found it necessary to raise the siege, and retire with precipitation. In 1740, another unsuccessful attempt was made on this fort by General Oglethorpe: it was, however, together with the whole country of Florida, ceded to Great Britain by the treaty of Paris in 1763; but was restored to Spain by the treaty of peace 1783. In 1817 the white population of the town consisted of about 1000 persons, of whom 150 were able to carry arms. There were about 150 white regular troops, and 250 black or coloured regulars, and 500 slaves.

AUGUSTINE, a cape of South America. W. Long. 35. 4. S. Lat. 8. 30.

AUGUSTINS, or AUGUSTINIANS, an order of religious; thus called from St Augustine, whose rule they observe. The Augustins, popularly also called Austin friars, were originally hermits, whom Pope Alexander IV. first congregated into one body, under their general Lanfranc, in 1256. Soon after their institution, this order was brought into England, where they had about thirty-two houses at the time of their suppression.

The Augustins are clothed in black, and make one of the four orders of mendicants. From these arose a reform, under the denomination of *bare-foot Augustins*, or *Minorets*, or *Friars minor*.

There are also canons regular of St Augustine, who are clothed in white, excepting their cope, which is black. At Paris they were known under the denomination of *religious of* GENEVIEVE; that abbey was the chief of of the order. There are also nuns and canonesses, who observe the rules of St Augustine.

Augustinians are also those divines who maintain, on the authority of St Augustine, that grace is effectual from its nature, absolutely and morally, and not relatively and gradually. They are divided into rigid and relaxed.

AUGUSTOBONA, a city of the Tricassers in ancient Gaul, from whom it was afterwards called *Tricasses*, and *Trecassæ;* and still farther corrupted to *Thracæ*, or *Treci;* whence the modern name *Troyes*, in Champagne, on the Seine. See Troyes.

AUGUSTODUNUM, the capital of the Ædui, where there was a famous academy or school for the education of youth; now Austun, or *Autun*, in the duchy of Burgundy, on the Arroux. See Autun.

AUGUSTOMAGUS, an ancient town of Gallia Belgica; now *Senlis*, in the Isle of France. E. Long. 2. 30. N. Lat. 49. 10.

AUGUSTORITUM, in *Ancient Geography*, according to some authors, the capital of the Pictones, afterwards called *Pictavi;* now *Poictiers*. But by Antonine's Itinerary from Burdigala to Argantomagus (or Argenton, as it is interpreted by many), it can be no other but the capital of the Lemovices, now *Limoges*, situated between Vesunna of the Petrocorii, or Perigeux, and Argantomagus. E. Long. 1. 22. Lat. 45. 52.

AUGUSTOW, a small but strong town of Poland, in the department of Lomza, seated on the river Narieu. E. Long. 24. 2. N. Lat. 53. 25.

AUGUSTUS, Fort, a small fortress seated on a plain at the head of Loch Ness in Scotland, between the rivers Taarf and Oich; the last is a considerable stream, and has over it a stone bridge of three arches. The fort consists of four bastions: within is the governor's house, and barracks for 400 men; it was taken by the rebels in 1746, who immediately deserted it after demolishing what they could. The name of this fort in Erse is *Kill Chumin*, or *the burial place of the Cumins*. It lies on the road to the isle of Sky, which is about 52 miles off; but on the whole way there is not a place fit for the reception of man or horse.

Augustus, the appellation conferred upon Cæsar Octavianus, the first Roman emperor. See Octavianus, and Rome.

The obscure name *Octavianus*, Mr Gibbon observes, he derived from a mean family, in the little town of Aricia. It was stained with the blood of the proscription; and he was desirous, had it been possible, to erase all memory of his former life. The illustrious surname of *Cæsar* he had assumed, as the adopted son of the dictator; but he had too much good sense either to hope to be confounded, or to wish to be compared, with that extraordinary man. It was proposed in the senate, to dignify their minister with a new appellation; and after a very serious discussion, that of *Augustus* was chosen among several others, as being the most expressive of the character of peace and sanctity, which he uniformly affected. *Augustus* was therefore a personal, *Cæsar* a family, distinction. The former should naturally have expired with the prince on whom it was bestowed: and however the latter was diffused by adoption and female alliance, Nero was the last prince who could allege any hereditary claims to the honour of the Julian line. But at the time of his death, the practice of a century had inseparably connected those appellations with the imperial dignity, and they have been preserved by a long succession of emperors, Romans, Greeks, Franks, and Germans, from the fall of the republic to the present time. A distinction was, however, soon introduced. The sacred title of *Augustus* was always reserved for the monarch; the name of *Cæsar* was more freely communicated to his relations; and from the reign of Hadrian at least, was appropriated to the second person in the state, who was considered as the presumptive heir of the empire.

AVIARY, a place set apart for feeding and propagating birds. It should be so large as to give the birds some freedom of flight; and turfed, to avoid the appearance of foulness on the floor.

AVICENNA, or Avicenes, the prince of Arabian philosophers and physicians, was born at Assena, a village in the neighbourhood of Bokhara. His father was from Balkh in Persia, and had married at Bokhara. The first years of Avicenna were devoted to the study of the Koran and the belles lettres. He soon showed what he was likely to become afterwards; and the progress he made was so rapid, that when he was but ten years old, he was perfectly intelligent in the most hidden senses of the Koran.

Abou-Abdoullah, a native of Napoulous in Syria, at that time professed philosophy at Bokhara with the greatest reputation. Avicenna studied under him the principles of logic; but soon, disgusted with the slow manner of the schools, he set about studying alone, and read all the authors that had written on philosophy, without any other help than that of their commentators. Mathematics had no fewer charms for him; and after reading the first six propositions of Euclid, he got alone to the last, having made himself perfect master of them, and treasured up all of them equally in his memory.

Possessed with an extreme avidity to be acquainted with all sorts of sciences, he likewise devoted himself to the study of medicine. Persuaded that this divine art consists as much in practice as in theory, he sought all opportunities of seeing the sick; and afterwards confessed, that he had learned more from experience than from all the old books he had read. He was now in his 16th year, and already was celebrated for being the light of his age. He resolved at this age to resume his studies of philosophy, which medicine had made him neglect: and he spent a year and a half in this painful labour, without ever sleeping all this time a whole night together. If he felt himself oppressed by sleep, or exhausted by study, a glass of wine refreshed his wasted spirits, and gave him new vigour for study; if in spite of him his eyes for a few minutes shut out the light, it then happened to him to recollect and meditate upon all the things that had occupied his thoughts before sleep. At the age of 21, he conceived the bold design of incorporating, in one work, all the objects of human knowledge; and carried it into execution in an Encyclopedie of 20 volumes, to which he gave the title of the *Utility of Utilities*.

Several great princes had been taken dangerously ill, and Avicenna was the only one that could know their ailments

Digitized by Google

Avicenna. ailments and cure them. His reputation increased daily, and all the kings of Asia desired to retain him in their families.

Mahmud, the son of Sabektekin, the first sultan of the dynasty of the Samanides, was then the most powerful prince of the east. Imagining that an implicit obedience should be paid by all manner of persons to the injunctions of his will, he wrote a haughty letter to Mamun sultan of Kharazm, ordering him to send Avicenna to him, who was at his court, with several other learned man. Philosophy, the friend of liberty and independence, looks down with scorn on the shackles of compulsion and restraint. Avicenna, accustomed to the most flattering distinction among the great, could not endure the imperious manner of Mahmud's inviting him to his court, and refused to go there. But the sultan of Karazm, who dreaded his resentment, obliged the philosopher to depart with others whom that prince had demanded to be sent to him.

Avicenna pretended to obey; but instead of repairing to Gazna, he took the route of Giorgian. Mahmud, who had gloried in the thoughts of keeping him at his palace, was greatly irritated at his flight. He despatched portraits done in crayons of this philosopher to all the princes of Asia, with orders to have him conducted to Gazna, if he appeared in their courts. But Avicenna had fortunately escaped the most diligent rearch after him. He arrived in the capital of Giorgian, where under a disguised name he performed many admirable cures.

Cabous then reigned in that country. A nephew, whom he was extremely fond of, being fallen sick, the most able physicians were called in, and none of them were able to know his ailment, or give him any ease. Avicenna was at last consulted. So soon as he had felt the young prince's pulse, he was confident with himself, that his illness proceeded from a violent love, which he dared not to declare. Avicenna commanded the person who had the care of the different apartments in the palace, to name them all in their respective order. A more lively motion in the prince's pulse, at hearing mentioned one of these apartments, betrayed a part of his secret. The keeper then had orders to name all the slaves that inhabited that apartment. At the name of one of those beauties, the young Cabous could not contain himself; an extraordinary beating of his pulse completed the discovery of what he in vain desired to keep concealed. Avicenna, now fully assured that this slave was the cause of the prince's illness, declared, that she alone had the power to cure him.

The sultan's consent was necessary, and he of course was curious to see his nephew's physician. He had scarce looked at him, when he knew in his features those of the crayoned portrait sent him by Mahmud; but Cabous, far from forcing Avicenna to repair to Gazna, retained him for some time with him, and heaped honours and presents on him.

This philosopher passed afterwards into the court of Nedjmeddevle, sultan of the race of the Bouides. Being appointed first physician to that prince, he found means to gain his confidence to so great a degree, that he raised him to the post of grand visir. But he did not long enjoy that illustrious dignity. Too great an attachment to pleasures, especially those of love and the table, made him lose at the same time his post and his master's favour. From that time Avicenna felt all the rigours of adversity, which he had brought upon himself by his ill conduct. He wandered about as a fugitive, and was often obliged to shift the place of his habitation to secure his life from danger. He died at Hamadan, aged 58 years, in the 428th year of the Hegira, and of Christ 1036. Avicenna.

The perfect knowledge he had of physic did not secure him from the ailments that afflict human nature. He was attacked by several maladies in the course of his life, and particularly was very subject to the colic. His excesses in pleasures, and his infirmities, made a poet say who wrote his epitaph, that the profound study of philosophy had not taught him good morals, nor that of medicine the art of preserving his own health.

No one composed with greater facility than Avicenna, writing, when he sat down to it, 50 pages generally in a day, without fatiguing himself. The doctors of Schiras, having made a collection of objections against one of his metaphysical works, sent it to him at Ispahan by Casem. This learned man, not arriving till towards evening, came to Avicenna's house, with whom he sat discoursing till midnight. When Casem had retired, he wrote an answer to the objections of the Schirazians, and finished it before sunrise. He immediately delivered it to Casem, telling him, that he had made all possible despatch in order not to detain him any longer at Ispahan.

Avicenna, after his death, enjoyed so great a reputation, that till the 12th century he was preferred for the study of philosophy and medicine to all his predecessors. His works were the only writings in vogue in schools, even in Europe. The following are the titles. 1. Of the Utility and Advantage of Science, twenty books. 2. Of Innocence and Criminality, two books. 3. Of Health and Remedies, eighteen books. 4. Canons of Physic, fourteen books. 5. On Astronomical Observations, one book. 6. On Mathematical Sciences. 7. Of Theorems, or Mathematical and Theological Demonstrations, one book. 8. On the Arabic Language, and its Properties, ten books. 9. On the Last Judgment. 10. On the Origin of the Soul, and the Resurrection of Bodies. 11. Of the end we should propose to ourselves in Harangues and Philosophical Argumentations. 12. Demonstration of the collateral Lines in the Sphere. 13. Abridgement of Euclid. 14. On Finity and Infinity. 15. On Physics and Metaphysics. 16. On Animals and Vegetables, &c. 17. Encyclopedie, 20 volumes.—Some, however, charge him with having stolen what he published from a celebrated physician who had been his master. This man had acquired so much honour and wealth, that he was solicited by many to take their sons to be his scholars, or even his servants; but being resolved not to discover the secrets of his art, he would receive none of them. Avicenna's mother formed the following stratagem: she offered him her son as a servant, pretending he was naturally deaf and dumb: and the youth, by his mother's instructions, counterfeited those defects so well, that the physician, after making several trials to discover the reality of them, took the boy into his service, and by degrees trusted him

Digitized by Google

him so far as to leave his writings open in his room when he went abroad: Avicenna took that opportunity to transcribe them, and carried the copies to his mother; and after the death of his master he published them under his own name. Indeed, if we reflect that he lived but 58 years, that he was a wanderer and a fugitive, and that he was much addicted to his pleasures, we shall have some difficulty to conceive how he could find time to compose so many works. Physic, however, is indebted to him for the discovery of cassia, rhubarb, mirabolans, tamarinds: and from him also, it is said, came to us the art of making sugar.

AVICENIA, Eastern Anacardium. See Botany *Index*.

AVIGATO pear. See Laurus, Botany *Index*.

AVIGLIANO, a small town of Piedmont in Italy. E. Long. 7. 5. N. Lat. 44. 40.

AVIGNON, a city of France, in the department of Vaucluse, the capital of the county of Venaissin, and seated on the banks of the Rhone. It was formerly an archbishop's see; and the residence of several popes at this place for 70 years has rendered it considerable. Near the Rhone there is a large rock, within the circumference of the walls, upon which is a platform, from whence may be had a prospect of the whole city and the places about it. This city is about three miles and two furlongs in circumference, and is in general ill built, irregular, and devoid of beauty. But it is surrounded by handsome battlemented walls and turrets, not unlike those of Rome; and its public edifices are large, solid, and grand as the taste of the fourteenth century could make them. Several popes and anti-popes, who, during their lives, shook the Romish church with violence and mutual altercation, repose quietly near each other in the various monasteries of the place. The church of the Cordeliers contains, in an obscure corner, the almost defaced tomb of Petrarch's Laura and her husband Hugh de Sade; and nearly opposite is the tomb of the brave Gullon, so well known for his invincible courage as well as for his inviolable attachment to his sovereign Henry IV. Many productions of Rene of Anjou are to be seen in the city. It contained 23,211 inhabitants in 1815, but the number was greater before the revolution. Avignon was at first included in the department of the Mouths of the Rhone, but is now the capital of the department of Vaucluse. It was annexed to France by a decree of the national assembly in 1791, but was not formally ceded by the pope till 1797.

The church of Notre Dame is ancient, but not large, and is one of the best adorned in the city. After having ascended about 50 steps, you come to a very ancient portico, which sustains a great tower; as you enter the church on the left hand, you see paintings which equal the finest in Italy. The great altar is very magnificent, and is adorned with a shrine that contains the relicks of we know not how many saints. The treasure of the sacristy is worthy of the curiosity of the traveller. The little palace where the archbishop resided is formed of three bodies of lodgings, accompanied with courts and small pavilions. It overlooks the Rhone, the city, and the fields. These buildings and the mint adorn a large square, which is the common walk of the inhabitants.

In Avignon they reckon seven gates, seven palaces, seven colleges, seven hospitals, seven monasteries, seven nunneries, and seven popes who have lived there in 70 years. The steeples are numerous, and the bells are never at rest; one of silver is rung only on the death of a pope. The church of the Celestines is very magnificent, and full of fine monuments; and the rest are not without their curiosities. The university has four colleges; and the place where the Jews live is a distinct quarter, from whence the Jews, who pay tribute, dare not stir out without yellow hats, and the women must have something yellow about their heads, to distinguish them from the Christians. Their number is very considerable in a very confined place, where the only way of enlarging their abodes is by building their houses higher. Their synagogne is so dark, that they are obliged to light lamps. However, they are forced to hear a monk preach a sermon every week. Across the Rhone, here, extend the ruinous and decayed arches of that bridge against which Madame de Grignan was so near being lost, and of which Madame de Sevigné makes terrified mention. It was demolished in 1699 by one of the inundations common to the Rhone. When entire, it was not less than a quarter of a mile in length; but being so narrow, as not to permit two carriages to pass in any part, it had previously become almost useless; and motives of policy prevent the construction of a new bridge, while Avignon belongs to the papal see. The curious that travel this way go to see the fountain of Vaucluse, where the river Sorgues, which passes through this city, has its source; and whither Petrarch so often retired to indulge his grief and hopeless love. It is situated in a valley five miles distant from the city. The sides of the river are skirted by meadows of the most lively green; above which rise abrupt and lofty rocks, that seem designed to seclude it from human view. The valley becomes gradually narrower towards the extremity, and winding continually describes the figure of a horse-shoe. The view is at length terminated by an enormous mass of rock, forming a barrier across it, of a prodigious height, and absolutely perpendicular. Through its vast recesses run the streams which supply the fountain of Vaucluse, and at its foot appears a bason of water, several hundred feet in circumference, stretched like an expanse, silent and quiet. The sides are very steep, and it is said that in the middle no bottom can be discovered, though attempts have been often made for that purpose; a circumstance probably resulting from the violence with which the springs bubble up, which prevents any weight from descending beyond a certain depth. Though the fountain is clearer in itself than crystal, yet the incumbent rock casts a continual shade, approaching to black, over its surface. The water escaping from this state of inaction by a narrow passage, is immediately precipitated in a cascade down a rocky channel, where it foams over a number of vast detached stones, which intercept and impede its progress. They are covered with a deep green moss of many ages, and have probably tumbled from the mountain that overhangs the torrent. The rocks themselves, which surround and invest this romantic

Digitized by Google

mantic spot, are worn by time and the inclemency of the weather into a thousand extraordinary and fantastic forms, to which imagination gives shape and figure. On one of the pointed extremities, and in a situation which appears almost inaccessible, are seen the remains of an ancient castle, projecting over the water. The peasants call it *Il Castello di Petrarca;* and add, with great simplicity, that Laura lived upon the opposite side of the river, under the bed of which was a subterranean passage by which the two lovers visited each other. Nothing is, however, more certain, than that these are the ruins of the chateau belonging to the lords or seigneurs of Avignon; and the bishop of Cavaillon resided in it during the frequent visits which he used to make to Petrarch.—The poet's dwelling was much lower down, and nearer to the bank of the Sorgues, as evidently appears from his minute description of it, and the relation he gives of his quarrel with the Naiads of the stream, who encroached during the winter on his little adjoining territory. No remains of it are now to be discerned. Below the bridge there is an island where the Sorgues joins the Rhone, in which are several pleasure-houses. E. Long. 4. 59. N. Lat. 43. 57.

Avignon Berry, the fruit of a species of lycium; growing plentifully near Avignon and in other parts of France. The berry is somewhat less than a pea; its colour is green, approaching towards a yellow; and it is of an astringent and bitter taste.—It is much used by the dyers, who stain a yellow colour with it: and by the painters, who also make a fine golden yellow of it.

AVILA, a city of Old Castile, in Spain, seated on an eminence on the banks of the river Adaja, and in sight of the mountains of Pico. It is fortified both by nature and art, having a wall 9075 feet in circumference, adorned with 26 lofty towers, and 10 handsome gates. There are 17 principal streets, containing many good houses, but the town is now in a state of decay. It hath nine squares, 2000 houses, nine parishes, as many monasteries, seven nunneries, two colleges, nine hospitals, 18 chapels, and an allowance of 10,000 ducats yearly for the maintenance of orphans and other poor people. It has an university, and a considerable bishopric; besides a noble cathedral, which has eight dignitaries, 20 canons, and the same number of minor canons. It stands in the middle of a fine large plain surrounded with mountains, and covered with fruit-trees and vineyards. Its woollen manufactures have sunk. W. Long. 4. 13. N. Lat. 40. 35.

AVIS, a small town of Alentejo in Portugal, seated on an eminence, with a castle near the river Avis. Hence the military order of the knights of Avis have their name. W. Long. 7. 0. N. Lat. 38. 40.

Avis (*Knights d'Avis*), an order of knighthood in Portugal established about the year 1162. When the city of Evora was taken from the Moors, in the reign of the first king of Portugal, it was garrisoned by several persons who assumed the title of knights of St Mary of Evora, which was soon after changed for that of knights d'Avis, which the king gave them, and whither they removed from Evora. The badge of the order is a green cross flory, and they observe the rule of St Benedict.

AVISO, a term chiefly used in matters of commerce to denote an advertisement, an advice, or piece of intelligence.

AVISON, Charles, organist of Newcastle, and a disciple of Geminiani, was the author of an essay on musical expression, published in the year 1752, in which are some judicious reflections on music in general, but his division of the modern authors into classes is rather fanciful than just. Throughout his book he celebrates Marcello and Geminiani; the latter frequently in prejudice to Mr Handel. In the year 1753 came out remarks on Mr Avison's essay on musical expression, the author whereof first points out sundry errors against the rules of composition in the works of Avison. In the same year Avison republished his essay, with a reply to the author of the remarks; and a letter, containing a number of loose particulars relating to music, collected in a course of various reading, unquestionably written by Dr Jortin. Avison promoted and assisted in the publication of Marcello's music to the psalms adapted to English words. Of his own composition there are extant five collections of concertos for violins, 44 in number; and two sets of sonatas for the harpsichord and two violins, a species of composition little known in England till his time. The music of Avison is light and elegant, but it wants originality; a necessary consequence of his too close attachment to the style of Geminiani, which in a few particulars only he was able to imitate.

AUK, in *Ornithology*. See Alca, Ornithology *Index*.

AUKLAND, Bishop's, a town in the bishopric of Durham in England, situated on the river Were. It is a sanctuary for debtors; and here the bishop has a princely palace and a noble park. W. Long. 0. 75. N. Lat. 54. 44.

AULA, is used for a court baron by Spelman; by some old ecclesiastical writers, for the nave of a church, and sometimes for a court-yard.

Aula Regia or *Regis*, a court established by William the Conqueror in his own hall, composed of the king's great officers of state, who resided in his palace, and were usually attendant on his person. This court was regulated by the article which forms the eleventh chapter of Magna Charta, and established in Westminster-hall, where it hath ever since continued. See *King's Bench*.

AULCESTER, a town of Warwickshire in England. W. Long. 1. 47. N. Lat. 52. 15.

AULETES, in antiquity, denotes a flute-player. One of the Ptolemies, kings of Egypt, father of Cleopatra, bore the surname or denomination of *Auletes*.

AULIC, an epithet given to certain officers of the empire, who compose a court which decides, without appeal, in all processes entered in it. Thus we say, *aulic council, aulic chamber, aulic counsellor*.

The aulic council is composed of a president, who is a catholic; of a vice chancellor, presented by the archbishop of Mentz; and of 18 counsellors, nine of whom are Protestants and nine Catholics. They are divided into a bench of lawyers, and always follow the emperor's court; for which reason they are called *justitium imperatoris*, the emperor's justice, and aulic council. The aulic court ceases at the death of the emperor; whereas the imperial chamber of Spire is perpetual, representing not only the deceased emperor,

 but

Digitized by Google

but the whole Germanic body, which is reputed never to die.

Aulic, in the Sorbonne and foreign universities, is an act which a young divine maintains upon being admitted a doctor of divinity. It begins by a harangue of the chancellor, addressed to the young doctor, after which he receives the cap, and presides at the aulic or disputation.

AULIS, in *Ancient Geography*, a town of Bœotia, over against Chalcis of Eubœa, on the Euripus, where that strait is narrowest; and which was sometimes joined with Chalcis together by a mole or causeway, (Diodorus Siculus): a craggy situation, (Homer, Nonnius); and a village of the Tanagræi, (Strabo), distant from Chalcis three miles: A harbour famous for the rendezvous of the Grecian fleet under Agamemnon, previous to the Trojan expedition, (Livy, Virgil, Pliny). Now entirely destroyed.

AULNEGER. See Alnager.

AULON, anciently a town and dock or station for ships in Illyricum, on the Adriatic; now *Valona*, or *Volana*, a port-town in the duchy of Ferrara, on one of the mouths of the Po, on the gulf of Venice. E. Long. 13. N. Lat. 44. 50.

Aulon, or *Aulona*, anciently a town of Elis, in Peloponnesus, on the confines of Messenia. Here stood a temple of Æsculapius; hence the epithet *Aulonius* given that divinity, (Pausanias).

AULOS, a Grecian long measure, the same with stadium.

AULPS, a town of Provence in France, in the diocese of Frejus, with the title of a vigurie. E. Long. 6. 25. N. Lat. 43. 40.

AULUS Gellius. See Gellius.

AUMBRY, a country word denoting a cupboard.

AUME, a Dutch measure for Rhenish wine, containing 40 English gallons.

AUNCEL-weight, an ancient kind of balance, now out of use, being prohibited by several statutes, on account of the many deceits practised by it. It consisted of scales hanging on hooks, fastened at each end of a beam, which a man lifted up on his hand. In many parts of England, auncel-weight signifies meat sold by the hand, without scales.

AUNE, a long measure used in France to measure cloths, stuffs, ribbons, &c. At Rouen, it is equal to one English ell; at Calais, to 1.52; at Lyons, to 1.061; and at Paris, to 0.95.

AUNGERVYLE, Richard, commonly known by the name of *Richard de Bury*, was born in 1281 at St Edmund's Bury in Suffolk, and educated at the university of Oxford: After which he entered into the order of Benedictine monks, and became tutor to Edward prince of Wales, afterwards King Edward III. Upon the accession of his royal pupil to the throne, he was first appointed cofferer, then treasurer of the wardrobe, archdeacon of Northampton, prebendary of Lincoln, Sarum, and Litchfield, keeper of the privy seal, dean of Wells, and last of all was promoted to the bishopric of Durham. He likewise enjoyed the offices of lord high chancellor and treasurer of England; and discharged two important embassies at the court of France. Learned himself, and a patron of the learned, he maintained a correspondence with some of the greatest geniuses of the age, particularly with the celebrated Italian poet Petrarch. He was also of a most humane and benevolent temper, and performed many signal acts of charity. Every week he made eight quarters of wheat into bread, and gave it to the poor. Whenever he travelled between Durham and Newcastle, he distributed eight pounds sterling in alms: between Durham and Stockton five pounds, between Durham and Aukland five marks, and between Durham and Middleham five pounds. He founded a public library at Oxford for the use of the students, which he furnished with the best collection of books then in England; and appointed five keepers, to whom he granted yearly salaries. At the dissolution of religious houses in the reign of Henry VIII. Durham college, where he fixed the library, being dissolved among the rest, some of the books were removed to the public library, some to Baliol college, and some came into the hands of Dr George Owen, a physician of Godstow, who bought that college of King Edward VI. Bishop Aungervyle died at his manor of Aukland, April 24. 1345, and was buried in the south part of the cross aisle of the cathedral church of Durham, to which he had been a benefactor. He wrote, 1. *Philobiblos*, containing directions for the management of his library at Oxford, and a great deal in praise of learning, in bad Latin. 2. *Epistolæ familiarium*; some of which are written to the famous Petrarch. 3. *Orationes ad principes*; mentioned by Bale and Pitts.

AUNIS, formerly a small province in France, but now included in the department of the Lower Charente, and belonging to the arrondisements of Rochefort, La Rochelle, and Varennes. It is watered by the rivers Seure and Sarente, the former of which has its source at Seure in Poictou. The coast of this small district has the advantage of several ports, the most remarkable of which are Rochefort, Rochelle, Brouge, St Martin de Re, Tremblade, Tonnai, and Charente. The soil of this country is dry, yet produces good corn and plenty of wine. The marshes feed a great number of cattle, and the salt marshes yield the best salt in Europe.

AVOCADO, or Avigato, *Pear*. See Laurus, Botany *Index*.

AVOCATORIA, a mandate of the emperor of Germany, addressed to some prince, in order to stop his unlawful proceedings in any cause appealed to him.

AVOIDANCE, in the canon law, is when a benefice becomes void of an incumbent; which happens either in fact, as by the death of the person; or in law, as by cession, deprivation, resignation, &c. In the first of these cases, the patron must take notice of the avoidance at his peril; but in avoidance by law, the ordinary is obliged to give notice to the patron, in order to prevent a lapse.

AVOIRDUPOIS. This is the weight for the larger and coarser commodities, such as groceries, cheese, wool, lead, &c. Bakers, who live not in corporation towns, are to make their bread by avoirdupois weight, those in corporations by troy weight. Apothecaries buy by avoirdupois weight, but sell by troy. The proportion of a pound avoirdupois to a pound troy is as 17 to 14.

AVOSETTA. See Recurvirostra, Ornithology *Index*.

AVOWEE, one who has a right to present to a benefice. He is thus called in contradistinction to those

Digitized by Google

those who only have the lands to which the advowson belongs for a term of years, or by virtue of intrusion or disseisin.

AVOWRY, in *Law*, is where a person distrained sues out a replevin; for then the distrainer must vow, and justify his plea, which is called his *avowry*.

AURA, among *Physiologists*, an airy exhalation or vapour. The word is Latin, derived from the Greek, *αυρα*, *gentle wind*.

AURACH, a town of Germany with a good castle, in the kingdom of Wirtemberg. It is the usual residence of the youngest sons of the house of Wirtemberg, and is seated at the foot of a mountain on the rivulet Ermst, nine miles east of Warzach. E. Long. 9. 20. N. Lat. 48. 25.

AURÆ, in *Mythology*, a name given by the Romans to the nymphs of the air. They are mostly to be found in the ancient paintings of ceilings; where they are represented as light and airy, generally with long robes and flying veils of some lively colour or other, and fluttering about in the rare and pleasing element assigned to them. They are characterized as sportive and happy in themselves, and wellwishers to mankind.

AURANCHES, the capital of a territory called *Auranchin*, about 30 miles in length, in Lower Normandy in France, now the department of the Channel. The city is mean; but its situation very fine, being on an eminence near which the river See runs, about a mile and a half from the ocean. The cathedral stands on a hill, which terminates abruptly; the front of the church extending to the extreme verge of it, and overhanging the precipice. It bears the marks of high antiquity; but the towers are decayed in many places. The population of the town in 1815 was 6000. Here, you are told, the English Henry II. received absolution from the Papal nuncio for the murder of St Thomas-a-Becket in 1172, and the stone on which he knelt during the performance of that ceremony is shewn to strangers. Its length is about 30 inches, and the breadth 12. It stands before the north portal, and on it is engraved a chalice in commemoration of the event. The ruins of the castle of Auranches are very extensive; and beneath lies a rich extent of country, abounding in grain, and covered with orchards, from the fruit of which is made the best cyder in Normandy. W. Long. 1. 20. N. Lat. 48. 51.

AURANTIUM, in *Botany*. See CITRUS, BOTANY *Index*.

AURAY, a small seaport town of Lower Britanny in France, situated on the gulf called *Morbihan*, and in the department of the same name. It consists of only one handsome street, and is chiefly known for its trade. W. Long. 2. 25. N. Lat. 47. 48.

AURELIA, in *Natural History*, the same with what is more usually called *chrysalis*, and sometimes *nymph*. See CHRYSALIS, ENTOMOLOGY *Index*.

AURELIANUS, LUCIUS DOMITIUS, emperor of Rome, was one of the greatest generals of antiquity, and commanded the armies of the emperor Claudius with such glory, that after the death of that emperor all the legions agreed to place him on the throne: this happened in the year 270. He carried the war from the east to the west, with as much facility, says a modern writer, as a body of troops marches from Alsace into Flanders. He defeated the Goths, Sarmatians, Marcomanni, the Persians, Egyptians and Vandals; conquered Zenobia queen of the Palmyrenians, and Tetricus general of the Gauls; both of whom were made to grace his triumph, in the year 274. He was killed by one of his generals in Thrace in the year 275, when he was preparing to enter Persia with a great army. See ROME.

AURELIUS VICTOR. See VICTOR.

AURENGABAD, a city in the East Indies, capital of a province of the same name, on the western side of the peninsula. It is furnished with handsome mosques and caravanseras. The buildings are chiefly of freestone, and pretty high, and the streets planted on each side with trees. They have large gardens well stocked with fruit trees and vines. The soil about it is also very fertile, and the sheep fed in its neighbourhood are remarkably large and strong. E. Long. 75. 30. N. Lat. 19. 10.

AURENG-ZEBE, a celebrated Mogul emperor. See HINDOSTAN.

AUREOLA, in its original signification, signifies a jewel, which is proposed as a reward of victory in some public dispute. Hence the Roman schoolmen applied it to denote the reward bestowed on martyrs, virgins, and doctors, on account of their works of supererogation; and painters use it to signify the crown of glory with which they adorn the heads of saints, confessors, &c.

AUREUS, a Roman gold coin, equal in value to 25 denarii. According to Ainsworth, the aureas of the higher empire weighed near five pennyweights; and in the lower empire, little more than half that weight. We learn from Suetonius, that it was customary to give aurei to the victors in the chariot races.

AUREUS MONS, in *Ancient Geography*, a mountain in the north-west of Corsica, whose ridge runs out to the north-east and south-east, forming an elbow.—Another mountain of Mœsia Superior, or Servia (Peutinger), to the south of the Danube, with a cognominal town at its foot on the same river. The emperor Probus planted this mountain with vines (Eutropius).

AURICK, a city of Germany, in East Friesland, in the kingdom of Hanover, containing 2200 inhabitants. It is situated in a plain surrounded with forests full of game. E. Long. 6. 50. N. Lat. 53. 28.

AURICLE, in *Anatomy*, that part of the ear which is prominent from the head, called by many authors *auris externa*.

AURICLES are likewise two muscular bags situated at the basis of the heart, and intended as diverticula for the blood during the diastole.

AURICULA, in *Botany*. See PRIMULA, BOTANY *Index*.

AURIFLAMMA, in the French history, properly denotes a flag or standard belonging to the abbey of St Dennis, suspended over the tomb of that saint, which the religious on occasion of any war in defence of their lands or rights, took down with great ceremony, and gave it to their protector or advocate, to be borne at the head of their forces.

AURIFLAMMA is also sometimes used to denote the chief flag or standard in any army.

AURICA,

Digitized by Google

AURIGA, *the Waggoner*, in *Astronomy*, a constellation of the northern hemisphere, consisting of 23 stars, according to Tycho; 40, according to Hevelius; and 68, in the Britannic catalogue.

AURILLAC, a town in France, in Lower Auvergne, now the department of Cantal, seated on a small river called *Jourdane*. It is one of the most considerable towns of the province, and contained 10,332 inhabitants in 1815. The castle is very high, and commands the town. The abbot was lord of Aurillac, and had episcopal jurisdiction; and was also chief justice of the town. This place is remarkable for having produced several great men. E. Long. 2. 33. N. Lat. 44. 55.

AURIPIGMENTUM, Orpiment, in *Natural History*. See Orpiment.

AURISCALPIUM, an instrument to clean the ears, and serving also for other operations in disorders of that part.

AURORA, the morning twilight, or that faint light which appears in the morning when the sun is within 18 degrees of the horizon.

Aurora, the goddess of the morning, according to the Pagan mythology. She was the daughter of Hyperion and Theia, according to Hesiod; but of Titan and Terra, according to others. It was under this name that the ancients deified the light which foreruns the rising of the sun above our hemisphere. The poets represent her as rising out of the ocean, in a chariot, with rosy fingers dropping gentle dew. Virgil describes her ascending in a flame-coloured chariot with four horses.

Aurora, one of the New Hebrides islands in the South sea, in which Mr Forster supposes the *Peak d'Etoile* mentioned by Mr Bougainville to be situated. The island is inhabited; but none of its inhabitants came off to visit Captain Cook. The country is woody, and the vegetation seemed to be excessively luxuriant. It is about 12 leagues long, but not above five miles broad in any part; lying nearly north and south. The middle lies in S. Lat. 15. 6. E. Long. 168. 24.

Aurora Borealis, *Northern Twilight*, or *Streamers*; a kind of meteor appearing in the northern part of the heavens, mostly in the winter time, and in frosty weather. It is now so generally known, that no description is requisite of the appearance which it usually makes in this country. But it is in the arctic regions that it appears in perfection, particularly during the solstice. In the Shetland islands, the *merry dancers*, as they are there called, are the constant attendants of clear evenings, and prove great reliefs amidst the gloom of the long winter nights. They commonly appear at twilight near the horizon, of a dun colour, approaching to yellow; sometimes continuing in that state for several hours without any sensible motion; after which they break out into streams of stronger light, spreading into columns, and altering slowly into ten thousand different shapes, varying their colours from all the tints of yellow to the obscurest russet. They often cover the whole hemisphere, and then make the most brilliant appearance. Their motions at these times are most amazingly quick; and they astonish the spectator with the rapid change of their form. They break out in places where none were seen before, skimming briskly along the heavens; are suddenly extinguished, and leave behind an uniform dusky track. This again is brilliantly illuminated in the same manner, and as suddenly left a dull blank. In certain nights they assume the appearance of vast columns, on one side of the deepest yellow, on the other declining away till it becomes undistinguished from the sky. They have generally a strong tremulous motion from end to end, which continues till the whole vanishes. In a word, we, who only see the extremities of these northern phenomena, have but a faint idea of their splendour and their motions. According to the state of the atmosphere, they differ in colour. They often put on the colour of blood, and make a most dreadful appearance. The rustic sages become prophetic, and terrify the gazing spectators with the dread of war, pestilence, and famine. This superstition was not peculiar to the northern islands; nor are these appearances of recent date. The ancients called them *Chasmata*, and *Trabes*, and *Bolides*, according to their forms or colours.

1
This meteor formerly very rare.

In old times they were extremely rare, and on that account were the more taken notice of. From the days of Plutarch to those of our sage historian Sir Richard Baker, they were supposed to have been portentous of great events, and timid imagination shaped them into aerial conflicts:

> Fierce fiery warriors fight upon the clouds
> In ranks and squadrons and right form of war.

Dr Halley tells us, that when he saw a great aurora borealis in 1716, he had begun to despair of ever seeing one at all: none having appeared, at least in any considerable degree, from the time he was born till then. Notwithstanding this long interval, however, it seems that in some periods the aurora borealis had been seen much more frequently; and perhaps this, as well as other natural phenomena, may have some stated times of returning.

2
History by Dr Halley.

The only thing that resembles a distinct history of this phenomenon, is what we have from the learned Dr Halley, Phil. Trans. N° 347. The first account he gives, is of the appearance of what is called by the author *burning spears*, and was seen at London on January 30th 1560. This account is taken from a book entitled, *A Description of Meteors*, by *W. F.* D. D. and reprinted at London in 1654. The next appearance, on the testimony of Stow, was on October 7th, 1564. In 1574 also, according to Camden, and Stow abovementioned, an aurora borealis was observed two nights successively, viz. on the 14th and 15th of November, with much the same appearances as described by Dr Halley in 1716, and which we now so frequently observe. Again, the same was twice seen in Brabant, in the year 1575; viz. on the 13th of February and 28th of September. Its appearances at both these times were described by Cornelius Gemm, professor of medicine in the university of Louvain, who compares them to spears, fortified cities, and armies fighting in the air. After this, Michael Mæstlin, tutor to the great Kepler, assures us, that at Baknang in the county of Wurtemberg in Germany, these phenomena, which he styles *chasmata*, were seen by himself no less than seven times in 1580. In 1581, they again appeared in an extraordinary manner in April and September, and in a less degree at some other times of the same year. In 1621, September 2d, this phenomenon was observed all over France,

Aurora Borealis.

France, and described by Gassendus, who gave it the name of *aurora borealis:* yet neither this, nor any similar appearances posterior to 1574, are described by English writers till the year 1707; which, as Dr Halley observes, shows the prodigious neglect of curious matters which at that time prevailed. From 1621 to 1707, indeed, there is no mention made of an aurora borealis being seen by any body; and considering the number of astronomers who during that period were in a manner continually poring on the heavens, we may very reasonably conclude that no such thing did make its appearance till after an interval of 86 years. In 1707, a small one was seen in November; and during that year and the next, the same appearances were repeated five times. The next on record is that mentioned by Dr Halley in March 1715—16, the brilliancy of which attracted universal attention, and by the vulgar was considered as marking the introduction of a foreign race of princes. Since that time those meteors have been so common, that no accounts have been kept of them.

3 Mr Forster's account of similar appearances in the southern hemisphere.

It was for a long time a matter of doubt whether this meteor made its appearance only in the northern hemisphere, or whether it was also to be observed near the south pole. This is now ascertained by Mr Forster; who in his late voyage round the world along with Captain Cook, assures us, that he observed them in the high southern latitudes, though with phenomena somewhat different from those which are seen here. On Feb. 17. 1773, as they were in Lat. 58° south, "A beautiful phenomenon (says he) was observed during the preceding night, which appeared again this and several following nights. It consisted of long columns of a clear white light, shooting up from the horizon to the eastward, almost to the zenith, and gradually spreading on the whole southern part of the sky. These columns were sometimes bent sidewise at their upper extremities; and though in most respects similar to the northern lights (*aurora borealis*) of our hemisphere, yet differed from them in being always of a whitish colour, whereas ours assume various tints, especially those of a fiery and purple hue. The sky was generally clear when they appeared, and the air sharp and cold, the thermometer standing at the freezing-point."

4 Rises very high.

Dr Halley observed that the aurora borealis described by him arose to a prodigious height, it being seen from the west of Ireland to the confines of Russia and Poland on the east; nor did he know how much farther it might have been visible; so that it extended at least 30 degrees in longitude, and from Lat. 50° north it was seen over all the northern part of Europe; and what was very surprising, in all those places where it was visible, the same appearances were exhibited which Dr Halley observed at London. He observes, with seeming regret, that he could by no means determine its height, for want of observations made at different places; otherwise he might as easily have calculated the height of this aurora borealis, as he did of the fiery globe in 1719 *. To other philosophers, however, he gives the following exhortation. "When therefore for the future any such thing shall happen, all those that are curious in astronomical matters are hereby *admonished* and *entreated* to set their clocks to the apparent time at London, for example, by allowing so many minutes as is the difference of meridians; and then to note, at the end of every half hour precisely, the exact situation of what at that time appears remarkable in the sky; and particularly the azimuths of those very tall pyramids so eminent above the rest, and therefore likely to be seen furthest: to the intent that, by comparing these observations taken at the same moment in distant places, the difference of their azimuths may serve to determine how far these pyramids are distant from us." This advice of Dr Halley seems to have been totally neglected by all the philosophical people in this country. In other countries, however, they have been more industrious. Father Boscovich has determined the height of an aurora borealis, observed on the 16th of December 1737 by the marquis of Poleni, to have been 825 miles high; the celebrated Mr Bergman, from a mean of 30 computations, makes the average height of the aurora borealis to be 70 Swedish, or upwards of 460 English miles. Euler supposes it to be several thousands of miles high; and Mairan also assigns them a very elevated region. In the 74th volume of the Philosophical Transactions, Dr Blagden, when speaking of the height of some fiery meteors, tells us, that the "aurora borealis appears to occupy as high, if not a higher region above the surface of the earth, as may be judged from the very distant countries to which it has been visible at the same time." The height of these meteors, however, none of which appear to have exceeded or even arrived at the height of a hundred miles, must appear trifling in comparison of the vast elevations above mentioned. But these enormous heights, varying so exceedingly, show that the calculators have not had proper data to proceed upon; and indeed the immense extent of space occupied by the aurora borealis itself, with its constant motion, must make it infinitely more difficult to determine the height of it than of a fiery globe, which occupies but a small portion of the visible heavens. The most certain method of making a comparison betwixt the aurora borealis and the meteors already mentioned, would be, if a ball of fire should happen to pass through the same part of the heavens where an aurora borealis was; when the comparative height of both could easily be ascertained. One instance of this only has come under our observation, where one of the small meteors, called *falling stars*, was evidently obscured by an aurora borealis; and therefore must have been higher than the lower part of the latter at least. A singularity in this meteor was, that it did not proceed in a straight line through the heavens, as is usual with falling stars, but described a very considerable arch of a circle, rising in the north-west, and proceeding southward a considerable way in the arch of a circle, and disappearing in the north. Its edges were ill defined, and five or six coruscations seemed to issue from it like the rays painted as issuing from stars. The aurora borealis was not in motion, but had degenerated into a crepusculum in the northern part of the hemisphere. Indeed, in some cases, this kind of crepusculum appears so plainly to be connected with the clouds, that we can scarcely avoid supposing it to proceed from them. We cannot, however, argue from this to the height of the aurora borealis wh[illegible] it moves with great velocity, because it then ma[illegible] and very probably does, ascend much higher. Dr B[illegible]agden, indeed,

* See *Atmosphere.*

Digitized by Google

Aurora Borealis.

deed, informs us, that instances are recorded, where the northern lights have been seen to join, and form luminous balls, darting about with great velocity, and even leaving a train like the common fire-balls. It would seem, therefore, that the highest regions of the aurora borealis are the same with those in which fire-balls move.

5 Conjectures concerning the cause of this meteor.

With regard to the cause of the aurora borealis many conjectures have been formed. The first which naturally occurred was, that it was occasioned by the ascent of inflammable sulphureous vapours from the earth. To this supposition Dr Halley objects the immense extent of such phenomena, and that they are constantly observed to proceed from north to south, but never from south to north. This made him very reasonably conclude, that there was some connexion between the poles of the earth and the aurora borealis; but being unacquainted with the electric power, he supposed, that this earth was hollow, having within it a magnetical sphere, which corresponded in virtue with all the natural and artificial magnets on the surface; and the magnetic effluvia passing through the earth, from one pole of the central magnet to another, might sometimes become visible in their course, which he thought was from north to south, and thus exhibit the beautiful coruscations of the aurora borealis. Had Dr Halley, however, known that a stroke of electricity would give polarity to a needle that had it not, or reverse the poles of one that had it before, he would undoubtedly have concluded the electric and magnetic effluvia to be the same, and that the aurora borealis was this fluid performing its circulation from one pole of the earth to the other. In fact, this very hypothesis is adopted by S. Beccaria: and by the supposed circulation of the electric fluid he accounts for the phenomena of magnetism and the aurora borealis in a manner perfectly similar to that of Dr Halley, only changing the phrase *magnetic effluvia* for *electric fluid*. The following is the account given us by Dr Priestley of Beccaria's sentiments on this matter.

"Since a sudden stroke of lightning gives polarity to magnets, he conjectures, that a regular and constant circulation of the whole mass of the fluid from north to south may be the original cause of magnetism in general.

"That this ethereal current is insensible to us, is no proof of its non-existence, since we ourselves are involved in it. He had seen birds fly so near a thunder-cloud, as he was sure they would not have done had they been affected by its atmosphere.

"This current he would not suppose to arise from one source, but from several, in the northern hemisphere of the earth; and he thinks that the aurora borealis may be this electric matter performing its circulation in such a state of the atmosphere as renders it visible, or approaching the earth nearer than usual. Accordingly, very vivid appearances of this kind have been observed to occasion a fluctuation in the magnetic needle."

A direct disproof of this circulation, however, is furnished by the observation of Mr Forster already mentioned: with which, though neither Dr Halley nor S. Beccaria could be acquainted, they might have thought of it as a final proof either of the truth or falsehood of their hypothesis.—If the aurora borealis is no other than the electric fluid performing the above-mentioned circulation, it ought to dart from the horizon towards the zenith in the northern hemisphere, and from the zenith to the horizon in the southern one: but Mr Forster plainly tells up, that the columns shot up from the horizon towards the zenith as well in the southern hemisphere as in the northern; so that if the aurora borealis is to be reckoned the flashings of electric matter, its course is plainly directed from both poles toward the equator, and not from one pole to the other.

Concerning the cause of this phenomenon, Mr Canton has the following query: "Is not the aurora borealis the flashing of electrical fire from positive towards negative clouds at a great distance, through the upper part of the atmosphere where the resistance is least?" But to this we must reply in the negative; for in this case it would flash in every direction according to the position of the clouds, as well as from north to south. Besides this query, he conjectures, that when the needle is disturbed by the aurora borealis, that phenomenon proceeds from the electricity of the heated air; and supposes the air to have the property of becoming electric by heat, like the tourmalin. But neither does this hypothesis appear at all probable; because, in such a case, the aurora borealis ought to be most frequent in summer when the air is most heated, whereas it is found to be the reverse. Lastly, with these electrical hypotheses we shall contrast that of Mr Mairan, who imagined this phenomenon to proceed from the atmosphere of the sun, particles of which were thrown off by its centrifugal force acquired by his rotation on his axis; and that these particles falling upon the atmosphere of the earth near its equatorial parts, were from thence propelled by the diurnal motion of the earth towards the polar regions, where they formed the aurora borealis. This hypothesis, besides its being a mere supposition unsupported by one single appearance in nature, is liable to the objection already mentioned; for in this case the light should dart from the equator to the poles, and not from the poles to the equator: or if we should suppose this matter to be gradually accumulated at each of the poles, we must then make other suppositions equally vague and ill founded, concerning its getting back with such surprising rapidity in direct opposition to the power which once brought it thither.

The first person who seems to have endeavoured to find any positive proof of the electrical quality of the aurora borealis, was Dr Hamilton of Dublin. He observes, that though this phenomenon is commonly supposed to be electrical, yet he had not seen any attempt to prove that it is so; but the only proof he himself brings is an experiment of Mr Hawksbee, by which the electric fluid is shown to put on appearances somewhat like the aurora borealis, when it passes through a vacuum. He observed, that when the air was most perfectly exhausted, the streams of electric matter were then quite white; but when a small quantity of air was let in, the light assumed more of a purple colour. The flashing of this light therefore from the dense regions of the atmosphere into such as are more rare, and the transitions through mediums of different density, he reckons the cause of the aurora borealis, and of the different colours it assumes.

Dr Hamilton's proof, then, of the electricity of the

Digitized by Google

Aurora Borealis. the aurora borealis, consists entirely in the resemblance the two lights bear to one another; and if to this we add, that during the time of an aurora borealis, the magnetic needle hath been disturbed, electric fire obtained from the atmosphere in plenty, and at some times different kinds of rumbling and hissing sounds heard, we have the sum of all the positive evidence in favour of the electric hypothesis.

Was the aurora borealis the first natural phenomenon the solution of which had been attempted by electricity, no doubt the proofs just now adduced would be very insufficient: but when it is considered, that we have indisputable evidence of the identity of the phenomena of thunder and of electricity; when we also consider that the higher parts of our atmosphere are continually in a strongly electrified state; the analogy becomes so strong that we can scarce doubt of the aurora borealis arising from the same cause. The only difficulty is, to give a good reason why the electricity of the atmosphere should be constantly found to direct its course from the poles towards the equator, and not from the equator to the poles; and this we think may be done in the following manner.

See *Electricity*, passim. 1. It is found that all electric bodies, when considerably heated, become conductors of electricity; thus hot air, hot glass, melted rosin, sealing-wax, &c. are all conductors, till their heat is dissipated, and then they again become electrics.

2. As the converse of every true proposition ought also to be true, it follows from the above one, that if electrics when heated become conductors, then nonelectrics when subjected to violent degrees of cold ought to become electric. In one instance this has been verified by experience; water, which is a conductor when warm or not violently cooled, is found to become electric when cooled to 20° below 0 of Fahrenheit's thermometer. With regard to metallic substances, indeed, no experiments have as yet been made to determine whether their conducting power is affected by cold or not. Very probably we might not be able to produce such a degree of cold as sensibly to lessen their conducting power; but still the analogy will hold; and, as we are by no means able to produce the greatest degree of cold possible, reason will always suggest to us, that if a certain degree of cold changes one conductor into an electric, a sufficient degree of it will also change all others into electrics.

3. If cold is sufficient to change conducting substances into electrics, it must also increase the electric power of such substances as are already electric; that is to say, very cold air, glass, rosin, &c. provided they are dry, will be more electric than when they are warmer. With regard to air, which is most to our present purpose, this is rendered extremely probable, by considering that clear frosty weather is of all others the most favourable for electric experiments. They may be made indeed to equal advantage almost in any state of the atmosphere, provided sufficient pains are used, but in dry hard frosts they will succeed much more easily than at any other time.

These three axioms being allowed, the cause of the aurora borealis is easily deduced from them. The air, all round the globe, at a certain height above its surface, is found to be exceedingly cold, and, as far as experiments have yet determined, exceedingly electrical also. The inferior parts of the atmosphere between the tropics, are violently heated during the day-time by the reflection of the sun's rays from the earth. Such air will therefore be a kind of conductor, and much more readily part with its electricity to the clouds and vapours floating in it, than the colder air towards the north and south poles. Hence the prodigious appearances of electricity in these regions, showing itself in thunder and other tempests of the most terrible kind. Immense quantities of the electric fluid are thus communicated to the earth; and the inferior warm atmosphere having once exhausted itself, must necessarily be recruited from the upper and colder region. This becomes very probable from what the French mathematicians observed when on the top of one of the Andes. They were often involved in clouds, which, sinking down into the warmer air, appeared there to be highly electrified, and discharged themselves in violent tempests of thunder and lightning: while in the mean time, on the top of the mountain, they enjoyed a calm and serene sky. In the temperate and frigid zones, the inferior parts of the atmosphere never being so strongly heated, do not part with their electricity so easily as in the torrid zone, and consequently do not require such recruits from the upper regions: but notwithstanding the difference of heat observed in different parts of the earth near the surface, it is very probable that at considerable heights the degrees of cold are nearly equal all round it. Were there a like equality in the heat of the under part, there could never be any considerable loss of equilibrium in the electricity of the atmosphere: but as the hot air of the torrid zone is perpetually bringing down vast quantities of electric matter from the cold air that lies directly above it; and as the inferior parts of the atmosphere lying towards the north and south poles do not conduct in any great degree; it thence follows, that the upper parts of the atmosphere lying over the torrid zone will continually require a supply from the northern and southern regions. This easily shows the necessity of an electric current in the upper parts of the atmosphere from each pole towards the equator: and thus we are also furnished with a reason why the aurora borealis appears more frequently in winter than in summer; namely, because at that time the electric power of the inferior atmosphere is greater on account of the cold than in summer; and consequently the abundant electricity of the upper regions must go almost wholly off to the equatorial parts, it being impossible for it to get down to the earth: hence also the aurora borealis appears very frequent and bright in the frigid zone, the degree of cold in the upper and under regions of the atmosphere being much more nearly equal in these parts than in any other. In some parts of Siberia particularly, this meteor appears constantly from October to Christmas, and its coruscations are said to be very terrifying. Travellers agree, that here the aurora borealis appears in greatest perfection; and it is to be remarked that Siberia is the coldest country on earth. In confirmation of this, it may also be observed, that from the experiments hitherto made with the electrical kite, the air appears considerably more electrical in winter than in summer, though the clouds are known to be often most violently electrified in the summer time; a proof, that the electricity naturally

turally belonging to the air is in summer much more powerfully drawn off by the clouds than in the winter, owing to the excess of heat in summer, as already observed.

A considerable difficulty, however, still remains from the upright position which the streams of the aurora borealis are generally supposed to have; whereas, according to the hypothesis above mentioned, they ought rather to run directly from north to south. This difficulty occurred to Dr Halley; but he answers it by supposing his magnetic effluvia to pass from one pole to another in arches of great circles, arising to a vast height above the earth, and consequently darting from the places whence they arose almost like the radii of a circle; in which case, being sent off in a direction nearly perpendicular to the surface of the earth, they must necessarily appear erect to those who see them from any part of the surface, as is demonstrated by mathematicians. It is also reasonable to think that they will take this direction rather than any other, on account of their meeting with less resistance in the very high regions of the air than in such as are lower.

But the greatest difficulty still remains: for we have supposed the equilibrium of the atmosphere to be broken in the daytime, and restored only in the night; whereas, considering the immense velocity with which the electric fluid moves, the equilibrium ought to be restored in all parts almost instantaneously; yet the aurora borealis never appears except in the night, although its brightness is such as must sometimes make it visible to us did it really exist in the daytime.

In answer to this it must be observed, that though the passage of electricity through a good conductor is instantaneous, yet through a bad conductor it is observed to take some time in passing. As our atmosphere therefore, unless very violently heated, is but a bad conductor of electricity; though the equilibrium in it is broken, it can by no means be instantaneously restored. Add to this, that as it is the action of the sun which breaks the equilibrium, so the same action, extending over half the globe, prevents almost any attempt to restore it till night, when flashes arise from various parts of the atmosphere, gradually extending themselves with a variety of undulations towards the equator.

It now remains to explain only one particularity of the aurora borealis, namely, that its streams do not always move with rapidity; sometimes appearing quite stationary for a considerable time, and sometimes being carried in different directions with a slow motion. To this indeed we can give no other reply, than that weak electric lights have been sometimes observed to put on the same appearance at the surface of the earth: and much more may we suppose them capable of doing so at great heights above it, where the conductors are both fewer in number and much more imperfect. When M. de Romas was making experiments with an electric kite in Italy, a cylinder of blue light about four or five inches diameter was observed surrounding the string. This was in the day time; but had it been night, he imagined it must have been four or five feet in diameter; and as the string was 780 feet long, it would probably have seemed pyramidal, pointing upwards like one of the streams of the aurora borealis. A still more remarkable appearance, Dr Priestley tells us, was observed by Mr Hartman. He had been making electrical experiments for four or five hours together in a very small room; and upon going out of it, and returning with a light in his hand, walking pretty quick, he perceived a small flame following him at about three feet distance. Being alarmed at this appearance, he stopped to examine it, upon which it vanished. This last instance is very remarkable, and singular in its kind; from both, however, we are sufficiently warranted to conclude, that small portions of our atmosphere may by various causes be so much electrified as to shine, and likewise be moved from one place to another without parting with the electricity they have received, for a considerable time.

The corona, or circle, which is often formed near the zenith by the aurora borealis, is easily accounted for in the same manner. As this corona is commonly stationary for some time, we imagine it would be a very proper mark whereby to determine the distance of the meteor itself. If an aurora borealis, for instance, was observed by two persons, one at London, and the other at Edinburgh; by noting the stars among which the corona was observed at each place, its true altitude from the surface of the earth could easily be determined by trigonometry.

Under the article ATMOSPHERE it was suggested, that no good proof had been as yet brought for the extreme rarity of the air usually supposed to take place at no very great heights above the earth. The brightness of the meteor there mentioned at 70 miles perpendicular from the surface, as also its figure, seemed to prove the air considerably dense at that distance from the earth. Though the height of the aurora borealis has never been determined, we can scarce imagine it to be greater than that of this meteor, or indeed so great: but although its streams resemble the passage of electric light through a vacuum, it cannot be from thence inferred, that the air is at all in a state similar to the vacuum of an air-pump in those places where the aurora borealis is produced; seeing we have instances of similar appearances being produced in very dense air. The plate of an electrophorus is often so highly electrified, as to throw out flashes from different parts as soon as it is lifted up, and by proper management it may be always made to emit long and broad flashes which shall scarcely be felt by the finger, instead of small, dense, and pungent sparks; so that, though long flashes may be produced in rarefied air, it by no means follows, that the same may not also be produced in denser air. As little can we infer any thing from the colour; for we observe the electric spark sometimes white, sometimes blue, and sometimes purple, in the very same state of the atmosphere, and from the same substance.

The aurora borealis is said to be attended with a peculiar hissing noise in some very cold climates; Gmelin speaks of it in the most pointed terms, as frequent and very loud in the north-eastern parts of Siberia; and other travellers have related similar facts. Gmelin's account is very remarkable. "These northern lights (says he) begin with single bright pillars, rising in the north, and almost at the same time in the north-east, which gradually increasing, comprehend a large space of the heavens, rush about from place to place with incredible velocity, and finally almost cover the whole sky

Aurora Borealis.

sky up to the zenith. The streams are then seen meeting together in the zenith, and produce an appearance as if a vast tent was expanded in the heavens, glittering with gold, rubies, and sapphire. A more beautiful spectacle cannot be painted; but whoever should see such a northern light for the first time, could not behold it without terror. For however fine the illumination may be, it is attended, as I have learned from the relation of many persons, with such a hissing, cracking, and rushing noise throughout the air, as if the largest fire-works were playing off. To describe what they then hear, they make use of the expression, *Spolochi chodjat*, that is 'the raging host is passing.' The hunters who pursue the white and blue foxes on the confines of the Icy sea, are often overtaken in their course by these northern lights. The dogs are then so much frightened, that they will not move, but lie obstinately on the ground till the noise has passed. Commonly clear and calm weather follows this kind of northern lights. I have heard this account, not from one person only, but confirmed by the uniform testimony of many, who have spent part of several years in these very northern regions, and inhabited different countries from the Yenesei to the Lena; so that no doubt of its truth can remain. This seems indeed to be the real birthplace of the *aurora borealis*."

The hissing or rushing noise above described, Dr Blagden is inclined to attribute to small streams of electric matter running off to the earth from the masses or accumulations of electricity by which the northern lights are supposed to be produced.

6
Aurora borealis succeeded by south-west winds.

We shall conclude this article with an account of a paper presented to the Royal Society by Mr Winn, in 1772, wherein he says that the appearance of an aurora borealis is a certain sign of a hard gale of wind from the south or south-west. This he never found to fail in 23 instances; and even thinks, that from the splendour of the meteor, some judgment may be formed concerning the ensuing tempest. If the aurora is very bright, the gale will come on within twenty-four hours, but will be of no long duration; if the light is faint and dull, the gale will be less violent and longer in coming on, but it will also last longer. His observations were made in the English channel, where such winds are very dangerous; and by attending to the auroræ, he says he often got easily out of it, when others narrowly escaped being wrecked. This is an exceeding useful observation for sailors: but it cannot be expected that the winds succeeding these meteors should in all places blow from the south-west; though no doubt a careful observation of what winds succeed the aurora borealis, and other meteors, in different parts of the world, might contribute in some measure to lessen the dangers of navigation.

7
Conjecture concerning the reason.

That the aurora borealis ought to be succeeded by winds, may be easily deduced from the hypothesis last mentioned. If this phenomenon is occasioned by the vast quantity of electric matter conveyed to the equatorial parts of the earth, it is certain that the earth cannot receive any great quantity of this matter at one place without emitting it at another. The electricity, therefore, which is constantly received at the equator, must be emitted near the poles, in order to perform its course, otherwise there could not be a constant supply of it for the common operations of nature. It is observed, that electrified bodies are always surrounded by a blast of air, which is sent forth from them in all directions; hence if the electric matter find a more ready passage through one part of the earth than another, a wind will be found to blow from that quarter. If therefore one of these places happen to be in the Atlantic ocean near the coast of France, or in the bay of Biscay, the electric matter which has been received at the equator during an aurora borealis will be discharged there for some time after, and consequently a wind will blow from that quarter, which will be from the south-west to those ships which are in the English channel. It cannot be imagined, however, that all the matter can be discharged from one place; and therefore, according to the different situations of those electrical vents, winds may blow in different directions; and thus the same aurora borealis may produce a south-west wind in the English channel, and a north west one in Scotland.

Aurora Borealis ‖ Ausi.

AURUM. See GOLD, CHEMISTRY, and MINERALOGY *Index*.

This metal was introduced into medicine by the Arabians, who esteemed it one of the greatest cordials and comforters of the nerves. From them Europe received it without any diminution of its character; in foreign pharmacopœias it is still retained, and even mixed with the ingredients from which simple waters are to be distilled. But no one, it is presumed, at this time, expects any singular virtues from it, since it certainly is not alterable in the human body. Mr Geoffroy, though unwilling to reject it from the cordial preparations, honestly acknowledges that he has no other reason for retaining it than complaisance to the Arabian schools. The chemists have endeavoured, by many elaborate processes, to extract what they call a sulphur or anima of gold; but no method is as yet known of separating the component parts of this metal; all the tinctures of it, and aurum potabile, which have hitherto appeared, are real solutions of it in aqua regia, diluted with spirit of wine or other liquors, and prove injurious to the body rather than beneficial. A place, however, is now given in some of the foreign pharmacopœias to the aurum fulminans; and it has of late been recommended as a remedy in some convulsive diseases, particularly in the chorea sancti viti.

AURUM Fulminans. See CHEMISTRY *Index*.

AURUM Mosaicum. See CHEMISTRY *Index*.

AURUNCI, in *Ancient Geography*, a people of Latium, towards Campania; the same with the Ausones, at least so intermixed as not to be easily distinguishable, though Pliny separates them.

AUSA, a town of Tarraconensis, in the middle age called *Ausona*; now *Vich de Osuna*, a town of Catalonia in Spain. E. Long. 2. 0. N. Lat. 41. 50.

AUSCH. See AUCH.

AUSI, an ancient and very savage people of Libya. Herodotus tells us that they were unacquainted with marriage, and had all their women in common. The children were brought up by their mothers till they were able to walk: after which they were introduced to an assembly of the men, who met every three months; and the man to whom any child first spoke, acknowledged himself its father. They celebrated annually a feast in honour of Minerva, in which the girls divided into two companies, fought with sticks

Digitized by Google

and stones, and those who died of their wounds were concluded not to have been virgins.

AUSIMUM, or AUXIMUM, an ancient Roman colony in the Picenum; now *Osimo* or *Osmo*, in the marquisate of Ancona in Italy. E. Long. 15. N. Lat. 43. 20.

AUSITÆ, or ÆSITÆ, a tribe of ancient Arabs, supposed by Bochart to have inhabited the land of Uz mentioned in Scripture.

AUSONA, in *Ancient Geography*, a town of the Ausones, a people who anciently occupied all the Lower Italy, from the Promontorium Circæum down to the straits of Sicily (Livy), but were afterwards reduced to a much narrower compass; namely, between the Montes Circæi and Massici: nor did they occupy the whole of this, but other people were intermixed. Concerning Ausona or its remains there is nothing particular recorded.

AUSONIA, the ancient name of Italy, from its most ancient inhabitants the Ausones, (Virgil, Servius).

AUSONEUM MARE, in *Ancient Geography*, a part of the Ionian sea, extending southward from the promontory Japygium to Sicily, which it washes on the east, as it does the Bruttii and Magna Græcia on the south and east. It is separated from the Tuscan sea by the strait of Messina.

AUSONIUS (in Latin, *Decius*, or rather *Decimus*, Magnus Ausonius), one of the best poets of the fourth century, was the son of an eminent physician, and born at Bourdeaux. Great care was taken of his education, the whole family interesting themselves in it, either because his genius was very promising, or that the scheme of his nativity, which had been cast by his grandfather on the mother's side, made them imagine that he would rise to great honour. He made an uncommon progress in classical learning, and at the age of 30 was chosen to teach grammar at Bourdeaux. He was promoted some time after to be professor of rhetoric; in which office he acquired so great a reputation, that he was sent for to court to be preceptor to Gratian the emperor Valentinian's son. The rewards and honours conferred on him for the faithful discharge of his office prove the truth of Juvenal's maxim, that when Fortune pleases, she can raise a man from a rhetorician to the dignity of a consul. He was actually appointed consul by the emperor Gratian, in the year 379, after having filled other considerable posts; for besides the dignity of quæstor, to which he had been nominated by Valentinian, he was made prefect of the prætorium in Italy and Gaul after that prince's death. His speech returning thanks to Gratian on his promotion to the consulship is highly commended. The time of his death is uncertain; he was still living in 392, and lived to a great age. The emperor Theodosius had a great esteem for Ausonius, and pressed him to publish his poem. There is a great inequality in his works; and in his manner and his style there is a harshness which was perhaps rather the defect of the times he lived in than of his genius. Had he lived in Augustus's reign, his verses, according to good judges, would have equalled the most finished of that age. He is generally supposed to have been a Christian: some ingenious authors indeed think otherwise, but, according to Mr Bayle, without just reason. The best edition of his poems is that of Amsterdam in 1671.

AUSPEX, a name originally given those who were afterwards denominated *augurs*. In which sense the word is supposed to be formed from *avis*, "bird," and *inspicere*, "to inspect;" *auspices*, q. d. *avispices*.

AUSPICIUM, AUSPICY, the same with augury.

AUSTER, one of the four cardinal winds, as Servius calls them, blowing from the south, (Pliny, Ovid, Manilius).

AUSTERE, rough, astringent. Thus an austere taste is such a one as constringes the mouth and tongue; as that of unripe fruit, harsh wines, &c.

AUSTERITY, among moral writers, implies severity and rigour. Thus we say, *austerity of manners*, *austerities of the monastic life*, &c.

AUSTIN, ST. See *St AUGUSTIN*.

AUSTRAL, AUSTRALIS, the same with southern. The word is derived from *auster*, "south wind." Thus the six austral signs of the zodiac, are those on the south side of the equinoctial.

AUSTRALASIA, a new division, lately introduced by geographers, forming the fifth great division of the globe. It comprehends New Holland, New Guinea, and a vast multitude of other islands scattered over the Pacific ocean. See SUPPLEMENT.

AUSTRALIS PISCIS, the SOUTHERN FISH, is a constellation of the southern hemisphere, not visible in our latitude; whose stars in Ptolemy's catalogue are 18, and in the Britannic catalogue 24.

AUSTRIA, one of the principal provinces of the empire of Germany towards the east; from which situation it takes its name, *Oost-rych* in the German language signifying the *East Country*. It is bounded on the north by Moravia; on the east by Hungary; on the south by Stiria; and on the west by Bavaria. It is divided into *Upper* and *Lower*, which are separated by the river Ens. Vienna the capital is in Lower Austria, which contains several other very considerable towns. The country is fertile, but rather mountainous; it has a great many mines, and produces vast quantities of salt and sulphur.

In the ninth and tenth centuries, Austria was the frontier of the empire against the barbarians. In 928, the emperor Henry the Fowler, perceiving that it was of great importance to settle some person in Austria who might oppose these incursions, invested Leopold, surnamed the *Illustrious*, with that country. Otho I. erected Austria into a marquisate in favour of his brother-in-law Leopold, whose descendant Henry II. was created duke of Austria by the emperor Frederic Barbarossa. His posterity becoming extinct in 1240, the states of the country, in order to defend themselves from the incursions of the Bavarians and Hungarians, resolved to put themselves under the protection of Henry marquis of Misnia; but Othogar II. king of Bohemia, being likewise invited by a party in the duchy, took possession of it, alleging not only the invitation of the states, but also the right of his wife, heiress of Frederic the last duke. The emperor Rodolphus I. pretending a right to this duchy, refused to give Othogar the investiture of it; and afterwards killing him in a battle, procured the right of it to his own family. From this Rodolphus the present house of Austria is descended, which

Digitized by Google

Austria. which for several centuries past has rendered itself so famous and so powerful, having given 14 emperors to Germany, and six kings to Spain.

In 1477, Austria was erected into an archduchy by the emperor Frederic the Pacific for his son Maximilian, with these privileges: That these shall be judged to have obtained the investiture of the states, if they do not receive it after having demanded it three times; that if they receive it from the emperor, or the imperial ambassadors, they are to be on horseback, clad in a royal mantle, having in their hand a staff of command, and upon their head a ducal crown of two points, and surrounded with a cross like that of the imperial crown. The archduke is born privy-counsellor to the emperor, and his states cannot be put to the ban of the empire. All attempts against his person are punished as crimes of lese-majesty, in the same manner as those against the king of the Romans, or electors. No one dared to challenge him to single combat. It is in his choice to assist at the assemblies, or to be absent; and he has the privilege of being exempt from contributions and public taxes, excepting 12 soldiers which he is obliged to maintain against the Turks for one month. He has rank immediately after the electors; and exercises justice in his states without appeal, by virtue of a privilege granted by Charles V. His subjects cannot even be summoned out of his province upon account of lawsuits, to give witness, or to receive the investiture of fiefs. Any of the lands of the empire may be alienated in his favour, even those that are feudal; and he has a right to create counts, barons, gentlemen, *poets*, and notaries. In the succession to his states, the right of birth takes place; and, failing males, the females succeed according to the lineal right, and, if no heir be found, they may dispose of their lands as they please.

Upper Austria, properly so called, has throughout the appearance of a happy country. Here are no signs of the striking contrast betwixt poverty and riches which offends so much in Hungary. All the inhabitants, those of the capital only excepted, enjoy that happy mediocrity which is the consequence of a gentle and wise administration. The farmer has property; and the rights of the nobility, who enjoy a kind of lower judicial power, are well defined. The south and south-west parts of the country are bounded by a ridge of hills, the inhabitants of which enjoy a share of prosperity unknown to those of the interior parts of France. There are many villages and market towns, the inhabitants of which have bought themselves off from vassalage, are now their own governors, and belong some of them to the estates of the country. The cloisters, the prelates of which belong to the estates of the country, are the richest in Germany, after the immediate prelacies and abbacies of the empire. One of the greatest convents of Benedictines is worth upwards of four millions of French livres, half of which goes to the exchequer of the country.

Lower Austria exports great quantities of wine to Moravia, Bohemia, Upper Austria, Bavaria, Saltzburg, and part of Stiria and Carinthia. This wine is sour, but has a great deal of strength, and may be carried all over the world without danger; when it is ten or twenty years old it is very good. The valleys near the Danube are fertile, but agriculture is generally in a rude state. The southern parts of Austria are covered with hills, which rise gradually from the banks of the Danube to the borders of Stiria, and are covered with woods. They lose themselves in the mass of mountains which run to the south of Germany, and stretch through all Stiria, Carniola, Carinthia, and Tyrol, to the Swiss Alps; and are probably, after Savoy and Switzerland, the highest part of the earth. The inhabitants of this extensive ridge of mountains are all very much alike; they are a strong, large, and, the GOITRES excepted, a very handsome people. Upper and Lower Austria together contain 45,760 square miles, and their population in 1818 amounted to 4,457,692. The revenue which these provinces yield is estimated at nearly four millions sterling.

The characteristic of the inhabitants of all this country is striking bigotry, united with striking sensuality. You need only see what is going forwards here to be convinced that the religion taught by the monks is as ruinous to the morals as it is repugnant to Christianity. The Cicisbeos accompany the married women from their bed to church, and lead them to the very confessional. The bigotry of the public in the interior parts of Austria, which, from the mixture of gallantry with it, is still to be found even amongst people of rank, degenerates amongst the common people into the grossest and most abominable buffoonery. The Windes, who are mixed with the Germans in these countries, distinguish themselves by a superstitious custom that does little honour to the human understanding, and would be incredible if we had not the most unequivocal proofs of the fact before our eyes. Many years ago, they set out in company with some Hungarian enthusiasts to Cologne on the Rhine, which is about 120 German miles distant, to cut off the beard of a crucifix there. Every seven years this operation is repeated, as in this space of time the beard grows again to its former length. The rich persons of the association send the poorer ones as their deputies, and the magistrates of Cologne receive them as ambassadors from a foreign prince. They are entertained at the expence of the state, and a counsellor shows them the most remarkable things in the town. This farce brings in large sums of money at stated times, and may therefore deserve political encouragement; but still, however, it is the most miserable and meanest way of gain that can be imagined. These Windes have alone the right to shave our Saviour, and the beard grows only for them. They firmly believe, that if they did not do this service to the crucifix, the earth would be shut to them for the next seven years, and there would be no harvests. For this reason they are obliged to carry the hair home with them, as the proof of having fulfilled their commission, the returns of which are distributed among the different communities, and preserved as holy relics. The imperial court has for a long time endeavoured in vain to prevent this emigration, which deprives agriculture of so many useful hands. When the Windes could not go openly they would go clandestinely. At length the court thought of the expedient of forbidding the regency of Cologne to let them enter the town. When this happened, the numerous embassy was-

Digitized by Google

was obliged to beg its way back again without the wonderful beard; which without doubt the Capuchins, to whom the crucifix belonged, used to put together from their own. The trade which the monks carry on with holy salves, oils, &c. is still very considerable; a prohibition which the court published, rather lessened it, but did not entirely suppress it.

For an account of the whole Austrian monarchy, see Austria, Supplement.

AUSTROMANCY, Austromantia, properly denotes soothsaying, or a vain method of predicting futurity, from observations of the winds.

AUTERFOITS Acquit.
Auterfoits Attaint.
Auterfoits Acquit.
} See the article *Plea to Indictment.*

AUTHENTIC, something of acknowledged and received authority. In law, it signifies something clothed in all its formalities, and attested by persons to whom credit has been regularly given. Thus we say, *authentic papers*, *authentic instruments*.

AUTHOR, properly signifies one who created or produced any thing. Thus God, by way of eminence is called the *Author of nature*, the *Author of the universe*.

Author, in matters of literature, a person who has composed some book or writing.

AUTHORITY, in a general sense, signifies a right to command, and make one's self obeyed. In which sense we say, *the royal authority, the episcopal authority, the authority of a father*, &c. It denotes also the testimony of an author, some apophthegm or sentence of an eminent person quoted in a discourse by way of proof.

Authority is represented, in painting, like a grave matron sitting in a chair of state, richly clothed in a garment embroidered with gold, holding in her right hand a sword, and in her left a sceptre. By her side is a double trophy of books and arms.

AUTOCHTHONES, an appellation assumed by some nations, importing that they sprung, or were produced, from the same soil which they still inhabited. In this sense, *Autochthones* amounts to the same with *Aborigines*. The Athenians valued themselves on their being Autochthones, *self-born*, or γηγενεις, *earth-born*; it being the prevailing opinion among the ancients, that, in the beginning, the earth, by some prolific power, produced men, as it still does plants. The proper Autochthones were those primitive men who had no other parent beside the earth. But the name was also assumed by the descendants of these men, provided they never changed their ancient state, nor suffered other nations to mix with them. In this sense it was that the Greeks, and especially the Athenians, pretended to be Autochthones; and as a badge thereof, wore a golden grasshopper woven in their hair, an insect supposed to have the same origin.

AUTOCRATOR, a person vested with an absolute independent power, by which he is rendered unaccountable to any other for his actions. The power of the Athenian generals, or commanders, was usually limited; so that, at the expiration of their office, they were liable to render an account of their administration. But, on some extraordinary occasions, they were exempted from this restraint, and sent with a full and uncontroulable authority: in which sense they were styled Αυτοκρατορες. The same people also applied the name to some of their ambassadors, who were vested with a full power of determining matters according to their own discretion. These were denominated Πρεσβεις Αυτοκρατορες, and resembled our plenipotentiaries.

AUTO DA FE, act of faith. See *Act of Faith*.

AUTODIDACTUS, a person self-taught, or who has had no master or assistant of his studies besides himself.

AUTOGRAPH, denotes a person's hand-writing, or the original manuscript of any book, &c.

AUTOLITHOTOMUS, he who cuts himself for the stone. Of this we have a very extraordinary instance given by Reiselius, in the Ephemerides of the Academy *Naturæ Curiosorum*, dec. 1. an. 3. obs. 192.

AUTOMATE, called also *Hiera*, one of the Cyclades, an island to the north of Crete (Pliny), said to have emerged out of the sea, between the islands Thera and Therasia, in the fifth year of the emperor Claudius; in extent 30 stadia, (Orosius).

AUTOMATON, (from αυτος, *ipse*, and μαιομαι, *excitor*), a self-moving machine, or one so constructed, by means of weights, levers, pulleys, &c. as to move for a considerable time, as though endowed with animal life. According to this description, clocks, watches, and all machines of that kind, are automata.

Under the article Androides we observed that the highest perfection to which automata could be carried was to imitate exactly the motions and actions of living creatures, especially of mankind, which are more difficultly imitated than those of other animals. Very surprising imitations, however, have been made of other creatures. So long ago as 400 years before Christ, Archytas of Tarentum is said to have made a wooden pigeon that could fly; nor will this appear at all incredible, when we consider the flute-player made by M. Vaucanson, and the chess-player by M. Kempel. Dr Hook is also said to have made the model of a flying chariot, capable of supporting itself in the air. But M. Vaucanson above mentioned hath distinguished himself still more eminently. That gentleman, encouraged by the favourable reception of his flute-player, made a duck, which was capable of eating, drinking, and imitating exactly the voice of a natural one. Nay, what is still more surprising, the food it swallowed was evacuated in a digested state; not that it was really in a state of natural excrement, but only considerably altered from what it was when swallowed; and this digestion was performed on the principles of solution, not of trituration. The wings, viscera, and bones, of this artificial duck, were also formed so as very strongly to resemble those of a living animal. Even in the actions of eating and drinking, this resemblance was preserved; the artificial duck swallowed with avidity and vastly quick motions of the head and throat; and likewise muddled the water with its bill, exactly like a natural one.

M. le Droz of La Chaux de Fonds, in the county of Neufchattel, hath also executed some very curious pieces of mechanism, which well deserve to be ranked with those already mentioned. One was a clock, which was presented to his Spanish majesty; and had among other curiosities, a sheep, which imitated the bleating of a natural one; and a dog watching a basket of fruit. When any one attempted to purloin the fruit, the dog gnashed

Digitized by Google

gnashed his teeth and barked; and if it was actually taken away, he never ceased barking till it was restored. Besides this, he made a variety of human figures, which exhibited motions truly surprising; but all inferior to Mr Kempel's chess-player, which may justly be looked upon as the greatest masterpiece in mechanics that ever appeared. See ANDROIDES.

AUTONOMIA, a power of living or being governed by our own laws and magistrates. The liberty of the cities which lived under the faith and protection of the Romans, consisted in their autonomia, i. e. they were allowed to make their own laws, and elect their own magistrates, by whom justice was to be administered, and not by Roman presidents or judges, as was done in other places which were not indulged the autonomia.

AUTOPYROS, from αυτος, and πυρος, *wheat;* in the ancient diet, an epithet given to a species of bread, wherein the whole substance of the wheat was retained without retrenching any part of the bran. Galen describes it otherwise, viz. as bread where only the coarser bran was taken out.—And thus it was a medium between the finest bread, called *similageneus*, and the coarsest called *furfuraceus*. This was also called *autopyrites* and *syncomistus*.

AUTRE-EGLISE, a village of Brabant, in the Netherlands; to which the left wing of the French army extended, when the confederates obtained the victory at Ramillies, in 1706. E. Long. 4. 50. N. Lat. 50. 40.

AUTRICUM, the capital of the Carnutes, a people of Gallia Celtica; afterwards called *Carnotena*, *Carnotenus*, and *Civitas Carnotenum*: Now *Chartres*, in the Orleanois, on the Eure. E. Long. 1. 32. N. Lat. 48. 47.

AUTUMN, the third season of the year, when the harvest and fruits are gathered in. Autumn is represented in painting, by a man at perfect age, clothed like the vernal, and likewise girded with a starry girdle; holding in one hand a pair of scales equally poised, with a globe in each; in the other hand a bunch of divers fruits and grapes. His age denotes the perfection of this season; and the balance, that sign of the zodiac which the sun enters when our autumn begins.

Autumn begins on the day when the sun's meridian distance from the zenith, being on the decrease, is a mean between the greatest and the least; which in these countries is supposed to happen when the sun enters Libra. Its end coincides with the beginning of winter. Several nations have computed the years by autumns; the English Saxons, by winters. Tacitus tells us, that the ancient Germans were acquainted with all the other seasons of the year, but had no notion of autumn. Lidyat observes of the beginning of the several seasons of the year, that

Dat Clemens hyemem, dat Petrus ver cathedratus,
Æstuat Urbanus, autumnat *Bartholomæus*.

Autumn has always been reputed an unhealthy season. Tertullian calls it *tentator valetudinum;* and the satirist speaks of it in the same light. *Autumnus Libitinæ questus acerbæ*.

AUTUMNAL POINT, is that part of the equinox from which the sun begins to descend towards the south pole.

AUTUMNAL Signs, in *Astronomy*, are the signs Libra, Scorpio, Sagittarius, through which the sun passes during the autumn.

AUTUMNAL Equinox, that time when the sun enters the autumnal point.

AUTUN, an ancient city of France, in the department of Saone and Loire, formerly the duchy of Burgundy, the capital of the Autonois, with a bishop's see. The length of this city is about three quarters of a mile, and its breadth nearly equal. The river Arroux washes its ancient walls, whose ruins are so firm, and the stones so closely united, that they seem almost to be cut out of the solid rock. In this city are the ruins of three ancient temples, one of which was dedicated to Janus, and another to Diana. Here are likewise a theatre and a pyramid, which last is probably a tomb; it stands in a place called the *field of urns*, because several urns had been found there. Here are also two antique gates of great beauty. The city contained about 8000 inhabitants in 1815. E. Long. 4. 15. N. Lat. 46. 58.

AUTURA, or AUDURA, a river of Gallia Celtica, only mentioned in the Lives of the Saints. Now the *Eure*, which falls into the Seine, on the left-hand or south side.

AUVERGNE, a late province of France, about 100 miles in length and 75 in breadth. It is bounded on the north by the Bourbonnois; on the east by Torez and Velay; on the west, by Limosin, Quercy, and La Marche: and on the south, by Rovergne and the Cevennes. It is divided into upper and lower: the latter, otherwise called *Limagne*, is one of the finest countries in the world. The mountains of Higher Auvergne render it less fruitful; but they afford good pasture, which feeds great numbers of cattle, which are the riches of that country. Auvergne supplies Lyons and Paris with fat cattle, makes a large quantity of cheese, and has manufactures of several kinds. The capital of the whole province is Clermont. It is now divided into the departments of Cantal and Puy de Dome.

AUVERNAS, a very deep-coloured heady wine, made of black raisins so called, which come from Orleans. It is not fit to drink before it is above a year old; but if kept two or three years, it becomes excellent.

AUXERRE, an ancient town of France in the department of Yonne, and capital of the Auxerrois, and lately a bishop's see. The episcopal palace was one of the finest in France, and the churches were also very beautiful. This town contained 11,300 inhabitants in 1815, and is well situated for trade with Paris, on the river Yonne. E. Long. 3. 35. N. Lat. 47. 54.

AUXESIS, in *Mythology*, a goddess worshipped by the inhabitants of Egina, and mentioned by Herodotus and Pausanias.

AUXESIS, in *Rhetoric*, a figure whereby any thing is magnified too much.

AUXILIARY, whatever is aiding or helping to another.

AUXILIARY Verbs, in *Grammar*, are such as help to form or conjugate others; that is, are prefixed to them, to form or denote the modes or tenses thereof; as *to have* and *to be*, in the English; *etre* and *avoir*, in the French; *ho* and *sono* in the Italian, &c. In the English language,

Digitized by Google

language, the auxiliary verb *am* supplies the want of passive verbs.

AUXO, in *Mythology*, the name of one of two Graces worshipped by the Athenians. See HEGEMONE.

AUXONNE, a small fortified town in France, in the department of Cote d'Or; seated on the river Saone, over which there is a bridge of 23 arches, to facilitate the running off of the waters after the overflowing of the river. It contained 2340 inhabitants in 1815. E. Long. 5. 22. N. Lat. 47. 11.

AUXY; the French give the name of *auxy wool* to that which is spun in the neighbourhood of Abbeville, by those workmen who are called *houpiers*. It is a very fine and beautiful wool, which is commonly used to make the finest stockings.

AWARD, in *Law*, the judgment of an arbitrator, or of one who is not appointed by the law a judge, but chosen by the parties themselves for terminating their difference. See ARBITER and ARBITRATION.

AWL, among shoemakers, an instrument wherewith holes are bored through the leather, to facilitate the stitching or sewing the same. The blade of the awl is usually a little flat and bended, and the point ground to an acute angle.

AWLAN, a small town of Germany, in the circle of Suabia, seated on the river Kochen. E. Long. 11. 15. N. Lat. 48. 52.

AWME, or AUME, a Dutch liquid measure containing eight steckens, or 20 verges or verteels, equal to the tierce in England, or to one sixth of a ton of France.

AWN. See ARISTA, BOTANY *Index*.

AWNING, in the sea-language, is the hanging a sail, tarpawling, or the like, over any part of the ship, to keep off the sun, rain, or wind.

AX, a carpenter's instrument, serving to hew wood. The ax differs from the joiner's hatchet, in that it is made larger and heavier, as serving to hew large stuff; and its edge tapering into the middle of its blade. It is furnished with a long handle or helve, as being to be used with both hands.

Battle-Ax. See CELT.

AXAMENTA, in antiquity, a denomination given to the verses or songs of the *salii*, which they sung in honour of all men. The word is formed, according to some, from *axare*, q. d. *nominare*. Others will have the *carmina saliaria* to have been denominated *axamenta*, on account of their having been written *in axibus*, or on wooden tables.

The *axamenta* were not composed, as some have asserted, but only sung by the *salii*. The author of them was Numa Pompilius; and as the style might not be altered, they grew in time so obscure, that the *salii* themselves did not understand them. Varro says they were 700 years old. Quint. Inst. Or. lib. i. c. 11.

AXAMENTA, or *Assamenta*, in ancient music, hymns or songs performed wholly with human voices.

AXAYACATL, the name of a species of fly, common in Mexico, about the lake; the eggs of which being deposited in immense quantities, upon the rushes and corn-flags, form large masses, which are taken up by fishermen and carried to market for sale. This caviare, called *ahuauhtli*, which has much the same taste with the caviare of fish, used to be eaten by the Mexicans, and is now a common dish among the Spaniards. The Mexicans eat not only the eggs, but the flies themselves, made up together into a mass, and prepared with saltpetre.

AXATI, a town of ancient Bætica, on the Bætis; now *Lora*, a small city of Andalusia, in Spain, seated on the Guadalquiver. W. Long. 5. 20. N. Lat. 37. 20.

AXBRIDGE, a town of Somersetshire in England, consisting of one long narrow street, and containing 853 inhabitants in 1811. W. Long. 2. 20. N. Lat. 51. 30.

AXEL, a small fortified town in Dutch Flanders. E. Long. 40. 0. N. Lat. 51. 17.

AXHOLM, an island in the north-west part of Lincolnshire in England. It is formed by the rivers Trent, Idel, and Dan; and is about ten miles long and five broad. The lower part is marshy, but produces an odoriferous shrub called *gall;* the middle is rich and fruitful, yielding flax in great abundance, as also alabaster which is used for making lime. The principal town is called *Axey*, and is now very thinly inhabited.

AXIACE, an ancient town of Sarmatia Europæa; now *Oczakow*, the capital of Budziac Tartary. E. Long. 32. 30. N. Lat. 46. 0.

AXILLA, in *Anatomy*, the arm-pit or the cavity under the upper part of the arm.

AXILLA, in *Botany*, is the space comprehended between the stems of plants and their leaves. Hence we say those flowers grow in the axillæ of the leaves; i. e. at the base of the leaves, or just within the angle of their pedicles.

AXILLARY, something belonging to or lying near the axilla. Thus, *axillary artery* is that part of the subclavian branches of the ascending trunk of the aorta which passeth under the arm-pits; *axillary glands* are situated under the arm-pits, enveloped in fat, and lie close by the axillary vessels; and *axillary vein* is one of the subclavians which passes under the arm pit, dividing itself into several branches, which are spread over the arm.

AXIM, a small territory on the Gold coast in Africa. The climate here is so excessively moist, that it is proverbially said to rain 11 months and 29 days of the year. This excessive moisture renders it very unhealthy; but it produces great quantities of rice, water melons, lemons, oranges, &c. Here are also produced vast numbers of black cattle, goats, sheep, tame pigeons, &c. The whole country is filled with beautiful and populous villages, and the intermediate lands well cultivated; besides which the natives are very wealthy, from the constant traffic carried on with them by the Europeans for their gold. The capital, which is also called *Axim*, by some *Achambone*, stands under the cannon of the Dutch fort St Antonio. Behind, it is secured by a thick wood that covers the whole declivity of a neighbouring hill. Between the town and the sea runs an even and spacious shore of beautiful white sand. All the houses are separated by groves of cocoa and other fruit trees, planted in parallel lines, each of an equal width, and forming an elegant vista. The little river Axim crosses the town; and the coast is defended by a number of small pointed rocks which project from the shore, and render all access to it dangerous. The capital is situated in W. Long. 24. 0. N. Lat. 5. 0. This canton is a kind of republic, the government being

Digitized by Google

being divided between the Caboceroes or chief men and Manaceroes or young men. It must be observed, however, that in their courts there is not even a pretence of justice: whoever makes the most valuable presents to the judges is sure to gain the cause, the judges themselves alleging the gratitude due for the bribes received as a reason: and if both parties happen to make presents of nearly equal value, they absolutely refuse to give the cause a hearing.

AXINOMANCY, Axinomantia, from ἀξίνη, *securis*, and μαντεία, *divinatio;* an ancient species of divination, or a method of foretelling future events by means of an ax or hatchet.—This art was in considerable repute among the ancients; and was performed, according to some, by laying an agate-stone on a red-hot hatchet; and also by fixing a hatchet on a round stake so as to be exactly poised; then the names of those that were suspected were repeated, and he at whose name the hatchet moved was pronounced guilty.

AXIOM, Axioma (from ἀξιόω, *I am worthy*); a self-evident truth, or a proposition whose truth every person perceives at first sight. Thus, that the whole is greater than a part; that a thing cannot be and not be at the same time; and that from nothing, nothing can arise; are axioms.

Axiom is also an established principle in some art or science. Thus, it is an axiom in physics, that nature does nothing in vain; that effects are proportional to their causes, &c. So it is an axiom in geometry, that things equal to the same thing are also equal to one another; that if to equal things you add equals, the sums will be equal, &c. It is an axiom in optics, that the angle of incidence is equal to the angle of reflection, &c.

AXIPOLIS, a town of the Triballi, in Mœsia Inferior; now *Axiopoli*, in Bulgaria. E. Long. 34. 0. N. Lat. 45. 40.

AXIS, in *Geometry*, the straight line in a plain figure, about which it revolves, to produce or generate a solid. Thus, if a semicircle be moved round its diameter at rest, it will generate a sphere, the axis of which is that diameter.

Axis, in *Astronomy*, is an imaginary right line supposed to pass through the centre of the earth and the heavenly bodies, about which they perform their diurnal revolutions.

Axis, in *Conic Sections*, a right line dividing the section into two equal parts, and cutting all its ordinates at right angles.

Axis, in *Mechanics*. The axis of a balance is that line about which it moves, or rather turns about. *Axis of oscillation*, is a right line parallel to the horizon, passing through the centre about which a pendulum vibrates.

Axis in Peritrochio, one of the six mechanical powers, consisting of a peritrochium or wheel concentric with the base of a cylinder, and moveable together with it about its axis.

Axis, in *Optics*, is that particular ray of light coming from any object which falls perpendicularly on the eye.

Axis, in *Architecture*. *Spiral axis*, is the axis of a twisted column drawn spirally in order to trace the circumvolutions without. *Axis of the Ionic capital*, is a line passing perpendicularly through the middle of the eye of a volute.

Axis of a Vessel, is an imaginary right line passing through the middle of it perpendicularly to its base, and equally distant from its sides.

Axis, in *Botany*, is a taper column placed in the centre of some flowers or catkins, about which the other parts are disposed.

Axis, in *Anatomy*, the name of the second vertebra of the neck; it hath a tooth which goes into the first vertebra, and this tooth is by some called the *axis*.

AXMINSTER, a town of Devonshire, situated on the river Ax, in the great road between London and Exeter, in W. Long. 3. 15. N. Lat. 50. 40. It was a place of some note in the time of the Saxons, and contained 2387 inhabitants in 1811. Here is a considerable manufactory of broad and narrow cloths, carpets, cotton tapes, druggets, and leather articles.

AXOLOTLF. See Lacerta.

AXUMA, formerly a large city, and capital of the whole kingdom of Abyssinia in Africa, but now reduced to a miserable village scarcely containing 100 inhabitants. E. Long. 36. 4. N. Lat. 14. 13.

AXUNGIA, in a general sense, denotes old lard, or the driest and hardest of any fat in the bodies of animals: but more properly it signifies only hog's lard.

Axungia Vitri, Sandiver, or *Salt of Glass*, a kind of salt which separates from the glass while it is in fusion. It is of an acrimonious and biting taste. The farriers use it for cleansing the eyes of horses. It is also made use of for cleansing the teeth; and it is sometimes applied to running ulcers, the herpes, or the itch, by way of desiccative.

AXYRIS. See Botany *Index*.

AY, a town of France, in the department of Marne, near the river Marne, remarkable for its excellent wines. E. Long. 3. 15. N. Lat. 49. 4.

AYAMONTE, a sea-port town of Andalusia in Spain, with a strong castle built on a rock; seated on the mouth of the river Guadiana. It has a commodious harbour, fruitful vineyards, and excellent wine. W. Long. 8. 5. N. Lat. 37. 9.

AYENIA. See Botany *Index*.

AYLESBURY. See Ailesbury. This place gave title of earl to the noble family of Bruce, now to a branch of the Brudenals by succession.

AYLMER, John, bishop of London, in the reign of Queen Elizabeth, was born in the year 1521, at Aylmer-hall in the parish of Tilney, in the county of Norfolk. Whilst a boy, he was distinguished for his quick parts by the marquis of Dorset, afterwards duke of Suffolk; who sent him to Cambridge, made him his chaplain and tutor to his children. One of these children was the unfortunate Lady Jane Gray, who soon became perfectly acquainted with the Latin and Greek languages. His first preferment was to the archdeaconry of Stow, in the diocese of Lincoln, which gave him a seat in the convocation held in the first year of Queen Mary, where he resolutely opposed the return to Popery, to which the generality of the clergy were inclined. He was soon after obliged to fly his country, and take shelter among the Protestants in Switzerland. On the accession of Queen Elizabeth, he returned to England. In 1562, he obtained the arch-

Digitized by Google

Aylmer, Ayr. deaconry of Lincoln; and was a member of the famous synod of that year, which reformed and settled the doctrine and discipline of the church of England. In the year 1576, he was consecrated bishop of London. He died in the year 1594, aged 73; and was buried in St Paul's. He was a learned man, a zealous father of the church, and a bitter enemy to the Puritans. He published a piece entitled, *An harbrowe for faithful and true subjects against the late blowne blaste concerning the government of women*, &c. This was written whilst he was abroad in answer to Knox, who published a book in Geneva under this title, *The first blast against the monstrous regiment and empire of women.* He is by Strype supposed to have published Lady Jane Gray's letter to Harding. He also assisted Fox in translating his History of Martyrs into Latin.

AYR, a royal borough, of great antiquity, and considerable extent, the county town of Ayrshire, and the seat of a justiciary court. It was erected into a royal borough by William the Lion, about the year 1180; and the privileges granted by that charter are still enjoyed by the town. It is pleasantly situated on a point of land, between the influx of the rivers Doon and Ayr into the Atlantic ocean. The principal street is a fine ornamented, broad, spacious way, with a row of elegant houses on each side. Its shape is somewhat of the form of a crescent, having the tolbooth and town-hall in the centre, with a fine spire, 135 feet high. In ancient times we find Ayr to have been a town of considerable trade. The merchants imported a great quantity of wine from France, and exported corn and other produce of the country. The rising trade of Glasgow proved very injurious to the trade of this town; but of late it has much revived. The sea shore is flat and shallow, and the entrance of the river Ayr, which forms the harbour, is subject to the inconvenience of a bar of sand, which is often thrown quite across the river, especially with a strong north-west wind. The water never rises above twelve feet; but from some improvements and extensive works now carrying on on the sides of the river, it is hoped the channel will be considerably deepened. There are erected two reflecting light-houses to conduct vessels safely into the harbour. There is great plenty of salmon in the two rivers, the fishings of which rent at upwards of 200l. Ship-building is carried on to a considerable extent, and about 60 vessels belong to the port, whose burden is nearly 6000 tons, and which are navigated by 500 seamen. The exports consist chiefly of cotton and woollen goods, pig-iron, coals; and the imports of grain, spirits, slates, &c. The trade is chiefly with Ireland. There is an extensive manufacture of leather and soap. Ayr was in ancient times, however, not only distinguished for trade, but also for military strength. Here the heroic exploits of Sir William Wallace began, and here Edward I. fixed one of his most powerful garrisons. Oliver Cromwell, too, judging it a proper place to build a fortress, took possession of the old church, and converted it and the neighbouring ground into a regular citadel. On one of the mounts, within the walls of this fortress, stood the old castle of Ayr, mentioned in ancient histories, and the old church, the tower of which still remains, noted for the meeting of the Scottish parliament, when Robert Bruce's title to the throne was unanimously confirmed. Ayr is a very gay and fashionable place. It has well-attended races, and is sometimes the seat of the Caledonian hunt. In 1801, the population amounted to 5560, and in 1811 to 6291. There is a strong chalybeate spring, which is famous in scrophulous and scorbutic complaints. Tradition reports an engagement to have taken place in the valley of Dalrymple, between two kings, Fergus and Coilus, in which both leaders lost their lives; the names of places in the neighbourhood seem derived from this circumstance, and a cairn of stones in the midst of the valley is said to point out the place of the engagement. History has only recorded two distinguished characters in literature, natives of Ayr: 1st, Joannes Scotus, surnamed *Erigena*, celebrated for his acumen of judgment, his readiness of wit, and fluency of elocution: and 2d, the Chevalier Ramsay, author of Cyrus's Travels, and other works. To these we may add the late Robert Burns, whose genius, at least, will bear a comparison with any of the former.

Ayr, Ayrshire. AYR, *Newton of.* While the borough of Ayr extends along the south side of the river Ayr, this small parish is situated on the north side of the same river. It is a burgh of considerable domain, having in that domain baronial jurisdiction; governed by a magistracy elected by freemen, but not having parliamentary representation. It is of very ancient erection, owing its privileges to Robert Bruce, who upon being attacked with leprosy, came to reside in this place, and was induced to establish a lazar-house, and to confer considerable favours on the town, and on the small village of Priestwick, about two or three miles distant. In the Newton of Ayr are a number of very good houses. It has a tolerable good harbour, chiefly employed in the coal trade. Lying on the banks of Ayr, and the sea coast, the soil is mostly flat and sandy. Its extent is about three miles long, and one and a half broad. In 1811, the population was 2809.

AYR, a river in the parish of Muirkirk, in Ayrshire; which after a course of about eighteen miles nearly due west falls into the sea at Ayr, where its æstuary forms a fine harbour. It is for a considerable course only a small rivulet; but joined by the Greenock and Garpel, tributary streams, it becomes a large body of water. It frequently shifts its bed, and does considerable damage by its encroachments. Its banks are steep and very romantic, and the number of seats which ornament them present a fine picturesque scenery. Sorn-castle, Auchincruive, and Auchinleck, may be mentioned as the chief beauties of the scene. The village of Catrine is situated on its banks. It forms the boundary between the districts of Ayrshire, denominated Kyle and Carrick.

AYRSHIRE, a county of Scotland, which is bounded on the north by the county of Renfrew; on the east by the shires of Lanark and Dumfries; on the south by Galloway; and on the west by the Irish channel, and the frith of Clyde. Its extent in length is about 80 miles, and about 30 in breadth. It is divided into three great districts or stewarties, which bear the names of Kyle, Cunningham, and Carrick. These divisions are not altogether artificial; the river Doon forming the separation between Carrick and Kyle (or Ayrshire Proper), and the river Irvine (at the mouth of which is a borough of the same name) is the limit between Kyle and Cunningham. These

Digitized by Google

These districts are very different from each other in appearance. Carrick, and the interior parts of Kyle, are mountainous, and more fitted for pasture; while the coast of Kyle, and the greater part of Cunningham, exhibit a fine level country, interspersed with numerous villages and towns. The sea coast is mostly sandy, with sunk rocks, possessing several good harbours. The island of Ailsa is in this county. From the ridge, of which the mountains of Carrick are a part, rise almost all the rivers of the south of Scotland. The Tweed, the Esk, the Nith, the Annan, the Urr, &c. flow to the east and south, while the Stinchar, the Girvan, the Doon, the Ayr, and the Lugar, pouring into the Irish channel, intersect the county of Ayr with their copious streams. Besides these, the Irvine and other smaller rivulets, water the more northerly parts of the county. Ayrshire has two royal boroughs, viz. Ayr and Irvine; and several populous towns and villages, of which Kilmarnock, Beith, Saltcoats, Kilwinning, Largs, Girvan, and Ballantrae, are the chief. Fitted as Ayrshire is in every respect for the carrying on of trade, and the extension of agricultural improvements, it is only of late years that much has been done in that way. Possessing valuable seams of excellent coal, and enriched with the returns from its exportation, little attention was paid to the culture of the ground. The establishment of the Douglas and Heron Bank, though ruinous to the proprietors, contributed greatly to promote the improvement of Ayrshire. The abundance of wealth which it fallaciously seemed to pour into the country, and the ready command of money it gave, set all the proprietors towards improving and planting their estates, furnished means for raising and burning lime for manure, and above all, with the money from the bank, canals and roads were opened through every part of the county. Upon the failure of that extravagant and ill-conducted speculation, the proprietors of many estates saw their property brought to the hammer, and the greater part of their lands purchased by new proprietors. The Ayrshire breed of cattle is much esteemed; and a particular district is celebrated for cheese. In 1808 the real rent of the county was 314,673l.; the valued rent, according to an old estimate by which certain taxes are imposed, is 191,605l. There are in the county considerable woollen manufactures. In the parish of Beith there are 70 mills for spinning thread; and the various branches of the cotton manufactures are carried on in many parts to a great extent. At Muirkirk there are extensive iron-works. Ayrshire, besides the inexhaustible seams of coal with which it abounds, possesses several other valuable minerals; as freestone, limestone, iron-stone, several rich ores of lead and copper. A few curious specimens are also to be found in the hills of Carrick, of agates, porphyries, and of calcareous petrifactions. In the parishes of Stair and New Cumnock, galena and plumbago have been found; and in several parts of the county is found that species of whetstone known by the name of *Ayrstone*. There is plenty of marl in most of the lochs; the chief of which is Loch Doon, from which the river of that name takes its rise. There is annually a great quantity of sea-weed thrown ashore, from which many tons of kelp are made. All the rivers of Ayrshire abound with salmon, and the coasts are admirably adapted for the white fishing.

The following is a statement of the population of this county at two different periods.

	Parishes.	Population in 1755.	Population in 1790—98.
	Ardrossan	1297	1518
	Auchinleck	887	775

Population in 1811, 103,954. See AYRSHIRE, SUPPLEMENT.

AYRY, or AERY, *of Hawks*, a nest or company of hawks; so called from the old French word *aire*, which signified the same.

AYSCUE, SIR GEORGE, a gallant English admiral, descended from a good family in Lincolnshire. He obtained the honour of knighthood from King Charles I. which, however, did not withhold him from

Digitized by Google

adhering to the parliament in the civil war: he was by them constituted admiral of the Irish seas, where he is said to have done great service to the Protestant interest, and to have contributed much to the reduction of the whole island. In 1651 he reduced Barbadoes and Virginia, then held for the king, to the obedience of the parliament: and soon after the Restoration behaved with great honour in the war with the Dutch. In the famous engagement in the beginning of June 1666, when Sir George was admiral of the white squadron, his ship the Royal Prince ran upon the Gallop-sand; where, being surrounded with enemies, his men obliged him to strike. He went no more to sea after this, but spent the rest of his days in retirement.

AYMOUTH. See EYMOUTH.

AYTONIA. See BOTANY *Index*.

AZAB, in the Turkish armies, a distinct body of soldiery, who are great rivals of the Janizaries.

AZAI, a town of Touraine in France, seated on the river Indre. E. Long. 10. 35. N. Lat. 47. 18.

AZALEA, AMERICAN UPRIGHT HONEYSUCKLE. See BOTANY *Index*.

AZAMOR, a small sea-port town of the kingdom of Morocco in Africa. It is situated on the river Morbeya, in the province of Duguella, at some considerable distance from its mouth. This town, though formerly very considerable, is not proper for maritime commerce, because the entrance of the river is dangerous. It was unsuccessfully besieged by the Portuguese in 1508; it was taken, however, in 1513, by the duke of Braganza, but abandoned about the end of the 16th century. W. Long. 7. 0. N. Lat. 32. 50.

AZARAKITES, a sect of Mahometan Arabs. See ARABIA, N° 143, *et seq.*

AZARIAH, or UZZIAH, a king of Judah, succeeded his father Amaziah, 810 years before Christ. He assembled an army of above 300,000 men, with which he conquered the Philistines, and demolished the walls of Gath, Jabniel, and Ashdod; built up the walls of Jerusalem; furnished the city with conduits; and planted gardens and vineyards: but at last, being elated with his prosperity, and resolving to usurp the office of high-priest, he was struck with a leprosy, which obliged him to remain shut up in his palace for the rest of his days. He died about 759 years before the Christian era, and was succeeded by Jotham his son.—There are several other persons of this name mentioned in the sacred Scriptures.

AZAZEL. The word relates to the history of the scape-goat, under the Jewish religion. Some call the goat itself by this name, as St Jerome and Theodoret. Dr Spenser says, the scape-goat was to be sent to Azazel; by which is meant the devil. Mr Le Clerc translates it *præcipitium*, making it to be that steep and inaccessible place to which the goat was sent, and where it was supposed to perish.

AZEKA, in *Ancient Geography*, a city of the Amorites, in the lot of Judah; situated between Eleutheropolis and Ælia (Jerome); where the five kings of the Amorites and their army were destroyed by hailstones from heaven, (Joshua).

AZEM, ASEM, ASSAM, or ACHAM, a country of Asia to the north of Ava, but which is very little known to Europeans. It is said to be very fertile, and to contain mines of gold, silver, iron, and lead, all which belong to the king, who, in consequence of enjoying the produce, requires no taxes from his people. They have also great quantities of gum lac, and coarse silk. It is also thought that the inhabitants of Azem were long ago the inventors of cannon and gun-powder; and that from them the invention passed to the inhabitants of Pegu, and from thence to the Chinese.

AZIMUTH, in *Astronomy*, an arch of the horizon, intercepted between the meridian of the place and the azimuth, or vertical circle passing through the centre of the object, which is equal to the angle of the zenith, formed by the meridian and vertical circle: or it is found by this proportion, As the radius to the tangent of the latitude of the place, so is the tangent of the sun's or star's altitude, for instance, to the cosine of the azimuth from the south, at the time of the equinox.

Magnetical AZIMUTH, an arch of the horizon intercepted between the azimuth, or vertical circle, passing through the centre of any heavenly body and the magnetical meridian. This is found by observing the object with an azimuth-compass.

AZIMUTH-Compass, an instrument for finding either the magnetical azimuth or amplitude of a heavenly object.

The learned Dr Knight invented some time since a very accurate and useful sea-compass, which is at present used in the navy. This instrument, with another invented by the ingenious Mr Smeaton, answers the purposes of an azimuth amplitude compass. See COMPASS.

AZIMUTH Circles, called also *azimuths*, or *vertical circles*, are great circles of the sphere intersecting each other in the zenith and nadir, and cutting the horizon at right angles. These azimuths are represented by the rhumbs on common sea-charts, and on the globe they are represented by the quadrant of altitude, when screwed in the zenith. On these azimuths is reckoned the height of the stars and of the sun when not in the meridian.

AZMER, or AJMEER, a town of the East Indies, capital of a province of the same name, with a very strong castle. It is about 62 leagues west from Agra. The principal trade of this province is in saltpetre. It was in this city that Sir Thomas Rowe had the honour of being introduced to the great Mogul in 1716.

AZOGA SHIPS, are those Spanish ships commonly called the *quicksilver ships*, from their carrying quicksilver to the Spanish West Indies, in order to extract the silver out of the mines of Mexico and Peru. These ships, strictly speaking, are not to carry any goods unless for the king of Spain's account.

AZONI, in ancient mythology, a name applied by the Greeks to such of the gods as were deities at large, not appropriated to the worship of any particular town or country, but acknowledged in general by all countries, and worshipped by every nation. These the Latins called *dii communes*. Of this sort were the Sun, Mars, Luna, &c.

AZORES, islands in the Atlantic ocean, lying between 25 and 33 degrees of west longitude, and between 36 and 40 degrees of north latitude. They belong to the Portuguese, and are also called the

Digitized by Google

Western Isles, on account of their situation. They were discovered by the Flemings in the 15th century. They are seven in number. See AZORES, SUPPLEMENT.

AZOTH, in *Ancient Chemistry*, the first matter of metals, or the mercury of a metal; more particularly that which they call the *mercury of philosophers*, which they pretended to draw from all sorts of metallic bodies.

AZOTUS, AZOTH, or ASHDOD, one of the five cities of the Philistines, and a celebrated sea-port on the Mediterranean, situated about 14 or 15 miles south of Ekron, between that and Ascalon. It was in this city that the idol Dagon fell down before the ark: and so strong a place it was, if we may believe Herodotus, that it sustained a siege of 29 years by Psammeticus king of Egypt. It was, however, taken by the Maccabees in a much shorter time; who burnt both the city and temple, and with them about 1000 men. The town is now called by the Arabs *Aasaneyun*. It is but thinly inhabited, though the situation is very pleasant: with regard to the houses, those that were built in the time of Christianity, and which are now inhabited by Mahometans, still preserve some claim to admiration; but the modern buildings, though generally of stone, have nothing in them which can attract the notice of a traveller. The streets are pretty broad, the inhabitants mostly Mahometans, with a few Christians of the Greek communion, who have a church under the jurisdiction of the archbishop of Gaza. The town is about a mile and a half in circumference; and has in it a mosque, a public bath, a market-place, and two inns. The number of the inhabitants is between two and three thousand. The most remarkable things in this place are an old structure with fine marble pillars, which the inhabitants say was the house that Sampson pulled down; and to the south-east, just out of the town, the water in which the eunuch Candace was baptized by the apostle Philip: besides these two, there are several ancient buildings, with capitals and pillars standing.

AZURE, in a general sense, the blue colour of the sky. See SKY and BLUE.

AZURE, among painters. This word, which at present signifies in general a fine blue colour, was formerly applied to *lapis lazuli*, called *azure stone*, and to the blue prepared from it. But since a blue has been extracted from cobalt, custom has applied to it the name of *azure*, although it differs considerably from the former, and is incapable of being used for the same purposes, and particularly for painting in oil. The former at present is called *lapis lazuli*, or only *lapis*; and the blue prepared from it for painting in oil, is called *ultramarine*.—The name *azure* is generally applied to the blue glass made from the earth of cobalt and vitrifiable matters. This glass, which is called *smalt* when in masses, is called *azure* only when it is reduced to a fine powder. Several kinds of azure are distinguished, according to its degrees of beauty, by the names of *fine azure*, *powdered azure*, and *azure of four fires*. In general, the more intense the colour, and the finer the powder, the more beautiful and dear it is. Azure is employed to colour starch; hence it has also been called *starch blue*. It is used for painting with colours, and for a blue enamel.

AZURE, in *Heraldry*, the blue colour in the arms of any person below the rank of a baron. In the escutcheon of a nobleman, it is called *sapphire*; and in that of a sovereign prince, *Jupiter*. In engraving, this colour is expressed by lines or strokes drawn horizontally.—This colour may signify Justice, Perseverance, and Vigilance; but according to G. Leigh, when compounded with

Or	it signifies	Cheerfulness.
Arg.		Vigilance.
Gul.		Readiness.
Ver.		Enterprise.
Pur.		Goodness.
Sab.		Mournfulness.

The French heralds, *M. Upton*, and his followers, rank this colour before gules.

AZYGOS, in *Anatomy*, a vein rising within the thorax, on the right side, having no fellow on the left; whence it is called *azygos*, or *vena sine pari*.

AZYMITES, in church history, Christians who administer the eucharist with unleavened bread. The word is formed from the Greek α priv. and ζυμη, *ferment*.—This appellation is given to the Latin by the Greek church, because the members of the former use fermented bread in the celebration of the eucharist. They also call the Armenians and Maronites by the same name, and for the same reason.

AZYMOUS, something unfermented, or made without leaven; as unleavened bread. Sea biscuit is of this kind; and therefore, according to Galen, less wholesome than bread that has been fermented.

B.

B, THE second letter of the English and most other alphabets. It is the first consonant, and first mute, and its pronunciation is supposed to resemble the bleating of a sheep; upon which account Pierius tells us in his hieroglyphics, that the Egyptians represented the sound of this letter by the figure of that animal.

B is also one of those letters which the eastern grammarians call *labial*, because the principal organs employed in its pronunciation are the lips. It is pronounced

Digitized by Google

ced by pressing the whole length of them together, and forcing them open with a strong breath. It has a near affinity with the other labials P and V, and is often used for P both by the Armenians and other orientals, as in *Betrus* for *Petrus*, *apsens* for *absens*, &c. and by the Romans for V, as in *amabit* for *amavit*, *berna* for *verna*, &c. whence arose that jest of Aurelian on the emperor Bonosus, *Non ut vivat natus est, sed ut bibat.*

Plutarch observes, that the Macedonians changed φ into B, and pronounced *Bilip*, *Berenice*, &c. for *Philip*, *Pherenice*, &c.; and those of Delphos used B instead of Π, βαθειν for παθειν, βικρον for πικρον, &c.—The Latins said *suppono*, *oppono*, for *subpono*, *obpono*; and pronounced *optinuit*, though they wrote *obtinuit*, as Quintilian has observed.—They also used B for F or PH: thus, in an ancient inscription mentioned by Gruter, OBRENDARIO is used for OFRENDARIO.

As a numeral, B was used by the Greeks and Hebrews to denote 2; but among the Romans for 300, and with a dash over it (thus $\bar{B}$) for 3000.

B is also used as an abbreviation. Thus B. A. stands for bachelor of arts; B. L. for bachelor of laws; and B. D. for bachelor of divinity. B. F. in the preface to the decrees or senatus consulta of the old Romans, signified *bonum factum*. In music, B stands for the tone above A; as B♭, or ♭B, does for B flat, or the semitone major above A. B also stands for bass; and B. C. for *basso continuo*, or thorough-bass.

BAAL, the same as BEL, or BELUS; an idol of the Chaldeans, and Phœnicians or Canaanites. The former worshipped Mars under this name, according to Josephus *; who, speaking of Thurus the successor of Ninus, says, "To this Mars the Assyrians erected the first statue, and worshipped him as a god, calling him *Baal*." It is probable the Phœnicians worshipped the sun under the name of Baal; for Josiah, willing to make some amends for the wickedness of Manasseh, in worshipping Baal, and all the host of heaven, *put to death the idolatrous priests that burnt incense unto Baal, to the sun, and to the moon, and to the planets, and to all the host of heaven. He likewise took away the horses that the kings of Judah had given to the sun, and burnt the chariots of the sun with fire* †.

* *Antiquit.* lib. viii. cap. 7.

† 2 Kings xxiii. 5. 11.

The temples consecrated to this god, are called in the Scripture *Chamanim*, which signifies *places enclosed with walls* in which was kept a perpetual fire. Maundrell, in his journey from Aleppo to Jerusalem, observed some traces of these enclosures in Syria. In most of them were no statues; in a few there were some, but of no uniform figure.

The word *baal* (in the Punic language), signifies *lord* or *master*; and doubtless meant the supreme Deity, the Lord and Master of the universe. It is often joined with the name of some false god, as *Baal-berith*, *Baal-peor*, *Baal-zephon*, and the like. This deity passed from the Phœnicians to the Carthaginians, who were a colony of the Phœnicians; as appears from the Carthaginian names, Hannibal, Asdrubal, &c. according to the custom of the east, where kings and great men added to their own names those of their gods.

This false deity is frequently mentioned in Scripture in the plural number (*Baalim*); which may signify, either that the name *Baal* was given to several different gods; or that there were many statues, bearing different appellations, consecrated to this idol. Arnobius tells us, that Baal was of an uncertain sex; and that his votaries, when they called upon him, invoked him thus: *Hear us, whether thou art a god or a goddess.*

Some learned men think, that the Baal of the Phœnicians is the Saturn of the Greeks; which is probable enough from the conformity there is between the human sacrifices offered to Saturn and those which the Scripture tells us were offered to Baal. Others are of opinion, that Baal was the Phœnician or Tyrian Hercules, a god of great antiquity in Phœnicia.

BAAL-BERITH, the god of the Shechemites. Bochart conjectures, that Berith is the same as *Beroe*, the daughter of Venus and Adonis, who was given in marriage to Bacchus; and that she gave her name to the city of Berith in Phœnicia, and became afterwards the goddess of it. Baal-berith, signifies *Lord of the covenant*, and may be taken for the god who presides over alliances and oaths, in like manner as the Greeks had their Ζευς ορκιος, and the Romans their *Deus Fidius*, or *Jupiter Pistius*. The idolatrous Israelites, we are told, *made Baal-berith their god*, Judg. viii. 33.

BAAL-PEOR, *Baal-phegor*, or *Beel-phegor*, an idol of the Moabites and Midianites. We are told, that *Israel joined himself to Baal-peor*; and that Solomon erected an altar to this idol upon the mount of Olives. Baal-peor has been supposed to be no other than a Priapus, and that the worship of him consisted in the most obscene practices. Others have thought, that as Baal is a general name signifying *Lord*, Peor may be the name of some great prince deified after his death. Mede imagines that *Peor* being the name of a mountain in the country of Moab, on which the temple of Baal was built, Baal-peor may be only another name of that deity, taken from the situation of his temple; in like manner as Jupiter is styled *Olympius*, because he was worshipped in a temple built on Mount Olympus. Selden, who is of this latter opinion, conjectures likewise that Baal-peor is the same with Pluto; which he grounds upon these words of the Psalmist *, *They joined themselves unto Baal-peor, and ate the offerings of the dead;* though by the *sacrifices* or *offerings of the dead*, in this passage, may be meant no more than sacrifices or offerings made to idols, or false gods, who are very properly called *the dead*, in contradistinction to the true God, who is styled in Scripture the *living God*.

* Ps. cvi.

BAAL-ZEBUB, *Beel-zebub*, or *Belzebub*; the idol, or god, of the Ekronites. In Scripture he is called the *Prince of Devils*. His name is rendered the *Lord of flies*, or the *God fly*; which some think was a mock appellation bestowed on him by the Jews. He had a famous temple and oracle at Ekron. Ahaziah king of Israel, having fallen from the terrace of his house into a lower room, and being dangerously hurt, sent to consult this deity, to know if he should be cured of his wounds. The worship of this false god must have prevailed in our Saviour's time, since the Jews accused him of driving out devils in the name of *Belzebub* their prince. Scaliger derives the name of this deity from *Baalim-zebahim*, which signifies the *Lord of sacrifices*.

BABBLING, among hunters, is when the hounds are too busy after they have found a good scent.

BABEL, a city and tower undertaken to be built by

Digitized by Google

by the whole human race soon after the flood, and remarkable for the miraculous frustration of the attempt by the confusion of languages. As to the situation of ancient Babel, most authors are of opinion that it was exactly in the place where the celebrated city of Babylon afterwards stood. That it was in the same country, appears indisputably from Scripture; but that it was exactly in the same place is what cannot be proved, nor is it a matter of any consequence.

Authors have been much divided about the motive by which the whole race of mankind were induced to join as one man in such an undertaking. Some have imagined that it was out of fear of a second deluge; others, that they knew beforehand that they were to be dispersed through all the different countries of the world, and built this tower in order to defeat the design of the Deity, because having a tower of such vast height as they proposed, those who were at a distance could easily find their way back again. Had either of these been their design, however, it is probable they would have chosen an eminence rather than a plain for the situation of their tower, or indeed that they would have chosen some high mountain, such as Ararat, for their mark, rather than any tower at all: for though it is said that they designed the top of their tower to reach to heaven, we can scarcely suppose them to have been so absurd, as to imagine this possible in the sense we understand it; and must therefore rather take it in the limited sense in which it is often used by Moses and his countrymen, where they speak of cities walled up to heaven. Others there are who imagine that the top of this tower was not to reach up to heaven, but to be consecrated to the heavens, i. e. to the worship of the sun, moon, and stars; of the fire, air, &c. and other natural powers, as deities; and therefore that the true Deity interposed in order to prevent a total and irrecoverable defection. Certain it is, that the species of idolatry which takes for the objects of its worship those natural agents, as it is the most ancient, so it is by far the most rational, and the most difficult to be disproved. It is much more difficult, for instance, to prove that the sun, which by his enlivening beams gives vigour to the whole creation, is not a deity, than that a log of wood is not one: and hence if such a system of religion became universally established among mankind, it would be impossible ever afterwards to eradicate it. Indeed, that the scheme of Babel, whatever it was, could have been put into execution by man, seems evident from the interposition of the Deity on the occasion; for we cannot suppose that he would have worked a miracle on purpose to defeat that which would have defeated itself if he had let it alone: and he expressly says, That now nothing could be restrained from them; which intimates very plainly, that, had this scheme gone on, the plan which God had laid for the government of the world would have been totally frustrated: and agreeable to this hypothesis Dr Tennison supposes that the tower was of a pyramidal form, in imitation of the spires of flame; and that it was erected in honour of the sun, as being the most probable cause of drying up the flood.

As to the materials made use of in the building of this tower, the Scripture informs us that they were bricks and slime or bitumen. According to an eastern tradition, three years were taken up in making the bricks, each of which was 13 cubits long, 10 broad, and five thick. Oriental writers say, that the city was 313 fathoms in length, and 151 in breadth; that the walls were 5533 fathoms high, and 33 in breadth; and that the tower itself was no less than 10,000 fathoms, or 12 miles high. Even St Jerome affirms from the testimony of eye-witnesses, who, as he says, had examined the remains of the tower, that it was four miles high; but Ado makes the height to have been no less than 5000 miles. The only account of its dimensions which can be at all depended upon (supposing it to have been the same which afterwards stood in the midst of the city of Babylon, and round which Nebuchadnezzar built the temple of Belus), is that given under the article BABYLON.

BABEL MANDEL, the GATE OF MOURNING; a famous strait in the Indian ocean, between the coast of Arabia Felix in Asia, and that of Adel and Zeila in Africa, at the entrance into the Red sea. By some it is also called the *straits of Moka*. It is narrow, and difficult to sail through, on account of the sand banks. At the mouth of the strait is a small island called also *Babel Mandel*, which is little else than a barren rock. E. Long. 44. 30. N. Lat. 12. 40.

BABENHAUSEN, a town of Bavaria, 16 miles SE. from Ulm. E. Long. 9. 16. N. Lat. 48. 39.

BABINA, COMMONWEALTH OF, a society ludicrously so called, which was founded in Poland in the reign of Sigismund Augustus, in the 16th century. It took its rise from a set of gentlemen, inhabitants of Lublin, who had agreed to meet at a place called *Babina*, merely for the purposes of mirth and jollity. In time their number increased, and they formed themselves into a regular government, under the presidency of a king, senate, and chief magistrate. The magistrates were elected from something which appeared ridiculous in the character or conduct of any of the members. For instance, if any person was meddling or officious, he was immediately created an archbishop; a blundering or disputatious member was promoted to the speaker's chair; a boaster of his own courage, and vain-glorious *Thraso*, was honoured with the commission of generalissimo, which was presented him with great ceremony by the subordinate heroes. Those who declined the office for which they were declared qualified were persecuted with hissings, and abandoned by the society. Thus every vice and every foible was attacked with ridicule; and Babina became in a short time the terror, the admiration, and the reformer of the Polish nation: genius flourished, wit was cultivated, and the abuses which had crept into government and society were corrected by the judicious application of good-humoured satire. Never did any institution of this nature become so general or so useful; but at length it degenerated into a set of buffoons, and banterers of every thing sacred or profane. For several years it was patronized by the kings of Poland, and Sigismund himself became a member; the starosta of Babina telling him jocularly, that "his majesty had certain qualities which entitled him to the first dignity in the commonwealth." Not the least remnant of the society now remains, though it was honoured with extraordinary privileges by kings and emperors.

BABINGTON, GERVASE, bishop of Worcester, was

Digitized by Google

was born, according to Fuller, in Nottinghamshire; but in what year is uncertain. He was sent to Trinity College, Cambridge, of which he was made fellow; and, in 1578, was incorporated master of arts at Oxford. He appears, however, to have made Cambridge the place of his residence, where he became an eminent preacher; and, being now doctor in divinity, was made domestic chaplain to Henry earl of Pembroke. In this station he is supposed to have assisted the countess in her translation of the Psalms. In 1588 he was installed prebend of Hereford, and in 1591 consecrated bishop of Landaff. In 1594 he was translated to the see of Exeter, and thence to Worcester in 1597. About this time, or soon after, he was made queen's counsel for the marches of Wales. He was a considerable benefactor to the library belonging to the cathedral of Worcester, where he was buried in May 1610 without a monument. The several historians who have mentioned this prelate agree in giving him the character of a learned and pious man. His writings, like those of most of his cotemporaries, abound with puns and quaint expressions. His works were printed both in folio and quarto in 1615, and again in folio in 1637, under this title: *The works of the right reverend father in God Gervase Babington, late bishop of Worcester, containing comfortable notes upon the five books of Moses, viz. Genesis, &c. As also an exposition upon the Creed, the Ten Commandments, the Lord's Prayer; with a conference betwixt man's frailtie and faith, and three sermons, &c.*

BABOON, in *Zoology*. See SIMIA, MAMMALIA *Index*.

BABYLON, the capital of the ancient kingdom of Babylonia or Chaldea, and supposed to have stood in E. Long. 44. 0. N. Lat. 32. 0. Semiramis is said by some, and Belus by others, to have founded this city. But, by whomsoever it was founded, Nebuchadnezzar was the person who put the last hand to it, and made it one of the wonders of the world. The most famous works in and about it were the walls of the city, the temple of Belus, Nebuchadnezzar's palace, the hanging gardens, the banks of the river, the artificial lake, and canals.

1 City described.

The city was surrounded with walls, in thickness 87 feet, in height 350 feet, and in compass 480 furlongs or 60 of our miles. Thus Herodotus, who was himself at Babylon; and though some disagree with him in these dimensions, yet most writers give us the same, or nearly the same, as he does. Diodorus Siculus diminishes the circumference of these walls very considerably, and takes somewhat from the height of them, as in Herodotus; though he seems to add to their breadth, by saying, that six chariots might drive abreast thereon: while the former writes, that one chariot only might turn upon them; but then he places buildings on each side of the top of these walls, which, according to him, were but one story high; which may pretty well reconcile them together in this respect. It is observed, that those who give the height of these walls but at 50 cubits, speak of them only as they were after the time of Darius Hystaspis, who caused them to be beaten down to that level. These walls formed an exact square, each side of which was 120 furlongs, or 15 miles, in length; and were all built of large bricks cemented together with bitumen, which in a short time grows harder than the very brick and stone which it cements. The city was encompassed, without the walls, with a vast ditch filled with water, and lined with bricks on both sides; and as the earth that was dug out of it served to make the bricks, we may judge of the depth and largeness of the ditch from the height and thickness of the walls. In the whole compass of the wall there were 100 gates, that is, 25 on each of the four sides, all made of solid brass. Between every two of these gates, at proper distances, were three towers, and four more at the four corners of this great square, and three between each of these corners and the next gate on either side, and each of these towers was ten feet higher than the walls. But this is to be understood only of those parts of the walls where towers were needful for defence. For some parts of them being upon a morass, and inaccessible by an enemy, there the labour and cost was spared, which, though it must have spoiled the symmetry of the whole, must be allowed to have savoured of good economy; though that is what one would not have expected from a prince who had been so determined, as Nebuchadnezzar must have been, to make the city complete both for strength and beauty. The whole number, then, of these towers amounted to no more than 250; whereas a much greater number would have been necessary to have made the uniformity complete all round. From each of the 25 gates on each side of the square, there was a straight street, extending to the corresponding gate in the opposite wall; whence the whole number of the streets must have been but 50; but then they were each about 15 miles long, 25 of them crossing the other 25 exactly at right angles. Besides these whole streets, we must reckon four half streets, which were but rows of houses facing the four inner sides of the walls. These four half streets were properly the four sides of the city within the walls, and were each of them 200 feet broad, the whole streets being about 150 of the same. By this intersection of the 50 streets, the city was divided into 676 squares, each of four furlongs and a half on each side, or two miles and a quarter in compass. Round these squares, on every side towards the streets, stood the houses, all of three or four stories in height, and beautified with all manner of ornaments: and the space within each of these squares was all void, and taken up by yards, or gardens, and the like, either for pleasure or convenience.

A branch of the Euphrates divided the city into two, running through the midst of it, from north to south; over which, in the very middle of the city, was a bridge, a furlong in length, or rather more; and indeed much more, if we hearken to others, who say it was no less than five stades or furlongs in length, though but 30 feet broad, a difference we shall never be able to decide. This bridge, however, is said to have been built with wonderful art, to supply a defect in the bottom of the river, which was all sandy. At each end of this bridge were two palaces: the old palace on the east side, the new one on the west side of the river; the former of which took up four of the squares abovementioned, and the latter nine. The temple of Belus, which stood next to the old palace, took up another of the same squares.

The whole city stood in a large flat or plain, in a very fat and deep soil: that part or half of it on the east

Digitized by Google

Babylon. east side of the river was the old city, and the other on the west was added by Nebuchadnezzar, both being included within the vast square bounded by the walls aforesaid. The form of the whole was seemingly borrowed from Nineveh, which was also 480 furlongs; but though it was equal in dimensions to this city, it was less with respect to its form, which was a parallelogram, whereas that of Babylon was an exact square. It is supposed, that Nebuchadnezzar, who had destroyed that old seat of the Assyrian empire, proposed that this new one should rather exceed it; and that it was in order to fill it with inhabitants, that he transported such numbers of the captives from other countries hither; though that is what may be disputed, seeing he therein only followed the constant practice of the kings of Assyria, who thought this the most certain means of ensuring their conquests either to themselves or their posterity.

2 Was never fully peopled.

But it plainly appears, that it was never wholly inhabited; so that, even in the meridian of its glory, it may be compared with the flower of the field, which flourishes to-day, and to-morrow is no more. It never had time to grow up to what Nebuchadnezzar visibly intended to have made it; for, Cyrus removing the seat of the empire soon after to Shushan, Babylon fell by degrees to utter decay: yet it must be owned, that no country was better able to support so vast and populous a city, had it been completed up to its first design. But so far was it from being finished according to its original design, that, when Alexander came to Babylon, Q. Curtius tells us, "No more than 90 furlongs of it were then built:" which can be no otherwise understood than of so much in length; and, if we allow the breadth to be as much as the length (which is the utmost that can be allowed), it will follow, that no more than 8100 square furlongs were then built upon: but the whole space within the walls contained 14,400 square furlongs; and therefore there must have been 6300 square furlongs remaining unbuilt, which, Curtius tells us, were ploughed and sown. And, besides this, the houses were not contiguous, but all built with a void space on each side, between house and house.

3 Temple of Belus.

The next great work of Nebuchadnezzar was the temple of Belus. The wonderful tower, however, that stood in the middle of it, was not his work, but was built many ages before; that, and the famous tower of Babel, being, as is commonly supposed, one and the same structure. This tower is said to have been composed of eight pyramidal ones raised above one another, and by Herodotus said to have been a furlong in height; but as there is an ambiguity in his expression, it has been disputed whether each of the towers was a furlong in height, or the whole of them taken together. On the latter supposition, which is the most probable, this tower must have exceeded the highest of the Egyptian pyramids by 179 feet, though it fell short of its breadth at the basis by 33. The way to go up was by stairs on the outside round it; whence it seems most likely, that the whole ascent was, by the benching in, drawn in a sloping line from the bottom to the top eight times round it; and that this made the appearance of eight towers, one above the other. Till the times of Nebuchadnezzar, it is thought this tower was all the temple of Belus; but as he did by the other ancient buildings of the city, so he did by this, making great additions thereto, by vast edifices erected round it, in a square of two furlongs on every side, and just a mile in circumference, which exceeded the square at the temple of Jerusalem by 1800 feet. On the outside of these buildings was a wall which enclosed the whole; and, in consideration of the regularity wherewith this city was to all appearance marked out, it is supposed, that this wall was equal to the square of the city wherein it stood, and so is concluded to have been two miles and a half in circumference. In this wall were several gates leading into the temple, and all of solid brass; which it is thought may have been made out of the brazen sea, and brazen pillars, and other vessels and ornaments of the kind, which Nebuchadnezzar had transported from Jerusalem; for in this temple he is said to have dedicated his spoils from that of Jerusalem.

4 Idols of gold, &c.

In this temple were several images or idols of massy gold, and one of them, as we have seen, 40 feet in height; the same, as supposed, with that which Nebuchadnezzar consecrated in the plains of Dura. For though this last is said to have been 60 cubits, or 90 feet high, these dimensions appear so incredible, that it has been attempted to reconcile them into one, by supposing, that in the 90 feet the height of the pedestal is included, and that the 40 feet are for the height of the statue without the pedestal; and being said to have weighed 1000 talents of Babylon, it is thence computed, that it was worth three millions and a half of our money. In a word, the whole weight of the statues and decorations, in Diodorus Siculus, amounting to 5000 and odd talents in gold, the whole is estimated at above 21,000,000l. of our money; and a sum about equal to the same, in treasure, utensils, and ornaments, not mentioned, is allowed for.

Next to this temple, on the east side of the river, stood the old palace of the kings of Babylon, being four miles in circumference. Exactly opposite to it, on the other side of the river, was the new palace built by Nebuchadnezzar, eight miles in circumference, and consequently four times as big as the old one.

5 Hanging gardens.

But nothing was more wonderful at Babylon than the hanging-gardens, which Nebuchadnezzar made in complaisance to his wife Amyte; who, being a Mede, and retaining a strong inclination for the mountains and forests of her own country, was desirous of having something like them at Babylon. They are said to have contained a square of four plethra, or 400 feet, on each side; and to have consisted of terraces one above another, carried up to the height of the wall of the city, the ascent from terrace to terrace being by steps ten feet wide. The whole pile consisted of substantial arches upon arches, and was strengthened by a wall surrounding it on every side, 22 feet thick; and the floors on each of them were laid in this order: First, on the tops of the arches was laid a bed or pavement of stones 16 feet long, and four feet broad; over this was a layer of reed mixed with a great quantity of bitumen; and over this two courses of brick, closely cemented together with plaster; and over all these were thick sheets of lead, and on these the earth or mould of the garden. This floorage was designed to retain the moisture of the mould; which was so deep, as to give root to the greatest trees which were planted upon

Babylon. on every terrace, together with great variety of other vegetables pleasing to the eye. Upon the uppermost of these terraces was a reservoir, supplied by a certain engine with water from the river, from whence the gardens on the other terraces were supplied.

6 Banks of the river, canals, &c. The other works attributed to Nebuchadnezzar by Berosus and Abydenus, were the banks of the river, the artificial canals, and the great artificial lake said to have been sunk by Semiramis. The canals were cut out on the east side of the Euphrates, to convey the water of the river, when it overflowed its banks, into the Tigris, before they reached Babylon. The lake was on the west side of Babylon; and, according to the lowest computation, 40 miles square, 160 in compass, and in depth 35 feet, as we read in Herodotus, or 75, as Megasthenes will have it; the former, perhaps, measured from the surface of the sides, and the latter from the tops of the banks that were cast up upon them. This lake was dug to receive the waters of the river, while the banks were building on each side of it. But both the lake, and the canal which led to it, were preserved after that work was completed, being found of great use, not only to prevent all overflowings, but to keep water all the year, as in a common reservoir, to be let out, on proper occasions, by sluices, for the improvement of the land.

The banks were built of brick and bitumen, on both sides of the river, to keep it within its channel; and extended on each side throughout the whole length of the city, and even farther, according to some, who reckon they extended 160 furlongs, or twenty miles; whence it is concluded they must have begun two miles and a half above the city, and have been continued an equal distance below it, the length of the city being no more than 15 miles. Within the city they were built from the bottom of the river, and of the same thickness with the walls of the city itself. Opposite to each street, on either side of the river, was a brazen gate in the said wall, with stairs leading down from it to the river; these gates were open by day, and shut by night.

Berosus, Megasthenes, and Abydenus, attribute all these works to Nebuchadnezzar; but Herodotus tells us, the bridge, the banks, and the lake, were the work of a queen after him, called *Nitocris*, who may have finished what Nebuchadnezzar left imperfect, and thence have had the honour this historian gives her of the whole.

The tower or temple stood till the time of Xerxes. But that prince, on his return from the Grecian expedition, having first plundered it of its immense wealth, demolished the whole, and laid it in ruins. Alexander, on his return to Babylon from his Indian expedition, proposed to rebuild it, and accordingly set 10,000 men to work to clear away the rubbish. But his death happening soon after, a stop was put to all further proceedings in that design. After the death of that conqueror, the city of Babylon began to decline apace; which was chiefly owing to the neighbourhood of Seleucia built by Seleucus Nicator, as is said, out of spite to the Babylonians, and peopled with 500,000 persons drawn from Babylon, which by that means continued declining till the very people of the country were at a loss to tell where it had stood.

Such is the description we have by ancient historians of the grandeur of this city; which, if these accounts are not exaggerated, must have exceeded every piece of human grandeur that hath yet appeared. Many of the moderns, however, are of opinion that these magnificent descriptions are very far from being true; although it is certain that few other arguments can be brought against the reality of them, than that we do not see things of a similar kind executed in our own days. The following are the arguments used on this subject by Goguet.

7 Goguet's arguments against the truth of the foregoing relation. "Authors have greatly extolled the public works and edifices which once rendered Babylon one of the wonders of the world. We may reduce all these objects to five principal heads: 1. The height of its walls; 2. The temple of Belus; 3. The hanging gardens; 4. The bridge built over the river Euphrates, and the quays which lined the river; 5. The lake and canals dug by the hand of man to distribute the waters of the Euphrates.

"All these works, so marvellous in the judgment of antiquity, appear to me to have been extremely exaggerated by the authors who have spoke of them. How can we conceive, in effect, that the walls of Babylon could have been 318 feet high, and 81 in thickness, in a compass of near ten leagues?

"I shall say the same of that square building, known under the name of *the temple of Belus*. It was composed of eight towers placed one above another, diminishing always as they went up. Herodotus does not tell us what was the height of this monument. Diodorus says, that it surpassed all belief. Strabo fixes it to one stadium, a measure which answers nearly to 600 of our feet: For in the time of this geographer, the stadia were much more considerable than in the first ages. The entire mass of this building ought to have been answerable to its excessive height; and this is also the idea that the ancients designed to give us of it. We may judge by the following fact. Xerxes had entirely demolished this temple. Alexander undertook to rebuild it. He designed to begin by clearing the place and removing the ruins. Ten thousand workmen who were employed two months in this work, were not, say they, able to finish it.

"The riches enclosed in the temple of Belus were proportioned to its immensity. Without speaking of the tables and censers, the cups and other sacred vases, of massy gold, there was a statue 40 feet high, which alone weighed 1000 Babylonish talents. In short, according to the inventory that the ancients have given us of the riches contained in this temple, the total sum would amount to two hundred and twenty millions and a half of French livres. Exaggerations like these destroy themselves.

"As to the hanging gardens, according to all appearance they never existed. The silence of Herodotus on a work so singular and so remarkable, determines one to place in the rank of fables all that the other writers have delivered upon this pretended wonder. Herodotus had carefully visited Babylon. He enters into such details as prove that he has omitted none of the rarities of that city. Can we presume that he would have passed over in silence such a work as the hanging gardens? All the authors who have spoken of it are of much later date than this great historian. None of them except Berosus speaks on his own testimony.

mony. It is always on the report of others. Diodorus had extracted from Ctesias what he says of these famous gardens. There is also great appearance that Strabo had drawn from the same source. In a word, the manner in which Quintus Curtius expresses himself, sufficiently shows how much the existence of these gardens appeared to him suspicious. He judged they owed the greatest part of it to the imagination of the Greeks.

"Let us now speak of the bridge of Babylon, which the ancients have placed in the number of the most marvellous works of the east. It was near 100 fathoms in length, and almost four in breadth. We cannot deny but that a great deal of art and labour was necessary to lay the foundations, which it could not be easy to settle in the bed of an extremely deep and rapid river, which also rolls along a prodigious quantity of mud, and whose bottom is entirely sandy. They had therefore taken many precautions to secure the piers of the bridge of Babylon. They were built of stones joined and fastened together with cramps of iron, and their joints filled with melted lead. The front of the piers, turned towards the current of the Euphrates, was defended by buttresses extremely advanced, which diminished the weight and force of the water, by cutting it at a great distance. Such was the bridge of Babylon.

"While we do justice to the skill of the Babylonians in constructing these works, we cannot help remarking the bad taste which at all times reigned in the works of the eastern nations. The bridge of Babylon furnishes a striking instance of it. This edifice was absolutely without grace, or any air of majesty. The breadth of it was in no sort of proportion to its length. The distance between the piers was also very ill contrived. They were distant from each other only 11 feet and a half. Finally, this bridge was not arched. We may judge of its effect on the view.

"As for the quays which lined the Euphrates, we may believe that they were grand and magnificent; but I shall not easily believe that they surpassed those which we have daily under our eyes. In this respect, I believe Paris may dispute it for magnificence, and for the extent of the work, with all the cities of the universe."

The ruins of this famous city have lately been described in detail by Mr Rich, British resident at Bagdad. They are situated near a village called Hellah, and consist of immense piles of bricks, partly decomposed into earth, and partly entire, and scattered over a great space on both sides of the Euphrates. See Babylon, Supplement.

Babylon, a town of Egypt near the eastmost branch of the river Nile, now supposed to be *Grand Cairo*, or this city to stand near its ruins. E. Long. 31. 12. N. Lat. 30. 5.

BABYLONIA, or Chaldea, a kingdom of Asia, and the most ancient in the world, being founded by Nimrod the grandson of Ham, who also, according to the margin of our Bibles, founded Nineveh the capital of the kingdom of Assyria. Indeed, these two kingdoms seem to have always continued in such a state of friendship, that we can scarce help thinking they must have been the same, or perhaps Babylonia was for some time a province of Assyria. Nothing certain is known concerning either of them, except what may be gathered from Scripture. From thence we learn, that in the days of Abraham there was a king of *Shinar*, called *Amraphel*, who, under the king of Elam or Persia, made war upon the Canaanites. From this time we have nothing that can be depended upon till the days of Nabonasser, the first king of Babylon mentioned in Ptolemy's canon. It is plain, indeed, both from Scripture and profane history, that Babylonia subsisted as a distinct kingdom from Assyria even when the latter was in all its glory. The most probable account of the matter is this: The empire of Assyria was founded by Pul, on the ruins of that of Damascus or Syria, in the days of Menahem king of Judah. This king left two sons, Tiglath-Pileser, and Nabonasser. To the former he bequeathed the empire of Assyria, and to the latter that of Babylon. Tiglath-Pileser resided at Nineveh, the original seat of the Assyrian empire; while Nabonasser, who was the younger brother, held his residence at Babylon. As the two kingdoms were governed by princes of the same family, we may well suppose a perfect harmony to have reigned between them, the younger branch at Babylon acknowledging a kind of subjection to the elder at Nineveh. That the Babylonian empire was of Assyrian origin, we are assured by the prophet Isaiah, in the following words: "Behold the land of the Chaldeans: this people was not till the Assyrian founded it for them that dwelt in the wilderness: they set up the towers thereof; they built the palace thereof." As to the kingdom of Assyria, the Scripture mentions only five kings, viz. Pul, Tiglath-Pileser, Shalmanaser, Sennacherib, and Esar-haddon; whose history, as related by the sacred writers, it is needless to mention particularly here. From the days of Nabonasser to Nabopolasser, that is, from the year before Christ 747 to 626, the kings of Babylon made no figure, and were therefore probably in a state of dependence on the kings of Assyria; but at that time, in the reign of *Chyniladan*, the Sardanapalus of the Greeks, Nineveh was taken and destroyed by the Medes and Babylonians, and the seat of the empire transferred to Babylon. This Nabopolasser was the father of the famous Nebuchadnezzar, for whose history we must refer to the sacred writers; and from his time to that of the *Belshazzar* of Daniel, and *Nabonadius* of other authors, the history of Babylon is little better than a mere blank. Of the reduction of Babylon by Cyrus, which happened at this time, we have the following account.

War had been begun betwixt the Medes, Persians, and Babylonians, in the reign of Neriglissar the father of Nabonadius, which had been carried on with very bad success on the side of the Babylonians. Cyrus, who commanded the Median and Persian army, having subdued the several nations inhabiting the great continent from the Ægean sea to the Euphrates, bent his march towards Babylon. Nabonadius, hearing of his march, immediately advanced against him with an army. In the engagement which ensued, the Babylonians were defeated; and the king, retreating to his metropolis, was blocked up and closely besieged by Cyrus. The reduction of this city was no easy enterprise. The walls were of a prodigious height, the number of men to defend them very great, and the place stored with all sorts of provisions for 20 years. Cyrus, despairing of being able to take such a city by storm, caused a line

Babylonia. of circumvallation to be drawn quite round it, with a large and deep ditch; reckoning that if all communication with the country were cut off, the besieged would be obliged to surrender through famine. That his troops might not be too much fatigued, he divided his army into twelve bodies, appointing each body its month to guard the trenches; but the besieged, looking upon themselves to be out of all danger by reason of their high walls and magazines, insulted him from the ramparts, and looked upon all the trouble he gave himself as so much unprofitable labour.

After Cyrus had spent two whole years before Babylon, without making any progress in the siege, he at last thought of the following stratagem, which put him in possession of it. He was informed, that a great annual solemnity was to be held at Babylon; and that the inhabitants on that occasion were accustomed to spend the whole night in drinking and debauchery. This he therefore thought a proper time for surprising them; and accordingly sent a strong detachment to the head of the canal leading to the great lake, with orders, at a certain time, to break down the great bank which was between the lake and the canal, and to turn the whole current into the lake. At the same time he appointed one body of troops at the place where the river entered the city, and another where it came out; ordering them to march in by the bed of the river as soon as they should find it fordable. Towards the evening he opened the head of the trenches on both sides the river above the city, that the water might discharge itself into them; by which means, and the breaking down of the great dam, the river was soon drained. Then the two above-mentioned bodies of troops, according to their orders, entered the channel; the one commanded by Gobryas and the other by Gadates: and finding the gates all left open by reason of the disorders of that riotous night, they penetrated into the very heart of the city without opposition; and meeting, according to agreement, at the palace, they surprised the guards, and cut them in pieces. Those who were in the palace opening the gates to know the cause of this confusion, the Persians rushed in, took the palace, and killed the king, who came out to meet them sword in hand. Thus an end was put to the Babylonian empire; and Cyrus took possession of Babylon for one called in Scripture *Darius the Mede*, most probably *Cyaxares II.* uncle to Cyrus. From this time Babylonia never was erected into a distinct kingdom, but hath always followed the fortune of those great conquerors who at different times have appeared in Asia. It is now frequently the object of contention between the Turks and Persians. See Assyria.

Concerning the nature of the country, manners, customs, &c. of the ancient Babylonians, the following account is collected by M. Sabbathier.
