War-Horse. The proper rules for choosing a horse for service in war, are these: he should be tall in stature, with a comely head, and out-swelling forehead. His eye should be bright and sparkling, and the white part of it covered by the eye-brow. The ears should be small, thin, short, and pricking; or if long, they should be moveable with ease, and well carried. The neck should be deep, and the breast large and swelling; the ribs bending, the chine broad and straight, and the buttocks round and full. The tail should be high and broad, neither too thick nor too thin; the thigh swelling; the leg broad and flat, and the pastern short. When such a horse is chosen, he must be kept high during the time of his teaching, that he may be full of vigour. His food must be sweet hay, and good clean oats, or two parts of oats and one part of beans or pease, well dried and hardened. The quantity should be half a peck in the morning, and the same quantity at noon and in the evening. Upon his resting days he is to be dressed between five and six in the morning, and watered at seven or eight. In the evening he is to be dressed at four, and watered about five, and he must always have provender given him after watering; he must be littered about eight, and then must have food given him for all night. The night before he is ridden, all

his

his hay is to be taken away about nine o'clock, and he must have a handful or two of oats about four in the morning; when he has eaten these, he is to be turned upon the snaffle, and rubbed very well with dry cloths; then saddled, and made fit for his exercise. When he has performed this, he is to be brought sweating into the stable, and rubbed down with dry whisps. When this has been done, the saddle is to be taken off, and he is to be rubbed down with dry cloths; the housing cloth is then to be laid on: and the saddle being again laid on, he is to be walked gently about till thoroughly cool. After this, he must stand without meat two or three hours, then he must be fed; and in the afternoon he is to be rubbed and dressed as before, and watered in the usual manner.

Horse-Worm, in *Natural History*, a species of fly-worm, called also *bott*, produced of eggs deposited by a two-winged fly of the shape and size of the humble bee in the intestines of horses. See Botts, Farriery *Index*.

River-Horse. See Hippopotamus, Mammalia *Index*.

Horse is also used in the military language, to express the cavalry; or the body of soldiers who serve on horseback.

The horse includes horse guards, horse grenadiers, and troopers. Dragoons are also frequently comprehended under this name, though they fight on foot: of these there are now 18 regiments; besides three regiments of dragoon-guards raised in 1685. See Granadier, Dragoons, and Guards.

Master of the Horse. See Master.

Light-Horse, are regiments of cavalry, mounted on light swift horses, whose men are small and lightly accoutred. They were first raised in 1757. The denomination arose hence, that anciently they were lightly armed, in comparison of the royal guards, which were armed at all points.

Hungarian Horse. See Hussars.

Horse is also a term used in various arts and manufactories, for something that helps to sustain their work from the ground, for the more commodious working at it.

The horse used by tanners and skinners, also called the *leg*, is a piece of wood cut hollow and roundish, four or five feet long, and placed aslope; upon which they pare their skins to get off the dirt, hair, flesh, &c.

Horse is also used in carpentry, for a piece of wood jointed across two other perpendicular ones, to sustain the boards, planks, &c. which make bridges over small rivers; and on divers other occasions.

Horse, in sea-language, is the name of a rope reaching from the middle of a yard to its extremity, or what is called the *yard-arm*, and depending about two or three feet under the yard, for the sailors to tread upon whilst they are loosing, reefing, or furling the sails, rigging out the studding-sail booms, &c. In order, therefore, to keep the horse more parallel to the yard, it is usually suspended to it at proper distances, by certain ropes called stirrups, which hang about two feet under the yard, having an eye in their lower ends through which the horse passes.

Horse is also a thick rope, extended in a perpendicular direction near the fore or after-side of a mast, for the purpose of hoisting or extending some sail upon it. When it is fixed before a mast, it is calculated for the use of a sail called the *square-sail*, whose yard being attached to the horse, by means of a traveller, or bull's eye, which slides up and down occasionally, is retained in a steady position, either when the sail is set, or whilst it is hoisting or lowering. When the horse is placed abaft or behind a mast, it is intended for the try-sail of a snow, and is accordingly very rarely fixed in this position, except in those sloops of war which occasionally assume the form of snows, in order to deceive the enemy.

Horse is also a cant name introduced into the management of lotteries, for the chance or benefit of a ticket or number for one or more days, upon condition, if it be drawn a prize within the time covenanted for, of returning to the seller an undrawn ticket.—To determine the value of a horse; multiply the amount of the prizes in the lottery by the time the horse is hired for; and from the product subtract the amount of the number of prizes by the value of an undrawn ticket into the time of the horse: the remainder being divided by the number of tickets into the whole time of drawing, the quotient is the value of the horse. See Lottery.

Horse-Bread. See Bread.

Horse-Dung, in *Gardening*, is of great use in making hot beds, for the raising all sorts of early crops as salading, cucumbers, melons, asparagus, &c. for which purposes no other kind of dung will do so well. Horse-dung ferments the strongest; and if mixed with litter and sea-coal ashes in a due proportion, will continue its heat much longer than any other sort of dung whatsoever; and afterward, when rotted, becomes an excellent manure for most sorts of land: more especially for such as are of a cold nature. For stiff clayey land, horse-dung mixed with sea-coal ashes, and the cleansing of streets, will cause the parts to separate much sooner than any other compost: so that where it can be obtained in plenty, it is always to be recommended for such lands. See Dung.

Animated Horse-Hairs, a term used to express a sort of long and slender water-worm, of a blackish colour, and so much resembling a horse-hair, that it is generally by the vulgar supposed to be the hair fallen from a horse's mane into the water as he drinks, and there animated by some strange power. Dr Lister has at large confuted this absurd opinion, in the Philosophical Transactions.

Horse-Hair Worms. See Amphisbæna.

Horse-Hoeing Husbandry. See Agriculture, N° 489.

HORSEMANSHIP;

HORSEMANSHIP;

Or, The Art of Riding, and of Training and Managing, Horses.

SECT. I. *The Method of preparing Horses to be mounted.*

Breaking of Horses.

THOUGH all horses are generally bought at an age when they have already been backed, they should be begun and prepared for the rider with the same care, gentleness, and caution, as if they had never been handled or backed, in order to prevent accidents, which might arise from skittishness or other causes: and as it is proper that they should be taught the figure of the ground they are to go upon when they are at first mounted, they should be previously trotted in a *longe* on circles, without any one upon them.

Earl of Pembroke's Directions.

The manner of doing this is as follows: Put an easy *cavesson* upon the horse's nose, and make him go forwards round you, standing quiet, and holding the *longe;* and let another man, if you find it necessary, follow him with a whip. All this must be done very gently, and but a little at a time: for more horses are spoiled by overmuch work, than by any other treatment whatever; and that by very contrary effects: for sometimes it drives them into vice, madness, and despair, and often stupifies and totally dispirits them.

The first obedience required in a horse is going forwards; till he perform this duty freely, never even think of making him rein back, which would inevitably make him restive: as soon as he goes forwards readily, stop and caress him. You must remember in this, and likewise in every other exercise, to use him to go equally well to the right and left; and when he obeys, caress him and dismiss him immediately. If a horse that is very young takes fright and stands still, lead on another horse before him, which probably will induce him instantly to follow. Put a snaffle in his mouth; and when he goes freely, saddle him, girting him at first very loose. Let the cord, which you hold, be long and loose; but not so much so as to endanger the horse's entangling his legs in it. It must be observed, that small circles, in the beginning, would constrain the horse too much, and put him upon defending himself. No bend must be required at first; never suffer him to gallop false; but whenever he attempts it, stop him without delay, and then set him off afresh. If he gallops of his own accord, and true, permit him to continue it; but if he does it not voluntarily, do not demand it of him at first. Should he fly and jump, shake the cord gently upon his nose without jerking it, and he will fall into his trot again. If he stands still, plunges, or rears, let the man who holds the whip make a noise with it; but never touch him till it be absolutely necessary to make him go on. When you change hands, stop and caress him, and entice him by fair means to come up to you; for by presenting yourself, as some do, on a sudden before horses, and frightening them to the other side, you run a great risk of giving them a shyness. If he keeps his head too low, shake the *cavesson* to make him raise it; and in whatever the horse does, whether he walks, trots, or gallops, let it be a constant rule that the motion be determined, and really such as is intended, without the least shuffling, pacing, or any other irregular gait.

Instructions concerning both Rider and Horses.

SECT. II. *The Method of placing the Rider and rendering him firm on Horseback, with some occasional Instructions for Riders and the Horses.*

IT is necessary that the greatest attention, and the same gentleness that is used in teaching the horses, be observed likewise in teaching the rider, especially at the beginning. Every method and art must be practised to create and preserve, both in man and horse, all possible feeling and sensibility; contrary to the usage of most riding-masters, who seem industriously to labour at abolishing these principles both in the one and the other. As so many essential points depend upon the manner in which a man is at first placed on horseback, it ought to be considered and attended to with the strictest care and exactness.

The absurdity of putting a man, who perhaps has never before been upon a horse, on a rough trotting horse, on which he is obliged to stick with all the force of his arms and legs, is too obvious to need mentioning. This rough work, all at once, is plainly as detrimental at first, as it is excellent afterwards in proper time. No man can be either well or firmly seated on horseback, unless he be master of the balance of his body, quite unconstrained, with a full possession of himself, and at his ease; none of which requisites can he enjoy, if his attention be otherwise engaged; as it must wholly be in a raw, unsuppled, and unprepared lad, who is put at once upon a rough horse; in such a distressful state, he is forced to keep himself on at any rate, by holding to the bridle (at the expence of the sensibility both of his own hand and the horse's mouth), and by clinging with his legs, in danger of his life, and to the certain deprivation of a right feeling in the horse.

The first time a man is put on horseback, it ought to be upon a very gentle one. He never should be made to trot, till he is quite easy in the walk; nor gallop, till he is able to trot properly. The same must be observed in regard to horses; they should never be made to trot till they are obedient, and their mouths are well formed on a walk, nor be made to gallop, till the same be effected on a trot. When he is arrived at such a degree of firmness in his seat, the more he trots, and the more he rides rough horses, the better. This is not only the best method, but also the easiest and the shortest: by it a man is soon made sufficiently.

Instructions concerning both Riders and Horses.

ciently a horseman for a soldier: but by the other detestable methods that are commonly used, a man, instead of improving, contracts all sorts of bad habits, and rides worse and worse every day; the horse too becomes daily more and more unfit for use. In proceeding according to the manner proposed, a man is rendered firm and easy upon the horse, both his own and the horse's sensibility is preserved, and each in a situation fit to receive and practise all lessons effectually.

Among the various methods that are used of placing people on horseback, few are directed by reason. Before you let the man mount, teach him to know, and always to examine, if the curb be well placed, (that is, when the horse has a bit in his mouth, which at first he should not, but only a snaffle, till the rider is firm in his seat, and the horse also somewhat taught); likewise to know if the nose-band be properly tight; the throat-band loosish; and the mouth-piece neither too high nor too low in the horse's mouth, but rightly put, so as not to wrinkle the skin nor to hang lax; the girts drawn moderately, but not too tight; and the crupper and the breast-plate properly adjusted. A very good and careful hand may venture on a bit at first, and succeed with it full as well as by beginning with a snaffle alone: on colts, indeed, it is better, in all schools whatsoever, to avoid any pressure of the bars just at first, which a curb, though ever so delicately used, must in some degree occasion. When the bridle, &c. have been well looked to, let the man approach the horse gently near the shoulder; then taking the reins and a handful of the mane in his left hand, let him put his foot softly in the left stirrup, by pulling it towards him, lest he touch the horse with his toe; then raising himself up, let him rest a moment on it with his body upright, but not stiff; and after that, passing his right leg clear over the saddle without rubbing against any thing, let him seat himself gently down. He must be cautious not to take the reins too short, for fear of making the horse rear, run, or fall back, or throw up his head; but let him hold them of an equal length, neither tight nor slack, and with the little finger betwixt them. It is fit that horses should be accustomed to stand still to be mounted, and not to stir till the rider pleases. All soldiers should be instructed to mount and dismount equally well on both sides, which may be of great use in times of hurry and confusion. Then place the man in his saddle, with his body rather back, and his head held up with ease, without stiffness; seated neither forwards, nor very far backwards; with the breast pushed out a little, and the lower part of the body likewise a little forwards; the thighs and legs turned in without constraint, and the feet in a straight line, neither turned in nor out. By this position, the natural weight of the thighs has a proper and sufficient pressure of itself, and the legs are in readiness to act when called upon; they must hang down easy and naturally; and be so placed, as not to be wriggling about, touching and tickling the horse's sides, but always near them in case they should be wanted, as well as the heels.

The body must be carefully kept easy and firm, and without any rocking when in motion; which is a bad habit very easily contracted, especially in galloping. The left elbow must be gently leant against the body, a little forwards; unless it be so rested, the hand cannot be steady, but will always be checking, and consequently have pernicious effects on the horse's mouth. And the hand ought to be of equal height with the elbow; if it were lower, it would constrain and confine the motion of the horse's shoulders; but, as the mouths of horses are different, the place of the hand also must occasionally differ: a leaning, low, heavy, fore-hand, requires a high hand; and a horse that pokes out his nose, a low one. The right-hand arm must be placed in symmetry with the left; only let the right hand be a little more forward or backward, higher or lower, as occasion may require, in order that both hands may be free; both arms must be a little bent at the elbow, to prevent stiffness.

A soldier's right hand should be kept unemployed in riding; it carries the sword, which is sufficient business for it.

There remains one farther observation, that ought not to be omitted, about the hand, that it must be kept clear of the body; i. e. about two inches and a half forwards from it, with the nails turned opposite to the belly, and the wrist a little rounded with ease; a position not less graceful than ready for slackening, tightening, and moving the reins from one side to the other, as may be found necessary.

When the men are well placed, the more rough trotting they have without stirrups the better; but with a strict care always, that their position be preserved very exactly. In all cases, great care must be taken to hinder their clinging with their legs; in short, no sticking by hands or legs is ever to be allowed of at any time. If the motion of the horse be too rough, slacken it, till the rider grows by degrees more firm; and when he is quite firm and easy on his horse in every kind of motion, stirrups may be given him; but he must never leave off trotting often without any.

The stirrups must be neither short nor long; but of such a length, that when the rider, being well placed, puts his feet into them (about one-third of the length of each foot from the point of it), the points may be between two and three inches higher than the heels. The rider must not bear upon his stirrups, but only let the natural weight of his legs rest on them: For if he bears upon them he would be raised above and out of his saddle; which he should never be, except in charging sword in hand, with the body inclined forwards at the very instant of attacking. Spurs may be given as soon as the rider is grown familiar with stirrups; or even long before, if his legs are well placed.

A hand should always be firm, but delicate: a horse's mouth should never be surprised by any sudden transition of it, either from slack to tight, or from tight to slack. Every thing in horsemanship must be effected by degrees, but at the same time with spirit and resolution. The hand which by giving and taking properly, gains its point with the least force, is the best; and the horse's mouth, under this same hand's directions, will also consequently be the best, supposing equal advantages in both from nature. This principle of gentleness should be observed upon all occasions in every branch of horsemanship. Sometimes the right hand may be necessary, upon some troublesome

Instructions concerning both Riders and Horses.

some horses, to assist the left; but the seldomer this is done, the better; especially in a soldier, who has a sword to carry, and to make use of.

The snaffle must on all occasions be uppermost; that is to say, the reins of it must be above those of the bridle, whether the snaffle or the bit be used separately, or whether they be both used together. When the rider knows enough, and the horse is sufficiently prepared and settled to begin any work towards suppling, one rein must be shortened according to the side worked to; but it must never be so much shortened, as to make the whole strength rest on that rein alone: for, not to mention that the work would be false and bad, one side of the horse's mouth would by that means be always deadened; whereas, on the contrary, it should always be kept fresh by its own play, and by the help of the opposite rein's acting delicately in a somewhat smaller degree of tension; the joint effect of which produces in a horse's mouth the proper, gentle, and easy, degree of *appui* or bearing.

A coward and a madman make alike bad riders, and are both alike discovered and confounded by the superior sense of the creature they are mounted upon, who is equally spoilt by both, though in very different ways. The coward, by suffering the animal to have his own way, not only confirms him in his bad habits, but creates new ones in him: and the madman, by false and violent motions and corrections, drives the horse, through despair, into every bad and vicious trick that rage can suggest.

It is very requisite in horsemanship, that the hand and legs should act in correspondence with each other in every thing; the latter always subservient and assistant to the former. Upon circles, in walking, trotting, or galloping, the outward leg is the only one to be used, and that only for a moment at a time, in order to set off the horse true, or put him right if he be false; and as soon as that is done, it must be taken away again immediately: but if the horse be lazy, or otherwise retains himself, both legs must be used and pressed to his sides at the same time together. The less the legs are used in general, the better. Very delicate good riders, with horses they have dressed themselves, will scarcely ever want their help. By the term *outward* is understood the side which is more remote from the centre; and by *inward* is meant the side next to the centre. In reining back, the rider should be careful not to use his legs, unless the horse backeth on his shoulders; in which case they must be both applied gently at the same time, and correspond with the hand. If the horse refuse to back at all, the rider's legs must be gently approached, till the horse lifts up a leg, as if to go forwards; at which time, when that leg is in the air, the rein of the same side with that leg which is lifted up will easily bring that same leg backwards, and accordingly oblige the horse to back; but if the horse offers to rear, the legs must be instantly removed away. The inward rein must be tighter on circles, so that the horse may bend and look inwards; and the outward one crossed over a little towards it; and both held in the left hand.

Let the man and horse begin on very slow motions, that they may have time to understand and reflect on what is taught them; and in proportion as the effects of the reins are better comprehended, and the manner of working becomes more familiar, the quickness of motion must be increased. Every rider must learn to feel, without the help of the eye, when a horse goes false, and remedy the fault accordingly: this is an intelligence, which nothing but practice, application, and attention, can give, in the beginning on slow motions. A horse may not only gallop false, but also trot and walk false. If a horse gallops false, that is to say, if going to the right he leads with the left leg, or if going to the left he leads with the right; or in case he is disunited, *i. e.* if he leads with the opposite leg behind to that which he leads with before; stop him immediately, and put him off again properly. The method of effecting this, is by approaching your outward leg, and putting your hand outwards; still keeping the inward rein the shorter, and the horse's head inwards, if possible; and if he should still resist, then bend and pull his head outwards also; but replace it again, bent properly inwards, the moment he goes off true. A horse is said to be disunited to the right, when going to the right, and consequently leading with the right leg before, he leads with the left behind; and is said to be disunited to the left, when going to the left, and consequently leading with the left leg before, he leads with the right behind. A horse may at the same time be both false and disunited; in correcting both which faults, the same method must be used. He is both false and disunited to the right, when in going to the right he leads with the left leg before, and the right behind; notwithstanding that hinder leg be with propriety more forward under his belly than the left, because the horse is working to the right: And he is false and disunited to the left, when in going to the left he leads with the right leg before and the left behind; notwithstanding, as above, that hinder leg be with propriety more forward under his belly than the right, because the horse is working to the left.

In teaching men a right seat on horseback, the greatest attention must be given to prevent stiffness, and sticking by force in any manner upon any occasion: stiffness disgraces every right work; and sticking serves only to throw a man (when displaced) a great distance from his horse by the spring he must go off with: whereas by a proper equilibrating position of the body, and by the natural weight only of the thighs, he cannot but be firm and secure in his seat.

As the men become more firm, and the horses more supple, it is proper to make the circles less, but not too much so, for fear of throwing the horses forwards upon their shoulders.

Some horses, when first the bit is put into their mouths, if great care be not taken, will put their heads very low. With such horses, raise your right hand with the *bridoon* in it, and play at the same time with the bit in the left hand, giving and taking.

On circles, the rider must lean his body inwards; unless great attention be given to make him do it, he will be perpetually losing his seat outwards. It is scarce possible for him to be displaced, if he leans his body properly inwards.

Sect.

Of Suppling Horses.

SECT. III. *The Method of suppling Horses with Men upon them, by the* EPAULE en dedans, *&c. with and without a* Longe, *on Circles and on straight Lines.*

WHEN a horse is well prepared and settled in all his motions, and the rider firm, it will be proper then to proceed on towards a farther suppling and teaching of both.

In setting out upon this new work, begin by bringing the horse's head a little more inwards than before, pulling the inward rein gently to you by degrees. When this is done, try to gain a little on the shoulders, by keeping the inward rein the shorter, as before, and the outward one crossed over towards the inward one. The intention of these operations is this: The inward rein serves to bring in the head, and procures the bend; whilst the outward one, that is a little crossed, tends to make that bend perpendicular and as it should be, that is to say, to reduce the nose and the forehead to be in a perpendicular line with each other; it also serves, if put forwards, as well as also crossed, to put the horse forwards, if found necessary; which is often requisite, many horses being apt in this and other works rather to lose their ground backwards than otherwise, when they should rather advance; if the nose were drawn in towards the breast beyond the perpendicular, it would confine the motion of the shoulders, and have other bad effects. All other bends, besides what are above specified, are false. The outward rein, being crossed, not in a forward sense, but rather a little backwards, serves also to prevent the outward shoulder from getting too forwards, and makes it approach the inward one; which facilitates the inward leg's crossing over the outward one, which is the motion that so admirably supples the shoulders. Care must be taken, that the inward leg pass over the outward one, without touching it: this inward leg's crossing over must be helped also by the inward rein, which you must cross towards and over the outward rein every time the outward leg comes to the ground, in order to lift and help the inward leg over it: at any other time, but just when the outward leg comes to the ground, it would be wrong to cross the inward rein, or to attempt to lift up the inward leg by it; nay, it would be demanding an absolute impossibility, and lugging about the reins and horse to no purpose: because in this case, a very great part of the horse's weight resting then upon that leg, would render such an attempt not only fruitless, but also prejudicial to the sensibility of the mouth, and probably oblige him to defend himself; and, moreover, it would put the horse under a necessity of straddling before, and also of leading with the wrong leg, without being productive of any suppling motion whatsoever.

When the horse is thus far familiarly accustomed to what you have required of him, then proceed to effect by degrees the same crossing in his hinder legs. By bringing in the fore legs more, you will of course engage the hinder ones in the same work; if they resist, the rider must bring both reins more inward: and, if necessary, put back also, and approach his inward leg to the horse; and if the horse throws out his croup too far, the rider must bring both reins outwards, and, if absolutely necessary, he must also make use of his outward leg, in order to replace the horse properly: observing that the croup should always be considerably behind the shoulders, which in all actions must go first; and the moment that the horse obeys, the rider must put his hand and leg again in their usual position.

Nothing is more ungraceful in itself, more detrimental to a man's seat, or more destructive of the sensibility of a horse's sides, than a continual wriggling unsettledness in a horseman's legs, which prevents the horse from ever going a moment together true, steady, or determined.

A horse should never be turned, without first moving a step forwards: and when it is doing, the rider must not lift his elbow, and displace himself; a motion only of the hand from the one side to the other being sufficient for that purpose. It must also be a constant rule, never to suffer a horse to be stopped, mounted, or dismounted, but when he is well placed. The slower the motions are when a man or horse is taught any thing, the better.

At first, the figures worked upon must be great, and afterwards made less by degrees, according to the improvement which the man and horse make; and the cadenced pace also, which they work in, must be accordingly augmented. The changes from one side to the other must be in a bold determined trot, and at first quite straight forwards, without demanding any side-motion on two *pistes*, which is very necessary to require afterwards when the horse is sufficiently suppled. By two *pistes* is meant, when the fore parts and hinder parts do not follow, but describe two different lines.

In the beginning, a *longe* is used on circles, and also on straight lines, to help both the rider and the horse; but afterwards, when they are grown more intelligent, they should go alone. At the end of the lesson, rein back; then put the horse, by a little at a time, forwards, by approaching both legs gently to his sides, and playing with the bridle: if he rears, push him out immediately into a full trot. Shaking the *cavesson* on the horse's nose, and also putting one's self before him and rather near to him, will generally make him back, though he otherwise refuse to do it: and moreover a slight use and approaching of the rider's legs, will sometimes be necessary in backing, in order to prevent the horse from doing it too much upon his shoulders; but the pressure of the legs ought to be very small, and taken quite away the moment that he puts himself enough upon his haunches. If the horse does not back upon a straight line properly, the rider must not be permitted to have recourse immediately to his leg, and so distort himself by it; but first try, if crossing over his hand and reins to which ever side may be necessary, it will not alone sufficient: which most frequently it will; if not, then employ the leg.

After a horse is well prepared and settled, and goes freely on in all his several paces, he ought to be in all his works kept, to a proper degree, upon his haunches, with his hinder legs well placed under him; whereby he will be always pleasant to himself and his rider, will be light in hand, and ready to execute whatever may be demanded of him, with facility, vigour, and quickness.

The common method that is used of forcing a horse sidewise, Of the Head to the Wall, &c.

sidewise, is a most glaring absurdity, and very hurtful to the animal in its consequences; for, instead of suppling him, it obliges him to stiffen and defend himself, and often makes a creature that is naturally benevolent, restive, frightened, and vicious.

For horses who have very high and long fore-hands, and who poke out their noses, a running snaffle is of excellent use; but for such as bore and keep their heads low, a common one is preferable; though any horse's head indeed may be kept up also with a running one, by the rider's keeping his hands very high and forwards: but whenever either is used alone without a bridle upon horses that carry their heads low and that bore, it must be sawed about from one side to the other.

This lesson of the *epaule en dedans* should be taught to such people as are likely to become useful in helping to teach men and to break horses; and the more of such that can be found the better; none others should ever be suffered upon any occasion to let their horses look any way besides the way they are going. But all horses whatever, as likewise all men who are designed for the teaching others, must go thoroughly and perfectly through this excellent lesson, under the directions of intelligent instructors, and often practise it too afterwards; and when that is done, proceed to and be finished by the lessons of head and tail to the wall.

Sect. IV. *Of the Head to the Wall, and of the Croup to the Wall.*

This lesson should be practised immediately after that of the *epaule en dedans*, in order to place the horse properly the way he goes, &c. The difference between the head to the wall, and the croup to the wall, consists in this: in the former, the fore-parts are more remote from the centre, and go over more ground; in the latter, the hinder parts are more remote from the centre, and consequently go over more ground: in both, as likewise in all other lessons, the shoulders must go first. In riding-horses, the head to the wall is the easier lesson of the two at first, the line to be worked upon being marked by the wall, not far from his head.

The motion of the legs to the right is the same as that of the *epaule en dedans* to the left, and so *vice versa*; but the head is always bent and turned differently: in the *epaule en dedans*, the horse looks the contrary way to that which he goes; in this, he looks the way he is going.

In the beginning, very little bend must be required: too much at once would astonish the horse, and make him defend himself: it is to be augmented by degrees. If the horse absolutely refuses to obey, it is a sign that either he or his rider has not been sufficiently prepared by previous lessons. It may happen that weakness or a hurt in some part of the body, or sometimes temper, though seldom, may be the cause of the horse's defending himself: it is the rider's business to find out from whence the obstacle arises; and if he finds it to be from the first-mentioned cause, the previous lessons must be resumed again for some time; if from the second, proper remedies must be applied; and if from the last cause, when all fair means that can be tried have failed, proper corrections with coolness and judgement must be used.

Of the Head to the Wall, &c.

In practising this lesson to the right, bend the horse to the right with the right rein; helping the left leg over the right (at the time when the right leg is just come to the ground), with the left rein crossed towards the right, and keeping the right shoulder back with the right rein towards your body, in order to facilitate the left leg's crossing over the right; and so likewise *vice versa* to the left, each rein helping the other by their properly mixed effects. In working to the right, the rider's left leg helps the hinder parts on to the right, and his right leg stops them if they get too forwards; and so *vice versa* to the left: but neither ought to be used, till the hand being employed in a proper manner has failed, or finds that a greater force is necessary to bring about what is required than it can effect alone: for the legs should not only be corresponding with, but also subservient to, the hand; and all unnecessary aids, as well as all force, ought always to be avoided as much as possible.

In the execution of all lessons, the equilibre of the rider's body is of great use to the horse; it ought always to go with and accompany every motion of the animal; when to the right, to the right; and when to the left, to the left.

Upon all horses, in every lesson and action, it must be observed, that there is no horse but has his own peculiar appui or degree of bearing, and also a sensibility of mouth, as likewise a rate of his own, which it is absolutely necessary for the rider to discover and make himself acquainted with. A bad rider always takes off at least the delicacy of both, if not absolutely destroys it. The horse will inform his rider when he has got his proper bearing in the mouth, by playing pleasantly and steadily with his bit, and by the spray about his chaps. A delicate and good hand will not only always preserve a light appui, or bearing, in its sensibility; but also of a heavy one, whether naturally so or acquired, make a light one. The lighter this appui can be made, the better; provided that the rider's hand corresponds with it; if it does not, the more the horse is properly prepared, so much the worse. Instances of this inconvenience of the best of appuis, when the rider is not equally taught with the horse, may be seen every day in some gentlemen, who try to get their horses *bitted* as they call it, without being suitably prepared themselves for riding them: the consequence of which is, that they ride in danger of breaking their necks; till at length, after much hauling about, and by the joint insensibility and ignorance of themselves and their grooms, the poor animals gradually become mere senseless unfeeling posts; and thereby grow, what they call, *settled*. When the proper appui is found, and made of course as light as possible, it must not be kept duly fixed without variation, but be played with; otherwise one equally continued tension of reins would render both the rider's hand and the horse's mouth very dull. The slightest and frequent giving and taking is therefore necessary to keep both perfect.

Whatever pace or degree of quickness you work in, (be

To make Horses stand Fire, &c.

(be it ever so fast, or ever so slow), it must be cadenced; time is as necessary for a horseman as for a musician.

This lesson of the head and of the tail to the wall, must be taught every soldier: scarce any manœuvre can be well performed without it. In closing and opening of files, it is almost every moment wanted.

Sect. V. *The Method of making Horses stand Fire, Noises, Alarms, Sights,* &c.

In order to make horses stand fire, the sound of drums, and all sorts of different noises, you must use them to it by degrees in the stable at feeding time; and instead of being frightened at it, they will soon come to like it as a signal for eating.

With regard to such horses as are afraid of burning objects, begin by keeping them still at a certain distance from some lighted straw; caress the horse; and in proportion as his fright diminishes, approach gradually the burning straw very gently, and increase the size of it. By this means he will very quickly be brought to be so familiar with it, as to walk undaunted even through it.

As to horses that are apt to lie down in the water, if animating them, and attacking them vigorously, should fail of the desired effect, then break a straw-bottle full of water upon their heads, and let the water run into their ears, which is a thing they apprehend very much.

All troop-horses must be taught to stand quiet and still when they are shot off from, to stop the moment you present, and not to move after firing till they are required to do it; this lesson ought especially to be observed in light troops: in short, the horses must be taught to be so cool and undisturbed, as to suffer the rider to act upon him with the same freedom as if he was on foot. Patience, coolness, and temper, are the only means requisite for accomplishing this end. Begin by walking the horse gently, then stop and keep him from stirring for some time, so as to accustom him by degrees not to have the least idea of moving without orders: if he does, then back him; and when you stop him, and he is quite still, leave the reins quite loose.

To use a horse to fire-arms, first put a pistol or a carabine in the manger with his feed: then use him to the sound of the lock and the pan; after which, when you are upon him, show the piece to him, presenting it forwards, sometimes on one side, sometimes on the other: when he is thus far reconciled, proceed to flash in the pan; after which, put a small charge into the piece, and so continue augmenting it by degrees to the quantity which is commonly used: if he seems uneasy, walk him forward a few steps slowly; and then stop, back, and caress him. Horses are often also disquieted and unsteady at the clash, and drawing, and returning of swords; all which they must be familiarized to by little and little, by frequency and gentleness.

It is very expedient for all cavalry in general, but particularly for light cavalry, that their horses should be very ready and expert in leaping over ditches, hedges, gates, &c. The leaps, of whatever sort they are, which the horses are brought to in the beginning, ought to be very small ones; the riders must keep their bodies back, raise their hands a little in order to help the fore-parts of the horse up, and be very attentive to their equilibre. It is best to begin at a low bar covered with furze, which pricking the horse's legs, if he does not raise himself sufficiently, prevents his contracting a sluggish and dangerous habit of touching, as he goes over, which any thing yielding and not pricking would give him a custom of doing. Let the ditches you first bring horses to be narrow; and in this, as in every thing else, let the increase be made by degrees. Accustom them to come up to every thing which they are to leap over, and to stand coolly at it for some time; and then to raise themselves gently up in order to form to themselves an idea of the distance. When they leap well standing, then use them to walk gently up to the leap, and to go over it without first halting at it; and after that practice is familiar to them, repeat the like in a gentle trot, and so by degrees faster and faster, till at length it is as familiar to them to leap flying on a full gallop as any other way: all which is to be acquired with great facility by calm and soft means, without any hurry.

As horses are naturally apt to be frightened at the sight and smell of dead horses, it is advisable to habituate them to walk over and leap over carcases of dead horses: and as they are particularly terrified at this sight, the greater gentleness ought consequently to be used.

Horses should also be accustomed to swim, which often may be necessary upon service; and if the men and horses both are not used to it, both may be frequently liable to perish in the water. A very small portion of strength is sufficient to guide a horse, any-where indeed, but particularly in the water, where they must be permitted to have their heads, and be no-ways constrained in any shape.

The unreasonable rage in Britain of cutting off all extremities from horses, is in all cases a very pernicious custom. It is particularly so in regard to a troop-horse's tail. It is almost incredible, how much they suffer at the picket for want of it: constantly fretting, and sweating, kicking about and laming one another, tormented, and stung off their meat, miserable, and helpless; while other horses, with their tails on, brush off all flies, are cool and at their ease, and mend daily; whilst the docked ones grow every hour more and more out of condition.

Of Reining Back, &c.

Sect. VI. *The Method of reining back,—and of moving forwards immediately after;—of Piafing,—of Pillars,* &c.

Never finish your work by reining back with horses that have any disposition towards retaining themselves; but always move them forwards, and a little upon the haunches also, after it, before you dismount, (unless they retain themselves very much indeed, in which case nothing at all must be demanded from the haunches). This lesson of reining back, and piafing, is excellent to conclude with, and puts a horse well and properly upon the haunches: It may be done, according as horses are more or less suppled, either going forwards, backing, or in the same place: if it is done well advancing, or at most on the same spot, it is fully sufficient for a soldier's

Of Curing Restiveness, &c.

dier's horse: For to piafe in backing, is rather too much to be expected in the hurry which cannot but attend such numbers both of men and horses as must be taught together in regiments. This lesson must never be attempted at all, till horses are very well suppled, and somewhat accustomed to be put together; otherwise it will have very bad consequences, and create restiveness. If they refuse to back, and stand motionless, the rider's legs must approach with the greatest gentleness to the horse's sides; at the same time that the hand is acting on the reins to solicit the horse's backing. This seldom fails of procuring the desired effect, by raising one of the horse's fore-legs, which being in the air, has no weight upon it, and is consequently very easily brought backwards by a small degree of tension in the reins. When this lesson is well performed, it is very noble and useful, and has a pleasing air; it is an excellent one to begin teaching scholars with.

The lesson is particularly serviceable in the pillars, for placing scholars well at first. Very few regimental riding-houses have pillars, and it is fortunate they have not; for though, when properly made use of with skill, they are one of the greatest and best discoveries in horsemanship; they must be allowed to be very dangerous and pernicious, when they are not under the direction of a very knowing person.

Sect. VII. *The Method of curing Restiveness, Vices, Defences, Starting*, &c.

Whenever a horse makes resistance, one ought, before remedy or correction is thought of, to examine very minutely all the tackle about him, if any thing hurts or tickles him, whether he has any natural or accidental weakness, or in short any the least impediment in any part. For want of this precaution, many fatal disasters happen: the poor dumb animal is frequently accused falsely of being restive and vicious; is used ill without reason; and, being forced into despair, is in a manner obliged to act accordingly, be his temper and inclination ever so well disposed. It is very seldom the case, that a horse is really and by nature vicious; but if such be found, he will despise all caresses, and then chastisements become necessary.

Correction, according as you use it, throws a horse into more or less violent action, which, if he be weak, he cannot support: but a vicious strong horse is to be considered in a very different light, being able both to undergo and consequently to profit by all lessons; and is far preferable to the best natured weak one upon earth. Patience and attention are never failing means to reclaim such a horse: in whatsoever manner he defends himself, bring him back frequently with gentleness (not however without having given him proper chastisement if necessary) to the lesson which he seems most averse to. Horses are by degrees made obedient, through the hope of recompense and the fear of punishment: how to mix these two motives judiciously together, is a very difficult matter; it requires much thought and practice; and not only a good head, but a good heart likewise. The coolest and best natured rider will always succeed best. By a dexterous use of the incitements above mentioned, you will gradually bring the horse to temper and obedience; mere force, and want of skill and coolness, would only tend to confirm him in bad tricks. If he be impatient or choleric, never strike him, unless he absolutely refuse to go forward; which you must resolutely oblige him to do, and which will be of itself a correction, by preventing his having time to meditate and put in execution any defence by retaining himself. Resistance in horses, you must consider, is sometimes a mark of strength and vigour, and proceeds from spirit, as well as sometimes from vice and weakness. Weakness frequently drives horses into viciousness, when any thing wherein strength is necessary is demanded from them; nay, it inevitably must: great care therefore should always be taken to distinguish from which of these two causes any remedy or punishment is thought of. It may sometimes be a bad sign when horses do not at all defend themselves, and proceed from a sluggish disposition, a want of spirit, and of a proper sensibility. Whenever one is so fortunate as to meet with a horse of just the right spirit, activity, delicacy of feeling, with strength and good nature, he cannot be cherished too much; for such a one is a rare and inestimable jewel, and, if properly treated, will in a manner do every thing of himself. Horses are oftener spoilt by having too much done to them, and by attempts to dress them in too great an hurry, than by any other treatment.

If after a horse has been well suppled, and there are no impediments, either natural or accidental, if he still persist to defend himself, chastisements then become necessary: but whenever this is the case, they must not be frequent but always firm, though always as little violent as possible; for they are both dangerous and very prejudicial when frequently or slightly played with, and still more so when used too violently.

It is impossible, in general, to be too circumspect in lessons of all kinds, in aids, chastisements, or caresses. Soom have quicker parts, and more cunning, than others. Many will imperceptibly gain a little every day on the rider. Various, in short, are their dispositions and capacities. It is the rider's business to find out their different qualities, and to make them sensible how much he loves them, and desires to be loved by them; but at the same time that he does not fear them, and will be master.

Plunging is a very common defence among restive and vicious horses: if they do it in the same place, or backing, they must, by the rider's legs and spurs firmly applied, be obliged to go forwards, and their heads kept up high. But if they do it flying forwards, keep them back, and ride them gently and very slow for a good while together. Of all bad tempers and qualities in horses, those which are occasioned by harsh treatment and ignorant riders are the worst.

Rearing is a bad vice, and, in weak horses especially, a very dangerous one. Whilst the horse is up, the rider must yield his hand; and when the horse is descending, he must vigorously determine him forwards: if this be done at any other time but whilst the horse is coming down, it may add a spring to his rearing, and make him fall backwards. With a good hand on them, horses seldom persist in this vice; for they are themselves naturally much afraid of falling backwards. If

Rules for Bad Horsemen.

this method fails, you must make the horse kick up behind, by getting somebody on foot to strike him behind with a whip; or, if that will not effect it, by pricking him with a goad.

Starting often proceeds from a defect in the sight; which therefore must be carefully looked into. Whatever the horse is afraid of, bring him up to it gently; if you caress him every step he advances, he will go quite up to it by degrees, and soon grow familiar with all sorts of objects. Nothing but great gentleness can correct this fault; for if you inflict punishment, the apprehension of chastisement becomes prevalent, and causes more starting than the fear of the object. If you let him go by the object, without bringing him up to it, you increase the fault, and confirm him in his fear: the consequence of which is, he takes his rider perhaps a quite contrary way from what he was going, becomes his master, and puts himself and the person upon him every moment in great danger.

With such horses as are to a very great degree fearful of any objects, make a quiet horse, by going before them, gradually entice them to approach nearer and nearer to the thing they are afraid of. If the horse, thus alarmed, be undisciplined and headstrong, he will probably run away with his rider; and if so, his head must be kept up high, and the snaffle sawed backwards and forwards from right to left, taking up and yielding the reins of it, as also the reins of the bit: but this latter must not be sawed backwards and forwards like the snaffle, but only taken up and yielded properly. No man ever yet did, or ever will stop a horse, or gain any one point over him, by main force, or by pulling a dead weight against him.

SECT. VIII. *Rules for bad Horsemen.*

Thomson's Rules.

In the first place, every horse should be accustomed to stand still when he is mounted. One would imagine this might be readily granted; yet we see how much the contrary is practised. When a gentleman mounts at a livery-stable, the groom takes the horse by the bit, which he bends tight round his under jaw: the horse striving to go on, is forced back; advancing again, he frets, as he is again stopped short, and hurt by the manner of holding him. The rider, in the mean time, mounting without the bridle, or at least holding it but slightly, is helped to it by the groom, who being thoroughly employed by the horse's fluttering, has at the same time both bridle and stirrup to give. This confusion would be prevented, if every horse was taught to stand still when he is mounted. Forbid your groom, therefore, when he rides your horse to water, to throw himself over him from a horse-block, and kick him with his leg, even before he is fairly upon him. This wrong manner of mounting is what chiefly teaches your horse the vicious habit against which we are here warning. On the other hand, a constant practice of mounting in the proper manner, is all that is necessary to prevent a horse's going on till the rider is quite adjusted in the saddle.

The next thing necessary therefore is, that the rider should mount properly. The common method is to stand near the croup or hinder part of the horse, with the bridle held very long in the right hand. By this manner of holding the bridle before you mount, you are liable to be kicked; and when you are mounted, your horse may go on some time, or play what gambols he pleases, before the rein is short enough in your hand to prevent him. It is common likewise for an awkward rider, as soon as his foot is in the stirrup, to throw himself with all his force to gain his seat; which he cannot do, till he hath first overbalanced himself on one side or the other: he will then wriggle into it by degrees. The way to mount with ease and safety is, to stand rather before than behind the stirrup. In this posture take the bridle short, and the mane together in your left hand, helping yourself to the stirrup with your right, so that your toe may not touch the horse in mounting. While your left foot is in the stirrup, move on your right, till you face the side of the horse, looking across over the saddle. Then with your right hand grasp the hinder part of the saddle; and with that and your left, which holds the mane and bridle, lift yourself upright on your left foot. Remain thus a mere instant on your stirrup, only so as to divide the action into two motions. While you are in this posture, you have a sure hold with both hands, and are at liberty, either to get safely down, or to throw your leg over and gain your seat. By this deliberate motion, likewise, you avoid, what every good horseman would endeavour to avoid, putting your horse into a flutter.

When you dismount, hold the bridle and mane together in your left hand, as when you mounted; put your right hand on the pommel of the saddle, to raise yourself; throw your leg back over the horse, grasp the hinder part of the saddle with your right hand, remain a moment on your stirrup, and in every respect dismount as you mounted; only what was your first motion when you mounted, becomes the last in dismounting. Remember not to bend your right knee in dismounting, lest your spur should rub against the horse.

It may be next recommended to hold your bridle at a convenient length. Sit square, and let not the purchase of the bridle pull forward your shoulder; but keep your body even, as it would be if each hand held a rein. Hold your reins with the whole grasp of your hand, dividing them with your little finger. Let your hand be perpendicular; your thumb will then be uppermost, and placed on the bridle. Bend your wrist a little outward: and when you pull the bridle, raise your hand toward your breast, and the lower part of the palm rather more than the upper. Let the bridle be at such a length in your hand, as, if the horse should stumble, you may be able to raise his head, and support it by the strength of your arms, and the weight of your body thrown backward. If you hold the rein too long, you are subject to fall backward as your horse rises.

If, knowing your horse perfectly well, you think a tight rein unnecessary, advance your arm a little (but not your shoulder) towards the horse's head, and keep your usual length of rein. By this means, you have a check upon your horse, while you indulge him.

If you ride with a curb, make it a rule to hook on the chain yourself; the most quiet horse may bring his rider into danger, should the curb hurt him. If, in fixing the curb, you turn the chain to the right, the

Rules for Bad Horsemen.

the links will unfold themselves, and then oppose a farther turning. Put on the chain loose enough to hang down on the horse's under lip, so that it may not rise and press his jaw, till the reins of the bridle are moderately pulled.

If your horse has been used to stand still when he is mounted, there will be no occasion for a groom to hold him: but if he does, suffer him not to touch the reins, but that part of the bridle which comes down the cheek of the horse. He cannot then interfere with the management of the reins, which belongs to the rider only; and holding a horse by the curb (which is ever painful to him) is evidently improper when he is to stand still.

Another thing to be remembered is, not to ride with your arms and elbows as high as your shoulders; not let them shake up and down with the motion of the horse. The posture is unbecoming, and the weight of the arms and of the body too if the rider does not sit still) acts in continual jerks on the jaw of the horse, which must give him pain, and make him unquiet, if he has a tender mouth or any spirit.

Bad riders wonder why horses are gentle as soon as they are mounted by skilful ones, though their skill seems unemployed: the reason is, the horse goes at his ease, yet finds all his motions watched; which he has sagacity enough to discover. Such a rider hides his whip, if he finds his horse is afraid of it; and keeps his legs from his sides, if he finds he dreads the spur.

Avoid the ungraceful custom of letting your legs shake against the sides of the horse: and as you are not to keep your arms and elbows high, and in motion; so you are not to rivet them to your sides, but let them fall easy. One may, at a distance, distinguish a genteel horseman from an awkward one: the first sits still, and appears of a piece with his horse; the latter seems flying off at all points.

It is often said with emphasis, that such a one has no *seat* on horseback; and it means, not only that he does not ride well, but that he does not sit on the right part of the horse. To have a *good seat*, is to sit on that part of the horse, which, as he springs, is the centre of motion; and from which, of course, any weight would be with most difficulty shaken. As in the rising and falling of a board placed in *æquilibrio*, the centre will be always most at rest; the true seat will be found in that part of your saddle, into which your body would naturally slide, if you rode without stirrups: and is only to be preserved by a proper poise of the body, though the generality of riders imagine it is to be done by the grasp of the thighs and knees. The rider should consider himself as united to his horse in this point; and when shaken from it, endeavour to restore the balance.

Perhaps the mention of the two extremes of a bad seat may help to describe the true one. The one is, when the rider sits very far back on the saddle, so that his weight presses the loins of the horse: the other, when his body hangs forward over the pommel of the saddle. The first may be seen practised by grooms, when they ride with their stirrups affectedly short; the latter, by fearful horsemen on the least flutter of the horse. Every *good* rider has, even on the hunting saddle, as *determined* a place for his thighs, as can be determined for him by the bars of a demi-peak. Indeed there is no difference between the seat of either: only, as in the first you ride with shorter stirrups, your body will be consequently more behind your knees.

To have a good seat yourself, your saddle must sit well. To fix a precise rule might be difficult: it may be a *direction*, to have your saddle press as nearly as possible on that part which we have described as the point of union between the man and horse; however, so as not to obstruct the motion of the horse's shoulders. Place yourself in the middle or lowest part of it: sit erect; but with as little constraint as in your ordinary sitting. The ease of action marks the gentleman: you may repose yourself, but not lounge. The set and studied erectness acquired in the riding-house, by those whose deportment is not easy, appears ungenteel and unnatural.

If your horse stops short, or endeavours by rising and kicking to unseat you, bend not your body forward, as many do in these circumstances: that motion throws the breech backward, and you off your fork or twist, and out of your seat; whereas, the advancing the lower part of your body, and bending back the upper part and shoulders, is the method both to keep your seat, and to recover it when lost. The bending your body back, and that in a great degree, is the greatest security in *flying* leaps; it is a security too, when your horse leaps *standing*. The horse's rising does not try the rider's seat; the lash of his hind legs is what ought chiefly to be guarded against, and is best done by the body's being greatly inclined back. Stiffen not your legs or thighs; and let your body be pliable in the loins, like the coachman's on his box. This loose manner of sitting will elude every rough motion of the horse; whereas the fixture of the knees, so commonly laid a stress on, will in great shocks conduce to the violence of the fall.

Was the cricket-player, when the ball is struck with the greatest velocity, to hold his hand firm and fixed when he receives it, the hand would be bruised, or perhaps the bones fractured by the resistance. To obviate this accident, he therefore gradually yields his hand to the motion of the ball for a certain distance; and thus by a due mixture of opposition and obedience, catches it without sustaining the least injury. The case is exactly the same in riding: the skilful horseman will recover his poise by giving some way to the motion; and the ignorant horseman will be flung out of his seat by endeavouring to be fixed.

Stretch not out your legs before you; this will push you against the back of the saddle; neither gather up your knees like a man riding on a pack; this throws your thighs upwards: each practice unseats you. Keep your legs straight down; and sit not on the most fleshy part of the thighs, but turn them inwards, so as to bring in your knees and toes: and it is more safe to ride with the ball of the foot pressing on the stirrup, than with the stirrup as far back as the heel: for the pressure of the heel being in that case behind the stirrup, keeps the thighs down.

When you find your thighs thrown upwards, widen your knees to get them and the upper part of your fork lower down on the horse. Grasp the saddle with the hollow or inner part of your thighs, but not more

than

Rules for Bad Horsemen.

than just to assist the balance of your body: this will also enable you to keep your spurs from the horse's sides, and to bring your toes in, without that affected and useless manner of bringing them in practised by many. Sink your heels straight down; for while your heels and thighs keep down, you cannot fall: this (aided with the bend of the back) gives the security of a seat, to those who bear themselves up in their stirrups in a swift gallop, or in the alternate rising and falling in a full trot.

Let your seat determine the length of your stirrups, rather than the stirrups your seat. If more precision is requisite, let your stirrups (in the hunting saddle) be of such a length, as that, when you stand in them, there may be the breadth of four fingers between your seat and the saddle.

It would greatly assist a learner, if he would practise riding in a large circle, as directed sect. ii. without stirrups; keeping his face looking on the outward part of the circle so as not to have a full view of the horse's head, but just of that ear which is on the outward part of the circle; and his shoulder, which is towards the centre of the circle, very forward. By this means you learn to balance your body, and keep a true seat, independent of your stirrups: you may probably likewise escape a fall, should you at any time lose them by being accidentally shaken from your seat.

As the seat in some measure depends on the saddle, it may not be amiss to observe, that because a saddle with a high pommel is thought dangerous, the other extreme prevails, and the pommel is scarce allowed to be higher than the middle of the saddle. The saddle should lie as near the back-bone as can be, without hurting the horse; for the nearer you sit to his back, the better seat you have. If it does so, it is plain the pommel must rise enough to secure the withers from pressure: therefore, a horse whose withers are higher than common, requires a higher pommel. If, to avoid this, you make the saddle of a more straight line, the inconvenience spoken of follows; you sit too much above the horse's back, nor can the saddle form a proper seat. There should be no ridge from the button at the side of the pommel, to the back part of the saddle. That line also should be a little concave, for your thighs to lie at ease. In short, a saddle ought to be, as nearly as possible, as if cut out of the horse.

When you want your horse to move forward, raise his head a little, and touch him gently with your whip; or else, press the calves of your legs against his sides. If he does not move fast enough, press them with more force, and so till the spur just touches him. By this practice he will (if he has any spirit) move upon the least pressure of the leg. Never spur him by a kick; but if it be necessary to spur him briskly, keep your heels close to his sides, and slacken their force as he becomes obedient.

When your horse attempts to be vicious, take each rein separate, one in each hand, and advancing your arms forward, hold him very short. In this case, it is common for the rider to pull him hard, with his arms low. But the horse by this means having his head low too, has it more in his power to throw out his heels: whereas, if his head be raised very high, and his nose thrown out a little, which is consequent, he can neither rise before nor behind; because he can give himself neither of those motions, without having his head at liberty. A plank placed in *æquilibrio*, cannot rise at one end unless it sinks at the other.

Rules for Bad Horsemen.

If your horse is headstrong, pull not with one continued pull, but stop, and back him often, just shaking the reins, and making little repeated pulls till he obeys. Horses are so accustomed to bear on the bit when they go forward, that they are discouraged if the rider will not let them do so.

If a horse is loose-necked, he will throw up his head at a continued pull; in which situation, the rider, seeing the front of his face, can have no power over him. When your horse does thus, drop your hand and give the bridle play, and he will of course drop his head again into its proper place: while it is coming down, make a second gentle pull, and you will find his mouth. With a little practice, this is done almost instantaneously; and this method will stop, in the distance of a few yards, a horse, which will run away with those who pull at him with all their might. Almost every one must have observed, that when a horse feels himself pulled with the bridle, even when he is going gently, he often mistakes what was designed to stop him, as a direction to bear on the bit and to go faster.

Keep your horse's head high, that you may raise his neck and crest; play a little with the rein, and move the bit in his mouth, that he may not press on it in one constant and continued manner: be not afraid of raising his head too high; he will naturally be too ready to bring it down, and tire your arms with its weight, on the least abatement of his mettle. When you feel him heavy, stop him, and make him go back a few paces: thus you break by degrees his propensity to press on his bridle.

You ought not to be pleased (though many are) with a round neck, and a head drawn in towards his breast: let your horse carry his head bridling in, provided he carries it high, and his neck arching upwards; but if his neck bends downwards, his figure is bad, his sight is too near his toes, he leans on the bridle, and you have no command over him. If he goes pressing but lightly on the bridle, he is the more sure-footed, and goes pleasanter; as your wrist only may guide him. If he hangs down his head, and makes you support the weight of that and his neck with your arms bearing on his fore-legs, (which is called *being on his shoulders*), he will strike his toes against the ground, and stumble.

If your horse is heavy upon the bit, tie him every day, for an hour or two, with his tail to the manger, and his head as high as you can make him lift it, by a rein on each post of the stall, tied to each ring of the snaffle bit.

Horse-breakers and grooms have a great propensity to bring a horse's head *down*, and seem to have no seat without a strong hold by the bridle. They know indeed, that the head should yield to the reins, and the neck form an arch; but do not take the proper pains to make it an arch *upward*. A temporary effect of attempting to raise a horse's head, may perhaps be making him push out his nose. They will here tell you, that his head is too high already; whereas it is not the distance from his *nose*, but from the *top* of his head

Rules for Bad Horsemen.

head to the ground, which determines the head to be high or low. Besides, although the fault is said to be in the manner of carrying the head, it should rather be said to be in that of the neck; for if the neck was raised, the head would be more in the position of one set on a well formed neck.

The design therefore of lifting up the head, is to raise the neck, and *thereby* bring in the head; for even while the bridle makes the same line from the rider's hand to the bit, the horse's nose may be either drawn in, or thrust out, according as his neck is raised or depressed. Instead of what has been here recommended, we usually see colts broke with their heads cavessoned very low, their necks stiff, and not in the least suppled. When the breaking-tackle is left off, and they are mounted for the road, having more food and rest, they frequently plunge, and a second breaking becomes necessary. Then, as few gentlemen can manage their own horses, they are put into the hands of grooms, from whom they learn a variety of bad habits.

If, on the other hand, your horse carries his head (or rather his nose) too high, he generally makes some amends by moving his shoulders lightly, and going safely. Attend to the cause of this fault. Some horses have their necks set so low on their shoulders, that they bend first down, then upwards, like a stag's. Some have the upper line of their necks, from their ears to their withers, too short. A head of this sort cannot possibly bend inwards and form an arch, because the vertebræ (or neck bones) are too short to admit of flexure; for in long and short-necked horses the number of the vertebræ is the same. In some, the jaw is so thick, that it meets the neck, and the head by this means has not room to bend. On the other hand, some have the under line from the jaw to the breast so short, that the neck cannot rise.

In all these cases you may gain a *little* by a nice hand with an easy bit; but no curb, martingale, or other forcible method, will *teach* a horse to carry his head or neck in a posture which nature has made uneasy to him. By trying to pull in his nose farther than he can bear, you will add a bad habit to nature. You could not indeed *contrive* a more effectual method to make him continually toss his nose up, and throw his foam over you.

The rule already given to ride a loose-necked horse, will be a proper one for all light-mouthed horses; one caution being added, which is, always to search whether his saddle or girths may not in some way pinch him; and whether the bit may not hurt his lip by being too high in his mouth: because, whenever he frets from either of these causes, his head will not be steady.

It is a common custom to be always pulling at the bridle, as if to set off to advantage either the spirit of the horse, or the skill of the rider. Our horses therefore are taught to hold their heads low, and pull so as to bear up the rider from the saddle standing in his stirrups, even in the gentlest gallop: how very improper is this, we are experimentally convinced, when we happen to meet with a horse which gallops otherwise. We immediately say, *he canters excellently*, and find the ease and pleasure of his motion. When horses are designed for the race, and swiftness is the only thing considered, the method may be a good one.

It is not to be wondered that *dealers* are always pulling at their horses, that they have the spur constantly in their sides, and are at the same time continually checking the rein: by this means they make them bound, and champ the bit, while their rage has the appearance of spirit. These people ride with their arms spread, and very low on the shoulders of their horses: this method makes them stretch their necks, and gives a better appearance to their fore-hands; it conceals also a thick jaw, which, if the head was up, would prevent its yielding to the bit; it hides likewise the ewe-neck, which would otherwise show itself. Indeed, if you have a horse unsteady to the bit, formed with a natural heavy head, or one which carries his nose obstinately in the air, you must find his mouth where you can, and make the best of him.

Many horses are taught to start, by whipping them for starting. How is it possible they can know it is designed as a punishment? In the riding-house, you teach your horse to rise up before, and to spring and lash out his hinder legs, by whipping him when tied between two pillars, with his head a little at liberty. If he understood this to be a punishment for doing so, he would not by that method learn to do it. He seems to be in the same manner *taught* to spring and fly when he is frightened. Most horses would go quietly past an object they were beginning to fly from, if their riders, instead of gathering up their bridles, and showing themselves so ready, should throw the reins loose upon their necks.

When a horse starts at any thing on one side, most riders turn him out of the road, to make him go up to what he starts at: if he does not get the better of his fear, or readily comply, he generally goes past the object, making with his hinder parts, or croup, a great circle out of the road; whereas, he should learn to keep straight on, without minding objects on either side.

If he starts at any thing on the left, hold his head high, and keep it straight in the road, pulling it *from* looking at the thing he starts at, and keeping your right leg hard pressed against his side, towards his flank: he will then go straight along the road. By this method, and by turning his head a little more, he may be forced with his croup close up to what frightened him; for as his head is pulled one way, his croup necessarily turns the other. Always avoid a quarrel with your horse, if you can: if he is apt to start, you will find occasions enough to exercise his obedience, when what he starts at lies directly in his way, and you *must* make him pass; if he is not subject to start, you should not quarrel with him about a trifle.

It must be observed, however, that this rule in going past an object may perhaps be a little irregular in a managed horse, which will always obey the leg: but even such a horse, if he is really afraid, and not restive, it may not be amiss to make look another way; unless the object be something you would particularly accustom him to the sight of.

The case will also be different with a horse whose fear is owing to his being not used to objects; but such

Rules for Bad Horsemen.

such a one is not to be rode by any horseman to whom these rules are directed: the starting here meant arises merely from the horse's being pampered, and springing through liveliness.

The notion of the necessity of making a horse go immediately up to every thing he is afraid of, and not suffering him to become master of his rider, seems to be in general carried too far. It is an approved and good method to conquer a horse's fear of the sound of a drum, by beating one near to him at the time of feeding him: this not only familiarizes the noise to him, but makes it pleasant, as a fore-runner of his meat *; whereas, if he was whipped up to it, he might perhaps start at it as long as he lived. Might not this be applied to his starting at other things, and show that it would be better to suffer him (provided he does not turn back) to go a little from and avoid an object he has a dislike to, and to accustom him to it by degrees, convincing him, as it were, that it will not hurt him; than to punish him, quarrel with him, and perhaps submit to his will at last, while you insist on his overcoming his fear in an instant? If he sees a like object again, it is probable he will recollect his dread, and arm himself to be disobedient.

* See Sect. v.

We are apt to suppose that a horse fears nothing so much as his rider; but may he not, in many circumstances, be afraid of instant destruction? of being crushed? of being drowned? of falling down a precipice? Is it a wonder that a horse should be afraid of a loaded waggon? may not the hanging load seem to threaten the falling on him? There cannot be a rule more general, than, in such a case, to shew him there is room for him to pass. This is done by turning his head a very little from the carriage, and pressing your leg, which is farthest from it, against his side.

A horse is not to stop without a sign from his rider. —Is it not then probable, that when driven up to a carriage he starts at it, he conceives himself obliged either to attack or run against it? Can he understand the rider's spurring him with his face directed to it, as a sign for him to pass it? That a horse is easily alarmed for his face and eyes (he will even catch back his head from a hand going to caress him); that he will not go with any force, face to face, even to another horse (if in his power to stop); and that he sees perfectly sideways,—may be useful hints for the treatment of horses with regard to starting.

Though you ought not to whip a horse for starting, there can be no good effect from clapping his neck with your hand to encourage him. If one took any notice of his starting, it should be rather with some tone of voice which he usually understood as an expression of dislike to what he is doing; for there is *opposition* mixed with his starting, and a horse will ever repeat what he finds has foiled his rider.

Notwithstanding the directions above given, of not pressing a horse up to a carriage he starts at; yet if one which you apprehend will frighten him meets you at a narrow part of the road, when you have once let him know he is to pass it, be sure you remain determined, and press him on. Do this more especially when part of the carriage has already passed you: for if, when he is frightened, he is accustomed to go back, and turn round, he will certainly do it if he finds, by your hand slackening, and legs not pressing, that you are irresolute; and this at the most dangerous point of time, when the wheels of the carriage take him as he turns. Remember not to touch the curb rein at this time; it will certainly check him. It is not known to every one, that the person who would lead a horse by the bridle, should not turn his face to him when he refuses to follow him: if, besides this, he raises his arms, shows his whip, or pulls the bridle with jerks, he frightens the horse, instead of persuading him to follow; which a little patience may bring about.

Ride with a snaffle; and use your curb, if you have one, only occasionally. Choose your snaffle full and thick in the mouth, especially at the ends to which the reins are fastened. Most of them are made too small and long; they cut the horse's mouth, and bend back over the bars of his jaw, working like pincers.

The management of the curb is too nice a matter to enter on here, farther than to prescribe great caution in the use of it: a turn of the wrist, rather than the weight of your arm, should be applied to it. The elasticity of a rod, when it hath hooked a fish, may give you some idea of the proper play of a horse's head on his bridle; his spirit and his pliableness are both marked by it.

A horse should never be put to do any thing in a curb which he is not ready at: you may force him, or pull his head any way with a snaffle; but a curb acts only in a straight line. It is true, that a horse will be turned out of one track into another by a curb, but it is because he knows it as a *signal*. When he is put to draw a chair and does not understand the necessity he is then under of taking a larger sweep when he turns, you frequently see him *restive*, as it is then called: but put him on a snaffle, or buckle the rein to that part of the bit which does not curb him; and the horse submits to be pulled about, till he understands what is desired of him. These directions suppose your horse to have spirit, and a good mouth; if he has not, you must take him as he is, and ride him with such a bit as you find most easy to yourself.

When you ride a journey, be not so attentive to your horse's nice carriage of himself, as to your encouragement of him, and keeping him in good humour. Raise his head; but if he flags, you may indulge him with bearing a little more upon the bit than you would suffer in an airing. If a horse is lame, tender-footed, or tired, he naturally hangs upon his bridle. On a journey, therefore, his mouth will depend greatly on his strength and the goodness of his feet. Be then very careful about his feet, and let not a farrier spoil them. You will be enabled to keep them from danger, by the directions given under the article FARRIERY.

Very few, although practised in riding, know they have any power over a horse but by the bridle; or any use for the spur, except to make him go forward. A little experience will teach them a farther use. If the left spur touches him (and he is at the same time prevented from going forward), he has a sign, which he will soon understand, to move sidewise to the right. In the same manner to the left, if the right spur is closed to him: he afterwards, through fear of the spur,

Rules for Bad Horsemen.

spur, obeys a touch of the leg; in the same manner as a horse moves his croup from one side of the stall to the other, when any one strikes him with his hand. In short, his croup is guided by the leg, as his head is by the bridle. He will never disobey the leg, unless he becomes restive. By this means you will have a far greater power over him; he will move sidewise, if you close one leg to him; and straight forward, if both: even when he stands still, your legs held near him will keep him on the watch; and with the slightest unseen motion of the bridle upwards, he will raise his head, and show his forehand to advantage.

On this use of the legs of the rider, and guidance of the croup of the horse, are founded all the *airs* (as the riding-masters express themselves) which are taught in the manege; the passage, or side-motion of troopers to close or open their files, and indeed all their evolutions. But the convenience of some degree of this discipline for common use is the reason of mentioning it here. It is useful if a horse is apt to stumble or start. If to the first, by pressing your legs to his flank, and keeping up his head, he is made to go light on his fore-legs, which is aiding and supporting him; and the same if he does actually stumble, by helping him at the very instant to exert himself, while as yet any part of him remains not irrecoverably impressed with the precipitate motion. Hence this use of the hand and legs of the rider is called *giving aids* to a horse; for, as to holding up the weight of a heavy unactive horse, by mere pulling, it is as impossible as to recover him when falling down a precipice.

A horse is supported and helped by the hands and legs of his rider in every action they require of him; hence he is said to perform his *airs* by the *aids* from his rider.

The same manner is useful if a horse starts. For if when he is beginning to fly to one side, you leg on the side he is flying to, he stops his spring immediately. He goes past what he started at, keeping straight on, or as you choose to direct him; and he will not fly back from any thing if you press him with both legs. You keep his haunches under him, going down a hill; help him on the side of a bank; more easily avoid the wheel of a carriage; and approach more gracefully and nearer to the side of a coach or horseman. When a pampered horse curvets irregularly, and twists his body to and fro, turn his head either to the right or left, or both alternately (but without letting him move out of the track), and press your leg to the opposite side: your horse cannot then spring on his hind-legs to one side, because your leg prevents him; nor to the other, because his head looks that way, and a horse does not start and spring to the side on which he looks. Here it may not be amiss to observe the impropriety of the habit which many riders have, of letting their legs shake against the sides of the horse: if a horse is taught, they are then continually pressing him to violent action; and if he is not, they render him insensible and incapable of being taught. The fretting of a hot horse will hence be excessive, as it can no otherwise be moderated than by the utmost stillness of the seat, hands, and legs of the rider.

Colts at first are taught to *bear* a bit, and by degrees to *pull* at it. If they did not press it, they could not be guided by it. By degrees they find their necks stronger than the arms of a man; and that they are capable of making great opposition, and often of foiling their riders. Then is the time to make them supple and pliant in every part. The part which of all others requires most this pliancy is the neck. Hence the metaphor of *stiff-necked* for *disobedient*. A horse cannot move his head but with the muscles of his neck: this may be called his *helm;* it guides his course, changes and directs his motion.

The use of this pliancy in the different parts and limbs of a horse has been already shown in a former section. The present section being directed to the *inexperienced* horseman, it may suffice to add that *his* idea of suppleness need only be, that of an ability and readiness in a horse to move every limb, on a sign given him by the hands or legs of his rider; as also to bend his body, and move in a short compass, quick and collected within himself, so as instantly to be able to perform any other motion.

Horsham.

HORSHAM, a town of Sussex, seated near St Leonard's forest, 38 miles from London. It has its name from Horsa, brother to Hengist the Saxon; and is one of the largest towns in the county. It has sent members to parliament ever since the 30th of Edw. I. and is the place where the county-gaol is held, and often the assizes. It is a borough by prescription, with the title of two bailiffs and burgage-holders within and without the borough, &c. who elect the members of parliament, and they are returned by the bailiffs chosen yearly by a court-leet of the lord of the manor, who return four candidates to the steward, and he nominates two of them for the office. Here is a very fine church, and a well endowed free-school. Great store of poultry is bought up for London at its market on Saturday, and it has a patent also for a monthly market. In 1811, the number of inhabitants was 3839.

Horsham ‖ Hortensius.

HORTALIGERS, in the grand signior's court, upholsterers, or tapestry-hangers, who go always a day's journey before the grand signior, to fix upon a proper place for his tent, which they prepare first; and afterwards those of the officers, according to their rank.

HORTENSIUS, Quintus, a celebrated Roman orator, the contemporary of Cicero, pleaded with universal applause at 19 years of age, and continued the same profession during 48 years. But being at last eclipsed by Cicero, he quitted the bar, and embraced a military life: became a military tribune, prætor, and afterwards consul about 80 B. C. Cicero speaks of him in such a manner as makes us regret the loss of of his orations. Hortensius had a wonderful memory, and delivered his orations without writing down a single word, or forgetting one particular that had been advanced by his adversaries. He died very rich, a little before the civil war, which he had endeavoured by all possible means to prevent.

HORTICULTURE, the art of cultivating fruits, flowers, and various esculent plants, being the same as gardening. See SUPPLEMENT.

HORTUS SICCUS, a DRY GARDEN; an appellation given to a collection of specimens of plants, carefully dried and preserved.

The value of such a collection is very evident, since a thousand minutiæ may be preserved in well-dried specimens of plants, which the most accurate engraver would overlook. We shall therefore give two methods of drying and preserving a *hortus siccus;* the first by Sir Robert Southwell in the Philosophical Transactions, N° 237.; and the other by Dr Hill, in his review of the works of the Royal Society, with his objections to Sir Robert's method.

According to the former gentleman, the plants are to be laid flat between papers, and then put between two smooth plates of iron, screwed together at the corners; and in this condition committed to a baker's oven for two hours. When taken out, they are to be rubbed over with a mixture of equal parts of aquafortis and brandy; and after this to be fastened down on paper with a solution of the quantity of a walnut of gum tragacanth dissolved in a pint of water. See HERBAL.

To this the Doctor objects, that the heat of an oven is much too uncertain to be employed in so nice an operation; and that the space of time ordered for continuing the plants in it is of no information, unless the degree of heat, and even the different nature of the plant as to its succulency and the firmness or tenderness of its fibres, be attended to; there being scarcely any two plants alike in these particulars: consequently the degree and duration of heat sufficient for one plant would destroy another. Beside which, the acid used destroys the colour of many plants; and never recovers that of others lost in the dyeing; and frequently after the plant is fixed down, rots both the paper it is fixed to, and that which falls over it. Dr Hill's method is as follows. Take a specimen of a plant in flower, and with it one of its bottom leaves if it have any; bruise the stalk if too rigid, or slit it if too thick: spread out the leaves and flowers on paper, cover it with more paper, and lay a weight over all. At the end of 18 hours take out the plants, now perfectly flattened, and lay them on a bed of dry common sand; sift more dry sand over them to the depth of two inches, and thus let them lie about three weeks: the less succulent dry much sooner, but they take no harm afterward. If the floor of a garret be covered in spring with sand two inches deep, leaving space for walking to the several parts, it will receive the collection of a whole summer; the covering of sand being sifted over every parcel as laid in, they need no farther care from the time of laying them till they are taken up to be stuck on paper. The cement used by the Doctor is thus prepared: early in the spring, put two ounces of camphor into three quarts of water in a large bottle; shake it from time to time, and when the first collected plants are ready for the fastening down, put into a pint of the water, poured off into an earthen vessel that will bear the fire, two ounces of common glue, such as is used by the carpenters, and the same quantity of ichthyocolla beat to shreds: let them stand 36 hours, then gently boil the whole a few moments, and strain it off through a coarse cloth: this is to be warmed over a gentle heat when it is to be used, and the back of the plants smeared over with a painter's brush: after this lay them on paper, and gently press them for a few minutes, then expose them to the air a little; and finally lay them under a small weight between quires of paper to be equally dried.

It is scarce to be conceived how strongly the water becomes impregnated with the camphor by this simple process: a part of it indeed flies off in the making of the cement and the using of it: but enough remains with the plants to prevent the breeding of insects in it. He farther observes, that plants may be dried very well without sand, by only putting them frequently into fresh quires of paper, or a few, by only pressing them between the leaves of a book: but the sand method preserves the colour best, and is done with least trouble.

Another method much better than that of the oven is the flattening and drying the plant by passing a common smoothing iron for linen over the papers between which it is laid; but for nice things the most perfect of all methods is that by a common sand heat, such as is used for chemical purposes. The cold sand is to be spread smooth upon this occasion, the plant laid on it carefully flatted, and a thick bed of sand sifted over: the fire is then to be made, and the whole process carefully watched until by a very gentle heat the plant be carefully dried. The colour of the tenderest herb may by this manner be preserved; and flowers, that can no way else be preserved, may be managed perfectly well thus.

HORUS, a renowned deity of ancient Egypt. He was an emblem of the sun. Plutarch (in his treatise *de Iside et Osiride*) says, "that virtue which presides over the sun, whilst he is moving through space, the Egyptians called *Horus* and the Greeks *Apollo.*" Job also calls *Ur* or *Orus* the sun—"If I gazed upon the sun (*Ur, Orus*) when he was shining, or on (*Järécha*) the moon walking in brightness, and my heart hath been secretly enticed (i. e. to worship), or my mouth hath kissed my hand; this also were an iniquity to be punished by the judge, for I should have denied the God who is above." Chap. xxxi. ver. 26, 27, 28.

The interpretation left by Hermapion of the hieroglyphics engraved on the obelisk of Heliopolis (according to Ammianus Marcellinus), offers these remarkable words: "Horus is the supreme lord and author of time." These qualities, it is known, were chiefly attributed to Osiris: that they may apply, therefore, to Horus, he must necessarily denote the star of the day in certain circumstances; and this is what is explained to us by the oracle of Apollo of Claros:

> Learn that the first of the gods is Jao.
> He is called *invisible* in winter, Jupiter in the spring,
> The *sun* in summer, and towards the end of autumn
> the tender *Jao.*

The star of the day, on attaining the summer solstice, and called *per excellentiam* the Sun, is the same as Horus.

rus. In fact, the Egyptians represented him borne on lions, which signified his entrance into the sign of the lion. They who presided over the divine institutions, then placed sphynxes at the head of the canals and sacred fountains, to warn the people of the approaching inundation. Macrobius *, who informs us why the Greeks gave Horus the name of Apollo, confirms this sentiment: "In the mysteries (says he) they discover as a secret, which ought to be inviolable, that the sun arrived in the upper hemisphere, is called Apollo." These testimonies concur in proving, that this emblematical deity was no other than the star of day, passing through the signs of summer.

* *Saturnal.* lib. i.

These lights may lead us to the explication of the sacred fable, which the priests published on the subject of Horus; for they enveloped in mystery every point of their religion. Plutarch gives it at length in his treatise of Isis and Osiris: The following are the principal traits. They said that he was the son of Osiris and of Isis; that Typhon, after killing his brother Osiris, took possession of the kingdom; that Horus, leaguing himself with Isis, avenged the death of his father, expelled the tyrant from his throne without depriving him of life, and reigned gloriously in Egypt. A person who has travelled ever so little in Egypt easily discovers natural phenomena hid under the veil of fable. In the spring, the wind khamsin frequently makes great ravages there. It raises whirlwinds of burning sand, which suffocate travellers, darken the air, and cover the face of the sun in such a manner as to leave the earth in perfect obscurity. Here is the death of Osiris and the reign of Typhon. These hurricanes break out usually in the months of February, March, and April. When the sun approaches the sign of the lion, he changes the state of the atmosphere, disperses these tempests, and restores the northerly winds, which drive before them the malignant vapours, and preserve in Egypt coolness and salubrity under a burning sky. This is the triumph of Horus over Typhon, and his glorious reign. As the natural philosophers acknowledge the influence of the moon over the state of the atmosphere, they united her with this god, to drive the usurper from the throne. The priests considering Osiris as the father of time, might bestow the name of his son on Horus, who reigned three months in the year. This, according to Mr Savary †, is the natural explication of this allegory. And all enlightened men, he thinks, must have understood this language, which was familiar to them. The people only, whose feeble sight extends no farther than the exterior, without diving into the true meaning of things, might regard these allegorical personages as real gods, and decree prayers and offerings to them.

† *Letters on Egypt*, ii. 403.

Jablonski, who has interpreted the epithet of Arueri, which the Egyptians gave to Horus, pretends that it signifies *efficacious virtue*. These expressions perfectly characterise the phenomena which happened during the reign of this god. It is in summer, in fact, that the sun manifests all its power in Egypt. It is then that he swells the waters of the rivers with rains, exhaled by him in the air, and driven against the summits of the Abyssinian mountains; it is then that the husbandman reckons on the treasures of agriculture. It was natural for them to honour him with the name of *Arueri*, or *efficacious virtue*, to mark these auspicious effects.

HOSANNA, in the Hebrew ceremonies, a prayer which they rehearsed on the several days of the feast of tabernacles. It was thus called, because there was frequent repetition therein of the word הושענא, *serva nunc*, or *serva precor*; i. e. save us now; or save us, we pray.

There are divers of these hosannahs. The Jews call them *hoschannoth*; i. e. the *hosannas*. Some are rehearsed on the first day, others on the second, &c. which they called *hosanna* of the first day, *hosanna* of the second day, &c.

Hosanna Rabba, or *Grand Hosanna*, is a name they give to their feast of tabernacles, which lasts eight days; because during the course thereof, they are frequently calling for the assistance of God, the forgiveness of their sins, and his blessing on the new year; and to that purpose they make great use of the hoschannoth, or prayers above mentioned.—The Jews also applied the term *hosanna rabba*, in a more peculiar manner, to the seventh day of the feast of tabernacles; because they apply themselves more immediately on that day to invoke the divine blessing, &c.

HOSE, from the Saxon *Hosa*, a stocking. See Stocking.

HOSEA, the first in number of the minor Hebrew prophets, as arranged in the Hebrew and Greek bibles, although probably the third in a chronological sense. He was the son of Beeri, but it is uncertain to what tribe he belonged. He prophesied in the reigns of Uzziah, Jotham, Ahaz, and Hezekiah, kings of Judah, and in the time of Jeroboam, who was king of Israel. If he uttered predictions during 66 years, between 790 and 724 before Christ, then he discharged the office of a sacred seer eight years during the reign of Jeroboam II. 33 in the reign of Uzziah, the entire reigns of Jotham and Ahaz, and three years in the reign of Hezekiah; but could not have survived the taking of Samaria. He reproved the vices of kings as well as their subjects, mixing threatenings of divine vengeance with promises of pardon in consequence of repentance. His style is concise, sententious, and abrupt. His short and lively comparisons are numerous. He is sometimes distinguished by great force of expression, has many beautiful passages, and in some parts is truly sublime. Dr Newcome was of opinion that the chief difficulty in understanding this prophet is owing to the corrupt readings which disfigure the printed text, and these he freely corrected from the collations of Dr Kennicott. On the other hand, Dr Horsley protests earnestly against Dr Newcome's opinion, declaring that the corruptions can be no cause of obscurity; but we must leave it to our readers to determine which of these two great men is in the right, from an attentive perusal of their own works, assured that they will decide in favour of him who furnishes the best helps for understanding this prophet.

HOSPINIAN, Rodolphus, one of the greatest writers that Switzerland has given birth to. He was born in 1547, at Altorf near Zurich; obtained the freedom of Zurich; and was made provisor of the abbey-school. Notwithstanding this employment, he undertook a noble work of vast extent, which was a *History of the Errors of Popery*. Though he could not

not complete this work according to his plan, he published some considerable parts of it: what he published on the Eucharist, and another work called *Concordia Discors*, exceedingly exasperated the Lutherans. He did not reply to them; but turning his arms against the Jesuits, published *Historia Jesuitica*, &c. These writings gained him preferment; he being appointed archdeacon of Caroline church, and then minister of the abbey-church. He died in 1626; and there was an edition of his works published at Geneva 1681, in seven volumes in folio.

HOSPITAL, popularly SPITTAL, a place or building erected, out of charity, for the reception and support of the poor, aged, infirm, sick, and otherwise helpless. The word is formed of the Latin *hospes*, "host, stranger." See HOST.

In the early ages of the church, the bishop had the immediate charge of all the poor, both sound and diseased, as also of widows, orphans, strangers, &c.—When the churches came to have fixed revenues allotted them, it was decreed, that at least one-fourth part thereof should go to the relief of the poor; and to provide for them the more commodiously, divers houses of charity were built, which are since denominated *hospitals*. They were governed wholly by the priests and deacons, under the inspection of the bishop. In course of time, separate revenues were assigned for the hospitals; and particular persons, out of motives of piety and charity, gave lands and money for erecting of hospitals. When the church discipline began to relax, the priests, who till then had been the administrators of hospitals, converted them into a sort of benefices, which they held at pleasure, without giving account thereof to any body; reserving the greatest part of the income to their own use; so that the intentions of the founders were frustrated.—To remove this abuse, the council of Vienne expressly prohibited the giving any hospital to secular priests in the way of a benefice; and directed the administration thereof to be given to sufficient and responsible laymen, who should take an oath, like that of tutors, for the faithful discharge thereof, and be accountable to the ordinaries.—This decree was executed and confirmed by the council of Trent.

In Britain, hospitals are buildings properly endowed, or otherwise supported by charitable contributions, for the reception and support of the poor, aged, infirm, sick, or helpless.

A charitable foundation laid thus for the sustenance and relief of the poor is to continue for ever. Any person seized of an estate in fee, may, by deed inrolled in chancery, erect and found an hospital, and nominate such heads and governors therein as he shall think fit; and this charitable foundation shall be incorporated, and subject to the inspection and guidance of the heads and visitors nominated by the founder. Likewise such corporations shall have, take, and purchase lands, so as not to exceed 200l. a year, provided the same be not held of the king; and to make leases, reserving the accustomed yearly rent. See CORPORATION.

HOSPITAL, MICHAEL DE L', chancellor of France in the 16th century, was one of the greatest men of his age, and had raised himself by degrees. He agreed to an edict much severer against the Protestants than he could have wished, to prevent the introduction of the inquisition. It was that of Romorantin. The speeches he made, in order to inspire a spirit of toleration, made him much suspected by the Roman Catholics, and extremely odious to the court of Rome. The maxims of state upon which he regulated himself were of great advantage to France, since he formed some disciples who opposed, in proper time, the pernicious attempts of the leaguers, and rendered them abortive. His pacific views being disliked by Catharine de Medicis, who had contributed to his advancement, she excluded him from the council of war, and occasioned his disgrace. He retired, however, of his own accord, in 1568; and spent the rest of his life at his country-seat at Vignai, where he died in 1573, aged 68. His poems are esteemed. He also published some excellent speeches and memoirs.

HOSPITAL, *William-Francis-Antony, Marquis of*, a great mathematician of France, was born of an ancient family in 1661. He was a geometrician almost from his infancy; for one day being at the duke of Rohan's, where some able mathematicians were speaking of a problem of Paschal's which appeared to them extremely difficult, he ventured to say, that he believed he could solve it. They were amazed at such presumption in a boy of 15, for he was then no more; nevertheless, in a few days he sent them the solution. He entered early into the army, and was a captain of horse; but being extremely short-sighted, and exposed on that account to perpetual inconveniences and errors, he at length quitted the army, and applied himself entirely to his favourite amusement. He contracted a friendship for Malebranche, and took his opinion upon all occasions. In 1693, he was received an honorary member of the academy of sciences at Paris; and he published a work upon Sir Isaac Newton's calculations, entitled, *L'Analyse des infinimens petits*. He was the first in France who wrote upon this subject; and on this account was regarded almost as a prodigy. He engaged afterwards in another work of the mathematical kind, in which he included *Les Sections Coniques, les Lieux Geometriques, la Construction des Equations, et Une Theorie des Courbes Mechaniques*: but a little before he had finished it, he was seized with a fever, of which he died Feb. 2. 1704, aged 43. It was published after his death.

HOSPITALITY, the practice of entertaining strangers. Dr Robertson, speaking of the middle ages, says, "Among people whose manners are simple, and who are seldom visited by strangers, hospitality is a virtue of the first rank. This duty of hospitality was so necessary in that state of society which took place during the middle ages, that it was not considered as one of those virtues which men may practise or not, according to the temper of their minds and the generosity of their hearts. Hospitality was enforced by statutes, and those who neglected the duty were liable to punishment. The laws of the Salvi ordained that the moveables of an inhospitable person should be confiscated, and his house burnt. They were even so solicitous for the entertainment of strangers, that they permitted the landlord to steal for the support of his guest."

The hospitality of our British ancestors, particularly of the great and opulent barons, hath been much admired,

mired, and considered as a certain proof of the nobleness and generosity of their spirits. The fact is well attested. The castles of the powerful barons were capacious palaces, daily crowded with their numerous retainers, who were always welcome to their plentiful tables. They had their privy counsellors, their treasurers, marshals, constables, stewards, secretaries, chaplains, heralds, pursuivants, pages, henshmen or guards, trumpeters, minstrels, and in a word all the officers of a royal court. The etiquette of their families was an exact copy of that of the royal household; and some of them lived in a degree of pomp and splendour little inferior to that of the greatest kings. Richard Neville, earl of Warwick, we are told, "was ever had in great favour of the commons of the land, because of the exceeding household which he daily kept in all countries wherever he sojourned or lay: and when he came to London, he held such an house, that six oxen were eaten at a breakfast; and every tavern was full of his meat." The earls of Douglas in Scotland, before the fall of that great family, rivalled or rather exceeded their sovereigns in pomp and profuse hospitality. But to this manner of living it is highly probable these great chieftains were prompted by a desire of increasing the number and attachment of their retainers, on which, in those turbulent times, their dignity, and even their safety, depended, as much as to the innate generosity of their tempers. Those retainers did not constantly reside in the families of their lords; but they wore their liveries and badges, frequently feasted in their halls, swelled their retinues on all great solemnities, attended them in their journeys, and followed them into the field of battle. Some powerful chieftains had so great a number of these retainers constantly at their command, that they set the laws at defiance, were formidable to their sovereigns, and terrible to their fellow-subjects; and several laws were made against giving and receiving liveries. But these laws produced little effect in this period.

Hospitality was not confined to the great and opulent, but was practised rather more than it is at present by persons in the middle and lower ranks of life. But this was owing to necessity, arising from the scarcity of inns, which obliged travellers and strangers to apply to private persons for lodging and entertainment; and those who received them hospitably acquired a right to a similar reception. This was evidently the case in Scotland in the first part of this period. James I. A. D. 1424, procured the following act of parliament. "It is ordanit, That in all burrow townis, and throuchfairis quhair commoun passages ar, that thair be ordanit hostillaries and resettis, havand stables and chalmers; and that men find with thame bread and aill, and all uther fude, alsweil for horse as men, for resonable price." But travellers had been so long accustomed to lodge in private houses, that these public inns were quite neglected; and those who kept them presented a petition to parliament, complaining, "That the liegis travelland in the realme, quhen they cum to burrowis and throuchfairis, herbreis thame not in hostillaries, bot with thair acquaintance and freindis." This produced an act prohibiting travellers to lodge in private houses where there were hostlaries, under the penalty of 40s. and subjecting those who lodged them to the same penalty.

The inhabitants of the Highlands and the Western Isles were remarkable for their hospitality and kindness to strangers, and still retain the same disposition. See Highlanders.

HOSPITALLERS, Hospitalarii, an order of religious knights, who built an hospital at Jerusalem, wherein pilgrims were received. To these Pope Clement V. transferred the effects and revenues of the Templars; whom, by a council held at Vienne, he suppressed for their many and great misdemeanours. These hospitallers were otherwise called *Knights of St John of Jerusalem;* and are the same with those whom we now call *Knights of Malta.*

HOSPITIUM, a term used in old writers either for an inn or a monastery, built for the reception of strangers and travellers. See Inn and Monastery.

HOSPODAR, a title borne by the princes of Walachia and Moldavia, who receive the investiture of their principalities from the grand signior. He gives them a vest and standard; they are under his protection, and obliged to serve him, and he even sometimes deposes them; but in other respects they are absolute sovereigns within their own dominions.

HOST, Hospes, a term of mutual relation, applied both to a person who lodges and entertains another, and to the person thus lodged, &c.—The word is formed of the Latin *hospes*, which some will have thus called *quasi hostium* or *ostium petens;* for *ostium* was anciently written with an aspirate.—Thus the innkeeper says, he has a good *host*, in speaking of the traveller who lodges with him: and the traveller, again, says, he has a kind *host*, in speaking of his landlord.

It must be observed then, that it was the custom among the ancients, when any stranger asked for lodging, for the master of the house, and the stranger, each of them to set a foot on their own side of the threshold, and swear they would neither of them do any harm to the other. It was this ceremony that raised so much horror against those who violated the law or right of hospitality on either side; inasmuch as they were looked on as perjured.

Instead of *hospes*, the ancient Latins called it *hostis;* as Cicero himself informs us: though, in course of time, *hostis* came to signify an enemy; so much was the notion of hospitality altered.

Host is also used by way of abbreviation for *hostia*, a victim or sacrifice offered to the Deity. In this sense, *host* is more immediately understood of the person of the Word incarnate, who was offered up an host or *hostia* to the Father on the cross for the sins of mankind. See Hostia.

Host, in the church of Rome, a name given to the elements used in the eucharist, or rather to the consecrated wafer; which they pretend to offer up every day a new host or sacrifice for the sins of mankind.—They pay adoration to the host, upon a false presumption that the elements are no longer bread and wine, but transubstantiated into the real body and blood of Christ. See Transubstantiation.—Pope Gregory IX. first decreed a bell to be rung, as the signal for the people to betake themselves to the adoration of the host.—The vessel wherein the hosts are kept is called the *cibory;* being a large kind of covered chalice.

HOSTAGE,

HOSTAGE, a person given up to an enemy as a security for the performance of the articles of a treaty.

HOSTIA, Host, in antiquity, a victim offered in sacrifice to a deity.

The word is formed from *hostis*, "enemy;" it being the custom to offer up a sacrifice before they joined battle, to render the gods propitious; or, after the battle was over to give them thanks. Some choose to derive the word from *hostio*, q. d. *ferio*, "I strike." Isidore on this word remarks, that the name *hostia* was given to those sacrifices which they offered before they marched to attack an enemy, (*antequam ad hostem pergerent*): in contradistinction from *victima*, which were properly those offered after the victory.

Hostia also signified the lesser sorts of sacrifice, and *victima* the larger. A. Gellius says, that every priest, indifferently, might sacrifice the *hostia*, but that the *victima* could be offered by none but the conqueror himself. But, after all, we find these two words promiscuously used one for the other by ancient writers. We read of many kinds of *hostiæ*: as *hostiæ puræ*, which were pigs or lambs ten days old; *hostiæ præcidaneæ*, sacrifices offered the day before a solemn feast; *hostiæ bidentes*, sacrifices of sheep or other animals of two years old; *hostiæ eximiæ*, a sacrifice of the flower of the flock; *hostiæ succedaneæ*, sacrifices offered after others which had exhibited some ill omen; *hostiæ ambarvales*, victims sacrificed after having been solemnly led round the fields at the *ambarvalia*; *hostiæ amburbiales*, victims slain after the *amburbium*; *hostiæ caneares* or *caviares*, victims sacrificed every fifth year by the college of pontiffs, in which they offered the part of the tail called *caviar*; *hostiæ prodigiæ*, sacrifices in which the fire consumed all, and left nothing for the priests; *hostiæ piaculares*, expiatory sacrifices; *hostiæ ambegnæ* or *ambiegnæ*, sacrifices of cows or sheep that had brought forth twins; *hostiæ harugæ*, victims offered to predict future events from; *hostiæ mediales*, black victims offered at noon.

HOSTILITY, the action of an enemy, or a state of warfare. The word is Latin, *hostilitas*, formed of the primitive *hostis*, which signifies "enemy;" and which anciently signified "stranger," *hospes*.

HOT-BEDS, in *Gardening*, beds made with fresh horse-dung, or tanners bark, and covered with glasses to defend them from cold winds.

By the skilful management of hot-beds, we may imitate the temperature of warmer climates; by which means, the seeds of plants brought from any of the countries within the torrid zone may be made to flourish even under the poles.

The hot-beds commonly used in kitchen-gardens are made with new horse-dung mixed with the litter of a stable, and a few sea-coal ashes, which last are of service in continuing the heat of the dung. This should remain six or seven days in a heap; and being then turned over, and the parts mixed well together, it should be again cast into a heap; where it may continue five or six days longer, by which time it will have acquired a due heat. These hot-beds are made in the following manner: In some sheltered part of the garden, dig out a trench of a length and width proportionable to the frames you intend it for; and if the ground be dry, about a foot or a foot and a half deep; but if it be wet, not above six inches: then wheel the dung into the opening, observing to stir every part of it with a fork, and to lay it exactly even and smooth on every part of the bed, laying the bottom part of the heap, which is commonly free from litter, upon the surface of the bed: and if it be designed for a bed to plant out cucumbers to remain for good, you must make a hole in the middle of the place designed for each light about ten inches over, and six deep, which should be filled with good fresh earth, thrusting in a stick to show the places where the holes are; then cover the bed all over with the earth that was taken out of the trench about four inches thick, and put on the frame, letting it remain till the earth be warm, which commonly happens in three or four days after the bed is made, and then the plants may be placed in it. But if your hot-bed be designed for other plants, there need be no holes made in the dung; but after having smoothed the surface with a spade, you should cover the dung about three or four inches thick with good earth, putting on the frames and glasses as before. In making these beds, care must be taken to settle the dung close with a fork; and if it be pretty full of long litter, it should be trod down equally on every part. During the first week or ten days after the bed is made, you should cover the glasses but slightly in the night, and in the day-time carefully raise them, to let out the steam: but as the heat abates, the covering should be increased; and as the bed grows cold, new hot dung should be added round the sides of it.

The hot-bed made with tanners bark is, however, much preferable to that described above, especially for all tender exotic plants and fruits, which require an even degree of warmth to be continued for several months, which cannot be effected with horse-dung. The manner of making them is as follows: Dig a trench about three feet deep, if the ground be dry; but if wet, it must not be above a foot deep at most, and must be raised two feet above the ground. The length must be proportioned to the frames intended to cover it; but it should never be less than ten or twelve feet, and the width not less than six. The trench should be bricked up round the sides to the above-mentioned height of three feet, and filled in the spring with fresh tanners bark that has been lately drawn out of their vats, and has lain in a round heap, for the moisture to drain out of it, only three or four days: as it is put in, gently beat it down equally with a dung-fork; but it must not be trodden, which would prevent its heating, by settling it too close: then put on the frame, covering it with glasses; and in about ten days or a fortnight it will begin to heat; at which time plunge your pots of plants or seeds into it, observing not to tread down the bark in doing it. These beds will continue three or four months in a good temper of heat; and if you stir up the bark pretty deep, and mix a load or two of fresh bark with the old when you find the warmth decline, you will preserve its heat two or three months longer. Many lay some hot horse-dung in the bottom of the trench under the bark; but this ought never to be practised unless the bed is wanted sooner than the bark would heat of itself, and even then there ought only to be a small quantity of dung at the bottom.

The

The frames which cover these beds should be proportioned to the several plants they are designed to contain. If they are to cover the ananas or pine-apple, the back part should be three feet high, and the lower part 14 inches: if the bed be intended for taller plants, the frame must be made of a depth proportionable to them; but if it be for sowing of seeds, the frame need not be above 14 inches high at the back, and 7 in the front; by which means the heat will be much greater.

Hot-House. See STOVE and HYPOCAUSTUM.

HOTEL, a French term, anciently signifying a house or dwelling place.—It is now more commonly used for the palaces or houses of the king, princes, and great lords. In this sense they say, the *hotel de Conde*, *hotel de Conti*, *hotel du Louvre*, &c.

The grand *prevot de l'hotel*, is the first judge of the officers of the king's household. His jurisdiction is much like that of lord steward of the household of the king of England.

The *hotel de ville* is what we call a *town-house* or *town-hall*.

HOTEL, is likewise used for a large inn, also for a large lodging-house ready furnished.

HOTTENTOTS, a people in the southern part of Africa, whose country extends north by west from the Cape of Good Hope beyond the mouth of Orange river, and from that cape in an east-north-east direction to the mouth of the great Fish river, which parts it from Caffraria. According to Sanutus, this coast, beginning at the Mountains of the Moon under the tropic of Capricorn in $23\frac{1}{2}°$ S. Lat. extends north beyond the Cape to the coast of Zanguebar; having the Indian sea on the east, the Ethiopic on the west, the southern ocean on the south; and on the north the kingdoms of Mattatan, Monomotapa, and the coast of Zanguebar, or rather the Mountains of the Moon, which divide it from the rest of the continent.

The Europeans first became acquainted with this country in the year 1493, when Bartholomew Diaz, a Portuguese admiral, discovered the most southerly point of Africa, now called the *Cape of Good Hope*, but by him *Cabos dos totos tormentos*, or Cape of all Plagues, on account of the storms he met with in the neighbourhood; but John, then king of Portugal, having from the account of Diaz concluded that a passage to the East Indies was now discovered, changed the name to that of the *Cape of Good Hope*, which it still retains. In 1497, it was circumnavigated by Vasco de Gama, who made a voyage to India that way; however, it remained useless to Europeans till the year 1650, when Van Riebeck a Dutch surgeon first saw the advantages that would accrue to the East India company in Holland from a settlement at such a convenient distance both from home and from India. The colony which he planted has ever since continued in the hands of the Dutch, has greatly increased in value, and is visited by all the European ships trading to the East Indies. See GOOD-*Hope*.

The country now possessed by the Dutch is of pretty considerable extent, and comprehends that part of the African coast on the west called *Terra de Natal*. It is naturally barren and mountainous; but the industry of the Dutch hath overcome all natural difficulties, and it now produces not only a sufficiency of all the necessaries of life for the inhabitants, but also for the refreshment of all the Europeans who pass and repass that way.

The coast abounds in capes, bays, and roads. Thirty leagues to the east of the Cape of Good Hope, in S. Lat. 34. 21. is another cape which runs out beyond 35°, called by the Portuguese, who first doubled it, *Cabo dos Agulhas*, or the *Cape of Needles*, on account of some strange variations in the magnetical needle observed as they came near it. Near this cape is a flat shore, with plenty of fish: it begins in the west near a fresh-water river, and, extending 15 leagues in the main sea, ends in the east near *Fish-bay*. Cabo Falso, so called by the Portuguese, who returning from India mistook it for the Cape of Good Hope, lies to the eastward between these two capes, about eight or nine leagues beyond that of Good Hope. Along the coasts, on both sides of the Cape of Good Hope, are many fine bays. Twenty-seven leagues to the north-west is Saldanha bay, so named from a Portuguese captain shipwrecked on the coast. The largest and most commodious is *Table Bay*, on the south, and near the mountain of that name, six leagues in circumference, with four fathoms water close to the beach. Opposite to this bay is *Robu Eilan*, or the island of Rabbits in 34. 30. S. Lat. 67 leagues east from the Cape of Good Hope. Peter Both, in 1661, discovered a bay, which he named *Uleest*, sheltered only from north winds, in which is a small island, and on the west a rivulet of fresh water extremely convenient for European mariners. Twenty-five or thirty leagues farther east Both discovered Marshal Bay, afterwards named by the Portuguese *Seno Formoso*. Next to this is *Seno de Lago*, from its resemblance to a lake. There are several roads in this bay, and an island called *Ilha dos Caos*. Cabo de S. Francisco, and Cabo das Serras, are marked upon charts between these two bays. Near the latter of these capes is Cabo de Arecito, and the island Contento; and something more north-east is St Christopher's river, called *San Christovano* by the Portuguese, and by the Hottentots *Nagod*. The country beyond this river was called by the Portuguese, who discovered it on the day of our Lord's nativity, *Terra de Natal*. Between the Cape of Good Hope and Cabo das Agulhas are the Sweet, Salt, and Jagulina rivers, which run into the sea, and Sweet-water river flows from the Table-mountain.

The most remarkable mountains in this country are, Table-mountain, Devil's Tower, Lion's Head, and the Tiger hills. The three first lie near Table-bay, and surround Table-valley, where the Cape-town stands. (See the article GOOD-*Hope*). Mr Forster, in his voyage, informs us, that "the extremity of Africa towards the south is a mass of high mountains, of which the outermost are craggy, black, and barren, consisting of a coarse granite, which contains no heterogeneous parts, such as petrified shells, &c. nor any volcanic productions. The ground gradually rises on all sides towards the three mountains which lie round the bottom of the bay, keeping low and level only near the sea-side, and growing somewhat marshy in the isthmus between False and Table bays, where a salt rivulet falls into the latter. The marshy part has some verdure, but inter-

mixed

Hottentots. mixed with a great deal of sand. The higher grounds, which, from the sea side, have a parched and dreary appearance, are, however, covered with an immense variety of plants, among which are a prodigious number of shrubs, but scarce one or two species that deserve the name of *trees*. There are also a few small plantations wherever a little run of water moistens the ground. The ascent of Table-mount is very steep and difficult, on account of the number of loose stones which roll away under the feet of the traveller. About the middle of the mountain is a bold, grand chasm, whose walls are perpendicular, and often impending rocks piled up in strata. Some rills of water ooze out of crevices, or fall from precipices in drops, giving life to hundreds of plants and low shrubs in the chasm. The summit of the mountain is nearly level, very barren, and bare of soil; several cavities, however, are filled with rain water, or contain a small quantity of vegetable earth, from whence a few odoriferous plants draw their nourishment. Some antelopes, howling baboons, solitary vultures, and toads, are sometimes to be met with on the mountain. The view from thence is very extensive and picturesque. The bay seems a little pond or bason, and the ships in it dwindled to little boats; the town under our feet, and the regular compartments of its gardens, look like the work of children.

Most accounts of this country that have been published mention a surprising phenomenon which is annually to be seen on the top of Table-hill from September to March; namely, a white cloud hovering on its top, and called by sailors *the Devil's table-cloth*. (See the article *Good-Hope*). This cloud is said by some to appear at first no bigger than a barley-corn; then increases to the size of a walnut, and soon after covers the whole top of the mount. But, according to Mr Kolben, it is never less, even on its first appearance, than the size of a large ox, often bigger. It hangs in several fleeces over the Table-hill and the Wind or Devil's-hill; which fleeces, at last uniting, form a large cloud that covers the summits of these two hills. After this has rested for some time without change or motion, the wind bursts out suddenly from it with the utmost fury. The skirts of the cloud are white, but seem much more compact than the matter of common clouds; the upper parts are of a leaden colour. No rain falls from it, but sometimes it discovers a great deal of humidity; at which times it is of a darker colour, and the wind issuing from it is broken, raging by fits of short continuance. In its usual state, the wind keeps up its first fury unabated for one, two, three, or eight days; and sometimes for a whole month together. The cloud seems all the while undiminished, though little fleeces are from time to time detached from it, and hurried down the sides of the hills, vanishing when they reach the bottom, so that during the storm the cloud seems to be supplied with new matter. When the cloud begins to brighten up, these supplies fail, and the wind proportionably abates. At length, the cloud growing transparent, the wind ceases. During the continuance of these south-east winds, the Table-valley is torn by furious whirlwinds. If they blow warm, they are generally of short duration; and in this case the cloud soon disappears. This wind rarely blows till after sunset, and never longer than till towards midnight, though the cloud remains; but then it is thin and clear: but when the wind blows cold, it is a sure sign, that it will last for some time, an hour at noon and midnight excepted; when it seems to lie still to recover itself, and then lets loose its fury anew.

The Europeans at the Cape consider the year as divided into two seasons, which they term *monsoons*; the wet monsoon or winter, and the dry one or summer. The first begins with our spring in March; the latter with September, when our summer ends. In the summer monsoon reign the south-east winds already mentioned; which though they clear and render the air more healthy, yet make it difficult for ships outward bound to enter Table-bay. In the bad season, the Cape is much subject to fogs; and the north-west winds and rain make the inhabitants stay much at home. But there are frequent intermissions and many clear days till June and July; when it rains almost continually, and from thence till summer. The weather in winter is cold, raw and unpleasant; but never more rigorous than autumn in Germany. Water never freezes to above the thickness of half a crown; and as soon as the sun appears the ice is dissolved. The Cape is rarely visited with thunder and lightning, excepting a little near the turn of the seasons, which never does any hurt. During the continuance of the south-east winds which rage in summer, the sky is free of all clouds except that on the Table and Wind Hills, already mentioned; but during the north-west winds, the air is thick, and loaded with heavy clouds big with rain. If the south-east winds should cease for any length of time, the air becomes sickly by reason of the sea weeds driving ashore and rotting; hence the Europeans are at such times affected with headachs and other disorders: but, on the other hand, the violence of those winds subjects them to inflammation of their eyes, &c.

The natives of this country are called *Hottentots*, in their own language; a word of which it is vain to inquire the meaning, since the language of this country can scarce be learned by any other nation. The Hottentot language is indeed said to be a composition of the most strange and disagreeable sounds, deemed by many the disgrace of speech, without human sound or articulation, resembling rather the noise of irritated turkeys, the chattering of magpies, hooting of owls, and depending on extraordinary vibrations, inflections, and clashings of the tongue against the palate.—If this account is true, however, it is obvious, that all the relations we have concerning the religion, &c. of the Hottentots derived from themselves, must fall to the ground, as nobody can pretend to understand a language in itself unintelligible. The manners and customs of those people, however, are easily observable, whether they themselves give the relation or not; and if their language is conformable to them, it is no doubt of a nature sufficiently wonderful.

Many accounts have been published concerning the extreme nastiness and filthy customs of the Hottentots; but from the observations of late travellers it appears, that these have either been exaggerated, or that the Hottentots (which is not improbable) have in some measure laid aside their former manners. Dr Sparrman describes them in much less disgustful terms, and M. Vaillant

Hottentots. Vaillant seems to have been charmed with their innocence and simplicity. According to the doctor, these people are as tall as the generality of Europeans, though more slender in their persons, which he attributes to their scanty supply of food, and not accustoming themselves to hard labour. The characteristic of the nation, however, and which he thinks has not been observed by any one before, is, that they have small hands and feet in proportion to the other parts of their body. The distance between the eyes appears greater than in Europeans, by reason of the root of the nose being very low. The tip is pretty flat, and the iris of the eye has generally a dark-brown cast, sometimes approaching to black. Their skin is of a yellowish brown, something like that of an European who has the jaundice in a high degree; though this colour does not in the least appear in the whites of the eyes. Their lips are thinner than those of their neighbours the *Negroes*, *Caffres*, or *Mozambiques*. "In fine (says our author), their mouths are of a middling size, and almost always furnished with a set of the finest teeth that can be seen; and, taken together with the rest of their features, as well as their carriage, shape, and every motion, in short their *tout ensemble* indicates health and delight, or at least an air of *sans souci*. This careless mien, however, discovers marks at the same time both of alacrity and resolution; qualities which the Hottentots, in fact, can show upon occasion." The hair of the head is black and frizzled, though not very close; and has so much the appearance of wool, that it would be taken for it, were it not for its harshness. They have but seldom any appearance of a beard, or hair upon other parts of their bodies; and when any thing of this kind happens to be visible, it is always very slight.

A general opinion has prevailed, that the Hottentot women have a kind of natural veil which covers the sexual parts; but this is denied by our author. "The women (says he) have no parts uncommon to the rest of their sex: but the clitoris and nymphæ, particularly of those who are past their youth, are pretty much elongated; a peculiarity which has undoubtedly got footing in this nation in consequence of the relaxation necessarily produced by the method they have of besmearing their bodies, their slothfulness, and the warmth of the climate."

The Hottentots besmear all their bodies copiously with fat mixed up with a little soot. "This (says our author) is never wiped off; on the contrary, I never saw them use any thing to clean their skins, excepting that when in greasing the wheels of their waggons their hands were besmeared with tar and pitch, they used to get it off very easily with cow-dung, at the same time rubbing their arms into the bargain up to the shoulders with this cosmetic; so that as the dust and other filth, together with their sooty ointment, and the sweat of their bodies, must necessarily, notwithstanding it is continually wearing off, in some measure adhere to the skin, it contributes not a little to conceal the natural hue of the latter, and at the same time to change it from a bright umber-brown to a brownish yellow colour, obscured with filth and nastiness."—The doctor was enabled to discover the natural colour of the Hottentots by means of the nicety of some Dutch farmers wives, who had made their Hottentot girls wash and scour their skins, that they might be less filthy in looking after the children, or doing any other work that required cleanliness. Many of the colonists, however, are of opinion, that this operation of washing is no improvement to the look of a Hottentot; but that their natural yellow is fully as disagreeable as the black or brown colour of the ointment; and that the washed skin of a native of this country seems to be deficient in dress, like shoes that want blacking. This the doctor does not pretend to determine; though, whatever may be supposed deficient in look, we should think must be made up in cleanliness.

The Hottentots perfume their bodies, by daubing them all over with the powder of an herb, the smell of which is at once rank and aromatic, approaching to that of the poppy mixed with spices. For this purpose they use various species of the diosma, called by them *bucku*, and which they imagine to be very efficacious in the cure of disorders. One species of this plant, growing about *Goud's river*, is said to be so valuable, that no more than a thimble-full of its powder is given in exchange for a lamb.

By the ointment of soot and grease stuck full of the powder of *bucku*, a paste is formed which defends the bodies of the Hottentots in a great measure from the action of the air; so that they require very few clothes, and in fact go almost quite naked. The only covering of the men consists of two leather straps, which generally hang down the back from the chine to the thighs, each of them in the form of an isosceles triangle, their points uppermost, and fastened to a belt which goes round their waist, their bases not being above three fingers broad; so that the covering they form is extremely trifling. These straps have very little dressing bestowed upon them, so that they make a rattling noise as the Hottentot runs along; and our author supposes that they may produce an agreeable coolness by fanning him. Besides this, the men have a bag or flap made of skin which hangs down before, and is fastened to the belt already mentioned. The hollow part of this seems designed to receive that which with us modesty requires to be concealed; but being only fastened by a small part of its upper end to a narrow belt, in other respects hanging quite loose, it is but a very imperfect concealment; and when the wearer is walking, or otherwise in motion, it is none at all. They call this purse by the Dutch name of *jackall*, it being almost always prepared of the skin of that animal, with the hairy side turned outwards.

The women cover themselves much more scrupulously than the men, having always two, and very often three coverings like aprons; though even these seem to be abundantly small for what we would term decency in this country. The outermost of these, which is the largest, measures only from about six inches to a foot in breadth. All of them are made of a skin well prepared and greased, the outermost being adorned with glass beads strung in different figures. The outermost reaches about half-way down the thighs, the middle about a third or one half less, and the third scarcely exceeds the breadth of the hand. The first is said to be designed for ornament, the second as a defence for modesty, and the third to be useful on certain occasions, which, however, are much less troublesome to the Hottentot than to the European females. Our author with

Hottentots. with great probability, supposes that it was the sight of this innermost apron which misled the reverend Jesuit Tackard, who, on his return to Europe, first propagated the stories concerning the natural veils or excrescences of the Hottentots.—A story was likewise commonly believed, that the men in general had but one testicle, and that such as were not naturally formed in this manner were artificially made so. But this our author likewise denies; and though he says that such an operation might have been formerly performed upon the males, yet it is not so now.

The other garments worn by the Hottentots are formed of a sheep's skin with the woolly side turned inwards; thus forming a kind of cloak, which is tied forwards over the breast: though sometimes, instead of a sheep's skin, some smaller kind of fur is used as a material. In warm weather they let this cloak hang carelessly over their shoulders, so that it reaches down to the calves of the legs, leaving the lower part of the breast, stomach, and fore part of the legs and thighs bare; but in cold weather they wrap it round them; so that the fore part of the body is likewise pretty well covered by it as far as the knees: But as one sheep-skin is not sufficient for this purpose, they sew on a piece on the top at each side with a thong or catgut. In warm weather they sometimes wear the woolly side outwards, but more frequently take off the cloak altogether, and carry it under their arm. This cloak or *krosse* serves them not only for clothes, but bedding also; and in this they lie on the bare ground, drawing up their bodies so close, that the cloak is abundantly sufficient to cover them.—The cloaks used by the women differ little from those already described, excepting only that they have a long peak on them, which they turn up; forming with it a little hood or pouch, with the hairy side inwards. In this they carry their little children, to which the mother's breasts are now and then thrown over the shoulders; a custom common among some other nations, where the breasts of the females, by continual want of support, grow to an enormous length. The men commonly wear no covering on their heads, though our author says he has seen one or two who wore a greasy night-cap made of skin with the hair taken off. Those who live nearest the colonists have taken a liking to the European hats, and wear them slouched all round, or with only one side turned up. The women also frequently go bare-headed; though they sometimes wear a cap made in the shape of a short truncated cone. This appears to be the section of some animal's stomach, and is perfectly blacked by soot and fat mixed up together. These caps are frequently prepared in such a manner as to look shaggy; others have the appearance of velvet; and in our author's apprehension are not inelegant. Over this they sometimes wear an oval wreath or kind of crown made of a buffalo's hide, with the hair outermost. It is about four fingers breadth in height, and surrounds the head so as to go a little way down upon the forehead, and the same depth on the neck behind, without covering the upper part of the cap above described. The edges of this wreath, both upper and under, are always smooth and even; each of them set with a row of small shells of the *cyprea* kind, to the number of more than 30, in such a manner, that, being placed quite close to one another, their beautiful white enamel, together with their mouths, are turned outwards. Between two rows of these shells run two others parallel, or else waved and indented in various ways. The Hottentots never adorn their ears or noses as other savages do: though the latter are sometimes marked with a black streak of soot; at others, though more rarely, with a large spot of red lead; of which last, on festivals and holidays, they likewise put a little on their cheeks. The necks of the men are bare, but those of the women are ornamented with a thong of undressed leather, upon which are strung eight or ten shells. These, which are about the size of beans, have a white ground, with large black spots of different sizes: but as they are always made use of in a burnished state, the doctor is uncertain whether they be of that kind which is described in the *Systema Naturæ* under the name of *nerita albicilla*, or *exuvia*. These shells are sold at an enormous price, no less than a sheep for each; as it is said that they come from the more distant coast of Caffraria. Both men and women are very fond of European beads, particularly the blue and white ones of the size of a pea; of which they tie several rows round the middle, and next to the girdles which hold the coverings above mentioned. Besides these ornaments, they use rings on their arms and legs, most of them made of thick leather straps generally cut in a circular shape; which, by being beat and held over the fire, are rendered tough enough to retain the curvature that is given them. From these rings it has been almost universally believed, that the Hottentots wrap guts about their legs in order to eat them occasionally. The men wear from one to five or six of these rings on their arms, just above the wrist, but seldom on their legs. The matrons of a higher rank have frequently a considerable number of them both on their arms and legs, especially on the latter: so that they are covered with them from the feet up to the knees. These rings are of various thicknesses, from that of a goose-quill to two or three times that size. Sometimes they are made of pieces of leather forming one entire ring; so that the arms and feet must be put through them when the wearer wishes to put them on. They are strung upon the legs, small and great, without any nicety; but are so large, that they shake and get twisted when the person walks. Rings of iron or copper, but especially of brass, of the size of a goose-quill, are considered as more genteel than those of leather. However, they are sometimes worn along with the latter, to the number of six or eight at a time, particularly on the arms. The girls are not allowed to use any rings till they are marriageable. The Hottentots seldom wear any shoes; but such as they do make use of are of the same form with those worn by the African peasants, by the Esthonians, and Livonians, as well as by some Finlanders; so that it is impossible to say whether they are the invention of the Dutch or the Hottentots themselves. They are made of undressed leather, with the hairy side outward; without any other preparation than that of being beat and moistened. If it be a thick and stout hide, as that of a buffalo, it is kept for some hours in cow-dung, which renders it besides very soft and pliable. Some kind of grease is afterwards used for the same purpose. The shoes are then made in the following manner. They take a piece of leather of a rectangular

Hottentots. lar form, something longer and broader than the foot of the person for whom the shoes are intended; the two foremost corners are doubled up together, and sewed down, so as to cover the fore-part of the foot; but this seam may be avoided, and the shoes made much neater at the toes, by fitting immediately over them a cap taken from the membrane in the knee-joint of the hind-leg of some animal. In order to make this piece of skin or leather rise up to the height of an inch on both sides of the foot, and close it in neatly, it is pierced with holes at small distances all round the edge, as far as the hind-quarters; and through these holes is passed a thong, by which the rim is drawn up into gathers. In order to make strong hind-quarters, the back part of the piece of leather is doubled inwards, and then raised up and pressed along the heel. The ends of the thong or gathering string are then threaded on both sides through the upper edge of the hind-quarters, to the height of about two inches; they are then carried forwards in order to be drawn through two of the above-mentioned holes on the inside of each rim. Lastly, They are tied over the instep, or if it be thought necessary to tie the shoe still faster, they are carried crosswise over the instep, and so downwards under the thong, which comes out from the hind quarters; then upwards again over the ancle, and even round the leg itself if the wearer chooses. Shoes of this kind are not without their advantages: they sit as neat upon the foot as a stocking, and at the same time preserve their form. They are easily kept soft and pliable by constantly wearing them; or if at any time they should become somewhat hard, this is easily remedied by beating and greasing them. They are extremely light and cool, by reason that they do not cover so much of the foot as a common shoe. They wear very well, as they are without any seam, and the soles of the shoes are both tough and yielding. These field shoes, as they are called, being made of almost raw leather, are much more durable than those of tanned leather, which are burnt up by the African sands, and slip and roll about in them; being also very ready to be torn in a rocky soil, which is not the case with the others. The doctor is of opinion, that these shoes would be particularly useful to sailors.

The huts of the Hottentots are built exactly alike; and we may readily give credit to our author when he tells us, that they are done in a style of architecture which does not a little contribute to keep envy from insinuating itself under the roofs. Some of these huts are circular, and others of an oblong shape, resembling a round bee-hive or vault; the ground-plot being from 18 to 24 feet in diameter. The highest are so low, that it is scarce ever possible for a middle-sized man to stand upright even in the centre of the arch; "but (says our author) neither the lowness thereof, nor that of the door, which is but just three feet high, can perhaps be considered as any inconvenience to an Hottentot, who finds no difficulty in stooping and crawling upon all fours, and is at any time more inclined to lie down than to stand. The fire-place is in the middle of each hut, by which means the walls are not so much exposed to danger from fire. From this situation of the fire-place also the Hottentots derive this additional advantage, that they can all sit or lie in a circle round it, enjoying equally the warmth of the fire. The door, low as it is, alone lets in day-light or lets out the smoke: and so much are these people accustomed to live in such smoky mansions, that their eyes are never affected by it in the least, nor even by the mephitic vapour of the fuel, which to Europeans would be certain death. Hottentots.

The frame of the arched roof is composed of slender rods or sprays of trees. These being previously bent into a proper form, are laid, either whole or pieced, some parallel to one another, others crosswise; after which they are strengthened by binding others round them in a circular form with withies. All these are taken principally from the *cliffortia conoides*, which grows plentifully in this country near the rivers. Large mats are then placed very neatly over this lattice work, so as perfectly to cover the whole. The aperture which is left for the door is closed occasionally by a skin or piece of matting. These mats are made of a kind of cane or reed in the following manner. The reeds being laid parallel to one another, are fastened together with sinews or catgut, or some kind of catgut which they have had an opportunity of getting from the Europeans; so that they have it in their power to make them as long as they please, and as broad as the length of the reeds, which is from six to ten feet. The colonists make use of the same kind of matting, next to the tilts of their waggons, to prevent the sail-cloth from being rubbed and worn, and likewise to help to keep out the rain.

In a *kraal*, or Hottentot village, the huts are most commonly disposed in a circle with the doors inwards; by which means a kind of court-yard is formed, where the cattle are kept at nights. The milk, as soon as taken from the cow, is put to other milk which is curdled, and kept in a leather sack with the hairy side inwards, as being the more cleanly; so that thus the milk is never drunk sweet. In some northern districts, where the land is dry and parched, both Hottentots and colonists are shepherds. When a Hottentot has a mind to shift his dwelling, he lays all the mats, skins, and rods, of which it is composed, on the backs of his cattle, which, to a stranger, makes a monstrous, unwieldy, and even ridiculous appearance.

There is a species of Hottentots named *Boshiesmen*, who dwell in the woody and mountainous parts, and subsist entirely by plunder. They use poisoned arrows, which they shoot from bows about a yard long and an inch in thickness in the middle, very much pointed at both ends. Dr Sparrman does not know the wood of which they are made, but thinks that it is not very elastic. The strings were made, some of sinews, and others of a kind of hemp, or the inner bark of some vegetable; but most of them in a very slovenly manner. The arrows are about a foot and a half long, headed with bone and a triangular bit of iron; having also a piece of quill bound on very strongly with sinews, about an inch and a half from the top, in order to prevent it from being easily drawn out of the flesh. The whole is lastly covered over with a very deadly poison of the consistence of an extract. Their quivers are two feet long and four inches in diameter; and are supposed by our author to be made of the branch of a tree hollowed out, or more probably of the bark of one of the branches taken off whole, the bottom and cover being made of leather.

It is daubed on the outside with an unctuous substance which grows hard when dry, and is lined about the aperture with the skin of the yellow serpent, supposed to be the most deadly in all that part of the world. The poison they make use of is taken from the most venomous serpents; and, ignorant as the Hottentots are, they all know that the poison of serpents may be swallowed with safety. See the article BOSHIESMEN.

In the year 1779, Lieutenant William Paterson, who took a long and dangerous excursion from the Cape along the western side of the continent, discovered a new tribe of Hottentots, whose living, he says, is in the highest degree wretched, and who are apparently the dirtiest of all the Hottentot tribes. Their dress is composed of the skins of seals and jackals, the flesh of which animals they feed upon. If a grampus happens to be cast ashore, they remove their huts to the place, and feed upon the carcase as long as it lasts, though perhaps it may be half rotten by the heat of the weather. They besmear their skins with the oil; by which means they smell so exceedingly rank that their approach may be thus perceived before they come in sight. Their huts, however, are much superior to those of the southern Hottentots already described; being higher, thatched with grass, and furnished with stools made of the back bones of the grampus. They dry their fish in the sun; as the lieutenant found several kinds of fish near their huts suspended from poles, probably for this purpose. He found also several aromatic plants which they had been drying.

With respect to the religion of the Hottentots, it does not appear that they have any. On being questioned on the subject of a Creator and Governor of the universe, they answer that they know nothing of the matter; nor do they seem willing to receive any instruction. All of them, however, have the most firm belief in the powers of magic; from whence it might be inferred that they believe in an evil being analogous to what we call *the devil;* but they pay no religious worship to him, though from this source they derive all the evil that happens, and among these evils they reckon cold, rain, and thunder. So monstrously ignorant are they, that many of the colonists assured Dr Sparrman, that their Boshiesmen would abuse the thunder with many opprobrious epithets, and threaten to assault the flashes of lightning with old shoes, or any thing that comes first to hand. Even the most intelligent among them could not be convinced by all the arguments our author could use, that rain was not always an evil, and that it would be an unhappy circumstance if it were never to rain. "A maxim (says he), from a race of men in other respects really endowed with some sense, and frequently with no small degree of penetration and cunning, ought, methinks to be considered as an indelible religious or superstitious notion entertained by them from their infancy, rather than as an idea taken up on due deliberation and consequent conviction."

As the Hottentots have so strong a belief in the powers of magic, it is no wonder that they have abundance of witches and conjurers among them. These will readily undertake any thing, even to put a stop to thunder and rain, provided they be well paid for their pains; and if it happen to thunder or rain longer than the time they promised, they have always for an excuse, that a more powerful conjurer has put a stop to their incantations. Many of the Hottentots believe that all disorders incident to the human body are cured by magic. The wizards are fond of encouraging this idea: but at the same time take care to employ both external and internal remedies. Among the former may be reckoned a cure performed upon Captain Cook in some of the South-sea islands, viz. that of pinching, cuffing, and kneading the whole body of the patient. To this, however, the Hottentot physicians add that of pretending to suck out a bone from some part of the patient's body. After this it sometimes happens that the sick person is relieved, and sometimes not. In the latter case the operation is repeated; and if he dies, his friends lament that he was bewitched beyond the power of any one to assist him. These conjurers appear to be possessed of considerable slight of hand. Our author was informed by a colonist, that when he was a child, and playing with a bone of an ox which he drew as a cart, it appeared to his great astonishment to be sucked out of a sick person's back by a wizard; and as far as he could remember, the patient recovered soon after. These pretensions of the wizards sometimes render them liable to persecutions; and there is an instance of a chief named *Paloo*, who ordered a general massacre among them, in hopes of cutting off the person who he believed had bewitched himself, and afflicted him with sore eyes.

The superstition of the Hottentots never operates in the way of making them afraid in the dark. They seem, however, to have some ideas of a future state, as they reproach their friends, when dead, with leaving them so soon: at the same time admonishing them from henceforth to demean themselves properly; by which they mean, that their deceased friends should not come back again and haunt them, nor allow themselves to be made use of by wizards to bring any mischief on those that survive them.

There is a genus of insects (the *mantis*) which, it has been generally thought, the Hottentots worship; but our author is so far from being of this opinion, that he tells us they have more than once catched several of them for him, and assisted him in sticking pins through them as he did through other insects. "There is (says he), however, a diminutive species of this insect, which some think it would be a crime, as well as very dangerous to do any harm to: but this we have no more reason to look upon as any kind of religious worship, than we have to consider in the same light a certain superstitious notion prevalent among many of the more simple people in our own country (Sweden), who imagine that their sins will be forgiven them, if they set a cock-chafer on its feet that has happened to fall upon its back. The moon, according to Kolbe, receives a kind of adoration from the Hottentots; but the fact is, that they merely take the opportunity of her beams, and at the same time of the coolness of the night, to amuse themselves with dancing, and consequently have no more thoughts of worshipping her than the Christian colonists who are seen at that time strolling in great numbers about the streets, and parading on the stone steps with which their houses are usually encircled. The conjurers themselves, according to our author, are generally freethinkers, who have neither religion nor superstition of any kind.

Lieutenant

Hottentots.

Lieutenant Paterson has given the following account of the Caffres, a nation whom no European but himself had then seen, and who inhabit the country to the north-east of the Cape as far down as 31° south latitude.

The men are from five feet ten inches to six feet high, and well proportioned; and in general manifest great courage in attacking lions or other wild beasts. The nation, at the time he visited them, was divided into two parties, one to the northward, commanded by a chief named *Cha Cha Bea*, or *Tambushie*, which latter appellation he had obtained from his mother, a woman of an Hottentot tribe named *Tambukies*. This man was the son of a chief named *Pharoa*, who died about three years before, and left two sons *Cha Cha Bea*, and another named *Dsirika*, who claimed the supreme authority on account of his mother being of the Caffre nation. This occasioned a contest between the two brothers, in the course of which *Cha Cha Bea* was driven out of his territories with a great number of his party; after which he took up his residence at a place named *Khouta*, where he had an opportunity of entering into an alliance with the Boshiesmen.—The Caffres are of a jet black colour, their eyes large, and their teeth as white as ivory. The clothing of both sexes is nearly the same; consisting entirely of the hides of oxen, which are made as pliant as cloth. The men wear tails of different animals tied round their thighs, pieces of brass in their hair, and large rings of ivory on their arms: they are likewise adorned with the hair of lions, feathers fastened on their heads, &c. They use the ceremony of circumcision, which is usually performed upon them when they are nine years of age. They are very fond of dogs, which they exchange for cattle, and will even give two bullocks in exchange for one dog which pleases them. They are expert in throwing lances, and in time of war use shields made of the hides of oxen. Throughout the day the men occupy themselves in hunting, fighting, or dancing; the women being employed in the cultivation of their gardens and corn. They seem not to be destitute of the knowledge of agriculture, as they cultivate several vegetables which do not naturally grow in their own country, viz. tobacco, water-melons, a small kind of kidney-beans, and hemp. The women also make their baskets, and the mats on which they lie. The men are very fond of their cattle, and cut their horns in such a manner as to be able to turn them into any shape they please, and teach them to answer to a whistle. Mr Paterson is of opinion, that the country they inhabit is greatly superior to any part of Africa.

Of the Dutch settlements and policy at the Cape, Mr Forster gives the following account.

"The income of the governor here is very considerable: for, besides a fixed appointment, and the use of houses, gardens, proper furniture, and every thing that belongs to his table, he receives about 10 dollars for every leagre of wine which the company buy of the farmer in order to be exported to Batavia. The company allows the sum of 40 dollars for each leagre, of which the farmer receives but 24: what remains is shared between the governor and second or deputy; the former taking two-thirds, which sometimes are said to amount to 4000 dollars per annum. The deputy-governor has the direction of the company's whole commerce here, and signs all orders to the different departments under him, as well as the governor to others. He and the fiscal have the rank of *upper koopman*. The fiscal is at the head of the police, and sees the penal laws put in execution: his income consists of fines, and of the duties laid on certain articles of commerce; but if he be strict in exacting them, he is universally detested. The sound policy of the Dutch has likewise found it necessary to place the fiscal as a check, to overawe the other officers of the company, that they may not counteract the interests of their masters, or infringe the laws of the mother-country. He is, to that end, commonly well versed in juridical affairs, and depends solely upon the mother-country. The major (at present Mr Von Prehn, who received us with great politeness) has the rank of *koopman* or merchant: this circumstance surprises a stranger, who, in all other European states, is used to see military honours confer distinction and precedence; and appears still more singular to one who knows the contrast in this particular between Holland and Russia, where the idea of military rank is annexed to every place, even that of a professor at the university. The number of regular soldiers at this colony amounts to about 700, of which 400 form the garrison of the fort, near the Cape-town. The inhabitants capable of bearing arms form a militia of 4000 men, of whom a considerable part may be assembled in a few hours, by means of signals made from alarm-places in different parts of the country. We may from hence make some estimate of the number of white people in this colony, which is at present so extensive, that the distant settlements are above a month's journey from the Cape: but these remote parts lie sometimes more than a day's journey from each other, are surrounded by various nations of Hottentots, and too frequently feel the want of protection from their own government at that distance. The slaves in this colony are at least in the proportion of five or more to one white person. The principal inhabitants at the Cape have sometimes from 20 to 30 slaves, who are in general treated with great lenity, and sometimes become great favourites with their masters, who give them very good clothing, but oblige them to wear neither shoes nor stockings, reserving these articles to themselves. The slaves are chiefly brought from Madagascar, and a little vessel annually goes from the Cape thither on that trade; there are, however, besides them, a number of Malays and Bengalese, and some negroes. The colonists themselves are for the greatest part Germans, with some families of Dutch and some of French Protestants. The character of the inhabitants of the town is mixed. They are industrious, but fond of good living, hospitable, and social, though accustomed to hire their apartments to strangers for the time they touch at this settlement, and used to be complimented with rich presents of stuffs, &c. by the officers of merchant ships. They have no great opportunities of acquiring knowledge, there being no public schools of note at the Cape; their young men are therefore commonly sent to Holland for improvement, and their female education is too much neglected. A kind of dislike to reading, and the want of public amusements, make their conversation uninteresting, and too frequently turn it upon scandal, Hottentots. scandal, which is commonly carried to a degree of inveteracy peculiar to little towns. The French, English, Portuguese, and Malay languages, are very commonly spoken, and many of the ladies have acquired them. This circumstance, together with the accomplishments of singing, dancing, and playing a tune on the lute, frequently united in an agreeable person, make amends for the want of refined manners and delicacy of sentiment. There are, however, among the principal inhabitants, persons of both sexes, whose whole deportment, extensive reading, and well-cultivated understanding, would be admired and distinguished even in Europe. Their circumstances are in general easy, and very often affluent, on account of the cheap rate at which the necessaries of life are to be procured: but they seldom amass such prodigious riches here as at Batavia; and I was told the greatest private fortune at the Cape did not exceed 100,000 dollars, or about 25,000l. sterling.

"The farmers in the country are very plain hospitable people; but those who dwell in the remotest settlements seldom come to town, and are said to be very ignorant. This may easily be conceived, because they have no better company than Hottentots, their dwellings being often several days journey asunder, which must in a great measure preclude all intercourse. The vine is cultivated in plantations within the compass of a few days journey from the town; which were established by the first colonists, and of which the ground was given in perpetual property to them and their heirs. The company at present never part with the property of the ground, but let the surface to the farmer for an annual rent, which, though extremely moderate, being only 25 dollars for 60 acres, yet does not give sufficient encouragement to plant vineyards. The distant settlements, therefore, chiefly raise corn and rear cattle; nay, many of the settlers entirely follow the latter branch of rustic employment, and some have very numerous flocks. We were told there were two farmers who had each 15,000 sheep, and oxen in proportion; and several who possessed 6000 or 8000 sheep, of which they drive great droves to town every year; but lions and buffaloes, and the fatigue of the journey, destroy numbers of their cattle before they can bring them so far. They commonly take their families with them in large waggons covered with linen or leather, spread over hoops, and drawn by 8, 10, and sometimes 12 pair of oxen. They bring butter, mutton-tallow, the flesh and skins of river-horses (hippopotamus), together with lion and rhinoceros skins, to sell. They have several slaves, and commonly engage in their service several Hottentots of the poorer sort, and (as we are told) of the tribe called BOSHIESMEN, *Boschemans*, or *Bushmen*, who have no cattle of their own, but commonly subsist by hunting, or by committing depredations on their neighbours. The opulent farmers set up a young beginner by intrusting to his care a flock of 400 or 500 sheep, which he leads to a distant spot, where he finds plenty of good grass and water; the one-half of all the lambs which are yeaned fall to his share, by which means he soon becomes as rich as his benefactor.

"Though the Dutch company seem evidently to discourage all new settlers, by granting no lands in private property; yet the products of the country have of late years sufficed not only to supply the isles of France and Bourbon with corn, but likewise to furnish the mother-country with several ship loads. These exports would certainly be made at an easier rate than at present, if the settlements did not extend so far into the country, from whence the products must be brought to the Table-bay by land-carriage, on roads which are almost impassable. The intermediate spaces of uncultivated land between the different settlements are very extensive, and contain many spots fit for agriculture; but one of the chief reasons why the colonists are so much divided and scattered throughout the country, is to be met with in another regulation of the company, which forbids every new settler to establish himself within a mile of another. It is evident, that if this settlement were in the hands of the commonwealth, it would have attained to a great population, and a degree of opulence and splendour of which it has not the least hopes at present; but a private company of East India merchants find their account much better in keeping all the landed property to themselves, and tying down the colonist, lest he should become too great and powerful.

"The wines made at the Cape are of the greatest variety possible. The best, which is made at M. Vander Spy's plantation of Constantia, is spoken of in Europe, more by report than from real knowledge; 30 leagres (or pipes) at the utmost are annually raised of this kind, and each leagre sells for about 50l. on the spot. The vines from which it is made were originally brought from Shiraz in Persia. Several other sorts grow in the neighbourhood of that plantation, which produce a sweet rich wine, that generally passes for genuine Constantia in Europe. French plants of burgundy, muscade, and frontignan, have likewise been tried, and have succeeded extremely well, sometimes producing wines superior to those of the original soil. An excellent dry wine, which has a slight agreeable tartness, is commonly drank in the principal families, and is made of Madeira vines transplanted to the Cape. Several low sorts, not entirely disagreeable, are raised in great plenty, and sold at a very cheap rate; so that the sailors of the East India ships commonly indulge themselves very plentifully in them whenever they come ashore.

"The products of the country supply with provisions the ships of all nations which touch at the Cape. Corn, flour, biscuit, salted beef, brandy, and wine, are to be had in abundance, and at moderate prices; and their fresh greens, fine fruits, good mutton and beef, are excellent restoratives to seamen who have made a long voyage."

Hottinger. HOTTINGER, JOHN HENRY, one of the most learned and eminent of the Protestant divines of Switzerland, was born at Zurich, in the year 1620. He discovered an invincible propensity to learning at a very early period, and acquired the knowledge of languages with astonishing facility. The trustees of the schools had their attention attracted towards Hottinger by his amazing progress in the knowledge of the Hebrew, Greek, and Latin, whom they determined to send to foreign universities at the public expence. In 1638 he studied for a short time at Geneva under the celebrated Spanheim, and went afterwards to France. He next visited Holland and Flanders, and became a student

dent in the university of Groningen, where he attended the theological lectures of the renowned Francis Gomar, and Professor Alting, and studied the Arabic language under Professor Pasor. Being anxious, however, to enjoy still more advantages than this situation afforded, he went to Leyden, where he became tutor to the children of Professor Golius, whose knowledge of oriental languages was at that time unrivalled. By his instructions and those of a Turk then at Leyden, Hottinger's knowledge of the Arabic became very extensive, and Golius allowed him to copy many of the Arabic manuscripts which he had in his possession. In 1641 he was chosen chaplain to the embassy of the states-general to Constantinople; but the magistrates of Zurich would not allow him to accept of it, resolving that his talents should be exerted for the glory and benefit of their own public schools. They permitted him to visit England prior to his return home, where he contracted habits of intimacy with some of the most distinguished literary characters. As soon as he returned to Zurich, he was appointed professor of church-history, when no more than 22 years of age; and when 23, he was chosen professor of catechetical divinity and oriental languages. About this period he married, and began his career as an author, in which he persevered for twenty years, with the most astonishing industry. In 1653 he was appointed professor of rhetoric, and professor extraordinary of the divinity of the Old Testament, and controversial theology.

So justly celebrated about this time was Hottinger as a man of uncommon erudition, that his aid was earnestly requested by the elector palatine, to restore the fame of the university of Heidelberg. The magistrates of Zurich consented to lend him for three years. At Heidelberg he was made professor of divinity, principal, ecclesiastical counsellor, and rector. He wrote in favour of the re-union of Lutherans and Calvinists; but he had no better success than all his predecessors in the same attempt. He continued at Heidelberg, by permission of the magistrates of Zurich, till 1661. On his return home, he was chosen president of the commissioners who were appointed to revise the German translation of the Bible. He was requested to accept of professorships from the magistrates of Deventer, the landgrave of Hesse, and the magistrates of Amsterdam and Bremen; but the love of his country made him reject the whole. He was offered the divinity chair at Leyden in 1667, but the magistrates would not part with him. This made the Dutch request him as a loan, to which the magistrates agreed, from their respect for the states of Holland; but while making preparations for his departure, he was unfortunately drowned in the river which runs through Zurich, while on his way to an estate of his own about six miles from that city.

Dr Hottinger was a man of extraordinary abilities, both natural and acquired, having few equals for his knowledge of oriental languages, and the antiquities of the church. He had a most retentive memory, and his literary industry was almost unexampled. His life was comparatively short, being only 47 when he found a watery grave, yet he was the author of no fewer than 40 volumes, on different subjects. He is frequently inaccurate, owing to the astonishing rapidity with which he wrote. For a correct list of his publications, see *Heidegger's Life of Hottinger*.

HOTTONIA, WATER-VIOLET, a genus of plants belonging to the pentandria class; and in the natural method ranking under the 21st order, *Preciæ*. See BOTANY *Index*.

HOUBRAKEN, JACOB, a celebrated engraver, whose great excellence consisted in the portrait line. His works are distinguished by an admirable softness and delicacy of execution, joined with good drawing and a fine taste. If his best performances have ever been surpassed, it is in the masterly determination of the features, which we find in the works of Nanteuil, Edelink, and Drevet; this gives an animation to the countenance, more easily to be felt than described. His works are pretty numerous; and most of them being for English publications, they are sufficiently known in this country. In particular the greater and best part of the collection of portraits of illustrious men, published in London by I. and P. Knapton, were by his hand.

HOVEDON, ROGER DE, born of an illustrious family in Yorkshire, most probably at the town of that name, now called *Howden*, some time in the reign of Henry I. After he had received the first parts of education in his native country, he studied the civil and canon law, which were then become most fashionable and lucrative branches of learning. He became domestic chaplain to Henry II. who employed him to transact several ecclesiastical affairs; in which he acquitted himself with honour. But his most meritorious work was his annals of England, from A. D. 731, when Bede's ecclesiastical history ends, to A. D. 1202. This work, which is one of the most voluminous of our ancient histories, is more valuable for the sincerity with which it is written, and the great variety of facts which it contains, than for the beauty of its style, or the regularity of its arrangement.

HOUGH, HAM, in the manege, the joint of the hind leg of a beast, which connects the thigh to the leg. See HAM.

To Hough, or *cut the Houghs*, is to ham-string, or to disable by cutting the sinews of the ham.

HOULIERES, ANTONIETTE DES, a French lady, whose poetry is highly esteemed in France. Her works and those of her daughter have been collected and printed together in two volumes. Most of the idyls, particularly those on sheep and birds, surpass every thing of the kind in the French language: the thoughts and expressions are noble; and the style pure, flowing, and chaste. Mademoiselle des Houlieres carried the poetic prize in the French academy against Fontenelle. Both of these ladies were members of the academy of Ricovatri; the mother was also a member of the academy of Arles. Those who desire to be more particularly acquainted with the history of Madame des Houlieres, may consult her life prefixed to her works in the Paris edition of 1747, 2 vols 12mo.

HOULSWORTHY, a large town of Devonshire, seated between two branches of the river Tamar, having a good market for corn and provisions. It had 1206 inhabitants in 1811. W. Long. 2. 42. N. Lat. 50. 50.

HOUND. See CANIS, *Blood-Hound*, and *Gre-Hound*.

Hound.

Training of HOUNDS. Before we speak of the methods proper to be used for this purpose, it will be necessary to point out the qualities which sportsmen desire to meet with in these animals. It is generally understood, that hounds of the middle size are the most proper, it being remarked, that all animals of that description are stronger than either such as are very small or very large. The shape of the hound ought to be particularly attended to; for if he be not well proportioned, he can neither run fast nor do much work. His legs ought to be straight, his feet round, and not very large; his shoulders back; his breast rather wide than narrow; his chest deep, his back broad, his head small, his neck thin; his tail thick and bushy, and if he carry it well so much the better. None of those young hounds which are *out at the elbows*, or such as are weak from the knee to the foot, should ever be taken into the pack. That the pack may look well, it is proper that the hounds should be as much as possible of a size: and if the animals be handsome at the same time, the pack will then be perfect. It must not, however, be thought, that this contributes any thing to the *goodness* of a pack; for very unhandsome packs, consisting of hounds entirely different in size and colour, have been known to afford very good sport. It is only necessary that they should run well together; to which indeed an uniformity in size and shape would seem to contribute in some degree. The pack that can run 10 miles, or any other considerable space, in the shortest time, may be said to go fastest, though the hounds taken separately might be considerably inferior to others in swiftness. A pack of hounds, considered in a collective body, go fast in proportion to the excellence of their noses and the head they carry. Packs which are composed of hounds of various kinds seldom run well. When the packs are very large, the hounds are seldom sufficiently hunted to be good; 20 or 30 couple, therefore, or at most 40, will be abundantly sufficient for the keenest sportsman in this country, as thus he may be enabled to hunt three or even four times a-week. The number of hounds to be kept must, however, in a considerable degree, depend on the strength of the pack, and the country in which you hunt. They should be left at home as seldom as possible; and too many old hounds should not be kept. None ought to be kept above five or six seasons, though this also is somewhat uncertain, as we have no rule for judging how long a hound will last.

In breeding of hounds, considerable attention ought to be paid to the dog from whom you breed. All such are to be rejected as have a tender nose, as are *babblers* or *skirters*. An old dog should never be put to an old bitch; nor should any attempts be made to cross the breed unless in a proper and judicious manner. Mr Beckford * informs us, that he has seen fox-hounds bred out of a Newfoundland dog and fox-hound bitch; the whelps were monstrously ugly, and had other bad qualities besides. The cross most likely to be of service to a fox-hound is the beagle. The reason of crossing the breeds sometimes is, that the imperfections of one may sometimes be remedied by another. The months of January, February, and March, are the best for breeding; late puppies seldom thrive. After the females begin to grow big with young, it will not be proper to let them hunt any more, or indeed to remain for a much longer time in the kennel. Sometimes these animals will have an extraordinary number of whelps. Mr Beckford informs us, that he has known a bitch have 15 puppies at a litter; and he assures us, that a friend of his informed him, that a hound in his pack brought forth 16, all of them alive. In these cases it is proper to put some of the puppies to another bitch, if you want to keep them all; but if any are destroyed, the best coloured ought to be kept. The bitches should not only have plenty of flesh, but milk also; and the puppies should not be taken from them till they are able to take care of themselves; their mothers will be relieved when they learn to lap milk, which they will do in a short time. After the puppies are taken away from the mothers, the litter should have three purging balls given them, one every other morning, and plenty of whey the intermediate day. If a bitch bring only one or two puppies, and you have another that will take them, by putting the puppies to her the former will soon be fit to hunt again. She should, however, be first physicked, and it will also be of service to anoint her dugs with brandy and water.

* Essay on Hunting.

Whelps are very liable to the distemper to which dogs in general are subject, and which frequently makes great havock among them at their walks; and this is supposed by Mr Beckford to be owing to the little care that is taken of them. "If the distemper (says he) once get among them, they must all have it: yet, notwithstanding that, as they will be constantly well fed, and will lie warm (in a kennel built on purpose), I am confident it would be the saving of many lives. If you should adopt this method, you must remember to use them early to go in couples: and when they become of a proper age, they must be walked out often; for should they remain confined, they would neither have the health, shape, or understanding, which they ought to have. When I kept harriers, I bred up some of the puppies at a distant kennel; but having no servants there to exercise them properly, I found them much inferior to such of their brethren as had the luck to survive the many difficulties and dangers they had undergone at their walks; these were afterwards equal to any thing, and afraid of nothing; whilst those that had been nursed with so much care, were weakly, timid, and had every disadvantage attending private education. I have often heard as an excuse for hounds not hunting a cold scent, that they were too *high-bred*. I confess I know not what that means: but this I know, that hounds are frequently too *ill-bred* to be of any service. It is judgment in the breeder, and patience afterwards in the huntsman, that makes them hunt.

"When young hounds are first taken in, they should be kept separate from the pack; and as it will happen at a time of the year when there is little or no hunting, you may easily give them up one of the kennels and grass court adjoining. Their play frequently ends in a battle; it therefore is less dangerous where all are equally matched.—If you find that they take a dislike to any particular hound, the safest way will be to remove him, or it is probable they will kill him at last. When a feeder hears the hounds quarrel in the kennel, he halloos to them to stop them; he then goes in among them, and flogs every hound he can come near. How

Hound.

How much more reasonable, as well as efficacious, would it be, were he to see which were the combatants before he speaks to them. Punishment would then fall, as it ought, on the guilty only. In all packs there are some hounds more quarrelsome than the rest; and it is to them we owe all the mischief that is done. If you find chastisement cannot quiet them, it may be prudent to break their holders; for since they are not necessary to them for the meat they have to eat, they are not likely to serve them in any good purpose. Young hounds should be fed twice a-day, as they seldom take kindly to the kennel meat at first, and the distemper is most apt to seize them at this time. It is better not to round them till they are thoroughly settled; nor should it be put off till the hot weather, for then they will bleed too much. It may be better perhaps to round them at their quarters, when about six months old; should it be done sooner, it would make their ears tuck up. The tailing of them is usually done before they are put out; it might be better, perhaps, to leave it till they are taken in. Dogs must not be rounded at the time they have the distemper upon them, as the loss of blood would weaken them too much.

"If any of the dogs be thin over the back, or any more quarrelsome than the rest, it will be of use to cut them; I also spay such bitches as I shall not want to breed from; they are more useful, are stouter, and are always in better order; besides it is absolutely necessary if you hunt late in the spring, or your pack will be very short for want of it. The latter operation, however, does not always succeed; it will be necessary therefore to employ a skilful person, and one on whom you can depend; for if it be ill done, though they cannot have puppies, they will go to heat notwithstanding. They should be kept low for several days before the operation is performed, and must be fed on thin meat for some time after."

It is impossible to determine how many young hounds ought to be bred in order to keep up the pack, as this depends altogether on contingencies. The deficiencies of one year must be supplied by the next; but it is probable, that from 30 to 35 couple of old hounds, and from eight to twelve couple of young ones, will answer the purpose where no more than 40 couple are to be kept. A considerable number, however, ought always to be bred; for it is undoubtedly and evidently true, that those who breed the greatest number of hounds must expect the best pack.

After the hounds have been rounded, become acquainted with the huntsman, and answer to their names, they ought to be coupled together, and walked out among sheep. Such as are particularly ill-natured ought to have their couples loose about their necks in the kennel till they become reconciled to them. The most stubborn ought to be coupled to old hounds rather than to young ones; and two dogs should not be coupled together when you can avoid it. As young hounds are awkward at first, a few ought only to be set out at at a time with people on foot, and they will soon afterwards follow a horse. When they have been walked out often in this manner amongst the sheep, they should be uncoupled by a few at a time, and those chastised who offer to run after the sheep; but it will be difficult to reclaim them after they have once been allowed to taste blood. Some are accustomed to couple the dogs with a ram in order to break them from sheep; but this is very dangerous for both parties. Mr Beckford relates a story of a nobleman who put a large ram into his kennel in order to break his hounds from sheep; but when he came some time after to see how nobly the ram defended himself, he found him entirely eaten up, and the hounds gone to sleep after having filled their bellies.

When hounds are to be aired, it is best to take them out separately, the old ones one day, and the young another; though, if they are to have whey from a distant dairy, both old and young may be taken out together, observing only to take the young hounds in couples, when the old ones are along with them. Young hounds are always apt to fall into mischief, and even old ones when idle will be apt to join them. Mr Beckford mentions a whole pack running after a flock of sheep through the mere accident of a horse's falling, and then running away.

With regard to the first entering of hounds to a scent, our author gives such directions as have subjected him to a severe charge of inhumanity. We shall give them in his own words. "You had better enter them at their own game: it will save you much trouble afterwards. Many dogs, I believe, like that scent best which they were first blooded to: but be this as it may, it is most certainly reasonable to use them to that which it is intended they should hunt. It may not be amiss first when they begin to hunt to put light collars on them. Young hounds may easily get out of their knowledge; and shy ones, after they have been much beaten, may not choose to return home. Collars, in that case, may prevent their being lost.—You say you like to see your young hounds run a trail-scent.—I have no doubt that you would be glad to see them run over an open down, where you could so easily observe their action and their speed. I cannot think the doing of it once or twice could hurt your hounds; and yet as a sportsman I dare not recommend it to you. All that I can say is, that it would be less bad than entering them at hare. A cat is as good a trail as any; but on no account should any trail be used after your hounds are stooped to a scent. I know an old sportsman who enters his young hounds first at a cat, which he drags along the ground for a mile or two, at the end of which he turns out a badger, first, taking care to break his teeth: he takes out about a couple of old hounds along with the young ones to hold them on. He never enters his young hounds but at vermin; for he says, Train up a child in the way he should go, and when he is old he will not depart from it."

Hounds ought to be entered as soon as possible, though the time must be uncertain, as it depends on the nature of country in which they are. In corn countries hunting may not be practicable till the corn is cut down; but you may begin sooner in grass countries, and at any time in woodlands. "If (says Mr Beckford) you have plenty of foxes, and *can afford to make a sacrifice of some of them* for the sake of making your young hounds steady, take them first where you have least riot, putting some of the steadiest of your old hounds among them. If in such a place you are fortunate enough to find a litter of foxes, you may assure yourself you will have but little trouble with your

your young hounds afterwards.—If, owing to a scarcity of foxes, you should stoop your hounds at hare, let them by no means have the blood of her; nor, for the sake of consistency, give them much encouragement. Hare-hunting has one advantage;——hounds are chiefly in open ground, where you can easily command them; but notwithstanding that, if foxes be in tolerable plenty, keep them to their own game.——Frequent hallooing is of use with young hounds; it keeps them forward, prevents them being lost, and hinders them from hunting after the rest. The oftener therefore that a fox is seen and hallooed, the better. I by no means, however, approve of much hallooing to old hounds; though it is true that there is a time when hallooing is of use, a time when it does hurt, and a time when it is perfectly indifferent: but long practice and great attention to hunting can only teach the application.

"Hounds at their first entrance cannot be encouraged too much. When they are become handy, love a scent, and begin to know what is right, it will then be soon enough to chastise them for what is wrong; in which case one severe beating will save a great deal of trouble. When a hound is flogged, the whipper-in should make use of his voice as well as his whip. If any be very unsteady, it will not be amiss to send them out by themselves when the men go out to exercise their horses. If you have hares in plenty, let some be found sitting, and turned out before them; and you will find that the most riotous will not run after them. If you intend them to be steady from deer, they should often see deer, and then they will not regard them, and if after a probation of this kind you turn out a cub before them, with some old hounds to lead them on, you may assure yourself they will not be unsteady long."

It is proper to put the young hounds into the pack when they stoop to a scent, become handy, know a rate, and stop easily. A few only are to be put to the pack at a time; and it is not adviseable even to begin this till the pack have been out a few times by themselves, and are "gotten well in blood." They should be low in flesh when you begin to hunt; the ground being generally hard at that time, so that they are liable to be shaken.—By hounds being *handy*, our author means their being ready to do whatever is required of them; and particularly, when cast, to turn easily which way the huntsman pleases.

Mr Beckford begins to hunt with his young hounds in August. The huntsman in the preceding months keeps his old hounds healthy by giving them proper exercise, and gets his young hounds forward; and for this purpose nothing answers so well as taking them frequently out. The huntsman should go along with them, get frequently off his horse, and encourage them to come to him:—too much restraint will frequently incline the hounds to be riotous. Our author frequently walks out his hounds among sheep, hares, and deer. Sometimes he turns down a cat before them, which they kill; and, when the time of hunting approaches, he turns out young foxes or badgers; taking out some of the most steady of his old hounds to lead on the young ones. Small covers and furze-brakes are drawn with them to use them to a halloo, and to teach them obedience. If they find improper game and hunt it, they are stopped and brought back; and as long as they will stop at a rate, they are not chastised. At such times as they are taken out to air, the huntsman leads them into the country in which they are designed to hunt; by which means they acquire a knowledge of the country, and cannot miss their way home at any time afterwards. When they begin to hunt, they are first brought into a large cover of his own, which has many ridings cut in it; and where young foxes are turned out every year on purpose for them. After they have been hunted for some days in this manner, they are sent to more distant covers, and more old hounds added to them. There they continue to hunt till they are taken into the pack, which is seldom later than the beginning of September; for by that time they will have learned what is required of them, and seldom give much trouble afterwards. In September he begins to hunt in earnest; and after the old hounds have killed a few foxes, the young ones are put into the pack, two or three couple at a time, till all have hunted. They are then divided; and as he seldom has occasion to take in more than nine or ten couple, one half are taken out one day, and the other the next, till they are steady.

To render fox-hunting complete, no young hounds should be taken into the pack the first season; a requisite too expensive for most sportsmen. The pack should consist of about 40 couple of hounds, that have hunted one, two, three, four or five seasons. The young pack should consist of about 20 couple of young hounds, and an equal number of old ones. They should have a separate establishment, and the two kennels should not be too near one another. When the season is over, the best of the young hounds should be taken into the pack, and the draught of old ones exchanged for them. Many must be bred to enable a sportsman to take in 20 couple of young hounds every season. It will always be easy to keep up the number of old hounds; for when your own draft is not sufficient, drafts from other packs may be obtained, and at a small expence. When young hounds are hunted together for the first season, and have not a sufficient number of old ones along with them, it does more harm than good.

Kennel of Hounds. See Kennel.

HOUNSLOW, a town of Middlesex, 10 miles from London. It is situated on a heath of the same name; and belongs to two parishes, the north side of the street to Heston, and the south side to Isleworth. Near it are powder-mills. It has fairs on Trinity-Monday, and Monday after September 29. Here is a charity-school and a chapel. In this place was formerly a convent of mendicant friars, who, by their institution, were to beg alms for the ransom of captives taken by the infidels.—The heath is noted for robberies and horse-races. Population 2304 in 1811.

HOU-QUANG, a province of China, occupying nearly the centre of the empire: the river Yang-tse-kiang traverses it from west to east, and divides it into two parts, the northern and southern. This province (the greater part of which is level, and watered by lakes, canals, and rivers) is celebrated for its fertility; the Chinese call it the store-house of the empire; and it is a common saying among them, that "the abundance

dance of Kiang-si could furnish all China with a breakfast; but the province of Hou-quang alone could supply enough to maintain all its inhabitants." Some princes of the race of Hong-vou formerly resided in this province; but that family was entirely destroyed by the Tartars when they conquered China. The people here boast much of their cotton cloths, simples, gold-mines, wax, and paper made of the bamboo-reed. The northern part of the province contains eight *fou*, or cities of the first class, and sixty of the second and third. The southern comprehends seven of the first class, and fifty-four of the second and third, exclusive of forts, towns, and villages, which are everywhere to be found.

HOUR, in *Chronology*, an aliquot part of a natural day, usually a 24th, but sometimes a 12th. The origin of the word *hora*, or ὥρα, comes, according to some authors, from a surname of the sun, the father of hours, whom the Egyptians call *Horus*. Others derive it from the Greek ὁρίζειν, to *terminate*, *distinguish*, &c. Others from the word οὖρον, *urine*; holding, that Trismegistus was the first that settled the division of hours which he did from observation of an animal consecrated to Serapis, named *cynocephalus*, which makes water 12 times a-day, and as often in the night, at equal intervals.

An hour, with us, is a measure or quantity of time, equal to a 24th part of the natural day, or nycthemeron; or the duration of the 24th part of the earth's diurnal rotation. Fifteen degrees of the equator answer to an hour; though not precisely, but near enough for common use. It is divided into 60 minutes; the minute into 60 seconds, &c.

The division of the day into hours is very ancient; as is shown by Kircher, *Oedipt. Egypt.* tom. ii. p. ii. class. vii. c. 8.: though the passages he quotes from Scripture do not prove it.—The most ancient hour is that of the 12th part of the day. Herodotus, lib. ii. observes, that the Greeks learnt from the Egyptians, among other things, the method of dividing the day into twelve parts.—The astronomers of Cathaya, &c. Bishop Beveridge observes, still retain this division. They call the hour *chag*; and to each chag give a peculiar name, taken from some animal: The first is called *zeth*, "mouse;" the second, *chiu*, "bullock;" the third, *zem*, "leopard;" the fourth, *mau*, "hare;" the fifth, *chin*, "crocodile," &c.

The division of the day into 24 hours, was not known to the Romans before the first Punic war.—Till that time they only regulated their days by the rising and setting of the sun. They divided the 12 hours of their day into four, viz. *prime*, which commenced at six o'clock; *third*, at nine; *sixth*, at twelve, and *none*, at three. They also divided the night into four watches, each containing three hours.

HOURS, HORÆ, in the ancient mythology, were certain goddesses, the daughters of Jupiter and Themis; at first only three in number, Eunomia, Dice, and Irene, to which were afterwards added two more, Carpo and Thallote.

Homer makes them the doorkeepers of heaven. Ovid allots them the employment of harnessing the horses of the Sun:

Jungere equos Titan velocibus imperat Horis.

And speaks of them as standing, at equal distances, about the throne of Sol:

——*et, positæ spatiis equalibus*, Horæ.

The poets represent them as dressed in fine coloured or embroidered robes, and gliding on with a quick and easy motion.

HOURS, *Horæ*, in the Romish church, are certain prayers performed at stated times of the day; as matins, vespers, lauds, &c. The lesser hours are, *prime*, *tierce*, *sixth*, and *none*. They are called *hours* or *canonical hours*, as being to be rehearsed at certain hours prescribed by the canons of that church, in commemoration of the mysteries accomplished at those hours. These hours were anciently also called *course*, *cursus*: F. Mabillon has a dissertation on them, entitled, *De Cursu Gallicano*.

The first constitution enjoining the observation of the canonical *hours* is of the ninth century, being found in a capitular of Heito bishop of Basil directed to his curates, importing that the priests shall never be absent at the canonical hours either by day or night.

Hour-Glass, a popular kind of chronometer or clepsydra, serving to measure the flux of time by the descent or running of sand out of one glass vessel into another. The best hour-glasses are those which, instead of sand, have egg-shells well dried in the oven, then beaten fine and sifted.—Hour-glasses are much used at sea for reckoning, &c.

HOURIS, in modern history, is a name given by the Mahometans to those females that are designed for the faithful in Paradise. These are not the same with whom they have lived on earth, but formed for this purpose with singular beauty and undecaying charms.

HOUSE, a habitation, or place built with conveniencies for dwelling in. See ARCHITECTURE.

HOUSES, among the Jews, Greeks, and Romans, were flat on the top for them to walk upon, and had usually stairs on the outside, by which they might ascend and descend without coming into the house. Each house, in fact, was so laid out, that it enclosed a quadrangular area or court. This court was exposed to the weather, and being open to the sky, gave light to the house. This was the place where company was received, and for that purpose it was strewed with mats or carpets for their better accommodation. It was paved with marble or other materials, according to the owner's ability, and provided with an umbrella of vellum to shelter them from the heat and inclemencies of the weather. This part of their houses, called by the Romans *impluvium* or *cava ædium*, was provided with channels to carry off the water into the common sewers. The top of the house was level, and covered with a strong plaster by way of terrace. Hither, especially among the Jews, it was customary to retire for meditation, private converse, devotion, or the enjoyment of the evening breezes.

The Grecian houses were usually divided into two parts, in which the men and women had distinct mansions assigned. The part assigned to the men was towards the gate, and called ἀνδρωνῖτις; the apartment of the women was the farthest part of the house, and called γυναικωνῖτις. Jews, Greeks, and Romans, supposed

sed their houses to be polluted by dead bodies, and to stand in need of purification.

House is also used for one of the estates of the kingdom of Britain assembled in parliament. Thus we say, the house of lords, the house of commons, &c. See Peers, Commons, &c.

House is also used for a noble family, or a race of illustrious persons issued from the same stock. In this sense we say, the house or family of the Stuarts, the Bourbons, the house of Hanover, of Austria, of Lorrain, of Savoy, &c.

Cheap, easy, and expeditious Method of constructing Houses, which have been found to be very useful hospitals for the recovery of the sick, and therefore may probably make very wholesome places of residence for the healthy.—The first thing to be done is to choose a dry and airy situation, on a gravelly or chalky soil if possible; upon this lay down the plan of your building, make one end of it face that quarter from whence the purest and healthiest winds may be expected to blow, of a breadth that can be conveniently roofed. Then, if boarding does not come so cheap, drive stakes, at about six feet distance from each other, into the ground, so as to stand about six feet above it; and, interlacing them with wattles, coat the wattles on the side next the weather with fresh straw; and make the roof in the same manner, but thicker, or of thatch in the usual way, with a hole at the very top of it, to open occasionally. Let the end of the building facing the wholesomest quarter lie open some feet back, so as to form a porch, where the convalescents may take the air without danger of any injury from the weather. A large chimney and kitchen grate may be erected at the other end. If the soil happens to be chalky or gravelly, you may hollow it four or five feet deep, within a foot or eighteen inches of the walls; but let the steps into this hollow lie far enough within the porch, that no water may get into it, and, if of chalk, the steps may not grow slippery in wet weather. From time to time open the vent-hole at the roof; by means of which all the unwholesome infectious air, as being warmer, and consequently lighter, than that which is pure and wholesome, will be driven out by the rushing in of the fresh air; a purpose, which the little openings that may be left in the sides and roofs of such rude and hasty buildings, will, even of themselves, answer so well, as sufficiently to compensate any cold they may let in, even in the coldest months. Let the floor likewise be scraped three or four inches deep every five or six days, and what comes off removed to some distance. Halls of this kind, 50 feet long and 20 broad, cost but a trifle to build; yet, with these precautions (even without the addition of clean straw for every new patient to lie on, inclosed in clean washed sacks fit for the purpose, which come infinitely cheaper than the bare cleaning of flock or even feather-beds, supposing it possible to wash such beds), proved of infinitely more advantage in the recovery of sick soldiers, than the low-roofed rooms of the farm-houses of the Isle of Wight, or even the better accommodations of Carisbrooke castle in the same island, in which there perished four times the number of sick that there did in these temporary receptacles; which were first thought of by Doctor Brocklesby, on occasion of some terrible infections from confined animal effluvia.

Is it not surprising, that we have not availed ourselves more of the above discovery in natural history, being, perhaps, the most important the moderns can boast of, in the most useful science, viz. the superior lightness of unwholesome and infectious air! The upper sashes in most houses, even of those who pretend to some knowledge in these matters, are generally immoveable, by means of which no part of the foul air above the level of the lowest rail of the other sash's greatest rise can escape by the window; and, if it escapes by the doors, it is generally, for want of a vent in the highest part of the roof, merely to accumulate in the upper story of the house, and add to the infection, which the great quantities of old furniture usually stored up there are of themselves but too apt to create, when care is not frequently taken to open the windows of it. Thus, the chief benefit to be expected from lofty rooms is in a great measure lost. Whereas, were the upper sashes contrived to come down, all the air might be easily changed, and that almost insensibly, by letting them down an inch or two. Nay, the upper sash might be often let entirely down with less danger or inconvenience from cold, than the lower thrown up the tenth part of an inch, though the doing of the former would be attended with infinitely more advantage to the health of the inhabitants than the latter. It is, perhaps, on this principle, that we are to account for the good health enjoyed by the poor who live crowded in damp cellars, and often with great numbers of rabbits, poultry, and even swine about them. These cellars are open to the street, with doors reaching from the floor to the very ceiling, but never so close at bottom or at top as to prevent a free circulation of air; in consequence of which, that all-vivifying fluid, as fast as it is spoiled by passing through the lungs of the inhabitants and their stock, or is infected by their insensible perspiration, excrements, &c. is driven out and replaced by the fresh air.

House, in *Astrology*, denotes the twelfth part of the heavens.

The division of the heavens into houses is founded upon the pretended influence of the stars, when meeting in them, on all sublunary bodies. These influences are supposed to be good or bad; and to each of these houses particular virtues are assigned, on which astrologers prepare and form a judgment of their horoscopes. The horizon and meridian are two circles of the celestial houses, which divide the heavens into four equal parts, each containing three houses; six of which are above the horizon, and six below it; and six of these are called *eastern* and six *western houses*.

A scheme or figure of the heavens is composed of 12 triangles, all called *houses*, in which are marked the stars, signs, and planets, so included in each of these circles. Every planet has likewise two particular houses, in which it is pretended that they exert their influence in the strongest manner; but the sun and moon have only one, the house of the former being Leo, and that of the latter Cancer.

The houses in astrology have also names given them according to their qualities. The first is the house of life:

House.

life: this is the ascendant, which extends five degrees above the horizon, and the rest below it. The second is the house of riches; the third, the house of brothers; the fourth, in the lowest part of the heavens, is the house of relations, and the angle of the earth; the fifth, the house of children; the sixth, the house of health; the seventh, the house of marriage, and the angle of the west; the eighth, the house of death; the ninth, the house of piety; the tenth, the house of offices; the eleventh, the house of friends; and the twelfth, the house of enemies.

* See *Villa*.

Country House, is the *villa** of the ancient Romans, the *quinta* of the Spaniards and Portuguese, the *closerie* and *cassine* of the French, and the *vigna* of the Italians.

It ought always to have wood and water near it, these being the principal beauties of a rural seat. The trees make a far better defence than hills, as they yield a cooling and healthy air, shade during the heat of summer, and very much break the severities of the winter season.

It should not be situated too low, on account of the moisture of the air; and, on the other hand, those built on places exposed to the winds are expensive to keep in repair. In houses not above two stories high, and upon a good foundation, the length of two bricks, or 18 inches, for the heading course, will be sufficient for the ground-work of any common structure; and six or seven courses above the earth, to a water-table, where the thickness of the walls is abated or taken in, on either side the thickness of a brick, viz. two inches and a quarter. But for large and high houses of three, four, or five stories, with garrets, their walls ought to be three heading courses of bricks, or 28 inches at least, from the foundation to the first water-table; and at every story a water-table, or taking in, on the inside, for the summers, girders, and joists to rest upon, laid into the middle, or one quarter of the wall at least, for the better bond. But as for the partition-wall, a brick and half will be sufficiently thick; and for the upper stories a brick length or nine inch brick will suffice.

Hot-House. See STOVE and HYPOCAUSTUM.

House-Breaking, or *Robbing*, is the breaking into and robbing a house in the day-time; the same crime being termed BURGLARY when done by night: both are felony without benefit of clergy.

† See *Revenue*.

House and Window Duty, a branch of the king's extraordinary revenue †.—As early as the Conquest, mention is made in Doomesday book of fumage or fugage, vulgarly called *smoke-farthings*; which were paid by custom to the king for every chimney in the house. And we read that Edward the Black Prince (soon after his successes in France), in imitation of the English custom, imposed a tax of a florin upon every hearth in his French dominions. But the first parliamentary establishment of it in England was by statute 13 and 14 Car. II. c. 10. whereby an hereditary revenue of 2s. for every hearth, in all houses paying to church and poor, was granted to the king for ever. And, by subsequent statutes, for the more regular assessment of this tax, the constable and two other substantial inhabitants of the parish, to be appointed yearly (or the surveyor appointed by the crown, together with such constable or other public officer), were, once in every year, empowered to view the inside of every house in the parish. But, upon the Revolution, by stat. 1 W. and M. c. 10. hearth-money was declared to be "not only a great oppression to the poorer sort, but a badge of slavery upon the whole people, exposing every man's house to be entered into and searched at pleasure, by persons unknown to him; and therefore, to erect a lasting monument of their majesties goodness, in every house in the kingdom the duty of hearth-money was taken away and abolished." This monument of goodness remains among us to this day: but the prospect of it was somewhat darkened, when in six years afterwards, by statute 7 W. III. c. 18. a tax was laid upon all houses (except cottages) of 2s. now advanced to 3s. per house, and a tax also upon all windows, if they exceeded nine, in such house. These rates have been from time to time varied, being now extended to all windows exceeding six; and power is given to surveyors, appointed by the crown, to inspect the outside of houses, and also to pass through any houses, two days in the year, into any court or yard, to inspect the windows there.

House ‖ Household.

Schemes of the different rates of duty upon houses and windows may be seen in the *Almanacks*, or in *Kearsley's Tax-Tables* published yearly.

House-Leek. See SEDUM and SEMPERVIVUM, BOTANY *Index*.

HOUSEHOLD, the whole of a family considered collectively, including the mistress, children, and servants. But the household of a sovereign prince includes only the officers and domestics belonging to his palace.

The principal officers of his majesty's household are, the lord steward, lord chamberlain of the household; the groom of the stole, the master of the great wardrobe, and the master of the horse.

The civil government of the king's house is under the care of the lord steward of the king's household; who, being the chief officer, all his commands are observed and obeyed. His authority extends over all the other officers and servants, except those of his majesty's chapel, chamber, and stable, and he is the judge of all crimes committed either within the court or the verge.

Under him are the treasurer of the household, the comptroller, cofferer, the master of the household, the clerks of the green-cloth, and the officers and servants belonging to the accounting-house, the marshalsea, the verge, the king's kitchen, the household kitchen, the acatery, bake-house, pantry, buttery, cellar, pastry, &c. Next to the lord steward is the lord-chamberlain of the household, who has under him the vice-chamberlain, the treasurer, and comptroller of the chamber; 48 gentlemen of the privy chamber, 12 of whom wait quarterly, and two of them lie every night in the privy-chamber; the pages of the presence-chamber; the mace-bearers, cup-bearers, carvers, musicians, &c. See *Lord* CHAMBERLAIN *of the Household*.

The groom of the stole has under him the 11 other lords of the bed-chamber, who wait weekly in the bed-chamber, and by turns lie there a-nights on a pallet-bed; and also the grooms of the bed-chamber, the pages of the bed-chamber and back-stairs, &c. See *Groom of the* STOLE.

The master or keeper of the great wardrobe has under

der him a deputy, comptroller, clerk of the robes, brusher, &c. and a number of tradesmen and artificers, who are all sworn servants to the king.

The master of the horse has under his command the equerries, pages, footmen, grooms, coachmen, farriers, saddlers, and all the other officers and tradesmen employed in his majesty's stables.

Next to the civil list of the king's court, is the military, consisting of the band of gentlemen pensioners, the yeomen of the guards, and the troops of the household; of which the two first guard the king above stairs.

When the king dines in public, he is waited upon at table by his majesty's cup-bearers, carvers, and gentlemen sewers; the musicians playing all the time. The dinner is brought up by the yeomen of the guard, and the gentleman sewers set the dishes in order. The carvers cut for the king, and the cup-bearer serves him the drink with one knee on the ground, after he has first tasted it in the cover.

HOUSING, or *House-Line*, in the sea-language, a small line, formed of three fine strands or twists of hemp, smaller than rope-yarn. It is chiefly used to seize blocks into their strops, to bind the corners of the sails, or to fasten the bottom of a sail to its bolt-rope, &c. See *Bolt-Rope*.

Housing, or *Housee*, a cover laid over the saddle of a horse, in order to save it from the weather, dirt, &c. The word is formed of the French *houssie*, which signifies the same thing; though it anciently denoted a kind of hood worn by country people.—The cavaliers appeared with their embroidered housings.

Housing, among bricklayers, a term used for a brick which is warped, or is cast crooked or hollow in burning; in such a case, they say it is *housing*.

HOUSSA, the metropolis of an empire in Africa, on the banks of the Niger, the population of which, according to the account of an Arab named *Shabeni*, which he delivered to the African Association, was only equalled by that of London and Cairo. The same person described the government as a limited monarchy, which administered justice in a severe manner, although in conformity to written laws. The rights of landed property are guarded by the institutions of particular hereditary officers, whose duties imply no ordinary degree of refinement and civilization. The merchants of Houssa have been celebrated for their probity, while the ladies are said not to be very remarkable for their conjugal fidelity. The art of writing is common, but their alphabet is entirely different from the Arabic and Hebrew. These observations appear to be confirmed by the testimony of Mr Park; and to such as may be disposed to doubt the possibility of so much refinement in the interior of a country deemed savage, it will be necessary to observe, that many of the Carthaginians may have retired to the southern parts of Africa, on the destruction of their own cities, and carried with them some portion of the arts, sciences, and commercial knowledge, for the knowledge of which we are assured that their ancestors were once so famous. According to some maps of North Africa, particularly that of Major Rennel, the city of Houssa lies in Lat. 16. 20. N. and Long. 4. 30. E.

HOUSTONIA, a genus of plants belonging to the tetrandria class and in the natural method ranking under the 47th order, *Stellatæ*. See Botany *Index*.

HOU-TCHEOU-FOU, a city of China, in the province of Tche-kiang. It is a city of the first class; and is situated on a lake, from which it takes its name. The quantity of silk manufactured here is almost incredible. To give some idea of it we shall only say, that the tribute paid by a city under its jurisdiction, named *Te-tsin-hien*, amounts to more than 500,000 *taels* or ounces of silver. Its district contains seven cities, one of which is of the second, and six of the third, class.

HOUZOUANAS, a wandering people, whose country, according to M. Vaillant, is situated between 16° and 29° E. Long. but in what latitude appears to be unknown, although it is extremely probable that it commences about the 23d parallel, and stretches towards the north a considerable way. It is the opinion of the above-mentioned author, that the Houzouanas are the origin of all the eastern and western tribes of the Hottentots: and as to the Houzouanas themselves, they seem wholly ignorant of their own origin; for when they are interrogated upon this subject, their answer invariably is, that they live in the country which their ancestors inhabited, which in point of information is no answer at all. They have been often confounded by the planters with the Boshmen, who are not a distinct people, but a band of fugitives and freebooters. The Houzouanas have nothing in common with them, and only form alliances among themselves. So great are their courage and habits of plunder, that all surrounding nations are afraid of them, and even the very Hottentots, according to Vaillant, tremble to enter their territories. They are often guilty of shedding human blood, yet this does not appear to originate from an innate love of carnage, but merely for the purpose of making just reprisals.

They survey the adjacent countries from the summits of their mountains, and make incursions to carry off cattle or slaughter them upon the spot; but although they rob, they never kill, except in their own defence, or by way of retaliation, so that they are by no means the unrelenting cannibals which some have represented them. Like the Arabs, who are also plunderers, they adhere with unshaken fidelity to their engagements, and the traveller who puts himself under their protection by civilly purchasing their services, may rest assured of being defended to the last drop of their blood; which is more than can be said for the people of many countries professing to be civilized.

Amidst all this superiority to the other natives of Southern Africa, their stature is low, so that a person among them measuring five feet four inches in height, is considered as very tall;—a proof that intellectual excellence is not always to be met with in men of a gigantic stature. Their complexion is not so black as that of the Hottentots, but their heads are rounder towards the chin. The heat of the climate renders clothing unnecessary, and the constant habit of going naked, makes them equally indifferent to the burning sands of the level country, or the frost and snow of the lofty mountains. They have no weapons but bows and arrows, in the use of which they discover remarkable dexterity. Their huts appear as if cut vertically through the middle, so that it would require two of them exactly

Houzouanas, Howard.

ly to make one of the Hottentots. The Houzouanas are remarkably nimble, considering the climbing of mountains as nothing more than an amusement; and they conducted M. Vaillant, that traveller informs us, over such tremendous precipices as the Hottentots would have deemed wholly impassable. The practice of making signals by means of nocturnal fires, is known in all savage countries; but the Houzouanas are said to display such uncommon sagacity and prudence in the arrangement and variations of position from time to time, as to render it impossible for the surrounding tribes to penetrate their designs.

HOWARD, Henry, earl of Surrey, a soldier and a poet, the son and grandson of two lord treasurers, dukes of Norfolk, was born probably about the year 1520, and educated in Windsor castle, with young Fitzroy earl of Richmond, natural son to King Henry VIII. Wood says, from tradition, that he was some time a student at Cardinal College, Oxford. In his youth he became enamoured of the Fair Geraldine, whom his sonnets have immortalized. In 1532, Howard with his companion Richmond was at Paris, where they continued some time. The latter died in 1536; after which our young hero made a tour to Italy, and at Florence, like a true *enamorato*, published a challenge against all comers, whether Christians, Jews, Saracens, Turks, or cannibals, in defence of the beauty of his fair Geraldine; and was victorious in the tournament instituted by the grand duke on the occasion. The duke, we are told, was so charmed with his gallant exploits, that he would gladly have retained him at his court; but he rejected the invitation, being determined to maintain the superlative beauty of his Geraldine in all the principal cities in Italy. This romantic resolution was however frustrated by the command of his sovereign, Henry VIII. to return to England.

In 1540, he signalized himself in a tournament at Westminter, against Sir John Dudley, Sir Thomas Seymour and others. In 1542, he marched, under the command of his father, against the Scots; and in the same year was confined in Windsor castle for eating flesh in Lent, contrary to the king's proclamation. In 1544, on the expedition to Boulogne in France, he was appointed field-marshal of the English army; and after the taking of that town, in 1546, made captain-general of the king's forces in France. He was at this time knight of the Garter. In the same year, attempting to intercept a convoy, he was defeated by the French, and soon after superseded in his command by the earl of Hertford.

Surrey, after his return to England, conscious of his former services, and peevish under his disgrace, could not help reflecting on the king and council. This was his first step towards destruction. He had married Frances, the daughter of John earl of Oxford; and, after her death, is said to have made love to the princess Mary. For this the Seymours, rivals of the Norfolk family, and now in favour with the king, accused him of aspiring to the crown, adding, that he already presumed to quarter part of the royal arms with his own: but, whatever might be the pretence, the cause of his ruin was the jealousy and power of his enemies. In short, the destruction of the Howards being determined, Surrey, and his father, the duke of Norfolk, were committed to the Tower, in December 1546; and on the 13th of January following, Surrey was tried at Guildhall by a common jury, and beheaded on Tower-hill on the 19th day of the same month, nine days before the death of the king; who thus, that the measure of his crimes might be full, finished his life with the murder of his best subject. The accusations brought against this amiable and innocent young nobleman on his trial, were so extremely ridiculous, that one is astonished how it was possible, even in the most despotic reign, to find a judge and jury so pusillanimously villanous as to carry on the farce of justice on the occasion. We boast of our excellent constitution, and our trial by juries; but this example may teach us, that our constitution and our juries are not incompatible with despotic monarchy. He was first interred in the church of All-hallows, Barkin, near Tower-hill; and afterwards in the reign of King James I. removed to Farmingham in Suffolk, by his son Henry earl of Northampton.

Howard.

As to the character of this unfortunate earl, all our poets have sung his praise. Mr Walpole begins his anecdotes of Surrey with these words: "We now emerge from the twilight of learning to an almost classic author, that ornament of a boisterous, yet not unpolished court, the earl of Surrey, celebrated by Drayton, Dryden, Fenton, Pope, illustrated by his own muse, and lamented for his unhappy death: a man (as Sir Walter Raleigh says) no less valiant than learned, and of excellent hopes." Leland calls him the conscript enrolled heir of Sir Thomas Wyatt, the elder, in his learning and other excellent qualities; and the author of *The Art of English Poetry* says, that the earl of Surrey and Sir Thomas Wyatt, may be justly called the *reformers of our poetry and style*. His poems were published in 1557, 12mo; and in 1565, 1574, 1585, 1587, 8vo. Several of the sonnets are by Sir Thomas Wyatt and others.

Howard, *Charles*, an able statesman and experienced seaman, was the son of Lord William Howard, baron of Effingham, and born in 1536. He served under his father, who was lord high admiral of England, till the accession of Queen Elizabeth. In January 1573, he succeeded his father in his title and estate; after which he successively became chamberlain of the household and knight of the Garter, and in 1585 was made lord high admiral, at that critical juncture when the Spaniards were sending their Armada, in their opinion, to the assured conquest of this kingdom. When he received intelligence of the approach of the Spanish fleet, and saw the prodigious consequence it was to get out the few ships that were ready at Plymouth, he not only gave orders in every thing himself, but wrought also with his own hands, and the first night left the port with six ships. The next morning, though he had only 30 sail, and those the smallest of the fleet, he attacked the Spanish navy; but first dispatched his brother-in-law, Sir Edward Hobby, to the queen, to desire her to make the proper disposition of her land-forces for the security of the coast, and to hasten as many ships as possible to his assistance. His valour was conspicuously displayed in his repeated attacks of a superior enemy. The coolness of his temper was no less conspicuous; and it was owing to his magnanimity and prudence that the victory was so great. The queen expressed

Howard.

expressed her sense of his merit in the most honourable terms; and granted him a pension for life. In 1596, he commanded in chief at sea, as Essex did by land, the forces sent against Spain, when his prudence and moderation were among the principal causes of the success the English met with in that great and glorious enterprise; so that, upon his return the next year he was advanced to the dignity of earl of Nottingham. The next eminent service in which his lordship was engaged was in 1599, when the Spaniards seemed to meditate a new invasion. Her majesty, who always placed her safety in being too quick for her enemies, drew together, in a fortnight's time, such a fleet, and such an army, as took away all appearance of success from her foreign and domestic enemies; and she gave the earl the sole and supreme command of both the fleet and army, with the title of *lord lieutenant general of all England*, an office unknown in succeeding times. When age and infirmity had unfitted him for action, he resigned his office, and spent the remaining part of his life in ease and retirement, till the time of his decease, which happened in 1624, in the 87th year of his age.

HOWARD, *John*, Esq. a man of singular and transcendant humanity, was the son of a reputable tradesman in St Paul's church-yard. He was born about the year 1725 or 1726; and at a proper age was put apprentice to Mr Nathaniel Newnham, a wholesale grocer in Watling street. His father died, leaving only this son and a daughter, to both of whom he bequeathed handsome fortunes; and by his will directed that his son should not be considered of age till he was five and twenty. His constitution was thought very weak, and his health appeared to have been injured by the necessary duties of his apprenticeship; and therefore, at the expiration of it, he took an apartment in a lodging house in Church-street, Stoke Newington, Middlesex; but not meeting with the tenderest treatment there, he removed to another lodging-house in the same street, which was kept by a widow lady Mrs Sarah Lardeau, a worthy sensible woman, but an invalid. Here he was nursed with so much care and attention, that he resolved to marry his landlady out of gratitude for her kindnesss. In vain she expostulated with him upon the extravagance of such a proceeding, he being about 28 and she about 51 years of age, and 20 years older in constitution: but nothing could alter his resolution, and they were privately married about the year 1752. She was possessed of a small fortune, which he presented to her sister. During his residence at Newington, the minister of the dissenting meeting-house there resigned his office, and a successor was elected; and Mr Howard, who was bred a dissenter, and stedfastly adhered all his life to that profession, proposed to purchase the lease of a house near the meeting-house, and to appropriate it as a parsonage-house for the use of the minister for the time being, and contributed 50l. for that purpose. His wife died November 10. 1755, aged 54; and he was a sincere and affectionate mourner for her death. About this time it is believed, he was elected F. R. S. In the year 1756 he had the fortune to experience some of the evils which it afterwards became the business of his life to redress. He embarked that year in a Lisbon packet, the Hanover, in order to make the tour of Portugal; when the vessel was taken by a French privateer. "Before we reached Brest (says he*) I suffered the extremity of thirst, not having for above 40 hours one drop of water, nor hardly a morsel of food. In the castle at Brest I lay six nights upon straw; and observing how cruelly my countrymen were used there and at Morlaix, whither I was carried next, during the two months I was at Carhaix upon parole, I corresponded with the English prisoners at Brest, Morlaix, and Dinnan: at the last of those towns were several of our ship's crew, and my servant. I had sufficient evidence of their being treated with such barbarity, that many hundreds had perished, and that 36 were buried in a hole at Dinnan in one day. When I came to England, still on parole, I made known to the commissioners of sick and wounded seamen the sundry particulars, which gained their attention and thanks. Remonstrance was made to the French court: our sailors had redress; and those that were in the three prisons mentioned above, were brought home in the first cartel ships.—Perhaps (adds Mr Howard) what I suffered on this occasion increased my sympathy with the unhappy people whose case is the subject of this book."

* On Prisons, 4to, 1784, p. 11.

He afterwards, it is said, made the tour of Italy; and at his return settled at Brokenhurst, a retired and pleasant villa in the New Forest, near Lymington in Hampshire, having, April 25. 1758, married a daughter of Edward Leeds, Esq. of Croxton, Cambridgeshire, king's serjeant. This lady died in 1765 in childbed, of her only child, a son, who unfortunately became lunatic. After her death Mr Howard left Lymington, and purchased an estate at Cardington, near Bedford.

"While he lived here in retirement (says Mr Palmer†), it was his meat and drink to make his neighbours happy. His neat but humble mansion was ever hospitable to a few select friends, but was never the scene of riot or luxurious banqueting. Though polite to all, he neither sought nor admitted the company of the profligate, however distinguished by rank or fortune.—His charity had no bounds, except those of prudence; and was not more commendable for the extent of it, than for the manner in which it was exercised. He gave not his bounty to countenance vice and idleness, but to encourage virtue and industry. He was singularly useful in furnishing employment for the labouring poor of both sexes, at those seasons when a scarcity of work rendered their situation most compassionable. And at other times, though never inattentive to the tale of woe, he was not easily imposed upon by it, but made himself acquainted with the case. He had indeed a general acquaintance with the cases and characters of the poor around him, and made it his business to visit the abodes of affliction. In circumstances of bodily disorder, he often acted the part of a physician as well as a friend. But his kindness was not confined to the bodies of his fellow-creatures, it extended to their spiritual and immortal part. He carefully watched over the morals of his neighbourhood, and used his advice, his admonitions, and influence, to discountenance immorality of all kinds, and to promote the knowledge and practice of religion. As a most effectual means to this great end, he provided for the instruction of poor children, by erecting and supporting schools which he carefully superintended. In short, he was an universal blessing to the village

† Funer. Sermon on the death of Mr Howard.

Howard.

lage where he resided, in every part of which are to be seen the pleasing monuments of his munificence and taste.—His liberality extended also to adjacent places, in which there are many who will call him blessed. Nor was it confined to persons of his own religious persuasion, but comprehended the necessitous and deserving of all parties; while he was particularly useful in serving the interest of the Christian society to which he belonged. What wonder if such a man were universally beloved? Was it possible he should have an enemy? One however he had (and I never heard of more), an idle and dissolute wretch, who, having been often reproved by him for his vices, formed the desperate resolution to murder him as he was going to public worship, which he almost always did on foot. But providence remarkably interposed to preserve so valuable a life, by inclining him that morning to go on horseback a different road."

But the sphere in which he had hitherto moved was too narrow for his enlarged mind. Being named in 1773 to the office of sheriff of Bedfordshire, from that time his scene of usefulness was extended. His office, as he himself observes, brought the distress of prisoners more immediately under his notice. A sense of duty induced him personally to visit the county-jail, where he observed such abuses and such scenes of calamity, as he had before no conception of; and he soon exerted himself in order to a reform. With a view to obtain precedents for certain regulations which he proposed, he went to inspect the prisons in some neighbouring counties. But finding in them equal room for complaint and commiseration, he determined to visit the principal prisons in England. The farther he proceeded, the more shocking were the scenes presented to his view: which induced him to resolve upon exerting himself to the utmost, in order to a general reform in these horrid places of confinement; considering it as of the highest importance, not only to the wretched objects themselves, but to the community at large. Upon this subject he was examined in the house of commons in March 1774, when he had the honour of their thanks. This encouraged him to proceed in his design. He revisited all the prisons in the kingdom, together with the principal houses of correction. He also in 1775 enlarged his circuit by going into Wales, Scotland, and Ireland, where he found the same need of reformation.

One grand object which he had in view was, to put a stop to that shocking distemper called the *jail-fever;* which raged so dreadfully in many of the prisons as to render them to the last degree offensive and dangerous: A distemper, by which more had been taken off than by the hands of the executioner; and which, in several instances, had been communicated from the prisons into the courts of justice, and had proved fatal to the magistrates and judges, and to multitudes of persons who attended the trials, as well as to the families of discharged felons and debtors. Another end he proposed was, to procure the immediate release of prisoners, who, upon trial, were acquitted, but who often continued long to be unjustly detained for want of being able to pay the accustomed fees: As also to abolish many other absurd and cruel usages which had long prevailed. But the great object of all was, to introduce a thorough reform of morals into our prisons; where he had found the most flagrant vices to prevail in such a degree, that they were become seminaries of wickedness and villany, and the most formidable nuisances to the community; in consequence of the promiscuous intercourse of prisoners of both sexes, and of all ages and descriptions; whereby the young and less experienced were initiated, by old and hardened sinners, into all the arts of villany and the mysteries of iniquity; so that, instead of being reformed by their confinement (which should be the chief end of punishment), those that were discharged became more injurious to society than before.

In order to the attainment of these great objects, Mr Howard spared no pains nor expence, and cheerfully exposed himself to much inconvenience, and hazard; particularly from that malignant distemper, of which he saw many dying in the most loathsome dungeons, into which none, who were not obliged, besides himself, would venture. "I have been frequently (says Mr Howard) asked what precautions I used to preserve myself from infections in the prisons and hospitals which I visited. I here answer, next to the free goodness and mercy of the Author of my being, temperance and cleanliness are my preservatives. Trusting in divine providence, and believing myself in the way of my duty, I visit the most noxious cells; and while thus employed, I fear no evil. I never enter an hospital or prison before breakfast; and in an offensive room, I seldom draw my breath deeply."

His laudable endeavours he had the pleasure to see, in some instances, crowned with success; particularly in regard to the healthiness of prisons, some of which were rebuilt under his inspection. Through his interposition also, better provision has been made for the instruction of prisoners, by the introduction of bibles and other pious books into their cells, and a more constant attendance of clergymen. The gaolers likewise have, by act of parliament, been rendered incapable of selling strong liquors, which had been the source of much drunkenness and disorder. But a minute detail of particulars is not to be expected here; for these the reader is referred to Mr Howard's publications, which show that much is yet wanting.

But in order to a more general and happy regulation, and the reformation of criminals, he determined to visit other countries, to see the plans there adopted; in hope of collecting some information which might be useful in his own country. For this purpose he travelled into France, Flanders, Holland, Germany, and Switzerland. Afterwards through the Prussian and Austrian dominions. He visited also the capitals of Denmark, Sweden, Russia, and Poland, and some cities in Portugal and Spain. In all these expensive and hazardous journeys, he denied himself the usual gratifications of travellers, and declined the honours which were offered him by persons of the first distinction, applying himself solely to his one grand object. To him the inspection of a jail, or hospital, was more grateful than all the entertainments of a palace. With what astonishment and gratitude he was received by their miserable inhabitants may easily be imagined, since while he made observations on their situation, he meditated their relief; and many distressed prisoners abroad, as well as at home, partook of his bounty, and some were liberated by it; for he considered all of every nation,

Howard.

tion, and people, and tongue, as brethren. Nor was he sparing of advice, or of reproof, as he saw occasion, to persons of rank and influence, whereby the miseries of their countrymen might be relieved. As he courted the favour of none, neither did he fear the frowns of any; but with a manly freedom and a Christian fortitude, spoke his mind to crowned heads (particularly the late emperor of Germany) in a manner to which they were not accustomed; which, however, in a person of such disinterested views, procured him reverence and esteem, and in some instances proved effectual for relieving the miserable and oppressed. On his return, he published in 1777, "The State of the Prisons in England and Wales, with Preliminary Observations, and an Account of some foreign Prisons." 4to. And in 1778 he took a third journey through the Prussian and Austrian dominions, and the free cities of Germany, and likewise extended his tour through Italy, and revisited some of the countries he had before seen. The observations he made in this tour were published in an appendix, 1780; containing also some remarks respecting the management of prisoners of war, and the hulks on the Thames. But wishing to acquire some further knowledge on the subject, he in 1781 again revisited Holland and some cities in Germany. He visited also the capitals of Denmark, Sweden, Russia, and Poland; and in 1783 some cities in Portugal and Spain, and returned through France, Flanders, and Holland. The substance of all these travels was afterwards thrown into one narrative, which was published in 1784. He also published a curious account of the Bastile, in 8vo.; that infamous French prison, happily now no more.

His travels and exertions, however, were not yet at an end. He conceived a further design, which was to visit the principal lazarettoes in France and Italy, in order to obtain information concerning the best methods to prevent the spreading of the plague, with a view to apply them with respect to other infectious disorders. Not gaining all the satisfaction here which he wished for, he proceeded to Smyrna and Constantinople, where that most dreadful of human distempers actually prevailed, "pleasing himself (as he said) with the idea of not only learning, but of being able to communicate somewhat to the inhabitants of those distant regions." In the execution of this design, though he was so much exposed to danger, and actually caught the plague, "that merciful Providence (as he himself piously remarks) which had hitherto preserved him, was pleased to extend his protection to him in this journey also, and to bring him home once more in safety." In his return he revisited the chief prisons and hospitals in the countries through which he passed; and afterwards went again to Scotland, and then to Ireland, where he proposed a new and very important object; namely, to inspect the Protestant Charter Schools, in some of which he had before observed shameful abuses, which he had reported to a committee of the Irish House of Commons. In this more extensive tour, he took a particular account of what he observed amiss in the conduct of this noble charity, with a view to a reformation, and not without considerable success. In the course of these journeys, particular cities and communities were not unmindful to pay him proper respect. At Dublin, he was created by the university a Doctor of Laws; and the city of Glasgow and the town of Liverpool did honour to themselves by enrolling him among their members. Upon his return home, having again inspected the prisons in England, and the hulks on the Thames, to see what alterations had been made for the better (which he found to be very considerable, though yet imperfect), he published the result of his last laborious investigations, in "An Account of the Principal Lazarettoes in Europe, with various Papers relative to the Plague, together with further Observations on some Foreign Prisons and Hospitals, and additional Remarks on the present State of those in Great Britain and Ireland," with a great number of curious plates. The work likewise contained Observations on Penitentiary Houses, which had been encouraged by act of parliament, for the correction and reformation of criminals, of which he and Dr Fothergill had been nominated by the king to be superintendants. Beside these, he published the Grand Duke of Tuscany's "new Code of Criminal Law, with an English Translation:" and of all his publications he gave away a vast number of copies among his acquaintance in the most liberal manner. His laying open the horrors of despotism in a neighbouring country had very nearly exposed him to the sufferings of them; and had it not been for the timely notice of our ambassador, he had ended his days in the Bastile.

Not satisfied, however, with what he had already done, he concludes his "Account of Lazarettoes" with announcing his "intention again to quit his country, for the purpose of revisiting Russia, Turkey, and some other countries, and extending his tour in the east. I am not insensible (says he) of the dangers that must attend such a journey. Trusting, however, in the protection of that kind Providence which has hitherto preserved me, I calmly and cheerfully commit myself to the disposal of unerring wisdom. Should it please God to cut off my life in the prosecution of this design, let not my conduct be uncandidly imputed to rashness or enthusiasm, but to a serious deliberate conviction that I am pursuing the path of duty, and to a sincere desire of being made an instrument of more extensive usefulness to my fellow-creatures than could be expected in the narrower circle of a retired life." Accordingly, to the great concern of his friends, he set out in summer 1789 on this hazardous enterprize; the principal object of which was to administer a medicine in high repute at home, in malignant fevers †, under a strong persuasion that it would be equally efficacious in the plague. In this second tour in the east, "it *did* please God to cut off his life:" for, having spent some time at Cherson, a new settlement of the empress of Russia, on the mouth of the Dnieper or Borysthenes, toward the northern extremity of the Black sea, near Oczakow, he caught, in visiting the Russian hospital of that place, or as some say a young lady who was ill of the same complaint, a malignant fever, which carried him off on the 20th of January, after an illness of about twelve days: and after having been kept, according to his express directions to his servant, five days, he was buried, by his own desire, in the garden of a villa in the neighbourhood, belonging to a French gentleman from whom he had received

† Dr James's Powder.

Howard

Howe.

received great civilities, by his faithful servant who had attended him on his former journeyings, and whom he expressly enjoined not to return home till five weeks from his death. While absent on his first tour to Turkey, &c. his character for active benevolence had so much attracted the public attention, that a subscription was set on foot to erect a statue to his honour, and in no long space above 1500l. was subscribed for that purpose. But some of those who knew Mr Howard best, never concurred in the scheme, being well assured that he would neither countenance nor accede to it; and in consequence of two letters from Mr Howard himself * to the subscribers, the design was laid aside. It has, however, been resumed since his death: And surely, of all the statues or monuments ever erected by public gratitude to illustrious characters either in ancient or modern times, none was ever erected in honour of worth so genuine and admirable as his—who devoted his time, his strength, his fortune, and finally sacrificed his life, in the pursuits of humanity:—who (to adopt the expressive words of Mr Burke †) "visited all Europe [and the east], not to survey the sumptuousness of palaces, or the stateliness of temples; not to make accurate measurements of the remains of ancient grandeur, nor to form a scale of the curiosity of modern art; not to collect medals, or to collate manuscripts: but to dive into the depth of dungeons; to plunge into the infection of hospitals; to survey the mansions of sorrow and of pain; to take the gauge and dimensions of misery, depression, and contempt; to remember the forgotten; to attend to the neglected; to visit the forsaken; and to compare and collate the distresses of all men in all countries. His plan is original; and it is as full of genius as it is of humanity. It is a voyage of discovery, a circumnavigation of charity; and already the benefit of his labour is felt more or less in every country."

† *Speech at Guildhall in Bristol,* 1780.

HOWDEN, a town in the east riding of Yorkshire, 180 miles from London, stands on the north side of the Ouse, has a market on Saturdays, and four fairs in the year. Here was formerly a collegiate church of five prebendaries; adjacent to which the bishops of Durham, who possess many estates here with a temporal jurisdiction, have a palace. One of them built a very tall steeple to the church here, whither the inhabitants might retire in case of inundations; to which it is very liable from the great freshes that come down the Ouse sometimes at ebb. This part of the county is from hence called Howdenshire, and is watered by a conflux of several large rivers that fall into the Humber. At Howdendike is a ferry over the Ouse. Population 1812, in 1811.

HOWE, Richard, Earl, an English naval commander of distinguished eminence, was born in the year 1725, being the second son of Lord Viscount Howe, by the daughter of Baron Kilmansegg. From his early attachment to the life of a mariner, he quitted the school of Eton at the age of 14, and went on board the Severn, the honourable Captain Legge being commander, destined for the South seas under Commodore Anson. Mr Howe next appeared in the Burford, Captain Lushington commander, who being killed in an expedition against the Caraccas, Commodore Knowles made Mr Howe an acting lieutenant. At the age of 20 he was promoted to the rank of commander in the Baltimore sloop of war, and he joined a squadron at that time cruising off the coast of Scotland, where he met with an opportunity of displaying his undaunted courage and intrepidity, by engaging and beating off two French frigates of 30 guns each, by the assistance of another armed ship, notwithstanding he was severely wounded in the head during the action. This service was immediately and very justly rewarded with the rank of post-captain. He was soon after appointed to the rank of captain on board Commodore Knowles's own ship of 80 guns, with which he returned to England in the year 1748. When hostilities again commenced, he commanded the Dunkirk of 60 guns, in North America; which ship constituted part of the squadron under Admiral Boscawen, and with which he captured a French man of war of superior metal off the coast of Newfoundland; viz. the Alcide of 64 guns. In order to annoy the coast of France, he received, in the year 1758, the command of a small squadron, with which he effected the destruction, at St Malo, of a number of magazines and ships. When he served on board the Essex, Prince Edward, afterwards duke of York, sailed with him, at which time he powerfully contributed to the reduction of the town of Cherbourg. In 1758 his elder brother fell in North America in the service of his king and country, on which event the young commodore succeeded to the family title and estate. In the following year he participated of the honourable victory gained by Sir Edward Hawke over the French fleet under Admiral Conflans. He afterwards served in the Channel, and was captain of the Amelia, the ship of admiral the duke of York. On the restoration of peace, he was nominated one of the lords of the admiralty, and some time afterwards, treasurer of the navy. He was in the year 1770, raised to the rank of rear-admiral of the blue, and chosen commander-in-chief on the Mediterranean station. In 1775, he rose to the station of rear-admiral of the blue; in consequence of which rapid promotions, Lord Hawke paid him the following compliment in the house of peers: "I advised his majesty to make the promotion. I have tried my Lord Howe on important occasions; he never asked me how he was to execute any service, but always went and performed it".

In the summer of 1776, Lord Howe appeared off Massachusets, as commander-in-chief of his Britannic majesty's fleet acting in North America, and in the capacity of a commissioner for restoring the blessings of an amicable reconciliation. All the provincial governors were made acquainted with his arrival by means of circular letters, expressive also of the full extent of the authority invested in him and his fellow commissioners; but as congress did not deem the conditions which these letters contained to be at all satisfactory, they were ordered to be inserted in all the gazettes for the examination of the people. His powers being thus circumscribed at the very commencement, he could only act in the capacity of a naval commander, in which he aided the operations of the land forces with uncommon skill. It was not to be imagined, however, that much glory could redound to his lordship from such an unequal contest, till the junction of France with America placed the contending parties more upon a level. On the arrival of Admiral D'Estaign in the month of July 1778, off Sandy Hook, Lord Howe was certainly in a

very

Howe. very critical situation; but by an exertion of uncommon skill and dexterity, the French commander thought it prudent to retire, when he was pursued by Lord Howe to Rhode island, after he obtained a reinforcement under Admiral Byron. The intentions of the enemy were completely counteracted, and the campaign was finally terminated with honour. Here he resigned his command, and came over to England; but in 1782 he was promoted to the rank of admiral of the blue, made a viscount of Great Britain, and chosen commander of the fleet which was sent for the relief of Gibraltar. The combined fleets of France and Spain were about a third superior to that under Lord Howe, who, with 34 sail of the line, appeared off Gibraltar in the month of October, being driven into the Mediterranean by contrary winds. Although he was pursued by the combined fleet, he found means to supply the fortress with provisions. He checked the enemy by a partial action, and notwithstanding he offered to give them battle, it was declined on their part; and he had the satisfaction to execute his commission prior to his return home, in spite of the numerous difficulties which he had to encounter.

He was nominated first lord of the admiralty on the termination of the war, which he both resigned and resumed by different changes of administration. In the year 1787 he was chosen admiral of the white, and created an earl of Great Britain in the following year. When hostilities were renewed with France in 1793, his lordship accepted the command of the channel fleet, at the express desire of his Britannic majesty, but he had it not in his power to do any thing decisive till the summer of 1794. On the ever memorable 1st of June, with a fleet consisting of 25 sail of the line, he gave battle to a French fleet of 26, gaining a most signal victory over the enemy, capturing seven of their ships, one of which was so shattered as to go to the bottom, and several others were, in the language of seamen, very much crippled. His lordship had the good fortune not to lose a ship, and comparatively but a few men, considering the prodigious loss in this respect sustained by the enemy. The gratitude of the nation was suitable to the importance of this naval victory, and it is more than probable that the first of June will never be forgotten. In 1795 he was made general of marines: but the infirmities which seldom fail to be the concomitants of old age, induced him to resign his naval command in the year 1797, and on his final retreat he was presented with the honours of the Garter. His great influence as a beloved officer, contributed greatly to stifle a spirit of mutiny and discontent which at this time exhibited alarming symptoms among the seamen of his majesty's fleets. He terminated his brilliant and honourable career on the 5th of August 1799, in the 73d year of his age, leaving none but female issue behind him. His lordship's valour, always cool and steady, was consequently of that nature which enables a commander to make the most of his situation; his judgment was sound and penetrating, which prevented him from being easily imposed upon by external appearances; and his seamanship was of the most consummate and masterly kind. It is with pleasure we close this concise account of his lordship's public life by observing, that his country was deeply sensible of the value and importance of his services, a truth fully evinced by the honours and preferments which it heaped upon him.

Howe, Howe's Island.

Howe-Island, a small island of the South sea, discovered by Captain Wallis, called by the inhabitants of the Society islands *Mopeha;* lies in S. Lat. 16. 46. and W. Long. 154. 8.

Lord Howe's Island, a small island in the neighbourhood of New South Wales, discovered on February 17th, 1788. S. Lat. 31. 36. E. Long. 159. 40. It is of an arched figure, lying from north-west to south-east, the two extremities including a space of about six miles, though, by reason of the curved figure of the island itself, it is near seven in length. It is deeply indented in the middle of the eastern part by a bay named Ross's bay, and on the opposite and western part has another named Prince William Henry's bay; so that the whole has the appearance of two islands joined together by an isthmus, which in some places is not above half a mile broad. On the southern part of that division which lies most to the northward are two considerable bays, named Callam's and Hunter's bay; and on the south-western part of the other are two high mountains, the most southerly named Mount Gower, and the other Mount Lidgbird. The convex part of the island lying towards the north-east, and the concave side towards the opposite quarter, is terminated by two points named Point King and Point Philip. No fresh water was found on the island; but it abounds with cabbage-palms, mangrove, and manchineel trees, even up to the summits of the mountains. There are plenty of gannets, and a land fowl of a dusky brown colour, with a bill about four inches long, and feet like those of a chicken. These were found to be remarkably fine meat, and were very fat. There are many large pigeons, and the white birds found in Norfolk island were also met with in this place. The bill of this bird is red, and very strong, thick, and sharp pointed. Great numbers of fine turtle frequent this island in summer, but go to the northward in winter. These, it was imagined, would prove of great service to the colony at Port Jackson; but, from some cause or other, it appears they have hitherto been disappointed. Plenty of fish were caught by a hook and line. At the distance of about four leagues from Lord Howe's island is a very remarkable and high rock, to which the name of Ball's Pyramid has been given. This island may be approached without danger; but about four miles from the south-west part of the pyramid there is a very dangerous rock, which shows itself above the surface of the water, and appears not to be larger than a boat. The southern part of the island is lined with a sandy beach, which is guarded against the sea by a reef of coral rocks, at the distance of half a mile from the beach, through which there are several small openings for boats; but there is nowhere a greater depth of water within the reef than four feet. By the account of Mr Watts, who visited this island in his return from Port Jackson, the isthmus which joins the two parts has evidently been overflowed, and the island disjoined, as in the very centre the men saw large beds of coral rocks and great quantities of shells; and on the east, which seems in general to be the weather-side, the sea has thrown up a bank of sand from 25 to 30 feet high, which serves as a barrier against future inundations. The island also appears

pears to have suffered by volcanic eruptions, as great quantities of pumice-stones and other matters of that kind were found upon it. Mr Austin also found the whole reef which shelters the west bay a burnt-up mass. The time he visited the island was that of the incubation of the gannets, of which there were then prodigious numbers, their nests being only hollows made in the sand, there not being any quadrupeds on the island to disturb them. Besides the large pigeons already mentioned, they met with beautiful parrots and parroquets; a new species of the coote, as well as of the rail and magpie. They found likewise a very beautiful small bird of a brown colour with a yellow breast, and yellow on the wing, which seemed to be a species of humming bird. They found also a black bird like a sheerwater, having a hooked bill; and which burrows in the ground. The only insects met with here were the common earth-worm and ants: which last were in great plenty. Besides the trees already mentioned, they found several esculent vegetables, as scurvy-grass, celery, spinach, endive, and samphire.

HOWITZ, a kind of mortar, mounted upon a field-carriage like a gun. The difference between a mortar and a howitz is, that the trunnions of the first are at the end, and at the middle in the last. The invention of howitzes is of much later date than mortars, for they really had their origin from them. The constructions of howitzes are as various and uncertain as those of mortars, excepting the chambers, which are all cylindric. They are distinguished by the diameter of the bore; for instance, a ten inch howitz is that the diameter of which is 10 inches; and so of the smaller ones.

HOWTH, a promontory which forms the northern entrance of the bay of Dublin, having a small village about seven miles north-east from that city in the province of Leinster. It gives title of earl to the family of St Lawrence, who were so called from a victory obtained by them over the Irish on St Lawrence's day 1177, their former name being Tristram; and this place has continued in possession of the family above 600 years. N. Lat. 53. 21. W. Long. 6. 22. The shores off this hill are rocky and precipitous, affording, however, a few harbours for small craft. It was formerly called Ben-hedar, i. e. "the birds promontory;" and celebrated for having Dun Criomthan, or the rath or royal palace of Criomthan erected on it, he having been chief or king of that district, and memorable for making several successful descents on the coast of Britain against the Romans in the time of Agricola. Howth, though now stript of trees, was formerly covered with venerable oaks, and was a seat of the Druids; one of their altars still remains in a sequestered valley on the east side of the hill. The mansion-house is built in form of a castle, and was probably erected by Sir Armoricus Tristram. Near the house stands the family chapel, and on the western shore are the ruins of St Mary's church, with some ancient monuments of Lord Howth's ancestors. Due west of Howth house are the ruins of St Fenton's church.

HOY, a small vessel chiefly used in coasting, or carrying goods to or from a ship, in a road or bay, where the ordinary lighters cannot be managed with safety or convenience.

It would be very difficult to describe precisely the marks of distinction between this vessel and some others of the same size, which are also rigged in the same manner; because what is called a *hoy* in one place, would assume the name of a *sloop* or *smack* in another; and even the people who navigate these vessels, have, upon examination, very vague ideas of the marks by which they are distinguished from those above mentioned. In Holland the hoy has two masts; in England, it has but one, where the main-sail is sometimes extended by a boom, and sometimes without it. Upon the whole, it may be defined a small vessel, usually rigged as a sloop, and employed for carrying passengers and luggage from one place to another, particularly on the sea-coast.

HOY, one of the Orkney islands, which lie off the north coast of Scotland, is situated between the island of Pomona and the north coast of Caithness, and is separated from the small island of Græmsay by a sound of a mile broad. The whole island is nearly occupied by three large hills, of which that to the north-east rises from a broad base to the height of 1200 feet. Some veins of lead and iron have been discovered in this island. Birch trees of considerable size seem to have been produced on it in former times. But at present its vegetable productions, excepting what are fit for sheep pasture, are extremely limited. A few hardy alpine plants and stunted shrubs include the whole. The number of inhabitants does not exceed 520. The Dwarfie stone is the only monument of antiquity in the island. This is a large mass of sand-stone 32 feet long, 18 broad, and $7\frac{1}{2}$ feet thick above the surface. It is hollowed within, and divided into three apartments, one of which, called the *dwarf's bed*, is five feet eight long, by two feet broad. It has probably been the retreat of a hermit. Tradition says that it was the habitation of a giant. Waas or Waes, which is often considered as a distinct island, makes part of Hoy. It is distinguished for the excellence of its harbours, particularly the Longhope, one of the finest and safest in Europe. Waas contains 750 inhabitants.

HOYE, a town of Germany in Westphalia, and capital of a county of the same name. It is seated on the river Weser, and is subject to the king of Hanover. E. Long. 9. 0. N. Lat. 53. 5.

HUAHEINE, one of the SOCIETY *Islands*, in the South sea, situated in S. Lat. 16. 43. W. Long. 150. 52. and is about seven or eight leagues in compass. Its surface is hilly and uneven, and it has a safe and convenient harbour. It was first discovered by Captain Cook in 1769. It is divided by a deep inlet into two peninsulas connected by an isthmus, which is entirely overflowed at high water. From the appearance of its hills it may be concluded, that the country has at some period or other been the seat of a volcano. The summit of one of them had much the appearance of a crater, and a blackish spongy earth was seen upon one of its sides, which seemed to be lava; and the rocks and clay every where had a burnt appearance. The island is plentifully supplied with water by many rivulets which descend from the mountains and broken rocks. The inhabitants are nearly as fair as Europeans; and their conduct is bolder than that of the inhabitants of the other Society islands. They are a stout large-made people, some of the tallest being six feet three inches in height: they are extremely indolent, and seem to have

have as little curiosity as fear. The dogs are in great favour with all their women, "who could not have caressed them (says Mr Forster) with a more ridiculous affection if they had been European ladies of fashion." Here was seen a middle-aged woman, whose breasts were full of milk, offering them to a little puppy who had been trained up to suck them. The sight disgusted those who saw it so much, that they could not forbear expressing their dislike to it; but the woman smiled, and told them that she allowed young pigs to do the same. It appeared afterwards that this woman had lost her child. Some of the gentlemen were present at a dramatic entertainment on this island: the piece represented a girl running away from her parents; and seemed to be levelled at a female passenger who had come in Captain Cook's ship from Otaheite, and who happened to be present at the representation. It made such an impression on the girl, that the gentlemen could scarce prevail upon her to see the piece out, or to refrain from tears while it was acting. It concluded with the reception she was supposed to meet with from her friends, which was made out not to be a very agreeable one.—These people introduce extempore pieces upon occasion; and it is most probable that this was meant as a satire upon the girl above mentioned, and to discourage others from acting in the same manner.

HUBERT, St, a town of the Netherlands, on the confines of Liege, with a very fine abbey, where they bring those that are bit by mad animals to be cured. E. Long. 5. 25. N. Lat. 50. 1.

HUBNER, John, a learned geographer of Germany, taught geography at Leipsic and Hamburg with extraordinary reputation; and died at Hamburg in 1732, aged 63. His principal work is A Geographical Treatise, printed at Basil in 1746, in 6 vols. 12mo.

HUDSON, Jeffrey. See Dwarf.

Hudson, *Henry*. Of this eminent naval discoverer we know nothing prior to the year 1607, when he was employed by some London merchants in a small vessel, for exploring a north-east passage to China and Japan. He set sail on the 1st of May with only ten men and a boy, and reached as high as 80° of N. Lat. where being stopt by the ice, he returned to England in the month of September following. In his next voyage he landed at Nova Zembla, but could make no farther east, and he returned in August next year. The Dutch East India Company fitted him out in 1609, with a crew of 20 men, English and Dutch, and after in vain attempting to penetrate eastward, he steered for the American coast, and went as far as Chesapeak bay. His crew mutinying, he durst not attempt a westerly passage through Davis's strait, and therefore returned home.

His knowledge in consequence of these voyages increased his ardour for discovery, and he again made an offer of his services to the Dutch East India Company, which were not accepted; and for his last voyage, Sir Thomas Smith, Sir Dudley Digges, and some of his friends, fitted him out. On the 17th of April he set sail, and came in sight of Greenland on the 4th of June. Sailing westward, he reached the mouth of the strait which bears his name, through which he advanced along the coast of Labrador, which he called *Noua Britannia*. Here he hoped he had discovered the long-wished-for passage; but he found he was only in a bay, in the southern part of which he determined to winter. After this he fitted out his shallop for farther discoveries, but as he had no means of revictualling his ship, he distributed his last remaining bread with tears in his eyes, among his people, and returned home. His mutinous crew entered his cabin by night, tied his hands behind his back, and set him ashore at the west end of the straits, with eight of the crew who were most attached to him. They were never more heard of, and it is probable they were swallowed up by the waves. Such was the unfortunate end of this adventurous mariner!

Hudson, *William*, a celebrated English botanist, was born at Westmoreland about 1730. He was bound apprentice to an apothecary in London, whose business he took, and proved a friend to the widow and daughters. It appears from the testimony of Dr Pulteney, that he had a residence in the British museum, but we are not informed in what capacity. He was also F.R.S. and died of a paralytic distemper in May 1793. He possessed a comprehensive knowledge of English plants, which induced him to undertake an arrangement of English botany according to the Linnæan classification, a task which had been previously attempted by Dr Hill, but the execution was very imperfect. Hudson's *Flora Anglica* appeared in 1762, in one volume 8vo, the Latin preface to which was written by the ingenious Mr Stillingfleet, and received with great applause, and contributed greatly to the adoption in England of the sexual system.

The merits of Mr Hudson are thus described by Dr J. E. Smith. "His memory requires no studied eulogium here, as every page of the present work is an index to his labours. May the writer of this leave no more errors behind him as an author, or as a man." Mr Hudson well understood the insects and shells of Great Britain, and always meditated a *Fauna Britannica*. His temper is said to have been gentle, rather close, but kind to those who gained his esteem.

Hudson's Bay, a large bay of North America, lying between 51 and 69 degrees of latitude, discovered in 1610, by Henry Hudson. This intrepid mariner, in searching after a north-west passage to the South seas, discovered three straits, through which he hoped to find out a new way to Asia by America. He had made two voyages before on the same adventure; the first in 1607, and the second in 1608. In his third and last, 1610, he entered the straits that lead into this new mediterranean, the bay known by his name; coasted a great part of it; and penetrated to eighty degrees and a half into the heart of the frozen zone. His ardour for the discovery not being abated by the difficulties he struggled with in this empire of winter, and world of frost and snow, he staid here until the ensuing spring, and prepared in the beginning of 1611 to pursue his discoveries; but his crew, who suffered equal hardships, without the same spirit to support them, mutinied, seized upon him and seven of those who were most faithful to him, and committed them to the fury of the icy seas in an open boat. Hudson and his companions were either swallowed up by the waves, or gaining the inhospitable coast were destroyed by the savages; but the ship and the rest of the men returned home. Other attempts towards a discovery

Hudson's Bay.

were made in 1612 and 1667; and a patent for planting the country, with a charter for a company, was obtained in the year 1670. In 1746 Captain Ellis wintered as far north as 57 degrees and a half, and Captain Christopher attempted farther discoveries in 1761. But besides these and the late voyages, which satisfy us that we must not look for a passage on this side of the latitude 67 degrees north, we are indebted to the Hudson's Bay company for a journey by land; which throws much additional light on this matter, by affording what may be called demonstration, how much farther north, at least in some parts of their voyage, ships must go, before they can pass from one side of America to the other. The northern Indians, who come down to the company's factories to trade, had brought to the knowledge of our people a river, which, on account of much copper being found near it, had obtained the name of the Copper-mine river. The company being desirous of examining into this matter with precision, directed Mr Hearne, a young gentleman in their service, and who having been brought up for the navy and served in it the war before last, was extremely well qualified for the purpose, to proceed over land under the convoy of those Indians, for that river, which he had orders to survey if possible quite down to its exit into the sea; to make observations for fixing the latitudes and longitudes; and to bring home maps and drawings both of it and the countries through which he should pass. Accordingly Mr Hearne set out from Prince of Wales's fort, on Churchill river, latitude 58° 47½' north, and longitude 94° 7½' west from Greenwich, on the 7th of December 1770. On the 13th of June he reached the Copper-mine river, and found it all the way, even to its exit into the sea, encumbered with shoals and falls, and emptying itself into it over a dry flat of the shore, the tide being then out, which seemed by the edges of the ice to rise about 12 or 14 feet. This rise, on account of the falls, will carry it but a very small way within the river's mouth, so that the water in it had not the least brackish taste. Mr Hearne was nevertheless sure of the place it emptied itself into being the sea, or a branch of it, by the quantity of whalebone and seal skins which the Esquimaux had at their tents, and also by the number of seals which he saw upon the ice. The sea at the river's mouth was full of islands and shoals as far as he could see by the assistance of a pocket telescope; and the ice was not yet (July 17th) broken up, but thawed away only for about three quarters of a mile from the shore, and for a little way round the islands and shoals which lay off the river's mouth. But he had the most extensive view of the sea when he was about eight miles up the river; from which station the extreme parts of it bore north-west by west and north-east. By the time Mr Hearne had finished his survey of the river, which was about one o'clock in the morning on the 18th, there came on a very thick fog and drizzling rain; and as he had found the river and sea in every respect unlikely to be of any utility, he thought it unnecessary to wait for fair weather to determine the latitude more exactly by observation; but by the extraordinary care he took in observing the courses and distances, walking from Congecathawhachaga, where he had two very good observations, he thinks the latitude may be depended on within 20' at the utmost. It appears from the map which Mr Hearne constructed of this singular journey, that the mouth of the Copper-mine river lies in latitude 72° north, and longitude 25° west from Churchill river; that is, about 119° west of Greenwich. Mr Hearne's journey back from the Copper-mine river to Churchill lasted till June 30th 1772: so that he was absent almost a year and seven months. The unparalleled hardships he suffered, and the essential service he performed, met with a suitable reward from his masters, and he was made governor of Prince of Wales's fort on Churchill river. The recent voyage of Captain Parry (1820) has shown that a sea does exist towards the parts where Hearne observed it, but whether this sea communicates directly with Hudson's bay remains to be discovered.

The country lying round Hudson's bay is called *New Britain*, or the country of the Esquimaux; comprehending *Labrador*, now North and South Wales. The entrance of the bay from the ocean, after leaving to the north Cape Farewell and Davis's straits, is between Resolution isles on the north, and Button's isles on the Labrador coast to the south, forming the eastern extremity of the straits distinguished by the name of its great discoverer. The coasts are very high, rocky, and rugged at top; in some places precipitous, but sometimes exhibit large beaches. The isles of Salisbury, Nottingham, and Digges, are also very lofty and naked. The depth of water in the middle of the bay is a hundred and forty fathoms. From Cape Churchill to the south end of the bay are regular soundings; near the shore shallow, with muddy or sandy bottom. To the north of Churchill the soundings are irregular, the bottom rocky, and in some parts the rocks appear above the surface at low water. From Moose river or the bottom of the bay to Cape Churchill the land is flat, marshy, and wooded with pines, birch, larch, and willows. From Cape Churchill to Wager's Water the coasts are all high and rocky to the very sea, and woodless, except the mouths of Pockerekesko and Seal rivers. The hills on their back are naked, nor are there any trees for a great distance inland.

The mouths of all the rivers are filled with shoals, except that of Churchill, in which the largest ships may lie; but ten miles higher, the channel is obstructed with land banks; and all these rivers, as far as has been navigated, are full of rapids and cataracts from ten to sixty feet perpendicular. Down these rivers the Indian traders find a quick passage; but their return is a labour of many months. As far inland as the company have settlements, which is six hundred miles to the west, at a place called Hudson House, lat. 53. long. 106. 27. from London, is a flat country: nor is it known how far to the eastward the great chain seen by our navigators from the Pacific ocean branches off.

The climate even about Haye's river, in only lat. 57. is during winter excessively cold. The snows begin to fall in October, and continue falling by intervals the whole winter; and when the frost is most rigorous, in form of the finest sand. The ice on the rivers is eight feet thick. Port-wine freezes into a solid mass; brandy coagulates. The very breath fell on the blankets of the beds in the form of a hoar frost, and the bed-clothes often were found frozen to the wall.

The

Hudson's Bay.

The sun rises in the shortest day at five minutes past nine, and sets five minutes before three. In the longest day the sun rises at three, and sets about nine. The ice begins to disappear in May, and hot weather commences about the middle of June, which at times is so violent as to scorch the face of the hunters. Thunder is not frequent, but very violent. But there must be great difference of heat and cold in this vast extent, which reaches from lat. 50. 40. to lat. 63. north.—During winter the firmament is not without its beauties. Mock suns and halos are not unfrequent; they are very bright, and richly tinged with all the colours of the rainbow. The sun rises and sets with a large cone of yellowish light. The night is enlivened with the Aurora Borealis, which spreads a thousand different lights and colours over the whole concave of the sky, not to be defaced even by the splendour of the full moon; and the stars are of a fiery redness.

The eastern boundary of the bay is Terra di Labrador; the northern part has a straight coast facing the bay, guarded with a line of isles innumerable. A vast bay, called the Archiwinnipy sea, lies within it, and opens into Hudson's bay by means of Gulf Hazard, through which the beluga whales dart in great numbers. Here the company had a settlement for the sake of the fishery, and for trading with the Esquimaux; but deserted it as unprofitable about the year 1758 or 1759. The eastern coast is barren past the efforts of cultivation. The surface is everywhere uneven, and covered with masses of stone of an amazing size. It is a country of fruitless valleys and frightful mountains, some of an astonishing height: the first watered by a chain of lakes, formed not from springs but rain and snow, so chilly as to be productive of only a few small trout. The mountains have here and there a blighted shrub, or a little moss. The valleys are full of crooked stunted trees, pines, fir, birch, and cedars, or rather a species of juniper. In lat. 60. on this coast, vegetation ceases. The whole shore, like that on the west, is faced with islands at some distance from land. The inhabitants among the mountains are Indians; along the coasts Esquimaux. The dogs of the former are very small; of the latter large, and headed like a fox. Notwithstanding they have rein-deer, they never train them for the sledge; but apply the dogs to that use. Walruses visit a place called Nuchvûnk, in lat. 60. during winter; from thence the natives purchase the teeth with which they head their darts. Davis suspected that he had found a passage on this coast in 1586, to the Western ocean; but it proves no more than a deep bay.

The laudable zeal of the Moravian clergy induced them to send, in the year 1752, missionaries from Greenland to his country. They fixed on Nisbet's harbour for their settlement; but the first party was partly killed, partly driven away. In 1764, under the protection of our government, another attempt was made. The missionaries were well received by the Esquimaux, and the mission goes on with success.

The animals of these countries are, the moose deer, stags, rein-deer, bears, buffaloes, wolves, foxes, beavers, otters, lynxes, martins, squirrels, ermines, wild cats, and hares. The rein-deer pass in vast herds towards the north in October, seeking the extreme cold. The male polar bears rove out at sea, on the floating ice, most of the winter, and till June: the females lie concealed in the woods, or beneath the banks of rivers till March, when they come abroad with their twin cubs, and bend their course to the sea in search of their consorts. Several are killed in their passage: and those which are wounded show vast fury, roar hideously, and bite and throw up into the air even their own progeny. The females and the young, when not interrupted, continue their way to sea. In June the males return to shore, and by August are joined by their consorts, with the cubs, by that time of a considerable size. The feathered kind are, geese, bustards, ducks, partridges, and all manner of wildfowls. Indeed multitudes of birds retire to this remote country, to Labrador and Newfoundland, from places most remotely south, perhaps from the Antilles; and some even of the most delicate little species. Most of them, with numbers of aquatic fowls, are seen returning southward with their young broods to more favourable climates. The savages, in some respects, regulate their months by the appearance of birds; and have their goose month from the vernal appearance of geese from the south. All the grous kind, ravens, cinereous crows, titmouse, and Lapland finch, brave the severest winter; and several of the falcons and owls seek shelter in the woods. Of fish, there are whales, morses, seals, cod-fish, and a white fish preferable to herrings; and in their rivers and fresh waters, pike, perch, carp, and trout.

All the quadrupeds of these countries are clothed with a close, soft, warm fur. In summer there is here, as in other places, a variety in the colours of the several animals; when that season is over, which holds only for three months. they all assume the livery of winter, and every sort of beasts, and most of their fowls, are of the colour of the snow; every thing animate and inanimate is white. This is a surprising phenomenon. But what is yet more surprising, and what is indeed one of the most striking things, that draw the most inattentive to an admiration of the wisdom and goodness of Providence, is, that the dogs and cats from Britain that have been carried into Hudson's bay, on the approach of winter have entirely changed their appearance, and acquired a much longer, softer, and thicker coat of hair than they had originally.

Hudson's-Bay Company. See Company.

Hudson's River, a large river of North America which rises on the east of Lake Ontario, and running by Albany, and on the back of the south part of New-England through part of New-York, falls into the bay of the sea beyond the west end of Long-Island, and below the town of New-York.

HUDSONIA, a genus of plants belonging to the dodecandria class. See Botany *Index*.

Hue and Cry.

HUE *and* Cry, in *Law*, the pursuit of a person who has committed felony on the highway.—Of this custom, which is of British origin, the following deduction is given by Mr Whitaker. "When it was requisite for the Britons to call out their warriors into the field, they used a method that was particularly marked by its expeditiousness and decisiveness, and remains partially among us to this moment. They raised a cry, which was immediately caught by others, and in an instant transmitted from mouth to mouth through all the region. And, as the notice passed along

along, the warriors snatched their arms, and hurried away to the rendezvous. We have a remarkable description of the fact in Cæsar, and there see the alarm propagated in 16 or 17 hours through 160 miles in a line. And the same practice has been retained by the Highlanders to our own time. When the lord of a clan received intelligence of an enemy's approach, he immediately killed a goat with his own sword, dipped the end of a half-burnt stick in the blood, and then gave it and the notice of the rendezvous to be carried to the next hamlet. The former symbolically threatened fire and sword to all his followers that did not instantly repair to the latter. The notice was despatched from hamlet to hamlet with the utmost expedition; and in three or four hours the whole clan was in arms, and assembled at the place appointed. This was within these few years the ordinary mode by which the chieftains assembled their followers for war. The first person that received the notice, set out with it at full speed, delivered it to the next that he met, who instantly set out on the same speed, and handed it to a third, And in the rebellion of 1745, it was sent by an unknown hand through the region of Breadalbane; and flying as expeditiously as the Gallic signal in Cæsar, traversed a tract of 32 miles in three hours. This quick method of giving a diffusive alarm is even preserved among ourselves to the present day; but is applied, as it seems from Cæsar's account above to have been equally applied among the Celtæ, to the better purposes of civil polity. The *hutesium and clamour* of our laws, and the *hue and cry* of our own times, is a well-known and powerful process for spreading the notice and continuing the pursuit of any fugitive felons. The cry, like the clamour of the Gauls or the summons of the Highlanders, is taken from town to town and from county to county; and a chain of communication is speedily carried from one end of the kingdom to the other."

HUER, a name given to certain fountains in Iceland, of a most extraordinary nature; forming at times *jets d'eaux* of scalding water ninety-four feet high and thirty in diameter, creating the most magnificent gerbes that can be imagined, especially when backed by the setting sun. They arise out of cylindrical tubes of unknown depths: near the surface they expand into apertures of a funnel shape, and the mouths spread into large extent of stalactitical matter, formed of successive scaly concentric undulations. The playing of these stupendous spouts is foretold by noises roaring like the cataract of Niagara. The cylinder begins to fill: it rises gradually to the surface, and gradually increases its height, smoking amazingly, and flinging up great stones. After attaining its greatest height, it gradually sinks till it totally disappears. Boiling *jets d'eaux* and boiling springs are frequent in most parts of the island. In many parts they are applied to the culinary uses of the natives. The most capital is that which is called *Geyer*, or *Geyser*, in a plain rising into small hills, and in the midst of an amphitheatre, bounded by the most magnificent and various shaped icy mountains; among which the three-headed Hecla soars pre-eminent. See ICELAND, N° 4. —These huers are not confined to the land; they rise in the very sea, and form scalding fountains amidst the waves. Their distance from the land is unknown; but the new volcanic isle, twelve miles off the point of Reickenes, emitting fire and smoke, proves that the subterraneous fires and waters extend to that space: for those awful effects arise from the united fury of these two elements.

HUESCA, an ancient and considerable town of Spain, in the kingdom of Arragon, with a bishop's see and a university. It is seated on the Issuela, in a soil producing excellent wine, in W. Long. 0. 2. N. Lat. 42. 18.

HUESCAR, or GUESCAR, a town of Spain, in the kingdom of Granada, seated on a plain, in W. Long. 2. 20. N. Lat. 37. 32.

HUESNE, or HUENA, a small island in the Baltic sea, in the Sound, where was the famous observatory of Tycho Brahé. E. Long. 12. 38. N. Lat. 55. 54.

HUET, PETER DANIEL, a very learned French writer, born at Caen in Normandy, on the 8th of February 1630. He discovered, from his infancy, a great inclination to the study of polite literature and the sciences, and at first applied himself to the law; but Des Cartes's principles, and Bochart's sacred geography, made him change his studies for those of philosophy, mathematics, the languages, and antiquities. His admiration for Bochart made him desirous of knowing him. He contracted a very strict friendship with him, and accompanied that learned man to Sweden. Here Christina would have engaged him in her service; but he, sensible of her inconstant temper, returned to France. All he brought with him was a copy of a MS. of Origen, which he transcribed at Stockholm. He refused several offers from Christina after she abdicated and went to Rome, and from Gustavus her successor. In 1670, Mr Bossuet being appointed by the king preceptor to the dauphin, his majesty chose Mr Huet for his colleague, with the title of *sub-preceptor to the prince*. It was he that formed the plan of the commentaries *in Usum Delphini*, and directed the execution. His sentiments of piety determined him to enter into holy orders, which he did at the age of 46. Soon after this, he was presented by the king to the abbey of Aunay; and in 1685 was nominated to the bishopric of Soissons, which he changed for the see of Avranches. After governing that diocese ten years, he resigned, and was made abbot of Fontenay near Caen. His love to his native place determined him to fix there. But lawsuits coming upon him, he retired to Paris, and lodged among the Jesuits in the *Maisson Professe*, whom he had made heirs to his library. A severe distemper weakened his body extremely, but not the vivacity of his genius: he wrote his own life in a very elegant style: and died in 1721, aged 91. He was a man of very agreeable conversation; and of great probity, as well as immense erudition.—The following are the titles of his principal works. 1. *De claris interpretibus, et de optimo genere interpretandi*. 2. An edition of Origen's Commentaries on the Holy Scriptures, in Greek and Latin. 3. A Treatise on the Origin of the Romans. 4. *Demonstratio evangelica*, folio. 5. *Quæstiones Alnetanæ de concordia rationis et fidei*. 6. Of the Situation of the terrestrial Paradise, in French. 7. A History of the Commerce and Navigation of the Ancients, which has been translated into English. 8. *Commentarius de rebus ad eum pertinentibus*. 9. *Huetiana*. 10. Latin and Greek verses, &c.

HUCHLY or HOOGLY, a town of Asia, in the kingdom of Bengal, seated on the most westerly branch of the river Ganges. It is now nearly in ruins, but was in the beginning of the 18th century a place of large extent, reaching about two miles along the river-side, and had a great trade in all the commodities of that country; affording rich cargoes for 50 or 60 ships annually, besides what was brought in carriages to the neighbouring towns. Saltpetre was brought hither from Patna in vessels above 50 yards long and five broad. The inhabitants are chiefly Indians; but there are also Portuguese, English, and other Europeans. E. Long. 88. 28. N. Lat. 32. 30.

HUGO CAPET, chief of the third race of the kings of France, being count of Paris and Orleans: he was raised to the throne for his military valour and public virtues in 987. See FRANCE, N° 38.

HUGONIA, a genus of plants belonging to the monadelphia class; and in the natural method ranking with those of which the order is doubtful. See BOTANY *Index*.

HUGUENOTS, an appellation given by way of contempt to the reformed or Protestant Calvinists of France.

The name had its first rise in 1560; but authors are not agreed as to the origin and occasion thereof; but one of the two following seems to be the least forced derivation.

One of the gates of the city of Tours is called the gate Fourgon, by corruption from *feu Hugon*, i. e. the late Hugon. This Hugon was once count of Tours according to Eginhardus in his life of Charles the Great, and to some other historians. He was it seems a very wicked man, who by his fierce and cruel temper made himself dreadful; so that after his death he was supposed to walk about in the night-time, beating all those he met with: this tradition the judicious Thuanus has not scrupled to mention in his history. Davila and other historians pretend, that the nickname of *Huguenots* was first given to the French Protestants, because they used to meet in the night-time in subterraneous vaults near this gate of Hugon; and what seems to countenance this opinion is, that they were first called by the name of *Huguenots* at this city of Tours.

Others assign a more illustrious origin to that name; and say that the leaguers gave it to the reformed, because they were for keeping the crown upon the head of the line descended from Hugh Capet; whereas they were for giving it to the house of Guise, as descended from Charles the Great.

Others again derive it from a French and faulty pronunciation of the German word *edignossen*, signifying confederates, and originally applied to that valiant part of the city of Geneva, which entered into an alliance with the Swiss cantons, in order to maintain their liberties against the tyrannical attempts of Charles III. duke of Savoy.

These confederates were called *Eignots*, whence Huguenots.

The persecution which they underwent has scarce its parallel in the history of religion: though they obtained a peace from Henry III. in 1576, it was only of short continuance; and their sufferings, mitigated by the famous edict of Nantes, granted to them in 1598 by Henry IV. were again renewed, after the revocation of that edict, by Louis XIV. in 1685.

HULK, an old ship of war, fitted with an apparatus to fix or take out the masts of his majesty's ships, as occasion requires.

The mast of this vessel is extremely high, and withal properly strengthened by *shrouds and stays*, in order to secure what are called the *sheers*, which serve, as the arm of a crane, to hoist out or in the masts of any ship lying alongside. The sheers are composed of several long masts, whose heels rest upon the side of the hulk, and having their heads declining outward from the perpendicular so as to hang over the vessel whose masts are to be fixed or displaced. The tackles, which extend from the head of the mast to the sheer-heads, are intended to pull in the latter towards the mast-head, particularly when they are charged with the weight of a mast after it is raised out of any ship, which is performed by strong tackles depending from the sheer-heads. The effort of these tackles is produced by two capsterns, fixed on the deck for this purpose.

HULK, is also a name bestowed on any old vessel laid by as unfit for further service. It is probably derived from the ὁλκάδες, or vessels of burthen, of the ancient Grecians.

HULL, in the sea-language, is the main body of a ship, without either masts, yards, sails, or rigging. Thus *to strike a hull* in a storm, is to take in her sails, and to lash the helm on the lee-side of the ship; and *to hull*, or *lie a-hull*, is said of a ship whose sails are thus taken in, and helm lashed a-lee.

HULL, a river in Yorkshire, which falls into the Humber at *Kingston upon Hull*. See KINGSTON.

HUMAN, in general, is an appellation given to whatever relates to mankind: thus we say, the human soul, human body, human laws, &c.

HUMANITY, the peculiar nature of man, whereby he is distinguished from all other beings.

HUMANITIES, in the plural, signify grammar, rhetoric, and poetry, known by the name of *literæ humaniores*; for teaching of which, there are professors in the universities of Scotland, called *humanists*.

HUMBER, a river formed by the Trent, Ouse, Derwent, and several other streams. By means of inland navigation, it has a communication with the rivers Mersey, Dee, Ribble, Severn, Thames, Avon, &c. which navigation, including its windings, extends above 500 miles, in the counties of Lincoln, Nottingham, York, Lancaster, Westmoreland, Chester, Stafford, Warwick, Leicester, Oxford, Worcester. It divides Yorkshire from Lincolnshire, and falls into the German ocean near Holderness.

HUME, DAVID, Esq. a celebrated philosopher and historian, was born in the south part of Scotland on the 26th of April O. S. in the year 1711. Being the younger son of a country gentleman of good family, but no great fortune, his patrimony was of consequence insufficient to support him. For this reason he was destined for the bar, and passed through his academical courses in the university of Edinburgh; but being more inclined to studies of a different nature, he never put on the gown, nor even took the introductory steps for that purpose. The writings of Locke and Berkeley had directed the attention of the generality of learned men towards

Hume.

wards metaphysics; and Mr Hume having early applied himself to studies of this kind, published in 1739 the two first volumes of his Treatise of Human Nature, and the third the following year. He had the mortification, however, to find his book generally decried; and to perceive, that the taste for systematic writing was now on the decline. He therefore divided this treatise into separate Essays and Dissertations, which he afterwards published at different times with alterations and improvements.

In 1742, Mr Hume published two small volumes, consisting of Essays moral, political, and literary. These were better received than his former publication; but contributed little to his reputation as an author, and still less to his profit; and his small patrimony being now almost spent, he accepted an invitation from the marquis of Annandale to come and live with him in England. With this nobleman he staid a twelvemonth; during which time his small fortune was considerably increased. He then received an invitation from General St Clair, to attend him as a secretary to his expedition, which was at first meant against Canada, but afterwards ended in an excursion against the coast of France. In 1747, he received an invitation from the general to attend him in the same station in his military embassy to the courts of Vienna and Turin. He then wore the uniform of an officer; and was introduced at these courts as aid-de-camp to the general, along with Sir Harry Erskine and Captain Grant, afterwards General Grant. In 1749, he returned to Scotland, and lived two years with his brother at his country-house; where he composed the second part of his essays, called *Political Discourses*. And now the general approbation of his performances was indicated by a more extensive sale than formerly, and likewise by the numerous answers published by different persons in order to counteract their supposed pernicious tendency. In 1752, were published at Edinburgh his Political Discourses, the only work of his which was well received on its first appearance; and the same year at London, his Inquiry concerning the Principles of Morals, which in his own opinion was incomparably the best of all his performances. This year also he was appointed librarian to the faculty of advocates at Edinburgh; the principal advantage resulting from which employment was, that he had by that means the command of a large library. He then formed the plan of writing the History of England: but deeming the whole to be too extensive, he confined his history to that of Britain under the house of Stuart. The book was almost universally decried on its first appearance, and soon after seemed to sink in oblivion. Dr Herring, primate of England, and Dr Stone, primate of Ireland, were the only literati of the author's acquaintance who approved of the work, and sent him messages not to be discouraged.

Notwithstanding the approbation of these eminent men, however, Mr Hume's spirits were so much sunk by his bad success, that he had some thoughts of retiring to France, changing his name, and bidding adieu to his own country for ever; but his design was rendered impracticable by the breaking out of the war of 1755 between France and Britain. He then published his Natural History of Religion; to which an answer was published, soon after its appearance, in the name of Dr Hurd bishop of Litchfield and Coventry; of which, however, he since disclaimed being the sole author. In 1756, the second volume of the History of the Stuarts was published, two years after the appearance of the first. This was better received, and helped to retrieve the character of the former volume. Three years after, his History of the House of Tudor made its appearance; which was almost as ill received as the History of the Stuarts had been, the reign of Elizabeth being particularly obnoxious. The author, however, had now learned to despise popular clamours; and continued to finish at his leisure the more early part of the English history, which was published in 1761, and was received with tolerable success.

Mr Hume being now turned of fifty, and having obtained by the sale of his books a competent and independent fortune, retired into his native country of Scotland, determined never more to set his foot out of it. From this resolution, however, he was diverted by the earl of Hertford; whom he attended as secretary on his embassy to Paris in 1763. In 1765, the earl being appointed lord-lieutenant of Ireland, Mr Hume was intrusted with the sole management of the business of the state till the arrival of the duke of Richmond towards the latter end of the year. In 1767, he returned to Edinburgh, with a much larger income, procured to him by the earl of Hertford, than he formerly had; and now formed the same design he had formerly entertained, namely, of burying himself in his philosophical retreat. In this, however, he was again disappointed, by receiving an invitation from General Conway to be under secretary; and this invitation he was prevented from declining, both by the character of the person, and his connexions with Lord Hertford. In 1769 he returned to Edinburgh, possessed of 1000l. a-year, healthy, and though somewhat stricken in years, yet having a prospect of long enjoying his ease, and of seeing the increase of his reputation. Of his last illness and character, he himself gives the following account. In spring 1775, I was struck with a disorder in my bowels; which at first gave me no alarm, but has since, as I apprehend it, become mortal and incurable. I now reckon upon a speedy dissolution. I have suffered very little pain from my disorder; and what is more strange, have notwithstanding the great decline of my person, never suffered a moment's abatement of my spirits; insomuch, that were I to name the period of my life which I should most choose to pass over again, I might be tempted to point to this latter period. I possess the same ardour as ever in study, and the same gaiety in company. I consider, besides, that a man of sixty-five, by dying, cuts off only a few years of infirmities; and though I see many symptoms of my literary reputation breaking out at last with additional lustre, I know that I could have but few years to enjoy it. It is difficult to be more detached from life than I am at present.

"To conclude, historically, with my own character, I am, or rather was (for that is the style I must now use in speaking of myself, which emboldens me the more to speak my sentiments)—I was, I say, a man of mild dispositions, of command of temper, of an open, social, and cheerful humour, capable of attachment, but little susceptible of enmity, and of great moderation

 in

in all my passions. Even my love of literary fame, my ruling passion, never soured my temper, notwithstanding my frequent disappointments. My company was not unacceptable to the young and careless, as well as to the studious and literary; and as I took particular pleasure in the company of modest women, I had no reason to be displeased with the reception I met with from them. In a word, though most men anywise eminent have found reason to complain of calumny, I never was touched, or even attacked, by her baleful tooth: and though I wantonly exposed myself to the rage of both civil and religious factions, they seemed to be disarmed in my behalf of their wonted fury. My friends never had occasion to vindicate any one circumstance of my character and conduct: not but that the zealots, we may well suppose, would have been glad to invent and propagate any story to my disadvantage, but they could never find any which they thought would wear the face of probability. I cannot say there is no vanity in making this funeral oration of myself, but I hope it is not a misplaced one; and this is a matter of fact which is easily cleared and ascertained."

His fears concerning the incurableness of his disorder proved too true. He died on the 25th of August 1776; and was interred in the Calton burying-ground, Edinburgh, where a monument is erected to his memory.

HUMECTATION, formed of humour, moisture, moistening, in pharmacy, the preparing of a medicine by steeping it a while in water, in order to soften and moisten it when too dry; or to cleanse it, or prevent its subtile parts from being dissipated in grinding, or the like.

Humectation is also used for the application of moistening remedies.

In this sense we say, embrocations, emplasters, unctions, humectations, fomentations, &c.

HUMERUS, or *Os Humeri*, in *Anatomy*, the uppermost bone of the arm, popularly called the *shoulder-bone;* extending from the scapula, or shoulder-blade, to the upper end of the cubitus, or elbow. See Anatomy *Index*.

HUMIDITY, that quality in bodies whereby they are capable of wetting other bodies. This differs very much from fluidity; and seems to be merely a relative thing, depending on the congruity of the component particles of the liquor to the pores of such particular bodies as it is capable of adhering to, penetrating a little into, or wetting. Thus, for instance, quicksilver is not a moist thing with regard to our hands or clothes; but may be called so in reference to gold, tin, or lead, to whose surfaces it will perfectly adhere, and render them soft and moist.

HUMILIATI, a congregation of religious in the church of Rome, established by some Milanese gentlemen on their release from prison, where they had been confined under the emperor Conrad, or, as others say, under Frederick I. in the year 1162. This order, which acquired great wealth, and had no less than 90 monasteries, was abolished by Pope Pius V. in 1570, and their houses given to the Dominicans and Cordeliers, for their luxury and cruelty.

HUMILIATION, the act of humbling, i. e. of abating a person's pride, and bringing him lower in his opinion.

In this sense humiliation stands distinguished from mortification: humiliation brings down the mind; mortification subdues the flesh.

HUMILITY, in *Ethics*, is a virtue consisting in the moderate value which a person puts upon himself, and every thing relating to him. Or, more particularly, it consists in not attributing to ourselves any excellence or good which we have not; in not overrating any thing which we have or do; in not taking an immoderate delight in one's self; in not assuming more of the praise of a quality or action than belongs to us; and in a lowly sense and acknowledgment of our imperfections, errors, and sins. This virtue expresses itself in the modesty of our appearance, of our pursuits, and of our behaviour towards other men. It is distinguished from affectation, bashfulness, and meanness.

HUMMING-bird. See Trochilus, Ornithology *Index*.

HUMOUR, from the Latin *humor*, in its original signification, stands for moisture in general; from whence it has been restrained to signify the moisture of animal bodies, or those fluids which circulate through them.

It is distinguished from moisture in general in this, that humours properly express the fluids of the body; when in a vitiated state, it would not be improper to say, that the fluids of such a person's body were full of humours.

The only fluids of the body, which, in their natural and healthful state, are called *humours*, are those in the eye; we talk of the aqueous humour, the crystalline humour, without meaning any thing that is morbid or diseased: yet when we say in general, that such a person has got a humour in his eye, we understand it in the usual sense of a vitiated fluid.

As the temper of the mind is supposed to depend upon the state of the fluids in the body, humour has come to be synonymous with temper and disposition. A person's humour, however, is different from his *disposition*, in this, that humour seems to be the disease of a disposition: it would be proper to say that persons of a serious temper or disposition of mind, were subject to melancholy humours; that those of a delicate and tender disposition, were subject to peevish humours.

Humour may be agreeable or disagreeable: but it is still humour; something that is whimsical, capricious, and not to be depended upon. An ill-natured man may have fits of good-humour, which seem to come upon him accidentally, without any regard to the common moral causes of happiness or misery.

A fit of cheerfulness constitutes the whole of good-humour; and a man who has many such fits, is a good-humoured man: yet he may not be good-natured; which is a character that supposes something more constant, equable, and uniform, than what is requisite to constitute good humour.

Humour is often made use of to express the quality of the imagination, which bears a considerable resemblance to wit.

Wit expresses something that is more designed, concerted, regular, and artificial; humour, something that is more wild, loose, extravagant, and fantastical; something which comes upon a man by fits, which he can neither command nor restrain, and which is not perfectly consistent with true politeness. Humour, it has been

been said, is often more diverting than wit; yet a man of wit is as much above a man of humour as a gentleman is above a buffoon; a buffoon, however, will often divert more than a gentleman. The duke of Buckingham, however, makes humour to be all in all; wit, according to him, should never be used, but to add an agreeableness to some proper and just sentiment, which, without some such turn, might pass without its effect. See WIT.

HUMPHREY, DR LAWRENCE, a very learned English divine in the 16th century, who, during the persecution under Queen Mary, retired with other Protestant refugees to Zurich. He returned on the accession of Queen Elizabeth; and was made president of Magdalene college, Oxford, dean of Gloucester, and then dean of Winchester. He was a great and general scholar, an able linguist, and a deep divine; and published, 1. *De religionis conservatione et reformatione, deque primatu regum.* 2. *De ratione interpretandi auctores.* 3. *Optimates; sive de nobilitate, ejusque origine.* 4. Sermons, and other works. He died in 1590.

HUMULUS, the HOP, a genus of plants belonging to the diœcia class; and in the natural method ranking under the 53d order, *Scabridæ*. For the culture and use of hops, see HOP.

HUNDRED, HUNDREDUM, or *Centuria*, a part or division of a county; which was anciently so called from its containing an hundred families, or from its furnishing an hundred able men for the king's wars. After King Alfred's dividing this kingdom into counties, and giving the government of each county to a sheriff, these counties were divided into hundreds, of which the constable was the chief officer. The grants of hundreds were at first made by the king to particular persons: but they are not now held by grant or prescription, their jurisdiction being devolved to the county-court; a few of them only excepted, that have been by privilege annexed to the crown, or granted to some great subjects, and still remain in the nature of a franchise.

HUNDRED Court. This is only a larger COURT *Baron*, being held for all the inhabitants of a particular hundred instead of a manor. The free suitors are here also the judges, and the steward the register, as in the case of a court-baron. It is likewise no court of record; resembling the former in all points, except that in point of territory it is of a greater jurisdiction. This is said by Sir Edward Coke to have been derived out of the county-court for the ease of the people, that they might have justice done them at their own doors, without any charge or loss of time: but its constitution was probably coeval with that of hundreds themselves, which were formerly observed to have been introduced though not invented by ALFRED, being derived from the policy of the ancient Germans. The *centeni*, we may remember, were the principal inhabitants of a district composed of different villages, originally in number an *hundred*, but afterwards only called by that name; and who probably gave the same denomination to the district out of which they were chosen. Cæsar speaks positively of the judicial power exercised in *their* hundred-courts and courts-baron. "*Principes regionum, atque pagorum*," (which we may fairly construe, the lords of hundreds and manors) *inter suos jus dicunt, controversiasque minuunt*." And Tacitus, who had examined their constitution still more attentively, informs us not only of the authority of the lords, but of that of the *centeni*, the hundreders, or jury; who were taken out of the common freeholders, and had themselves a share in the determination. "*Eliguntur in conciliis et principes, qui jura per pagos vicosque reddunt: centeni singulis, ex plebe comites, consilium simul et auctoritas, adsunt*." This hundred-court was denominated *hæreda* in the Gothic constitution. But this court, as causes are equally liable to removal from hence as from the common court-baron, and by the same writs, and may also be reviewed by writ of false judgment, is therefore fallen into equal disuse with regard to the trial of actions.

HUNGARY, a kingdom of Europe, the greatest part of which was anciently called *Pannonia*. It had the name of *Hungary* from the Hunns, a Scythian or Tartar nation, who subdued it in the ninth century. It lies between the 17th and 25th degrees of east long. and betwixt the 44th and 49th degrees of north lat. being bounded to the north by the Carpathian mountains, which separate it from Poland; to the south by Servia, and the river Drave, which separates it from Sclavonia; to the west by Moravia, Austria, and Stiria; and to the east by Wallachia and Transylvania. It is about 380 miles in length, and 300 in breadth; and is divided into the Upper and Lower Hungary, the former being that part which lies towards the east, and the latter that which lies towards the west.

The northern parts of the kingdom are mountainous and barren, but healthy; the southern, on the contrary, are level, and exceeding fruitful, but not very healthy. The country along the Danube, from Presburg to Belgrade, for upwards of 200 miles, is one continued plain, and no soil can be more fertile; but the air, by reason of the many swamps and morasses, is not so wholesome as on the higher and drier grounds. Here are mines of gold, silver, copper, iron, lead, quicksilver, cinnabar, antimony, yellow orpiment, sulphur, vitriol, marcasite, salt native and factitious, saltpetre, magnets, asbestos or stone-flax, marble of several colours, alabaster, with diamonds, and all sorts of precious stones. Corn is in such plenty, that it is sold for one-sixth of its price in England. Their grapes are large and luscious; and their wines preferred to any in Europe. They have vast numbers of cattle and horses, the latter mostly mouse-coloured, with buffaloes, deer, wild fowl, game, and fish, and many species of wild-beasts, particularly chamois goats, bears, and lynxes. Of vegetables, besides vines, and the common sorts, here are tobacco, saffron, buck-wheat, millet, melons, and chesnuts. Here also are excellent warm baths, and springs of various kinds and qualities. The chief mountains of Hungary are the Crapack or Carpathian, which is the general name for all those that separate this kingdom from Poland, Moravia, Silesia, and some part of Austria. The sides of most of them are covered with wood, and their tops with snow. The chief rivers are the Danube, the Drave, the Save, the Wag or Waag, the Gran, the Temes, the Raab, and Theiss, all well stocked with fish. There are several lakes among the Carpathian mountains, and some also in the lowlands.

Hungary.

The inhabitants are a mixture of the descendants of the ancient Hunns, Sclavonians, Camani, Germans, Wallachians, Greeks, Jews, Turks, and a wandering people called *Zigduns*, said to be of uncertain origin, but probably the same as those we called *gypsies*. The Hungarians are said to be of a sanguine choleric temper, and somewhat fierce, cruel, proud, and revengeful. They have been always reputed good soldiers, being much more inclined to arms, martial exercises, and hunting, than to arts, learning, trade, or agriculture. The nobility affect great pomp and magnificence, and are much addicted to feasting and carousing. The men in general are strong and well proportioned. They shave their beards, but leave whiskers on the upper lip; wearing fur caps on their heads, a close-bodied coat girt with a sash, with a short cloak or mantle over all, so contrived as to be buckled under the arm, and leave the right hand at liberty. Their horse are called *hussars*, and their foot *heydukes*. The former wear a broadsword or scimitar, and carry a hatchet or battle-axe. Their horses are fleet, but not near so large as the German horses, and therefore they stand up on their short stirrups when they strike. The heydukes usually wear feathers in their caps, according to the number of the enemies they pretend to have killed. Both horse and foot are an excellent militia, very good at a pursuit, or ravaging and plundering a country, but not equal to regular troops in a pitched battle. The women, when they go abroad, wear short cloaks and a veil.

There are four languages spoken in this country, viz. the Hungarian, which, like the people, is of Scythian origin, and has little or no affinity with any European tongue; the German, Sclavonian, Wallachian, and Latin. The last is spoken, not only by the better sort, but also by the common people, though very corruptly. The people called *Zigduns* have also a particular jargon.—Christianity was planted in Hungary in the ninth and tenth centuries. In the sixteenth the reformation made a great progress in it; and at present the Roman Catholic religion is predominant, the Protestants enjoying only a bare toleration.

As to the traffic of this country, it is chiefly in the hands of the Greeks and Jews. The exports consist chiefly of wine, horses, cattle, metals, minerals, saffron, wool, and leather. Hungary, in particular, furnishes Austria, and other countries west of it, with vast droves of cattle, as well as a variety of excellent wines, of which those of Tokay are reckoned the best. The principal manufactures are those of copper, brass, iron, and other hard wares. Great quantities of brass and iron are exported, wrought and unwrought.

Hungary at first, like most other countries, was divided into many little principalities and states, which at length were united under one head, who had the title of *duke*. The last of these dukes was Geysa; who, becoming a proselyte to Christianity, was baptized; after which he resigned the government to his son Stephen, who took the title of *king*, *anno* 1000. But as the throne was filled by election, though generally out of the same family, the disposal of the crown was disputed between the Turkish and German emperors for near 200 years: but after the year 1527, when Ferdinand, archduke of Austria, was advanced to the throne, the Austrians found means to influence the elections in such a manner, as to keep the crown in their family till 1687, when it was settled hereditarily on their heirs male; and now, in consequence of an act made by the diet at Presburg in 1723, in case of the failure of heirs-male, it is to descend to females. The states of the kingdom consist of the prelates, the barons, the gentry, and the royal towns. To the first class belong two archbishops, about a dozen bishops, near as many abbots and provosts, with the Pauline and Præmonstratensian Jesuits. To the second, the stadtholder or palatine, who represents the king; the court-judge; the ban or viceroy of Dalmatia, Croatia, and Sclavonia; the stadtholder of Transylvania; the great treasurer, the great cup-bearer, the steward of the household, the master of the horse, the lord chamberlain, the captain of the yeomen of the guards, and the grand marshal of the courts, who are styled the great barons. To the third class belong the gentry, some of whom have noble manors, and others only the privileges of nobles. To the fourth class belong the royal free cities, which are not subject to the counts, but hold immediately of the king. The gentry also, who hold of the archbishops and bishops, have the same privileges as the Hungarian nobility. The common people are vassals to the lords on whose lands they live, whether these lands belong to the crown, the clergy, nobility or gentry.

Hungary contained eight millions of inhabitants in 1805, including 13,728 nobles (males only), and 162,495 clergy. Of these 4,647,832 were Catholics, 1,161,138 were of the Greek church, 1,002,490 were Calvinists or Reformed, and 624,776 were Lutherans. The Jews amounted to 72,128. The whole surface of the country amounts to 88,000 square miles, or 39,000,000 of jochs (each equal to $1\frac{1}{2}$ English acres). Of this soil only 23,900,000 acres are computed to be in cultivation or under wood. The total exports in 1802 amounted to 24,000,000 of florins, or about 2,400,000l. sterling. The imports were about 1,800,000. The revenue is reckoned to be about two millions sterling, of which only a very small portion finds its way to Vienna. The military force of Hungary has long been the chief support of the Austrian monarchy. It consists of 12 complete regiments of infantry of 3857 men each, and 10 complete hussar regiments of 1698 men each, making together 63,364 regulars. But in times of imminent danger this force is increased by a large body of irregulars. Pest, the principal town of Hungary, contained 41,882 inhabitants in 1817. See HUNGARY, SUPPLEMENT.

Hungary, Hunger.

HUNGARY-Water, a distilled water prepared from the tops of flowers of rosemary; so denominated from a queen of Hungary, for whose use it was first made. See PHARMACY.

HUNGER, an uneasy sensation occasioned by long abstinence from food when the body is in a healthy state.—See ABSTINENCE; FASTING; and ANATOMY, N° 103.

The following useful observations upon hunger or famine are extracted from a paper by Dr Percival in the second volume of the Manchester Transactions.

In famine, life may be protracted (the doctor observes) with less pain and misery, by a moderate allowance of water. For the acrimony and putrefaction of the humours are obviated by such dilution, the small vessels are kept permeable, and the lungs are furnished with that moisture which is essential

Published by A. Constable & Co. Edinburgh, 1819.

Hunger.

sential to the performance of their functions. Fontanus, a writer of respectable authority in the estimation of Morgagni, relates the history of a woman who obstinately refused to take any sustenance, except twice, during the space of 50 days, at the end of which period she died. But he adds, that she used water by way of drink, though in small quantity. Redi, who made many experiments (cruel and unjustifiable in my opinion), to ascertain the effects of fasting on fowls, observed, that none were able to support life beyond the ninth day to whom drink was denied; whereas one indulged with water lived more than 20 days.

Hippocrates has observed, that children are more affected by abstinence than young persons; these, more than the middle-aged; and the middle-aged, more than old men. The power to endure famine, however, must depend no less upon the state of health and strength than on the age of the sufferer. There are also particular constitutions which do not suffer much pain from the calls of hunger. Dr Percival was informed by a young physician from Geneva, that when he was a student at Montpelier, he fasted three nights and four days, with no other refreshment than a pint of water daily. His hunger was keen, but never painful, during the first and second days of his abstinence; and the two following days, he perceived only a faintness when he attempted either bodily or mental exertion: A sense of coldness was diffused over his whole frame, but more particularly affected the extremities. His mind was in a very unusual state of pusillanimity; and he experienced a great tendency to tears whenever he recollected the circumstance which had been the occasion of his fasting. During the whole period, the alvine excretions were suppressed, but not those by the kidneys: and at the close of it, his skin became tinged with a shade of yellow. The first food he took was veal broth; which had something of an intoxicating effect, producing a glow of warmth, and raising his spirits, so as to render him ashamed of his despondency. Perhaps in the case of Sextius Baculus, as recorded in the commentaries of Cæsar *, the extraordinary courage and prowess which he suddenly exerted, might be aided by the exhilarating effect of sustenance, which, under such circumstances, it is probable he would no longer decline. The fact, however, evinces, that neither his sickness nor the sensations of hunger had been so violent as much to impair his strength of body or vigour of mind. Pomponius Atticus, the celebrated friend of Cicero, who put a voluntary end to his life in the 77th year of his age by refusing all food, appears to have experienced ease from his disorder, rather than any acute sufferings by famine. "Sic cum biduò cibo se abstinuisset, subito febris decessit, leviorque morbus esse cœpit: tamen propositum nihilo secius perigit. Itaque die quinto, postquam id consilium inierat, decessit." (*Corn. Nepos in Vit. Pomp. Attic.*) From the former circumstance it has been conjectured, that he did not wholly deny himself the use of water, or of some other diluent. But though a few examples of this kind may be adduced, we have the evidence of numerous melancholy facts to show, that the pressure of want is agonizing to the human frame. "I have talked (says an ingenious writer ‡) with a captain of a ship, who was one of six that endured it in its extremity, and who was the only person that had not lost his senses when they received accidental relief. He assured me his pains at first were so great, as to be often tempted to eat a part of one of the men who died, and which the rest of his crew actually for some time lived upon. He said, that during the continuance of this paroxysm, he found his pains insupportable, and was desirous at one time of anticipating that death which he thought inevitable: But his pains, he said, gradually decreased after the sixth day (for they had water in the ship, which kept them alive so long), and then he was in a state rather of languor than desire; nor did he much wish for food, except when he saw others eating; and that for a while revived his appetite, though with diminished importunity. The latter part of the time, when his health was almost destroyed, a thousand strange images rose upon his mind; and every one of his senses began to bring him wrong information. The most fragrant perfumes appeared to him to have a fetid smell; and every thing he looked at took a greenish hue, and sometimes a yellow. When he was presented with food by the ship's company that took him and his men up, four of whom died shortly after, he could not help looking upon it with loathing instead of desire; and it was not till after four days that his stomach was brought to its natural tone; when the violence of his appetite returned with a sort of canine eagerness."

* Lib. vi.

‡ Dr Goldsmith's Hist. of the Earth, vol. ii. 126.

To those who by their occupations are exposed to such dreadful calamities, it is of serious importance to be instructed in the means of alleviating them. The American Indians are said to use a composition of the juice of tobacco, and the shells of snails, cockles, and oysters calcined, whenever they undertake a long journey, and are likely to be destitute of provisions. It is probable the shells are not burnt into quicklime, but only so as to destroy their tenacity, and to render them fit for levigation. The mass is dried, and formed into pills, of a proper size to be held between the gum and lip, which, being gradually dissolved and swallowed, obtund the sensations both of hunger and of thirst. Tobacco, by its narcotic quality, seems well adapted to counteract the uneasy impressions which the gastric juice makes on the nerves of the stomach when it is empty; and the combination of testaceous powder with it may tend to correct the secretion that is supposed to be the chief agent in digestion, and which, if not acid, is always united with acidity. Certain at least it is, that their operation is both grateful and salutary; for we find the luxurious inhabitants of the East Indies mix them with the betel nut, to the chewing of which they are universally and immoderately addicted. Perhaps such absorbents may be usefully applied, both to divide the doses and to moderate the virulence of the tobacco. For, in the internal exhibition of this plant, much caution is required, as it produces sickness, vertigo, cold clammy sweats, and a train of other formidable symptoms, when taken in too large a quantity. During the time of war, the impressed sailors frequently bring on these maladies, that they may be admitted into the hospitals, and released from servitude. It would be an easy and safe experiment to ascertain the efficacy, and to adjust the ingredients, of the Indian composition mentioned. And there is reason to believe, that the trial would be in some degree successful; for it is known that smoking tobacco

Hunger.

tobacco gives relief to those habitual pains of the stomach which appear to arise from the irritation of the gastric secretion. The like effect is sometimes produced by increasing the flow of saliva, and swallowing what is thus discharged. And Dr Percival has related the case of a gentleman, who used to masticate, many hours daily, a piece of lead, which being neither hard, friable, nor offensive to the palate, suited his purpose, as he thought, better than any other substance. He continued the custom many years, deriving great ease from it, and suffering no sensible injury from the poisonous quality of the metal. On mentioning this fact to a navy surgeon, the doctor was told, that the sailors, when in hot climates, are wont to mitigate thirst by rolling a bullet in their mouths. A more innocent mean, the doctor observes, might be devised; but the efficacy of this evinces, that the salivary glands are for a while capable of furnishing a substitute for drink. When a scarcity of water occurs at sea, Dr Franklin has advised, that the mariners should bathe themselves in tubs of salt-water: For, in pursuing the amusement of swimming, he observed, that, however thirsty he was before immersion, he never continued so afterwards; and that, though he soaked himself several hours in the day, and several days successively, in salt-water, he perceived not, in consequence of it, the least taste of saltness in his mouth. He also further suggests, that the same good effect might perhaps be derived from dipping the sailor's apparel in the sea; and expresses a confidence that no danger of catching cold would ensue.

To prevent the calamity of famine, at sea, it has been proposed by Dr Lind, that the powder of salep should constitute part of the provisions of every ship's company. This powder and portable soup, dissolved in boiling water, form a rich thick jelly; and an ounce of each of these articles furnishes one day's subsistence to a healthy full grown man. Indeed, from Dr Percival's experiments it appears, that salep contains more nutritious matter, in proportion to its bulk, than any other vegetable production now used as food, It has the property also of concealing the nauseous taste of salt-water; and consequently may be of great advantage at sea, when the stock of fresh water is so far consumed, that the mariners are put upon short allowance. By the same mucilaginous quality, it covers the offensiveness, and even in some measure, corrects the acrimony, of salted and putrescent meats. But, as a preservative against hunger, salep would be most efficacious combined with an equal weight of beef suet. By swallowing little balls of this lubricating compound at proper intervals, the coats of the stomach would be defended from irritation: and as oils and mucilages are highly nutritive, of slow digestion, and indisposed to pass off by perspiration, they are peculiarly well adapted to support life in small quantities. This composition is superior in simplicity, and perhaps equal in efficacy, to the following one, so much extolled by Avicenna the celebrated Arabian physician; to whom we are indebted for the introduction of rhubarb, cassia, tamarinds, and senna, into the materia medica. "Take sweet almonds and beef suet, of each one pound; of the oil of violets two ounces; and of the roots of marshmallows one ounce: bray these ingredients together in a mortar, and form the mass into boluses, about the size of a common nut." Animal fat is singularly powerful in assuaging the most acute sensations of thirst, as appears from the narrative of the sufferings experienced by those who were confined in the black hole at Calcutta. A hundred and forty-six persons, exhausted by fatigue and military duty, were there thrust together into a chamber of 18 cubic feet, having only two windows, strongly barred with iron, from which, in a close sultry night, and in such a climate as that of Bengal, little or no circulation of fresh air could be enjoyed. In a few minutes, these unhappy wretches fell into so profuse a perspiration, that an idea can hardly be formed of it; and this was succeeded by a raging thirst, which increased in proportion as the body was drained of its moisture. Water! Water! became the universal cry; and an old soldier on the outside, through pity, furnished them with a few skinfuls of it. But these scanty supplies, like sprinklings on the fire, served only to feed and increase the flame. From this experience of its effects, Mr Holwell, their chief, determined to drink no more; and kept his mouth moist by sucking the perspiration out of his shirt sleeves, and catching the drops as they fell from his head and face. "You cannot imagine (says he) how unhappy I was if any of them escaped me." He came into the prison without his coat, the season being too hot to bear it; and one of his miserable companions, observing the expedient he had hit upon of allaying his thirst, robbed him from time to time of a considerable part of his store. This plunderer, whom he found to be a young gentleman in the service of the East India Company, afterwards acknowledged, that he owed his life to the many comfortable draughts which he derived from him. Before Mr Holwell adopted this mode of relief, he had attempted, in an ungovernable fit of thirst, to drink his own urine: but it was so intensely bitter, that a second taste could not be endured; whereas, he assures us, no Bristol water could be more soft and pleasant than his perspiration. And this, we may presume, consisted chiefly of animal fat, melted by excessive heat, and exuding from the cellular membrane through the pores of the skin.

Persons who have been accustomed to animal food, are soon reduced when supplied only with the farinacea. Several years ago, to determine the comparative nutritive powers of different substances, an ingenious young physician, as Dr Percival informs us, made a variety of experiments on himself, to which he unfortunately fell a sacrifice. He lived a month upon bread and water; and under this regimen of diet he every day diminished much in his weight. But in 1784, a student of physic at Edinburgh confined himself for a longer space of time to a pint of milk and half a pound of white bread daily: And he assured our author, that he passed through the usual labours of study and exercise without feeling any decay of health or strength, and without any sensible loss of bulk. The cutaneous, urinary, and alvine excretions, were very scanty during the whole period; and the discharge of fæces occurred only once in a week. In this case the oily and coagulable parts of the milk probably furnished a larger proportion of aliment, and at the same time contributed to check the waste by perspiration and other discharges; for oleaginous substances are retained long in the body by their viscidity. Dr Russel,

Russel, in his Natural History of Aleppo, relates, that in those seasons when oil abounds, the inhabitants, by indulgence in it, are disposed to fever, and affected with infarctions of the lungs; maladies which indicate both retention and obstruction. Milk has been suspected by some of producing similar effects, though in a slighter degree; and the free use of it has been on this account forbidden to asthmatics.

Gum arabic might be a good substitute for salep in the composition already recommended; and as it will give such firmness to the mass, as to require manducation, the saliva, by this means separated and carried into the stomach, would further contribute to assuage the sensations both of hunger and of thirst. See *Gum-Arabic*. This gum, combined with sugar and the whites of eggs, has been lately extolled in France, under the name of *patigumo*, as a remedy for catarrhal defluxions. Dr Percival has seen cakes made of these ingredients, and thinks they might very well be applied to the purpose of obviating hunger. They are not perishable in the hottest climates, may be carried about the person with convenience, and though very tough are pleasant to the taste. In the formula by which they are made, the proportion of sugar is too large, and that of gum arabic too small, if the mass be intended to assuage the cravings of appetite. According to our author's information, the receipt is as follows. "Take of fine sugar four ounces, and of gum-arabic one ounce: Levigate them well together; and add half an ounce of rose water, and of the white of eggs a sufficient quantity."

In our attempts to recover those who have suffered under the calamities of famine, great circumspection is required. Warmth, cordials, and food, are the means to be employed; and it is evident that these may prove too powerful in their operation, if not administered with caution and judgment. For the body, by long fasting, is reduced to a state of more than infantile debility; the minuter vessels of the brain, and of the other organs, collapse for want of fluids to distend them; the stomach and intestines shrink in their capacity; and the heart languidly vibrates, having scarcely sufficient energy to propel the scanty current of blood. Under such circumstances, a proper application of heat seems an essential measure, and may be effected by placing on each side a healthy man in contact with the patient. Pediluvia or fomentations may also be used with advantage. The temperature of these should be lower than that of the human body, and gradually increased according to the effects of their stimulus. New milk, weak broth, or water gruel, ought to be employed both for the one and the other; as nutriment may be conveyed into the system this way, by passages probably the most pervious in a state of fasting, if not too long protracted. "A lad at Newmarket †, a few years ago, having been almost starved in order that he might be reduced to a proper weight for riding a match, was weighed at nine o'clock in the morning, and again at ten; and he was found to have gained near 30 ounces in weight in the course of an hour, though he had only drank half a glass of wine in the interval. The wine probably stimulated the action of the nervous system, and incited nature, exhausted by abstinence, to open the absorbent pores of the whole body, in order to suck in some nourishment from the air." But no such absorption as this can be expected in a state of extreme weakness and emaciation gradually induced; because the lymphatics must partake of the general want of tone and energy. And notwithstanding the salutary effects of wine in the case of the jockey, who, it is likely, had been reduced by sweating as well as by abstinence, such a stimulant might prove dangerous, and even fatal in other cases. It appears safer therefore to advise the exhibition of cordials in very small doses, and at first considerably diluted. Slender wine-whey will perhaps best answer this purpose; and afford, at the same time, an easy and pleasant nourishment. When the stomach has been a little strengthened, an egg may be mixed with the whey, or administered under some other agreeable form. The yolk of one was, to Cornaro, sufficient for a meal; and the narrative of this noble Venetian, in whom a fever was excited by the addition of only two ounces of food to his daily allowance, shows, that the return to a full diet should be conducted with great caution, and by very slow gradations.

† *Watson's Chemical Essays*, vol. iii. p. 101.

HUNGERFORD, a town of Berkshire in England, seated on the river Kennet, in a low and watery soil. It is a great thoroughfare in the Bath and Bristol road, sixty-five miles from London; and was formerly called *Ingleford-Charnamstreet*. The constable of this town, who is chosen annually, is lord of the manor, which he holds immediately of the crown. They have a horn here which holds about a quart, and appears by an inscription on it to have been given by John of Gaunt, together with a grant of the royal fishery, in a part of the river which abounds with good trouts and craw-fish. Here is a market on Wednesdays, and fair in August. Population 1957.

HUNNINGUEN, a town of Alsace, subject to the French; seated on the Rhine, and fortified by Vauban. Its fortifications were demolished since 1816. E. Long. 11. 40. N. Lat. 47. 42.

HUNNS, a fierce and savage nation, who formerly inhabited that part of Sarmatia bordering on the Palus Mæotis and the Tanais, the ancient boundary between Europe and Asia. Their country, as described by Procopius, lay north of Mount Caucasus, which, extending from the Euxine to the Caspian seas, parts Asiatic Sarmatia from Colchis, Iberia, and Albania; lying on the isthmus between the two seas above mentioned. Here they resided unknown to other nations, and themselves ignorant of other countries, till the year 376. At this time, a hind pursued by the hunters, or, according to some authors, an ox stung by a gad-fly, having passed the marsh, was followed by some Hunns to the other side, where they discovered a country much more agreeable than their own. On their return, having acquainted their countrymen with what they had seen, the whole nation passed the marsh, and falling upon the Alans, who dwelt on the banks of the Tanais, almost exterminated them. They next fell upon the Ostrogoths, whom they drove out of their country, and forced to retire to the plains between the Borysthenes and the Tanais, now known by the name of *Podolia*. Then attacking the Visigoths, they obliged them to shelter themselves in the most mountainous parts of their country; till at last the Gothic nations finding it impossible to withstand such an inundation of barbarians, obtained leave from the emperor Valens to settle in Thrace.

The Hunns thus became masters of all the country between the Tanais and Danube in 376, where they continued quietly till the year 388, when great numbers of them were taken into the pay of Theodosius I. but, in the mean time, a party of them, called the *Nephthalite* or *White Hunns*, who had continued in Asia, overran all Mesopotamia, and even laid siege to Edessa, where they were repulsed with great slaughter by the Romans. The European Hunns frequently passed the Danube, committing the greatest ravages in the western empire; sometimes they fell upon the eastern provinces, where they put all to fire and sword. They were often defeated and repulsed by the Romans, but the empire was now too weak to subdue or confine them from making excursions; so that they continued to make daily encroachments, and became every day more formidable than before. In 411, the Hunns, under Attila, threatened the western empire with total destruction. This monarch, having made himself master of all the northern countries from the confines of Persia to the banks of the Rhine, invaded Mæsia, Thrace, and Illyricum; where he made such progress, that the emperor not thinking himself safe in Constantinople, withdrew into Asia. Attila then broke into Gaul; where he took and destroyed several cities, massacring the inhabitants with the greatest cruelty. At last he was driven out with great slaughter by Aetius the Roman general, and Theodoric king of the Goths, and could never afterwards make any great progress. About the year 452 or 453 Attila died, and his kingdom was immediately split into a number of small ones by his numerous children, who waged perpetual war with each other. The Hunns then ceased to be formidable, and became daily less able to cope with the other barbarous nations whom Attila had kept in subjection. Still, however, their dominion was considerable; and in the time of Charles the Great they were masters of Transylvania, Wallachia, Servia, Carniola, Carinthia, and the greater part of Austria, together with Bosnia, Sclavonia, and that part of Hungary which lies beyond the Danube. In the year 776, while Charles was in Saxony, two princes of the Hunns, Caganus and Jugunus, sent ambassadors to him, desiring his friendship and alliance. Charles received them with extraordinary marks of friendship, and readily complied with their request. However, they entered, not long after, into an alliance with Taffila duke of Bavaria, who had revolted from Charles, and raised great disturbances in Germany. Charles dissembled his resentment till he had entirely reduced Bavaria, when he resolved to revenge himself on the Hunns for those succours they had underhand given to his enemy. Accordingly, he ordered levies to be made throughout his dominions; and having by that means assembled a very numerous army, he divided it into two bodies, one of which he commanded himself, and the other he committed to the care of his generals. The two armies entered the kingdom of the Hunns at different places, ravaged their country far and near, burnt their villages, and took all their strong holds. This he continued for eight years, till the people were almost totally extirpated; nor did the Hunns ever afterwards recover themselves, or appear as a distinct nation.

There were two different nations that went by the name of *Hunns;* the Nephthalite or White Hunns, and the Sarmatian or Scythian Hunns. The former inhabited a rich country, bordering to the north on Persia, and at a great distance from the Sarmatian or Scythian Hunns, with whom they had no intercourse, nor the least resemblance either in their persons or manners. They were a powerful nation, and often served against the Romans in the Persian armies; but in the reign of the emperor Zeno, being provoked by Perozes king of Persia laying claim to part of their country, they defeated the Persians in two pitched battles, slew their king, overran all Persia, and held it in subjection for the space of two years, obliging Cabades, the son and successor of Perozes, to pay them a yearly tribute. These Hunns, called by the writers of those times the *white Hunns*, did not wander, like the others, from place to place; but, contented with their own country, which supplied them with all necessaries, they lived under a regular government, subject to one prince, and seldom made inroads, unless provoked, either into the Persian or Roman territories. They lived according to their own laws, and dealt uprightly with one another, as well as with the neighbouring people. Each of their great men used to choose twenty or more companions to enjoy with him his wealth, and partake of all his diversions; but, upon his decease, they were all buried with him in the same grave. This custom savours of barbarity; but in every other respect, the Nephthalite were a far more civilized nation than the Scythian Hunns, who, breaking into the empire, filled most of the provinces of Europe with blood and slaughter.

The latter were, according to Ammianus Marcellinus, a savage people, exceeding in cruelty the most barbarous nations. They began to practise their cruelty, says Jornandes, upon their own children the very first day they come into the world, cutting and mangling the cheeks of their males, to prevent the growth of hair which they must have looked upon, contrary to the sentiments of other nations, as unbecoming and unmanly. They had, perhaps, in this practice another view, which Jornandes seems to insinuate elsewhere, viz. to strike terror into the enemy with their countenances, thus deformed and covered with scars. They had no other food but roots and raw meat, being quite unacquainted with the use of fire, and no houses at all, not even huts; but lived constantly exposed to the air in the woods, and on the mountains, where, from their infancy, they were inured to hunger, thirst, and all manner of hardships: nay, they had such an aversion to houses, which they called the *sepulchres of the living*, that, when they went into other countries, they could hardly be prevailed upon to come within the walls of any house, not thinking themselves safe when shut up and covered. They used even to eat and sleep on horseback, scarce ever dismounting; which, in all likelihood, induced Zosimus to write, that the Hunns could not walk. They covered their nakedness with goats skins, or the skins of a sort of mice sewed together. Day and night were indifferent to them, as to buying, selling, eating, and drinking. They had no law, nor any kind of religion; but complied with their inclinations, whatever they prompted them to, without the least restraint, or distinction between good and evil. In war, they began the battle with great fury, and a hideous noise: but if they met with a vigorous opposition, their

Huns, Hunter.

their fury began to abate after the first onset; and when once put into disorder, they never rallied, but fled in the utmost confusion. They were quite unacquainted with the art of besieging towns; and authors observe, that they never attacked the enemy's camp. They were a faithless nation, and thought themselves no longer bound by the most solemn treaties, than they found their advantage in observing them. Hence we often find them, upon the least prospect of obtaining more advantageous conditions, breaking into the Roman empire, in defiance of the most solemn oaths and engagements. Several corps of Hunns, after their coming into Europe, served in the Roman armies against the Goths and other barbarous nations; nay, they were ready, for hire, to fight against each other, being blind to every other regard and consideration.

HUNTER, a name given to a horse qualified to carry a person in the chase. The shape of the horse designed for this service, should be strong and well knit together, as the jockeys express it. Irregular or unequal shapes in these creatures are always a token of weakness. The inequalities in shape which show a horse improper for the chase, are the having a large head and a small neck, a large leg and a small foot, and the like. The head of the hunter should indeed always be large, but the neck should also be thick and strong to support it. The head should be lean, the nostrils wide, and the windpipe straight.

The hunter, in order to his behaving well in the field, ought to have great care and indolgence in the stable: he ought to have as much rest and quiet as may be, to be kept well supplied with good meat, clean litter, and fresh water by him; he should be often dressed, and suffered to sleep as much as he pleases. He should be so fed, that his dung may be rather soft than hard, and it must be of a bright and clean colour. All this may be easily managed by the continual observance and change of his food, as occasion requires. After his usual scourings he should have exercises and mashes of sweet malt, or bread and beans; or wheat and beans mixed together, are to be his best food, and beans and oats his worst.

Some very great sportsmen are for keeping their horses out at grass all the buck-hunting season, never taking them up into the stable at all, but allowing them in the field as much oats with their grass as they will eat. The horse may be thus rid three days in the week for the whole season, and never damaged by it, nor ever showing any marks of harm afterwards.

The whole shape of a horse intended for a hunter, should be this: The ears should be small, open, and pricked; or though they be somewhat long, yet if they stand up erect and bold like those of a fox, it is a sign of toughness or hardiness. The forehead should be long and broad, not flat, or, as it is usually termed, *mare-faced*, but rising in the middle like that of a hare; the feather should be placed above the eye, the contrary being thought by some to threaten blindness. The eyes should be full, large, and bright; the nostrils not only large, but looking red and fresh within; for an open and fresh nostril is always esteemed a sign of a good wind. The mouth should be large, deep in the wicks, and hairy. The windpipe should be large, and appear straight when he bridles his head; for if, on the contrary, it bends like a bow on his bridling, it is not formed for a free passage of the breath. This defect in a horse is expressed among the dealers by the phrase *cock-throppled*. The head should be so set on to the neck, that a space may be felt between the neck and the chine; when there is no such space, the horse is said to be bull-necked; and this is not only a blemish in the beauty of the horse, but it also occasions his wind not to be so good. The crest should be strong, firm, and well risen; the neck should be straight and firm, not loose and pliant; the breast should be strong and broad, the ribs round like a barrel, the fillets large, the buttocks rather oval than broad, the legs clean, flat, and straight; and, finally, the mane and tail ought to be long and thin, not short and bushy, the last being counted a mark of dulness. When a hunter is thus chosen, and has been taught such obedience, that he will readily answer to the rider's signals both of the bridle and hand, the voice, the calf of the leg, and the spurs; that he knows how to make his way forward, and has gained a true temper of mouth, and a right placing of his head, and has learned to stop and to turn readily, if his age be sufficiently advanced, he is ready for the field. It is a rule with all staunch sportsmen, that no horse should be used in hunting till he is full five years old; some will hunt them at four, but the horse at this time is not come up to his true strength and courage, and will not only fail at every tough trial, but will be subject to strains and accidents of that kind, much more than if he were to be kept another year first, when his strength would be more confirmed.

When the hunter is five years old, he may be put to grass from the middle of May till Bartholomew-tide; for the weather between these is so hot, that it will be very proper to spare him from work. At Bartholomew-tide, the strength of the grass beginning to be nipped by frosts and cold dews, so that it is apt to engender crudities in the horse, he should be taken up while his coat is yet smooth and sleek, and put into the stable. When he is first brought home, he should be put in some secure and spacious place, where he may evacuate his body by degrees, and be brought not all at once to the warm keeping; the next night he may be stabled up. It is a general rule with many not to clothe and stable up their horses till two or three days after they are taken from grass, and others who put them in the stable after the first night, yet will not dress and clothe them till three or four days afterward; but all this, except the keeping the horse one day in a large and cool place, is needless caution.

There is a general practice among the grooms, in many places, of giving their hunters wheat-straw as soon as they take them up from grass. They say they do this to take up their bellies; but there seems much reason to disapprove of this. The change is very violent, and the nature of the straw so heating and drying, that there seems great reason to fear that the astringent nature of it would be prejudicial, more than is at first perceived. It is always found that the dung is hard after this food, and is voided with pain and difficulty, which is in general very wrong for this sort of horse. It is better therefore to avoid this straw-feeding, and to depend upon moderate airing, warm clothing, and good old hay and old corn, than to have recourse to any thing of this kind.

Hunter.

When the horse has evacuated all his grass, and has been properly shod, and the shoes have had time to settle to his feet, he may be ridden abroad, and treated in this manner: the groom ought to visit him early in the morning, at five o'clock in the long days, and at six in the short ones; he must then clean out the stable, and feel the horse's neck, flank, and belly, to find the state of his health. If the flank feels soft and flabby, there is a necessity of good diet to harden it, otherwise any great exercise will occasion swellings and goutiness in the heels. After this examination, a handful or two of good old oats, well sifted, should be given him; this will make him have more inclination to water, and will also make the water sit better on his stomach, than if he drank fasting. After this, he is to be tied up and dressed. If in the doing of this he opens his mouth, as if he would bite, or attempts to kick at the person, it is a proof that the teeth of the currycomb are too sharp, and must be filed blunter. If after this he continues the same tricks, it is through wantonness, and he should be corrected for it with the whip. The intent of currying being only to raise the dust, this is to be brushed off afterwards with a horse-tail nailed to a handle, or any other light brush. Then he is to be rubbed down with the brush, and dusted a second time; he should then be rubbed over with a wet hand, and all the loose hairs, and whatever foulness there is, should be picked off. When this is done, and he is wiped dry as at first, a large saddle-cloth is to be put on, reaching down to the spurring place; then the saddle is to be put on, and a cloth thrown over it that he may not take cold: then rub down his legs, and pick his feet with an iron picket, and let the mane and tail be combed with a wet mane-comb. Lastly, it is a custom to spurt some beer in his mouth just before the leading him out of the stable. He should then be mounted, and walked a mile at least to some running water, and there watered; but he must only be suffered to take about half his water at one drinking.

It is the custom of many to gallop the horse at a violent rate as soon as he comes out of the water; but this is extremely wrong for many reasons. It endangers the breaking a horse's wind more than any other practice, and often has been the occasion of bursting very good horses. It uses them also to the disagreeable trick we find in many horses, of running away as soon as ever they come out of the water: and with some it makes them averse to drinking, so that they will rather endure thirst, and hurt themselves greatly by it, than bring on the violent exercise which they remember always follows it. The better way is to walk him a little after he is out of the water, then put him to a gentle gallop for a little while, and after this to bring him to the water again. This should be done three or four times, till he will not drink any more. If there is a hilly place near the watering place, it is always well to ride up to it: if otherwise, any place is to be chosen where there is free air and sun. That the creature may enjoy the benefit of this, he is not to be galloped, but walked about in this place an hour, and then taken home to the stable. The pleasure the horse himself takes in these airings when well managed is very evident; for he will gape, yawn, and shrug up his body: and in these, whenever he would stand still to stale, dung, or listen to any noise, he is not to be hindered from it, but encouraged in every thing of this kind.

The advantages of these airings are very evident; they purify the blood, teach the creature how to make his breathing agree with the rest of the motions of his body, and give him an appetite to his food, which hunters and racers that are kept stalled up are otherwise very apt to lose. On returning from airing, the litter of the stable should be fresh, and by stirring this and whistling, he will be brought to stale. Then he is to be led to his stall, and tied up, and again carefully rubbed down; then he should be covered with a linen cloth next his body, and a canvas one over that, made to fit him, and reaching down to his legs. This, as the duke of Newcastle observes, is a custom which we learned of the Turks, who are of all people the most nice and careful of their horses. Over this covering there should be put a body-cloth of six or eight straps; this keeps his belly in shape, and does not hurt him. This clothing will be sufficient while the weather is not very sharp; but in severe seasons, when the hair begins to rise and start in the uncovered part, a woollen cloth is to be added, and this will always prove fully sufficient.

Different horses, and different seasons, make variety of the degree of clothing necessary; but there always is an obvious rule to point out the necessary changes, the roughness of the coat being a mark of the want of clothing, and the smoothness of it a proof that the clothing is sufficient. Therefore if at any time the hair is found to start, it is a notice that some farther clothing is to be added.

If the horse sweat much in the night, it is a sign that he is over fed and wants exercise: this therefore is easily remedied. An hour or more after the horse is come in from his airing, the groom should give him a wisp of clean hay, making him eat it out of his hand; after this let the manger be well cleaned out, and a quartern of oats clean sifted be given him. If he eats up this with an appetite, he should have more given him; but if he is slow and indifferent about it, he must have no more. The business is to give him enough, but not to cloy him with food.

If the horse gets flesh too fast on this home feeding, he is not to be stinted to prevent it, but only his exercise increased; this will take down his flesh, and at the same time give him strength and wind. After the feeding in the morning is over the stable is to be shut up, only leaving him a little hay on his litter. He need be no more looked at till one o'clock, and then only rubbed down, and left again to the time of his evening watering, which is four o'clock in the summer and three in the winter. When he has been watered, he must be kept out an hour or two, or more if necessary, and then taken home and rubbed as after the morning watering. Then he is to have a feed of corn at six o'clock, and another at nine at night; and being then cleaned, and his litter put in order, and hay enough left for the night, he is to be left till morning. This is the direction for one day, and in this manner he is to be treated every day for a fortnight; at the end of which time his flesh will be so hardened, his wind so improved, and his mouth so quickened, and his gallop brought to so good a stroke, that he will be fit to be put to moderate hunting. During the time that he is used

used to hunting, he must be ordered on his days of rest exactly as is directed for the fortnight when he is in preparation; but as his exercise is now greatly increased, he must be allowed a more strengthening food, mixing some old split beans at every feeding with his oats.

And if this is not found to be sufficient, the following bread must be given: let two pecks of old beans and one peck of wheat be ground together, and made into an indifferently fine meal; then knead it into dough with some warm water, and a good quantity of yeast; let it lie a time that it may rise and swell, which will make the bread the lighter; then make it into loaves of a peck each, and let it be baked in a slow oven, that it may be thoroughly done without being burnt; when it is taken out of the oven, it must be set bottom upwards to cool; when it is one day old the crust is to be chipped off, and the crumb given him for food. When this is ready, he should have some of it at least once in the day: but it is not to be made the only food, but some feeds are to be of oats alone, some of oats and this bread, and some of oats and beans mixed together. The making a variety in this manner being the best of all methods for keeping up the appetite, which is often apt to fail.

The day before the horse is to hunt, he must have no beans, because they are hard of digestion, but only some oats with this bread: or if he will be brought to eat the bread alone, that will be best of all. His evening feed should on this day be somewhat earlier than usual; and after this he is only to have a wisp of hay out of the groom's hand till he return from hunting.

Dr Foart Simmons's account of the life and writings of Dr W. Hunter.

HUNTER, *Dr William*, a celebrated anatomist and physician, was born on the 23d of May 1718, at Kilbride in the county of Lanerk in Scotland. He was the seventh of the children of John and Agnes Hunter, who resided on a small estate in that parish called *Long Calderwood*, which had been long in the possession of his family. His great grandfather by his father's side, was a younger son of Hunter of Hunterston, chief of the family of that name. At the age of fourteen his father sent him to the college of Glasgow. In this seminary he passed five years, and by his prudent behaviour and diligence acquired the esteem of the professors, and the reputation of being a good scholar. His father had designed him for the church: but the idea of subscribing to articles of faith was so repugnant to the liberal mode of thinking he had already adopted, that he felt an insuperable aversion to his theological pursuits. In this state of mind he happened to become acquainted with Dr Cullen, the late celebrated professor at Edinburgh, who was then just established in practice at Hamilton under the patronage of the duke of Hamilton. Dr Cullen's conversation soon determined him to lay aside all thoughts of the church, and to devote himself to the profession of physic. His father's consent having been previously obtained, Mr Hunter in 1737 went to reside with Dr Cullen. In the family of this excellent friend and preceptor he passed nearly three years: and these, as he has been often heard to acknowledge, were the happiest years of his life. It was then agreed, that he should go and prosecute his medical studies at Edinburgh and London, and afterwards return to settle at Hamilton in partnership with Dr Cullen. He accordingly set out for Edinburgh in November 1740; and continued there till the following spring, attending the lectures of the medical professors, and amongst others those of the late Dr Alexander Monro, who many years afterwards, in allusion to this circumstance, styled himself his *old master*.

Mr Hunter arrived in London in the summer of 1741, and took up his residence at Mr, afterwards Dr, Smellie's, who was at that time an apothecary in Pall Mall. He brought with him a letter of recommendation to his countryman Dr James Douglas, from Mr Foulis, printer in Glasgow, who had been useful to the doctor in collecting for him different editions of Horace. Dr Douglas was then intent on a great anatomical work on the bones, which he did not live to complete, and was looking out for a young man of abilities and industry whom he might employ as a dissector. This induced him to pay particular attention to Mr Hunter; and finding him acute and sensible, he desired him to make him another visit. A second conversation confirmed the doctor in the good opinion he had formed of Mr Hunter; and without any farther hesitation he invited him into his family to assist in his dissections and to superintend the education of his son.—Mr Hunter having accepted Dr Douglas's invitation, was by his friendly assistance enabled to enter himself as a surgeon's pupil at St George's Hospital under Mr James Wilkie, and as a dissecting pupil under Dr Frank Nichols, who at that time taught anatomy with considerable reputation. He likewise attended a course of lectures on experimental philosophy by Dr Desaguliers. Of these means of improvement he did not fail to make a proper use. He soon became expert in dissection, and Dr Douglas was at the expence of having several of his preparations engraved. But before many months had elapsed, he had the misfortune to lose this excellent friend.—The death of Dr Douglas, however, made no change in the situation of our author. He continued to reside with the doctor's family, and to pursue his studies with the same diligence as before.

In 1743 he communicated to the Royal Society an essay on the Structure and Diseases of articulating Cartilages. This ingenious paper, on a subject which till then had not been sufficiently investigated, affords a striking testimony of the rapid progress he had made in his anatomical inquiries. As he had it in contemplation to teach anatomy, his attention was directed principally to this object; and it deserves to be mentioned as an additional mark of his prudence, that he did not precipitately engage in the attempt, but passed several years in acquiring such a degree of knowledge and such a collection of preparations, as might insure him success. Dr Nichols, to whom he communicated his scheme, and who declined giving lectures about that time in favour of the late Dr Lawrence, did not give him much encouragement to prosecute it. But at length an opportunity presented itself for the display of his abilities as a teacher. A society of navy surgeons had an apartment in Covent Garden, where they engaged the late Mr Samuel Sharpe to deliver a course of lectures on the operations of surgery. Mr Sharpe continued to repeat this course, till finding that it interfered too much with his other engagements,

engagements, he declined the task in favour of Mr Hunter; who gave the society so much satisfaction, that they requested him to extend his plan to anatomy, and at first he had the use of their room for his lectures. This happened in the winter of 1746. He is said to have experienced much solicitude when he began to speak in public: but the applause he met with soon inspired him with courage; and by degrees he became so fond of teaching, that for many years before his death he was never happier than when employed in delivering a lecture. The profits of his two first courses were considerable; but by contributing to the wants of different friends, he found himself at the return of the next season obliged to defer his lectures for a fortnight, merely because he had not money enough to defray the necessary expence of advertisements.

In 1747 he was admitted a member of the corporation of surgeons; and in the spring of the following year, soon after the close of his lectures, he set out in company with his pupil, Mr James Douglas, on a tour through Holland to Paris. His lectures suffered no interruption by this journey, as he returned to England soon enough to prepare for his winter-course, which began about the usual time.

At first he practised both surgery and midwifery: but to the former of these he had always an aversion. His patron, Dr James Douglas, had acquired considerable reputation in midwifery; and this probably induced Mr Hunter to direct his views chiefly to the same line of practice. His being elected one of the surgeon men-midwives, first to the Middlesex, and soon afterwards to the British Lying-in Hospital, assisted in bringing him forward in this branch of his profession, in which he was recommended by several of the most eminent surgeons of that time, who respected his anatomical talents and wished to encourage him. But these were not the only circumstances that contributed to his success. He owed much to his abilities, and much to his person and manner, which eminently qualified him for the practice of midwifery.

In 1750 he seems to have entirely relinquished his views in surgery; as in that year he obtained the degree of Doctor of Physic from the university of Glasgow, and began to practise as a physician. About this time he quitted the family of Mrs Douglas, and went to reside in Jermyn-street. In the summer of 1751 he revisited his native country, for which he always retained a cordial affection. His mother was still living at Long Calderwood, which was now become his property by the death of his brother James. Dr Cullen, for whom he always entertained a sincere regard, was then established at Glasgow, and had acquired considerable reputation both as a practitioner and teacher of physic; so that the two friends had the pleasure of being able to congratulate each other on their mutual prosperity. During this visit he showed his attachment to his little paternal inheritance by giving many instructions for repairing and improving it, and for purchasing any adjoining lands that might be offered for sale. After this journey to Scotland, to which he devoted only a few weeks, he was never absent from London, unless his professional engagements, as sometimes happened, required his attendance at a distance from the capital.

In 1755, on the resignation of Dr Layard, one of the physicians of the British lying-in hospital, we find the governors of that institution voting their "thanks to Dr Hunter for the services he had done the hospital, and for his continuing in it as one of the physicians:" so that he seems to have been established in this office without the usual form of an election. The year following he was admitted a licentiate of the Royal College of Physicians. Soon afterwards he was elected a member of the Medical Society; and to the *Observations and Inquiries* published by that society, he at different periods contributed several valuable papers.

In 1762, we find him warmly engaged in controversy, supporting his claim to different anatomical discoveries, in a work entitled Medical Commentaries, the style of which is correct and spirited. As an excuse for the tardiness with which he brought forth this work, he observes in his introduction, that it required a good deal of time, and he had little to spare; that the subject was unpleasant, and therefore he was very seldom in the humour to take it up. In this publication he confined himself chiefly to a dispute with the present learned professor of anatomy at Edinburgh, concerning injections of the testicle, the ducts of the lachrymal gland, the origin and use of the lymphatic vessels, and absorption by veins. He likewise defended himself against a reproach thrown upon him by Professor Monro senior, by giving a concise account of a controversy he was involved in with Mr Pott concerning the discovery of the Hernia Congenita. It was not long before Mr Pott took occasion to give the public his account of the dispute; and, in reply, Dr Hunter added a supplement to his commentaries. No man was ever more tenacious than Dr Hunter of what he conceived to be his anatomical rights. This was particularly evinced in the year 1780, when his brother communicated to the Royal Society a discovery he had made 25 years before, relative to the structure of the placenta, the communication between it and the uterus, and the vascularity of the spongy chorion. At the next meeting of the society, a letter was read, in which Dr Hunter put in his claim to the discovery in question. This letter was followed by a reply from Mr John Hunter, and here the dispute ended.

In 1762, when the queen became pregnant, Dr Hunter was consulted: and two years afterwards he had the honour to be appointed physician extraordinary to her majesty.

About this time his avocations were so numerous, that he became desirous of lessening his fatigue; and having noticed the ingenuity and assiduous application of the late Mr William Hewson, F. R. S. who was then one of his pupils, he engaged him first as an assistant, and afterwards as a partner in his lectures. This connection continued till the year 1770, when some dispute happened which terminated in a separation. Mr Hewson was succeeded in the partnership by Mr Cruikshank, whose anatomical abilities were deservedly respected.

In 1767, Dr Hunter was elected a fellow of the Royal Society: and in the year following communicated to that learned body observations on the bones, commonly supposed to be elephants bones, which have been found near the river Ohio in America. This was not the only subject of natural history on which

our

our author employed his pen; for in a subsequent volume of the Philosophical Transactions, we find him offering his remarks on some bones found in the rock of Gibraltar, and which he proves to have belonged to some quadruped. In the same work, likewise, he published an account of the nyl-ghau, an Indian animal not described before. In 1768, Dr Hunter became a fellow of the Society of Antiquaries; and the same year, at the institution of a Royal Academy of Arts, he was appointed by his majesty to the office of professor of anatomy. This appointment opened a new field for his abilities; and he engaged in it, as he did in every other pursuit of his life, with unabating zeal. He now adapted his anatomical knowledge to the objects of painting and sculpture, and the novelty and justness of his observations proved at once the readiness and extent of his genius. In January 1781, he was unanimously elected to succeed the late Dr John Fothergill as president of the Medical Society. As his name and talents were known and respected in every part of Europe, so the honours conferred on him were not limited to his own country. In 1780, the Royal Medical Society at Paris elected him one of their foreign associates; and in 1782, he received a similar mark of distinction from the Royal Academy of Sciences in that city.

The most splendid of Dr Hunter's medical publications was the Anatomy of the Human Gravid Uterus. The appearance of this work, which had been begun so early as the year 1751 (at which time 10 of the 34 plates it contains were completed), was retarded till the year 1775, only by the author's desire of sending it into the world with fewer imperfections. This great work is dedicated to the king. In his preface to it, we find the author very candidly acknowledging, that in most of the dissections he had been assisted by his brother Mr John Hunter, "whose accuracy (he adds) in anatomical researches is so well known, that to omit this opportunity of thanking him for that assistance would be in some measure to disregard the future reputation of the work itself." He likewise confesses his obligations to the ingenious artists who made the drawings and engravings; "but particularly to Mr Strange, not only for having by his hand secured a sort of immortality to two of the plates, but for having given his advice and assistance in every part with a steady and disinterested friendship." An anatomical description of the gravid uterus was a work which Dr Hunter had in contemplation to give the public. He had likewise long been employed in collecting and arranging materials for a history of the various concretions that are formed in the human body. Amongst Dr Hunter's papers have been found two introductory lectures, which are written out so fairly, and with such accuracy, that he probably intended no farther correction of them before they should be given to the world. In these lectures Dr Hunter traces the history of anatomy from the earliest to the present times, along with the general progress of science and the arts. He considers the great utility of anatomy in the practice of physic and surgery; gives the ancient divisions of the different substances composing the human body, which for a long time prevailed in anatomy; points out the most advantageous mode of cultivating this branch of natural knowledge; and concludes with explaining the particular plan of his own lectures. Besides these manuscripts, he has also left behind him a considerable number of cases of dissection; mostly relating to pregnant women.

The same year in which the Tables of the Gravid Uterus made their appearance, Dr Hunter communicated to the Royal Society an Essay on the Origin of the Venereal Disease. In this paper he attempted to prove, that this dreadful malady was not brought from America to Europe by the crew of Columbus, as had been commonly supposed, although it made its first appearance about that period. After this paper had been read to the Royal Society, Dr Hunter, in a conversation with the late Dr Musgrave, was convinced that the testimony on which he placed his chief dependence was of less weight than he had at first imagined, as many of Martyr's letters afford the most convincing proofs of their having been written a considerable time after the period of their dates. He therefore very properly laid aside his intention of giving his essay to the public. In the year 1777 Dr Hunter joined with Mr Watson in presenting to the Royal Society a short account of the late Dr Maty's illness, and of the appearances on dissection; and the year following he published his Reflections on the Section of the Symphysis Pubis.

We must now go back a little in the order of time to describe the origin and progress of Dr Hunter's museum, without some account of which the history of his life would be very incomplete.

When he began to practise midwifery, he was desirous of acquiring a fortune sufficient to place him in easy and independent circumstances. Before many years had elapsed, he found himself in possession of a sum adequate to his wishes in this respect; and this he set apart as a resource of which he might avail himself whenever age or infirmities should oblige him to retire from business. After he had obtained this competency, as his wealth continued to accumulate, he formed a laudable design of engaging in some scheme of public utility, and at first had it in contemplation to found an anatomical school in this metropolis. For this purpose, about the year 1775, during the administration of Mr Grenville, he presented a memorial to that minister, in which he requested the grant of a piece of ground in the Mews, for the site of an anatomical theatre. Dr Hunter undertook to expend 7000l. on the building, and to endow a professorship of anatomy in perpetuity. This scheme did not meet with the reception it deserved. In a conversation on this subject soon afterwards with the earl of Shelburne, his lordship expressed a wish that the plan might be carried into execution by subscription, and very generously requested to have his name set down for a thousand guineas. Dr Hunter's delicacy would not allow him to adopt this proposal. He chose rather to execute it at his own expence; and accordingly purchased a spot of ground in Great Windmill-street, where he erected a spacious house, to which he removed from Jermyn-street in 1770. In this building, besides a handsome amphitheatre and other convenient apartments for his lectures and dissections, there was one magnificent room, fitted up with great elegance and propriety as a museum. Of the magnitude and value of his anatomical collection some idea may be formed, when we consider the great length of years

years he employed in the making of anatomical preparations and in the dissection of morbid bodies, added to the eagerness with which he procured additions from the collections of Sandys, Hewson, Falconer, Blackall, and others, that were at different times offered for sale in this metropolis. His specimens of rare diseases were likewise frequently increased by presents from his medical friends and pupils; who, when any thing of this sort occurred to them, very justly thought they could not dispose of it more properly than by placing it in Dr Hunter's museum. Speaking of an acquisition in this way in one of his publications, he says, "I look upon every thing of this kind which is given to me, as a present to the public; and consider myself as thereby called upon to serve the public with more diligence."

Before his removal to Windmill-street, he had confined his collection chiefly to specimens of human and comparative anatomy and of diseases; but now he extended his views to fossils, and likewise to the promotion of polite literature and erudition. In a short space of time he became possessed of "the most magnificent treasure of Greek and Latin books that has been accumulated by any person now living since the days of Mead." A cabinet of ancient medals contributed likewise much to the richness of his museum. A description of part of his coins in this collection, struck by the Greek free cities, was afterwards published by the Doctor's learned friend Mr Combe. In a classical dedication of this elegant volume to the queen, Dr Hunter acknowledges his obligations to her majesty. In the preface some account is given of the progress of the collection, which has been brought together since the year 1770, with singular taste, and at the expence of upwards of 20,000l. In 1781, the museum received a valuable addition of shells, corals, and other curious subjects of natural history, which had been collected by the late worthy Dr Fothergill, who gave directions by his will, that his collection should be appraised after his death, that Dr Hunter should have the refusal of it at 500l. under the valuation. This was accordingly done, and Dr Hunter purchased it for the sum of 1200l. The fame of this museum spread throughout Europe. Few foreigners distinguished for their rank or learning visited this metropolis without requesting to see it. Men of science of our own country always had easy access to it.—Considered in a collective point of view, it is perhaps without a rival.

Dr Hunter, at the head of his profession, honoured with the esteem of his sovereign, and in possession of every thing that his reputation and wealth could confer, seemed now to have attained the summit of his wishes. But these sources of gratification were embittered by a disposition to the gout, which harassed him frequently during the latter part of his life, notwithstanding his very abstemious manner of living. On Saturday the 15th of March 1783, after having for several days experienced a return of a wandering gout, he complained of great headach and nausea. In this state he went to bed, and for several days felt more pain than usual both in his stomach and limbs. On the Thursday following he found himself so much recovered, that he determined to give the introductory lecture to the operations of surgery. It was to no purpose that his friends urged to him the impropriety of such an attempt. He was determined to make the experiment, and accordingly delivered the lecture; but towards the conclusion his strength was so exhausted that he fainted away, and was obliged to be carried to bed by two servants. The following night and day his symptoms were such as indicated danger; and on Saturday morning Mr Combe, who made him an early visit, was alarmed on being told by Dr Hunter himself, that during the night he had certainly had a paralytic stroke. As neither his speech nor his pulse were affected, and he was able to raise himself in bed, Mr Combe encouraged him to hope that he was mistaken. But the event proved the doctor's idea of his complaint to be but too well founded; for from that time till his death, which happened on Sunday the 30th of March, he voided no urine without the assistance of the catheter, which was occasionally introduced by his brother: and purgative medicines were administered repeatedly without procuring a passage by stool. These circumstances, and the absence of pain, seemed to show, that the intestines and urinary bladder had lost their sensibility and power of contraction; and it was reasonable to presume that a partial palsy had affected the nerves distributed to those parts.

By his will, the use of his museum, under the direction of trustees, devolved to his nephew Dr Matthew Baillie, and in case of his death to Mr Cruikshank for the term of thirty years; at the end of which period the whole collection is bequeathed to the university of Glasgow, with eight thousand pounds sterling as a fund for the support and augmentation of the collection, which is now deposited at Glasgow.

Dr Hunter was regularly shaped, but of a slender make, and rather below a middle stature. His manner of living was extremely simple and frugal, and the quantity of his food was small as well as plain. He was an early riser; and when business was over, was constantly engaged in his anatomical pursuits, or in his museum. There was something very engaging in his manner and address; and he had such an appearance of attention to his patients, when he was making his inquiries, as could hardly fail to conciliate their confidence and esteem. In consultation with his medical brethren, he delivered his opinions with diffidence and candour. In familiar conversation he was cheerful and unassuming. As a teacher of anatomy he has been long and deservedly celebrated. He was a good orator; and having a clear and accurate conception of what he taught, he knew how to place in distinct and intelligible points of view the most abstruse subjects of anatomy and physiology. Among other methods of explaining and illustrating his doctrines, he used frequently to introduce some apposite story or case that had occurred to him in his practice; and few men had acquired a more interesting fund of anecdotes of this kind, or related them in a more agreeable manner.

Hunter, *John*, an eminent surgeon, was the youngest child of John Hunter of Kilbride, in the county of Lanark. He was born at Long Calderwood on the 13th of July 1728. His father died when he was about ten years of age, from which circumstance his mother was induced to grant him too much indulgence. In consequence he made no progress at the grammar-school, and was almost wholly illiterate at the age of 20, when he

Hunter.

he arrived in London. His brother Dr W. Hunter was at that time the most eminent teacher of anatomy, and John expressed a wish to attend him in his researches. The doctor, anxious to make trial of his talents, gave him an arm to dissect for the muscles, with proper instructions how it was to be performed; and the dexterity with which he managed his undertaking exceeded the expectations of his brother.

Having acquired some reputation from this first attempt, his brother employed him in a more difficult dissection, which was an arm wherein all the arteries were injected, and these and the muscles were to be preserved and exposed. In the execution of this task he also gave the highest satisfaction, and his brother predicted that he would become a good anatomist, and never want employment. Under the instructions of his brother, and Mr Symonds his assistant, he enjoyed every favourable opportunity of increasing his anatomical knowledge, since that school monopolized all the dissections then carried on in London.

He was admitted into partnership with his brother in the winter of 1755, and a certain department of the lectures was allotted to him, and he also lectured when the doctor was called away to attend his patients. The mind of Mr Hunter was peculiarly fitted for the study of anatomy, and the indefatigable ardour with which he prosecuted it is scarcely to be equalled. He applied to human anatomy for ten years, during which period he made himself master of every thing then known, and also made some considerable additions. He was the first who discovered the existence of the lymphatic vessels in birds.

With such eagerness did he apply himself to the study of comparative anatomy, that he even applied to the keeper of wild beasts in the Tower for the bodies of such as died there, and to all those who were in the habit of exhibiting wild beasts to the public. He made a purchase of every rare animal that came in his way, which, together with those presented to him by his friends, he gave to the showmen to keep till they died, the more effectually to prevail with them to assist him in his labours. So much was his health impaired by unwearied attention to his favourite pursuits, that in 1760 his friends advised him to go abroad, as he exhibited many symptoms of an incipient consumption. In October that year he was appointed a surgeon on the staff by the inspector-general of hospitals (Mr Adair), and in the spring of the ensuing year he went to Belleisle with the army.

He served during the continuance of the war, as senior surgeon on the staff, when he acquired his knowledge of gun-shot wounds. He settled in London on his return to England; but finding that his half pay and private practice could not support him, he taught practical anatomy and surgery for several winters. He built a house near Brompton, where he pursued the study of comparative anatomy with unabated ardour. He discovered the changes which animal and vegetable substances undergo in the stomach by the action of the gastric juice; the mode in which a bone retains its shape during its growth; and explained the process of exfoliation, by which a piece of dead bone is separated from the living.

On the 5th of February 1767, he was chosen F. R. S. In the year 1768 he became a member of the incorporation of surgeons, and in the following year was elected one of the surgeons of St George's hospital, through the influence of his brother. He published his treatise on the natural history of the teeth in May 1771, and in July the same year he married Miss Home, daughter of Mr Home, surgeon to Burgoyne's regiment of light horse. His private practice and professional reputation advanced with rapidity after his marriage, and although his family increased, he devoted much of his time to the forming of his collection. He discovered the cause of failure in the cure of every case of hydrocele, and proposed a mode of operating in which that event may certainly be avoided. He ascertained that simple exposure to the air can neither produce nor increase inflammation; and he considered the blood as alive in its fluid state. He also discovered that the stomach after death is sometimes acted on and dissolved by the gastric juice, respecting which he communicated a paper to the Royal Society.

Comparative anatomy occupied the greater part of his time and attention, and he suffered no opportunity to escape him. He dissected the torpedo in 1773, and laid an account of its electrical organs before the Royal Society. A young elephant which had been presented to the queen, having died, it was given to Dr Hunter, which afforded our author an opportunity of examining the structure of that monstrous animal, as did also two others which died in the queen's menagerie. In the year 1774, he published an account, in the Philosophical Transactions, of certain receptacles of air in birds, communicating with the lungs, and lodged in the muscular parts and hollow bones of these animals. Several animals belonging to the species called *Gymnotus electricus* of Surinam having been brought alive to Britain in 1775, their electrical properties excited a considerable share of the public attention, and Mr Hunter purchased many of them after they died, for the purpose of prosecuting his favourite experiments. He published an account of their electrical organs in the Philosophical Transactions for 1775; and in the same volume appeared his experiments on the power of animals and vegetables to produce heat.

Mr Hunter was appointed surgeon extraordinary to his majesty in 1776; in the autumn of which year he grew extremely ill, when both himself and his friends apprehended that his life was in danger, but he happily recovered so far as to be able to publish the second part of his treatise on the Teeth in 1778, which completed the subject; and in 1779 he published in the Philosophical Transactions his account of the Free Martin. He was chosen a fellow of the Royal Society of Sciences and Belles Lettres at Gottenburg, and in 1783 he became a member of the Royal Society of Medicine and the Royal Academy of Surgery in Paris.

In the building which he formed for his valuable collection, there was a room 52 feet by 28, lighted from the top, with a gallery all round, for containing his preparations. At this time he had reached the height of his career as a surgeon, with his mind and body in full vigour; and his hands were capable of performing whatever was suggested by his capacious mind, and his judgement was fully ripened by long experience.

He removed a tumor from the head and neck of a patient in St George's hospital, as large as the head to which it was attached; and by bringing the cut edges

edges of the skin into contact, the whole was almost healed by the first intention. He dissected or cut out a tumor on the neck, which one of the best surgeons in this country declared that none but a fool or a madman would ever attempt; yet the patient perfectly recovered. He discovered a new method of performing the operation for the popliteal aneurism, by taking up the femoral artery on the anterior part of the thigh, without doing any thing to the tumor or the ham. This, from many subsequent experiments which have been successfully performed, must be allowed to stand high among the modern improvements in surgery.

Mr Hunter was engaged in a very extensive private practice; he was surgeon to St George's hospital; he gave a very long course of lectures during the winter season; he carried on his inquiries in comparative anatomy; he had a school of practical human anatomy in his own house, and was continually employed in some experiments respecting the animal economy. In 1786 he was chosen deputy surgeon-general to the army, at which time he published his work on the venereal disease, the first edition of which met with a very rapid sale.

In the year 1787 he published a treatise on the effect of extirpating one ovarium on the number of young, which procured him the annual gold medal of Sir John Copley. His collection was now brought into a state of arrangement, which he shewed to his friends and acquaintances twice a year, and in May to noblemen and gentlemen, who were only in town during the spring. When Mr Adair died, Mr Hunter was appointed inspector general of hospitals, and surgeon-general to the army. This event happened in 1792, at which time he was elected honorary member of the Chirurgo-Physical Society of Edinburgh, and one of the vice-presidents of the Veterinary College of London, then first established. He published also three papers on the treatment of inflamed veins, on introsusception, and on the mode of conveying food into the stomach in cases of paralysis of the œsophagus.

The collection of comparative anatomy left by Mr Hunter remains an unequivocal testimony of his perseverance and abilities, and an honour to the country in which he was educated. In it is beheld the natural gradation from the lowest state in which life is found to exist, up to the most perfect and complex of the animal creation—man himself.

Mr Hunter enjoyed a good state of health, for the first 40 years of his life, during which he had no complaint of any consequence, except an inflammation of his lungs in 1759. The first attack of the gout which he ever experienced was occasioned by an affection of the mind, and every subsequent fit originated from the same source.

Mr Hunter was of a short stature, uncommonly strong and active, well formed, and capable of great bodily exertion. His countenance was open, animated, and deeply impressed with thoughtfulness towards the close of his life. Lavater seeing a print of him, is said to have exclaimed, "that man thinks for himself." For the last twenty years of his life he drank nothing stronger than water, and wine at no period agreed with his stomach. He was easily irritated, and not soon pacified when once provoked. He was an enemy to dissimulation, and free even to a fault. Few men require so little relaxation as Mr Hunter did, for he seldom slept above four hours in the night, but always an hour after dinner. In private practice he was scrupulously honest in declaring his opinion of the case before him, and ready on all occasions to confess his ignorance of what he did not understand. He sometimes spoke harshly of his cotemporaries; which did not originate from envy, but from a full conviction that surgery was as yet in its infancy, and he himself a novice in his own art.

On October the 16th 1793, when in his usual state of health, he went to St George's hospital, and meeting with some things which irritated his mind, and not being perfectly master of the circumstances, he withheld his sentiments; in which state of restraint he went into the next room, and turning round to Dr Robertson, one of the physicians of the hospital, he gave a deep groan and dropt down dead, being then in his 65th year, the same age at which his brother Dr Hunter had died.

HUNTING, the exercise or diversion of pursuing four-footed beasts of game. See the article GAME.

Four-footed beasts are hunted in the fields, woods, and thickets, and that both with guns and grehounds.

Birds, on the contrary, are either shot in the air, or taken with nets and other devices, which exercise is called *fowling*; or they are pursued and taken by birds of prey, which is called *hawking*. See the articles FOWLING, HAWKING, FALCONRY, SHOOTING, *Bird-Catching*, and DECOY.

F. de Launay, professor of the French laws, has an express treatise of hunting. From those words of God to Adam, Gen. i. 26. and 28. and to Noah, Gen. ix. 2, 3. hunting was considered as a right devolved or made over to man; and the following ages appear to have been of the same sentiment. Accordingly we find, that among the more civilized nations it made one of their diversions; and as to the wilder and more barbarous it served them with food and necessaries. The Roman jurisprudence, which was formed on the manners of the first ages, made a law of it, and established it as a maxim, that as the natural right of things which have no master belongs to the first possessor, wild beasts, birds, and fishes, are the property of whomsoever can take them first.

But the northern nations of barbarians who overran the Roman empire, bringing with them a stronger taste for the diversion, and the people being now possessed of other and more easy means of subsistence from the lands and possessions of those they had vanquished, their chiefs and leaders began to appropriate the right of hunting, and, instead of a natural right, to make it a royal one. Thus it continues to this day; the right of hunting, among us, belonging only to the king, and those who derive it from him.

The hunting used by the ancients was much like that now practised for the rein-deer; which is seldom hunted at force, or with hounds; but only drawn with a blood-hound, and forestalled with nets and engines. Thus did they with all beasts; whence a dog is never commended by them for opening before he has discovered where the beast lies. Hence, they were not in any manner curious as to the music of their hounds, or the composition of their kennel or pack, either for

deepness,

Hunting.

deepness, loudness, or sweetness of cry, which is a principal point in the hunting of our days. Their huntsmen, indeed, were accustomed to shout and make a great noise, as Virgil observes in the third of his Georgics: *Ingentem clamore premes ad retia cervum.* But that confusion was only to bring the deer to the nets laid for him.

The Sicilian way of hunting had something in it very extraordinary.—The nobles or gentry being informed which way a herd of deer passed, gave notice to one another, and appointed a meeting; every one bringing with him a cross-bow or long-bow, and a bundle of staves shod with iron, the heads bored, with a cord passing through them all: thus provided, they came to the herd, and, casting themselves about in a large ring, surrounded the deer.—Then, each taking his stand, unbound his faggot, set up his stake, and tied the end of the cord to that of his next neighbour, at the distance of ten feet from one another.—Then taking feathers, dyed in crimson, and fastened on a thread, they tied them to the cord; so that with the least breath of wind they would whirl round.—Which done, the persons who kept the stands withdrew, and hid themselves in the next covert. Then the chief ranger entering within the line with hounds to draw after the herd, roused the game with their cry; which flying towards the line, were turned off, and, still gazing on the shaking and shining feathers, wandered about as if kept in with a real wall or pale. The ranger still pursued, and calling every person by name as he passed by their stand, commanded him to shoot the first, third, or sixth, as he pleased: and if any of them missed, or singled out another than that assigned him, it was counted a grievous disgrace. By such means, as they passed by the several stations, the whole herd was killed by the several hands. *Pier. Hieroglyphic.* lib. vii. cap. 6.

Hunting formed the greatest part of the employment of the ancient Germans, and probably of the Britons also, when they were not engaged in war. We are informed by some ancient historians, that this was the case even as late as the third century with the unconquered Britons who lived beyond Adrian's wall; nay, that they subsisted chiefly by the prey they took in this way. The great attachment shown by all the Celtic nations to hunting, however, proceeded most probably from its being a kind of apprenticeship to war. Thus their youth acquired that courage, strength, swiftness, and dexterity in handling their arms, which made them so formidable in time of war to their enemies. Thus also they freed the country from many mischievous animals which abounded in the forests, furnishing themselves also with materials for those feasts which seem to have constituted their greatest pleasure. The young chieftains had thus likewise an opportunity of paying court to their mistresses, by displaying their bravery and agility, and making them presents of their game; nay, so strong and universal was the passion for hunting among the ancient Britons, that young ladies of the highest quality and greatest beauty spent much of their time in the chase. They employed much the same weapons in hunting that they did in war, viz. long spears, javelins, and bows and arrows; having also great numbers of dogs to assist them in finding and pursuing their game. These dogs, we are also told, were much admired among other nations, on account of their swiftness, strength, fierceness, and exquisite sense of smelling. They were of several different kinds, called by different names, and formed a considerable article of commerce. They were highly valued by all the Celtic nations, insomuch that some very comical penalties were inflicted upon those who were convicted of stealing them (A). From the poems of Ossian also it appears, that the Britons were not unacquainted with the art of catching birds with hawks trained for that purpose; but they seem to have been absolutely ignorant of the method of catching fish; for there is not a single allusion to this art in all the works of that venerable bard. Their ignorance of this art is both confirmed and accounted for by Dio Niceus, who assures us, that the ancient Britons never tasted fish, though they had innumerable multitudes in their seas, rivers, and lakes. "By the bye (says Dr Henry), we may observe that this agreement between the poems of Ossian and the Greek historian, in a circumstance so singular, is at once a proof of the genuine antiquity of these poems, and that the Greek and Roman writers were not so ill informed about the affairs and manners of the ancient Britons as some have imagined."

The Mexicans, whatever imbecility may be imputed to them in other respects, were very dexterous in hunting. They used bows and arrows, darts, nets, snares, and a kind of tubes named *carbottane*, through which they shot by blowing out little balls at birds. Those which the kings and great men made use of were curiously carved and painted, and likewise adorned with gold and silver. Besides the exercise of the chase which private individuals took either for amusement or to provide food for themselves, there were general hunting-matches, sometimes appointed by the king; at others, undertaken with a view to provide plenty of victims for sacrifices. A large wood, generally that of Zacatapec, not far distant from the capital, was pitched upon as the scene of these grand hunting-matches. Here they chose the place best adapted for setting a great number of snares and nets. The wood was inclosed by some thousands of hunters, forming a circle of six, seven, or eight miles, according to the number of animals they intended to take. Fire was then set to the grass in a great number of places, and a terrible noise made with drums, horns, shouting, and whistling. The hunters gradually contracted their circle, continuing the noise till the game were inclosed in a very small space. They were then killed or taken in snares, or with the hands of the hunters. The number of animals taken or destroyed on these occasions was so great, that the first Spanish viceroy of Mexico would not believe it without making the experiment himself. The place chosen for his hunting-match was a great plain in the country of the

(A) Si quis canem veltraum aut segutium vel petrunculum, præsumserit involare, jubemus ut convictus, coram omni populo, posteriora ipsius osculetur.

the Otomies, lying between the villages of Xilotepec and S. Giovani del Rio; the Indians being ordered to proceed according to their usual customs in the times of their paganism. The viceroy, attended by a vast retinue of Spaniards, repaired to the place appointed, where accommodations were prepared for them in houses of wood erected for the purpose. A circle of more than 15 miles was formed by 11,000 Otomies, who started such a quantity of game on the plain, that the viceroy was quite astonished, and commanded the greater part of them to be set at liberty, which was accordingly done. The number retained, however, was still incredibly great, were it not attested by a witness of the highest credit. On this occasion upwards of 600 deer and wild goats, 100 cajotes, with a surprising number of hares, rabbits, and other smaller animals. The plain still retains the Spanish name *Cazadero*, which signifies the "place of the chase."

The Mexicans, besides the usual methods of the chase, had particular contrivances for catching certain animals. Thus, to catch young asses, they made a small fire in the woods, putting among the burning coals a particular kind of stone named *cacalotl*, "raven or black stone," which bursts with a loud noise when heated. The fire was covered with earth, and a little maize laid around it. The asses quickly assembled with their young, in order to feed upon the maize; but while they were thus employed, the stone burst, and scared away the old ones by the explosion, while the young ones, unable to fly, were carried off by the hunters. Serpents were taken even by the hands, seizing them intrepidly by the neck with one hand, and sewing up their mouths with the other. This method is still practised. They showed the greatest dexterity in tracing the steps of wild beasts, even when an European could not have discerned the smallest print of their feet. The Indian method, however, was by observing sometimes the herbs or leaves broken down by their feet; sometimes the drops of blood which fell from them when wounded. It is said that some of the American Indians show still greater dexterity in discovering the tracks of their enemies, which to an European would be altogether imperceptible.

Hunting was a favourite diversion of the great and bloody conqueror Jenghiz Khan, if indeed we can apply the word *diversion* to a monster whose mind was set upon the destruction of his own species, and who only endeavoured to make the murder of brutes subservient to that of men, by keeping his soldiers in a kind of warfare with the beasts when they had no human enemies to contend with. His expeditions were conducted on a plan similar to that of the Mexicans already mentioned; and were no doubt attended with still greater success, as his numerous army could enclose a much greater space than all the Indians whom the Spanish viceroy could muster. The East Indian princes still show the same inclination to the chase; and Mr Blane, who attended the hunting excursions of Asoph Ul Dowlah visir of the Mogul empire and nabob of Oude in 1785 and 1786, gives the following account of the method practised on this occasion.

The time chosen for the hunting party is about the beginning of December; and the diversion is continued till the heats, which commence about the beginning of March, oblige them to stop. During this time a circuit of between 400 and 600 miles is generally made; the hunters bending their course towards the skirts of the northern mountains, where the country is wild and uncultivated. The visir takes along with him not only his court and seraglio, but a great part of the inhabitants of his capital. His immediate attendants may amount to about 2000; but besides these he is also followed by 500 or 600 horse, and several battalions of regular sepoys with their field-pieces. Four or five hundred elephants are also carried along with him: of which some are used for riding, others for fighting, and some for clearing the jungles and forests of the game. About as many sumpter horses of the beautiful Persian and Arabian breeds are carried along with him. A great many wheel carriages drawn by bullocks likewise attend, which are used chiefly for the convenience of the women; sometimes also he has an English chaise or two, and sometimes a chariot; but all these as well as the horses are merely for show, the visir himself never using any other conveyance than an elephant, or sometimes when fatigued or indisposed a palanquin. The animals used in the sport are principally grehounds, of which there may be about 300; he has also about 200 hawks, and a few trained leopards for hunting deer. There are a great number of marksmen, whose profession it is to shoot deer; with many fowlers, who provide game: as none of the natives of India know how to shoot game with small shot, or to hunt with slow hounds. A vast number of matchlocks are carried along with the company, with many English pieces of various kinds, 40 or 50 pairs of pistols, bows and arrows, besides swords, daggers, and sabres without number. There are also nets of various kinds, some for quail, and others very large, for fishing, which are carried along with him upon elephants, attended by fishermen, so as always to be ready for throwing into any river or lake that may be met with. Every article that can contribute to luxury or pleasure is likewise carried along with the army. A great many carts are loaded with the Ganges water, and even ice is transported for cooling the drink. The fruits of the season and fresh vegetables are daily sent to him from his gardens by bearers stationed at the distance of every ten miles; by which means each article is conveyed day or night at the rate of four miles an hour. Besides the animals already mentioned, there are also fighting antelopes, buffaloes, and rams in great numbers; also several hundred pigeons, some fighting cocks, with a vast variety of parrots, nightingales, &c.

To complete the magnificence or extravagance of this expedition, there is always a large bazar, or moving town, which attends the camp; consisting of shopkeepers and artificers of all kinds, money-changers, dancing-women; so that, on the most moderate calculation, the whole number of people in his camp cannot be computed at fewer than 20,000. The nabob himself, and all the gentlemen of his camp, are provided with double sets of tents and equipage, which are always sent on the day before to the place to which he intends to go; and this is generally eight or ten miles in whatever direction most game is expected; so that by the time he has finished his sport in the morning, he finds his whole camp ready pitched for his reception.

The

The nabob, with the attending gentlemen, proceed in a regular moving court or durbar, and thus they keep conversing together and looking out for game. A great many foxes, hares, jackals, and sometimes deer, are picked up by the dogs as they pass along: the hawks are carried immediately before the elephants, and let fly at whatever game is sprung for them, which is generally partridges, bustards, quails, and different kinds of herons; these last affording excellent sport with the falcons or sharp-winged hawks. Wild boars are sometimes started, and either shot or run down by the dogs and horsemen. Hunting the tyger, however, is looked upon as the principal diversion, and the discovery of one of these animals is accounted a matter of great joy. The cover in which the tyger is found is commonly long grass, or reeds of such a height as frequently to reach above the elephants; and it is difficult to find him in such a place, as he commonly endeavours either to steal off, or lies so close to the ground that he cannot be roused till the elephants are almost upon him. He then roars and skulks away, but is shot at as soon as he can be seen; it being generally contrived that the nabob shall have the compliment of firing first. If he be not disabled, the tyger continues to skulk along, followed by the line of elephants; the nabob and others shooting at him as often as he can be seen till he falls. The elephants themselves are very much afraid of this terrible animal, and discover their apprehensions by shrieking and roaring as soon as they begin to smell him or hear him growl; generally attempting to turn away from the place where he is. When the tyger can be traced to a particular spot, the elephants are disposed of in a circle round him; in which case he will at last make a desperate attack, springing upon the elephant that is nearest, and attempting to tear him with his teeth or claws. Some, but very few, of the elephants, can be brought to attack the tyger; and this they do by curling up their trunks under their mouths, and then attempting to toss, or otherwise destroy him with their tusks, or to crush him with their feet or knees. It is considered as good sport to kill one tyger in a day; though sometimes, when a female is met with her young ones, two or three will be killed.

The other objects of pursuit in these excursions are wild elephants, buffaloes, and rhinoceroses. Our author was present at the hunting of a wild elephant of vast size and strength. An attempt was first made to take him alive by surrounding him with tame elephants, while he was kept at bay by crackers and other fire-works; but he constantly eluded every effort of this kind. Sometimes the drivers of the tame elephants got so near him, that they threw strong ropes over his head, and endeavoured to detain him by fastening them around trees; but he constantly snapped the ropes like pack-threads, and pursued his way to the forest. Some of the strongest and most furious of the fighting elephants were then brought up to engage him; but he attacked them with such fury that they were all obliged to desist. In his struggle with one of them he broke one of his tusks, and the broken piece, which was upwards of two inches in diameter, of solid ivory, flew up into the air several yards above their heads. Orders were now given to kill him, as it appeared impossible to take him alive; but even this was not accomplished without the greatest difficulty. He twice turned and attacked the party who pursued him; and in one of these attacks struck the elephant obliquely on which the prince rode, threw him upon his side, but then passed on without offering farther injury. At last he fell dead, after having received as was supposed upwards of 1000 balls into his body.

Notwithstanding the general passion among most nations for hunting, however, it has by many been deemed an exercise inconsistent with the principles of humanity. The late king of Prussia expressed himself on this subject in the following manner. "The chase is one of the most sensual of pleasures, by which the powers of the body are strongly exerted, but those of the mind remain unemployed. It is an exercise which makes the limbs strong, active, and pliable: but leaves the head without improvement. It consists in a violent desire in the pursuit, and the indulgence of a cruel pleasure in the death, of the game. I am convinced that man is more cruel and savage than any beast of prey: We exercise the dominion given us over these our fellow-creatures in the most tyrannical manner. If we pretend to any superiority over the beasts, it ought certainly to consist in reason; but we commonly find that the most passionate lovers of the chase renounce this privilege, and converse only with their dogs, horses, and other irrational animals. This renders them wild and unfeeling; and it is probable that they cannot be very merciful to the human species. For a man who can in cold blood torture a poor innocent animal, cannot feel much compassion for the distresses of his own species. And, besides, can the chase be a proper employment for a thinking mind?"

The arguments used by his majesty against hunting seem indeed to be much confirmed by considering the various nations who have most addicted themselves to it. These, as must be seen from what has already been said, were all barbarous; and it is remarkable, that Nimrod, the first great hunter of whom we have any account, was likewise the first who oppressed and enslaved his own species. As nations advanced in civilization, it always became necessary to restrain by law the inclination of the people for hunting. This was done by the wise legislator Solon, lest the Athenians should neglect the mechanic arts on its account. The Lacedæmonians, on the contrary, indulged themselves in this diversion without controul; but they were barbarians, and most cruelly oppressed those whom they had in their power, as is evident from their treatment of the Helots. The like may be said of the Egyptians, Persians, and Scythians; all of whom delighted in war, and oppressed their own species. The Romans, on the other hand, who were somewhat more civilized, were less addicted to hunting. Even they, however, were exceedingly barbarous, and found it necessary to make death and slaughter familiar to their citizens from their infancy. Hence their diversions of the amphitheatre and circus, where the hunting of wild beasts was shown in the most magnificent and cruel manner; not to mention their still more cruel sport of gladiators, &c.

In two cases only does it seem possible to reconcile the practice of hunting with humanity; viz. either

when

when an uncultivated country is overrun with noxious animals; or when it is necessary to kill wild animals for food. In the former case, the noxious animals are killed because they themselves would do so if they were allowed to live; but if we kill even a lion or a tyger merely for the pleasure of killing him, we are undoubtedly chargeable with cruelty. In like manner, our modern foxhunters expressly kill foxes, not in order to destroy the breed of these noxious animals, but for the pleasure of seeing them exert all their power and cunning to save their lives, and then beholding them torn in pieces after being half dead with fatigue. This refinement in cruelty, it seems, is their favourite diversion; and it is accounted a crime for any person to destroy these animals in self-defence, as appears from the following passage in Mr Beckford's treatise on hunting. "Besides the digging of foxes, by which method many young ones are taken and old ones destroyed, traps, &c. are too often fatal to them. Farmers for their lambs, (which, by the bye, few foxes ever kill), gentlemen for their game, and old women for their poultry, are their inveterate enemies. In the country where I live, most of the gentlemen are sportsmen; and even those who are not, show every kind of attention to those who are. I am sorry it is otherwise with you; and that your old gouty neighbour should destroy your foxes, I must own concerns me. I know some gentlemen, who, when a neighbour had destroyed all their foxes, and thereby prevented them from pursuing a favourite amusement, loaded a cart with spaniels, and went all together and destroyed his pheasants. I think they might have called this very properly *lex talionis:* and it had the desired effect; for as the gentleman did not think it prudent to fight them all, he took the wiser method, he made peace with them. He gave an order that no more foxes should be destroyed, and they never afterwards killed any of his pheasants."

In the first volume of the Manchester Transactions we have a dissertation upon the diversions of hunting, shooting, &c. as compatible with the principles of humanity. One argument used by the author is, that death is no positive evil to brutes. "It would perhaps (says he) be too hasty an assertion to affirm, that death to brutes is no evil. We are not competent to determine whether their existence, like our own, may not extend to some future mode of being, or whether the present limited sphere is all in which they are interested. On so speculative a question little can be advanced with precision; nor is it necessary for the investigation of the subject before us. If we may be allowed to reason from what we know, it may be safely conjectured, that death to brutes is no positive evil: we have no reason to believe they are endowed with foresight; and therefore, even admitting that with them the pleasures of life exceed its pains and cares, in terminating their existence, they only suffer a privation of pleasure."

On this extraordinary piece of reasoning we may observe, that it would hold much more against the human species than against the brutes. There are few amongst us willing to allow that the pleasures we enjoy are equivalent to our pains and cares: death therefore must be to us a relief from pain and misery, while to the brutes it is a privation of pleasure. Hence, if it be no positive evil for a brute to suffer death, to a man it must be a positive good: add to which, that a man lives in hope of an endless and glorious life, while a brute has no such hope; so that, if to kill a brute, on our author's principles, be no cruelty, to kill a man must be an act of tenderness and mercy!

Another argument, no less inconclusive, is our author's supposing that death from disease is much more to be dreaded in a brute than a violent death. Were brutes naturally in as helpless a state as man, no doubt their want of support from society in cases where they are attacked by sickness would be very deplorable; but it must be considered that the parallel betwixt the two species is in this respect by no means fair. A brute has everywhere its food at hand, and is naturally capable of resisting the inclemencies of the weather; but man has not only a natural inability to procure food for himself in the way that the brutes do, but is, besides, very tender and incapable of resisting the inclemency of the air. Hence, a man unassisted by society must very soon perish; and, no doubt, it would be much more merciful for people to kill one another at once, than to deprive them of the benefits of society, as is too frequently done in various ways needless to be mentioned at present. A brute, however, has nothing to fear. As long as its stomach can receive food, nature offers an abundant supply. One that feeds upon grass has it always within reach; and a carnivorous one will content itself with worms or insects, which, as long as it is able to crawl, it can still make a shift to provide; but so totally helpless is man when left to himself in a state of weakness, that many barbarous nations have looked upon the killing of their old and infirm people to be an act of mercy.

Equally unhappy is our author in his other arguments, that the quick transition from a state of perfect health to death mitigates the severity. The transition is not quick. The sportsmen estimate their diversion by the length of the chase; and during all that time the creature must be under the strongest agonies of terror; and what person of humanity is there who must not feel for an animal in this situation? All this is assented to by our author, who says, "Hard is the heart who does not commiserate the sufferer." Is not this an acknowledgment on his part, that before a person can become a thorough sportsman, he must harden his heart, and stifle those amiable sensations of compassion, which on all occasions ought to be encouraged towards every creature, unless in cases of necessity. But in the present case no necessity is or can be pretended. If a gentleman chooses to regale himself with venison of any kind, he may breed the animals for the purpose. We call Domitian cruel, because he took pleasure in catching flies, and stabbing them with a bodkin. A butcher is excluded from sitting on a jury on account of his being accustomed to sights which are deemed inhuman; but whether it is more inhuman to knock down an ox at once with an axe, or to tear him in pieces with dogs, (for they would accomplish the purpose if properly trained), must be left to the sportsmen to determine.

Lastly, the great argument in favour of hunting, that it contributes to the health of the body and exhilaration of the spirits, seems equally fallacious with the rest. It cannot be proved that hunters are more healthy or long-lived than other people. That exercise will contribute to the preservation of health, as well as to the exhilaration of the mind, is undoubted; but many other kinds of exercise will do this as well as hunting. A man may ride from morning to night, and amuse himself with viewing and making remarks on the country through which he passes; and surely there is no person will say that this exercise will tend to impair his health or sink his spirits. A man may amuse and exercise himself not only with pleasure, but profit also, in many different ways, and yet not accustom himself to behold the death of animals with indifference. It is this that constitutes the cruelty of hunting; because we thus wilfully extinguish in part that principle naturally implanted in our nature, which if totally eradicated would set us not only on a level with the most ferocious wild beasts, but perhaps considerably below them; and it must always be remembered, that whatever pleasure terminates in death is cruel, let us use as many palliatives as we please to hide that cruelty from the eyes of others, or even from our own.

The gentlemen and masters of the sport have invented a set of terms which may be called the *hunting-language*. The principal are those which follow:

1. For beasts as they are in company.—They say, a *herd* of harts, and all manner of deer. A *bey* of roes. A *sounder* of swine. A *rout* of wolves. A *richess* of martens. A *brace* or *leash* of bucks, foxes, or hares. A *couple* of rabbits or coneys.

2. For their lodging.—A hart is said to *harbour*. A buck *lodges*. A roe *beds*. A hare *seats* or *forms*. A coney *sits*. A fox *kennels*. A marten *trees*. An otter *watches*. A badger *earths*. A boar *couches*.—Hence, to express their dislodging, they say, *Unharbour* the hart. *Rouse* the buck. *Start* the hare. *Bolt* the coney. *Unkennel* the fox. *Untree* the marten. *Vent* the otter. *Dig* the badger. *Rear* the boar.

3. For their noise at rutting time.—A hart *belleth*. A buck *growns* or *troats*. A roe *bellows*. A hare *beats* or *taps*. An otter *whines*. A boar *freams*. A fox *barks*. A badger *shricks*. A wolf *howls*. A goat *rattles*.

4. For their copulation.—A hart or buck goes to *rut*. A roe goes to *tourn*. A boar goes to *brim*. A hare or coney goes to *buck*. A fox goes to *clickitting*. A wolf goes to *match* or *make*. An otter *hunteth* for his kind.

5. For the footing and treading.—Of a hart, we say the *slot*. Of a buck, and all fallow-deer, the *view*. Of all deer, if on the grass and scarce visible, the *foiling*. Of a fox, the *print*; and of other the like vermin, the *footing*. Of an otter, the *marks*. Of a boar, the *track*. The hare when in open field, is said to *sore*; when she winds about to deceive the hounds, she *doubles*; when she beats on the hard highway, and her footing comes to be perceived, she *pricketh*: in snow, it is called the *trace* of the hare.

6. The tail of a hart, buck, or other deer, is called the *single*. That of a boar, the *wreath*. Of a fox, the *brush* or *drag*; and the tip at the end, the *chape*. Of a wolf, the *stern*. Of a hare and coney, the *scut*.

7. The ordure or excrement of a hart and all deer, is called *fewmets* or *fewmishing*. Of a hare, *crotiles* or *crotising*. Of a boar, *lesses*. Of a fox, the *billiting*; and of other the like vermin, the *fuants*. Of an otter, the *spraints*.

8. As to the attire of deer, or parts thereof, those of a stag, if perfect, are the *bur*, the *pearls*, the little *knobs* on it, the *beam*, the *gutters*, the *antler*, the *sur-antler*, *royal*, *sur-royal*, and all at top the *croches*. Of the buck, the *bur*, *beam*, *brow-antler*, *black-antler*, *advancer*, *palm*, and *spellers*. If the croches grow in the form of a man's hand, it is called a *palmed head*. Heads bearing not above three or four, and the croches placed aloft, all of one height, are called *crowned heads*. Heads having double croches, are called *forked heads*, because the croches are planted on the top of the beam like forks.

9. They say, a *litter* of cubs, a *nest* of rabbits, a squirrel's *dray*.

10. The terms used in respect of the dogs, &c. are as follow.—Of grehounds, two make a *brace*; of hounds a *couple*. Of grehounds, three make a *leash*; of hounds, a *couple* and *half*.—They say, *let slip* a grehound; and, *cast off* a hound. The string wherein a grehound is led, is called a *leash*; and that of a hound, a *lyome*. The grehound has his *collar*, and the hound his *couples*. We say a *kennel* of hounds, and a *pack* of beagles.

Hunting, as practised among us, is chiefly performed with dogs; of which we have various kinds, accommodated to the various kinds of game, as, *hounds*, *grehounds*, *bloodhounds*, *terriers*, &c. See Canis, Hound, &c.

In the kennels or packs they generally rank them under the heads of *enterers*, *drivers*, *flyers*, *tyers*, &c.

On some occasions, nets, spears, and instruments for digging the ground, are also required: nor is the hunting horn to be omitted.

The usual chases among us are, the *hart*, *buck*, *roe*, *hare*, *fox*, *badger*, and *otter*.—We shall here give something of what relates to each thereof: first premising an explanation of some general terms and phrases, more immediately used in the progress of the sport itself; what belongs to the several sorts of game in particular being reserved for the respective articles.

When the hounds, then, being cast off, and finding the scent of some game, begin to open and cry; they are said to *challenge*. When they are too busy ere the scent be good, they are said to *babble*. When too busy where the scent is good, to *bawl*. When they run it endwise orderly, holding in together merrily, and making it good, they are said to be in *full cry*. When they run along without opening at all, it is called *running mute*.

When spaniels open in the string, or a grehound in the course, they are said to *lapse*.

When beagles bark and cry at their prey, they are said to *yearn*.

When the dogs hit the scent the contrary way, they are said to *draw amiss*.

When they take fresh scent, and quit the former chase for a new one, it is called *hunting change*.

When they *hunt* the game by the heel or track, they are said to *hunt counter*.

When

Hunting.

When the chase goes off, and returns again, traversing the same ground, it is called *hunting the foil.*

When the dogs run at a whole herd of deer, instead of a single one, it is called *running riot.*

Dogs set in readiness where the game is expected to come by, and cast off after the other hounds are passed, are called a *relay.* If they be cast off ere the other dogs be come up, it is called *vauntlay.*

When, finding where the chase has been, they make a proffer to enter, but return, it is called a *blemish.*

A lesson on the horn to encourage the hounds, is named a *call*, or a *recheat.* That blown at the death of a deer, is called the *mort.* The part belonging to the dogs of any chase they have killed, is the *reward.* They say, *take off* a deer's skin; *strip* or *case* a hare, fox, and all sorts of vermin; which is done by beginning at the snout, and turning the skin over the ears down to the tail.

Hunting is practised in a different manner, and with different apparatus, according to the nature of the beasts which are hunted, a description of which may be found under their respective articles, *infra.*

With regard to the seasons, that for hart and buck-hunting begins a fortnight after midsummer, and lasts till Holy-rood day; that for the hind and doe, begins on Holy-rood day, and lasts till Candlemas; that for fox-hunting begins at Christmas, and holds till Lady-day; that for roe-hunting begins at Michaelmas, and ends at Christmas; hare-hunting commences at Michaelmas, and lasts till the end of February; and where the wolf and boar are hunted, the season for each begins at Christmas, the first ending at Lady-day, and the latter at the Purification.

When the sportsmen have provided themselves with nets, spears, and a hunting horn to call the dogs together, and likewise with instruments for digging the ground, the following directions will be of use to them in the pursuit of each sort of game.

Badger-Hunting. In doing this, you must seek the earths and burrows where he lies, and in a clear moonshine night go and stop all the burrows, except one or two, and therein place some sacks, fastened with drawing strings, which may shut him in as soon as he straineth the bag. Some use no more than to set a hoop in the mouth of the sack, and so put it into the hole; and as soon as the badger is in the sack and straineth it, the sack slippeth off the hoop, and follows him to the earth, so he lies tumbling therein till he is taken. These sacks or bags being thus set, cast off the hounds, beating about all the woods, coppices, hedges, and tufts, round about, for the compass of a mile or two; and what badgers are abroad, being alarmed by the hounds, will soon betake themselves to their burrows; and observe, that he who is placed to watch the sacks, must stand close and upon a clear wind: otherwise the badger will discover him, and will immediately fly some other way into his burrow. But if the hounds can encounter him before he can take his sanctuary, he will then stand at a bay like a boar, and make good sport, grievously biting and clawing the dogs; for the manner of their fighting is lying on their backs, using both teeth and nails; and by blowing up their skins, defend themselves against all bites of the dogs, and blows of the men upon their noses. And for the better preservation of your dogs, it is good to put broad collars about their necks made of gray skins.

When the badger perceives the terriers to begin to yearn him in his burrow, he will stop the hole betwixt him and the terriers, and if they still continue baying, he will remove his couch into another chamber or part of the burrow, and so from one into another, barricading the way before them, as they retreat, until they can go no further. If you intend to dig the badger out of his burrow, you must be provided with the same tools as for digging out a fox; and besides, you should have a pail of water to refresh the terriers, when they come out of the earth to take breath and cool themselves. It will also be necessary to put collars of bells about the necks of your terriers, which making a noise may cause the badger to bolt out. The tools used for digging out of the badger, being troublesome to be carried on men's backs, may be brought in a cart. In digging, you must consider the situation of the ground, by which you may judge where the chief angles are; for else, instead of advancing the work, you will hinder it. In this order you may besiege them in their folds, or castles; and may break their platforms, parapets, casements, and work to them with mines and countermines until you have overcome them.

Having taken a live and lusty badger, if you would make sport, carry him home in a sack and turn him out in your court-yard, or some other enclosed place, and there let him be hunted and worried to death by your hounds.

There are the following profits and advantages which accrue, by killing this animal. Their flesh, blood, and grease, though they are not good food, yet are very useful for physicians and apothecaries for oils, ointments, salves, and powders for shortness of breath, the cough of the lungs, for the stone, sprained sinews, colt-aches, &c.; and the skin being well dressed, is very warm and good for old people who are troubled with paralytic distempers.

Boar-Hunting. See Boar.

Buck-Hunting. Here the same hounds and methods are used as in running the stag; and, indeed, he that can hunt a hart or stag well, will not hunt a buck ill.

In order to facilitate the chase, the game-keeper commonly selects a fat buck out of the herd, which he shoots in order to maim him, and then he is run down by the hounds.

As to the method of hunting the buck. The company generally go out very early for the benefit of the morning. Sometimes they have a deer ready lodged; if not, the coverts are drawn till one is roused: or sometimes in a park a deer is pitched upon, and forced from the herd, then more hounds are laid on to run the chase. If you come to be at a fault, the old staunch hounds are only to be relied upon till you recover him again: if he be sunk, and the hounds thrust him up, it is called an *imprime*, and the company all sound a recheat; when he is run down, every one strives to get in to prevent his being torn by the hounds, fallow deer seldom or never standing at bay.

He that first gets in, cries hoo-up, to give notice that he is down, and blows a death. When the company are all come in, they paunch him, and reward the hounds, and generally the chief person of quality amongst them *takes say*, that is, cuts his belly open, to see how fat he is.

is. When this is done, every one has a chop at his neck, and the head being cut off is showed to the hounds, to encourage them to run only at a male deer, which they see by the horns, and to teach them to bite only at the head: then the company all standing in a ring, one blows a single death; which being done, all blow a double recheat, and so conclude the chase with a general halloo of hoo-up, and depart the field to their several homes, or to the place of meeting; and the huntsman, or some other, hath the deer cast across the buttocks of his horse, and so carries him home.

Fox-Hunting makes a very pleasant exercise, and is either above or below ground.

1. *Above ground.* To hunt a fox with hounds, you must draw about groves, thickets, and bushes, near villages. When you find one, it will be necessary to stop up the earth, the night before you design to hunt, and that about midnight; at which time he is gone out to prey: this may be done by laying two white sticks across in his way, which he will imagine to be some gin or trap laid for him; or else they may be stopped up with black thorns and earth mixed together.

Mr Beckford is of opinion that for fox-hunting the pack should consist of 25 couple. The hour most favourable for the diversion is an early one; and he thinks that the hounds should be at the cover at sunrising. The huntsman should then throw in his hounds as quickly as he can, and let the two whippers in keep wide of him on either hand; so that a single hound may not escape them; let them be attentive to his halloo, and let the sportsmen be ready to encourage or rate as that directs. The fox ought on no account to be hallooed too soon, as in that case he would most certainly turn back again, and, spoil all the sport.—Two things our author particularly recommends, viz. the making all the hounds steady, and making them all draw. "Many huntsmen (says he) are fond of having them at their horse's heels; but they never can get so well or so soon together as when they spread the cover; besides, I have often known where there have been only a few finders, that they have found their fox gone down the wind, and been heard of no more that day. Much depends upon the first finding your fox; for I look upon a fox well found to be half killed. I think people are generally in too great a hurry on this occasion. There are but few instances where sportsmen are not too noisy, and too fond of encouraging their hounds, which seldom do their business so well as when little is said to them. The huntsman ought certainly to begin with his foremost hounds; and I should wish him to keep as close to them as he conveniently can; nor can any harm arise from it, unless he should not have common sense. No hounds can then slip down the wind and get out of his hearing; he will also see how far they carry a scent, a necessary requisite; for without it he never can make a cast with any certainty.—You will find it not less necessary for your huntsman to be active in pressing forward his hounds when the scent is good, than to be prudent in not hurrying them beyond it when it is bad. It is his business to be ready at all times to lend them that assistance which they so frequently need, and which when they are first at a fault is then most critical. A fox-hound at that time will exert himself most; he afterwards cools and becomes most indifferent about his game. Those huntsmen who do not get forward enough to take advantage of this eagerness and impetuosity, and direct it properly, seldom know enough of hunting to be of much use to them afterwards. Though a huntsman cannot be too fond of hunting, a whipper-in easily may. His business will seldom allow him to be forward enough with the hounds to see much of the sport. His only thought therefore should be to keep the hounds together, and to contribute as much as he can to the killing of the fox: keeping the hounds together is the surest means to make them steady. When left to themselves they seldom refuse any blood they can get; they become conceited; learn to tie upon the scent; and besides this they frequently get a trick of hunting by themselves, and are seldom good for much afterwards.

"Every country is soon known; and nine foxes out of ten, with the wind in the same quarter, will follow the same track. It is therefore easy for the whipper-in to cut short, and catch the hounds again. With a high scent you cannot push on hounds too much. Screams keep the fox forward, at the same time that they keep the hounds together, or let in the tail-hounds: they also enliven the sport; and, if discreetly used, are always of service; but in cover they should be given with the greatest caution. Halloos seldom do any hurt when you are running up the wind, for then none but the tail hounds can hear you: when you are running down the wind, you should halloo no more than may be necessary to bring the tail hounds forwards; for a hound that knows his business seldom wants encouragement when he is upon a scent.—Most fox-hunters wish to see their hounds run in a *good style.* I confess I myself am one of those; I hate to see a string of them; nor can I bear to see them creep where they can leap. A pack of harriers, if they have time, may kill a fox, but I defy them to kill him in the style in which he ought to be killed; they must hunt him down. If you intend to tire him out, you must expect to be tired also yourself; I never wish a chase to be less than one hour, or to exceed two: It is sufficiently long if properly followed: it will seldom be longer unless there be a fault somewhere either in the day, the huntman, or the hounds.

"Changing from the hunted fox to a fresh one is as bad an accident as can happen to a pack of fox-hounds, and requires all the ingenuity and observation that man is capable of to guard against it. Could a fox-hound distinguish a hunted fox as the deer-hound does the deer that is blown, fox-hunting would then be perfect. A huntsman should always listen to his hounds while they are running in cover; he should be particularly attentive to the headmost hounds, and he should be constantly on his guard against a skirter: for if there be two scents, he must be wrong. Generally speaking, the best scent is least likely to be that of the hunted fox: and as a fox seldom suffers hounds to run up to him as long as he is able to prevent it; so, nine times out of ten, when foxes are hallooed early in the day, they are all fresh foxes. The hounds most likely to be right are the hard-running line-hunting ones; or such as the huntsman knows had the lead before there arose any doubt of changing. With regard to the fox, if he break over an open country, it is no sign that he is hard run; for they seldom at any time will do that unless they are a great way before the hounds. Also if he run up up the wind; they seldom or never do that when they have been long hunted and grow weak; and when they turn their foil, that also may direct him. All this requires a good ear and nice observation; and indeed in that consists the chief excellence of a huntsman.

"When the hounds divide, and are in two parts, the whipper-in, in stopping, must attend to the huntsman and wait for his halloo, before he attempts to stop either: for want of proper management in this respect, I have known the hounds stopped at both places, and both foxes lost. If they have many scents, and it is quite uncertain which is the hunted fox, let him stop those that are farthest down the wind; as they can hear the others, and will reach them soonest: in such a case there will be little use in stopping those that are up the wind. When hounds are at a check, let every one be silent and stand still. Whippers-in are frequently at this time coming on with the tail hounds. They should never halloo to them when the hounds are at fault; the least thing does them harm at such a time, but a halloo more than any other. The huntsman, at a check, had better let his hounds alone; or content himself with holding them forward, without taking them off their noses.—Should they be at a fault, after having made their own cast (which the huntsman should always first encourage them to do), it is then his business to assist them further; but except in some particular instances, I never approve of their being cast as long as they are inclined to hunt. The first cast I bid my huntsman make it generally a regular one, not choosing to rely entirely on his judgment: if that should not succeed, he is then at liberty to follow his own opinion, and proceed as observation or genius may direct. When such a cast is made, I like to see some mark of good sense and meaning in it; whether down the wind, or towards some likely cover or strong earth. However, as it is at best uncertain, I always wish to see a regular cast before I see a knowing one; which, as a last resource, should not be called forth till it be wanted: The letting hounds alone is but a negative goodness in a huntsman; whereas it is true this last shows real genius; and to be perfect it must be born with him. There is a fault, however, which a knowing huntsman is too apt to commit: he will find a fresh fox, and then claim the merit of having recovered the hunted one. It is always dangerous to throw hounds into a cover to retrieve a lost scent; and unless they hit him in, is not to be depended on.

"Gentlemen, when hounds are at fault, are too apt themselves to prolong it. They should always stop their horses some distance behind the hounds; and if it be possible to remain silent, this is the time to be so. They should be careful not to ride before the hounds or over the scent; nor should they ever meet a hound in the face, unless with a design to stop him. Should you at any time be before the hounds, turn your horse's head the way they are going, get out of their track, and let them pass by you. In dry weather, and particularly in heathy countries, foxes will run the roads. If gentlemen at such times will ride close upon the hounds, they may drive them miles without any scent. —High-mettled fox-hounds are seldom inclined to stop while horses are close at their heels. No one should ever ride in a direction which if persisted in would carry him amongst the hounds, unless he be at a great distance behind them.

"The first moment that hounds are at fault is a critical one for the sport people, who should then be very attentive. Those who look forward may perhaps see the fox; or the running of sheep, or the pursuit of crows, may give them some tidings of him. Those who listen may sometimes get a hint which way he is gone from the chattering of a magpie; or perhaps be at a certainty from a distant halloo: nothing that can give any intelligence at such a time ought to be neglected. Gentlemen are too apt to ride all together: were they to spread more, they might sometimes be of service; particularly those who, from a knowledge of the sport, keep down the wind: it would then be difficult for either hounds or fox to escape their observation.—You should, however, be cautious how you go to a halloo. The halloo itself must in a great measure direct you; and though it afford no certain rule, yet you may frequently guess whether it can be depended upon or not. At the sowing time, when boys are keeping off the birds, you will sometimes be deceived by their halloo; so that it is best, when you are in doubt, to send a whipper-in to know the certainty of the matter."

Hounds ought not to be cast as long as they are able to hunt. It is a common, though not very just idea, that a hunted fox never stops; but our author informs us that he has known them stop even in wheel-ruts in the middle of a down, and get up in the middle of the hounds. The greatest danger of losing a fox is at the first finding him, and when he is sinking; at both which times he frequently will run short, and the eagerness of the hounds will frequently carry them beyond the scent. When a fox is first found, every one ought to keep behind the hounds till they are well settled on the scent; and when the hounds are catching him, our author wishes them to be as silent as possible; and likewise to eat him eagerly after he is caught. In some places they have a method of *treeing* him; that is, throwing him across the branch of a tree, and suffering the hounds to bay at him for some minutes before he is thrown among them; the intention of which is to make them more eager, and to let in the tail hounds; during this interval also they recover their wind, and are apt to eat him more readily. Our author, however, advises not to keep him too long, as he supposes that the hounds have not any appetite to eat him longer than while they are angry with him.

2. *Under-ground.* In case a fox does so far escape as to earth, countrymen must be got together with shovels, spades, mattocks, pick-axes, &c. to dig him out, if they think the earth not too great. They make their earths as near as they can in ground that is hard to dig, as in clay, stony ground, or amongst the roots of trees; and their earths have commonly but one hole, and that is straight a long way in before you come at their couch. Sometimes craftily they take possession of a badger's old burrow, which hath a variety of chambers, holes, and angles.

Now to facilitate this way of hunting the fox, the huntsman must be provided with one or two terriers to put into the earth after him, that is, to fix him into an angle; for the earth often consists of many angles: the use

Hunting.

use of the terrier is to know where he lies; for as soon as he finds him, he continues baying or barking, so that which way the noise is heard that way dig to him. Your terriers must be garnished with bells hung in collars, to make the fox bolt the sooner; besides, the collars will be some small defence to the terriers.

The instruments to dig withal are these; a sharp-pointed spade, which serves to begin the trench where the ground is hardest and broader tools will not so well enter; the round hollowed spade, which is useful to dig among roots, having very sharp edges; the broad flat spade to dig withal, when the trench has been pretty well opened, and the ground softer; mattocks and pick-axes to dig in hard ground, where a spade will do but little service; the coal-rake to cleanse the hole, and to keep it from stopping up; clamps, wherewith you may take either fox or badger out alive to make sport with afterwards. And it would be very convenient to have a pail of water to refresh your terriers with, after they are come out of the earth to take breath.

Hare-Hunting. As, of all chases, the hare makes the greatest pastime, so it gives no little pleasure to see the craft of this small animal for her self-preservation. If it be rainy, the hare usually takes to the high-ways; and if she come to the side of a young grove, or spring, she seldom enters, but squats down till the hounds have over-shot her; and then she will return the very way she came, for fear of the wet and dew that hangs on the boughs. In this case, the huntsman ought to stay a hundred paces before he comes to the wood-side, by which means he will perceive whether she return as aforesaid; which if she do, he must halloo in his hounds; and call them back; and that presently, that the hounds may not think it the counter she came first.

The next thing that is to be observed, is the place where the hare sits, and upon what wind she makes her form, either upon the north or south wind: she will not willingly run into the wind, but run upon a side, or down the wind; but if she form in the water, it is a sign she is foul and measled: if you hunt such a one, have a special regard all the day to the brook-sides; for there, and near plashes, she will make all her crossings, doublings, &c.

Some hares have been so crafty, that as soon as they have heard the sound of a horn, they would instantly start out of their form, though it was at the distance of a quarter of a mile, and go and swim in some pool, and rest upon some rush bed in the midst of it; and would not stir from thence till they have heard the sound of the horn again, and then have started out again, swimming to land, and have stood up before the hounds four hours before they could kill them, swimming and using all subtilities and crossings in the water. Nay, such is the natural craft and subtility of a hare, that sometimes after she has been hunted three hours, she will start a fresh hare, and squat in the same form. Others having been hunted a considerable time, will creep under the door of a sheep cot, and hide themselves among the sheep; or, when they have been hard hunted, will run in among a flock of sheep, and will by no means be gotten out from among them till the hounds are coupled up, and the sheep driven into their pens. Some of them (and that seems somewhat strange will take the ground like a coney, and that is called *going 'to the vault*. Some hares will go up one side of the hedge, and come down the other, the thickness of the hedge being the only distance between the courses. A hare that has been sorely hunted, has got upon a quickset hedge, and run a good way upon the top thereof, and then leapt off upon the ground. And they will frequently betake themselves to furze bushes, and will leap from one to the other, whereby the hounds are frequently in default.

Having found where a hare hath relieved in some pasture or corn-field, you must then consider the season of the year, and what weather it is: for if it be in the spring-time, or summer, a hare will not then set in bushes, because they are frequently infested with pismires, snakes, and adders; but will set in corn-fields, and open places. In the winter-time, they set near towns and villages, in tufts of thorns and brambles, especially when the wind is northerly or southerly. According to the season and nature of the place where the hare is accustomed to sit, there beat with your hounds, and start her; which is much better sport than trailing of her from her relief to her form.

After the hare has been started and is on foot, then step in where you saw her pass, and halloo in your hounds, until they have all undertaken it and go on with it in full cry: then recheat to them with your horn, following fair and softly at first, making not too much noise either with horn or voice; for at the first, hounds are apt to overshoot the chase through too much heat. But when they have run the space of an hour, and you see the hounds are well in with it, and stick well upon it, then you may come in nearer with the hounds, because by that time their heat will be cooled, and they will hunt more soberly. But above all things, mark the first doubling, which must be your direction for the whole day; for all the doublings that she shall make afterwards will be like the former; and according to the policies that you shall see her use, and the place where you hunt, you must make your compasses great or little, long or short, to help the defaults, always seeking the moistest and most commodious places for the hounds to scent in.

To conclude: Those who delight in hunting the hare must rise early, lest they be deprived of the scent of her footsteps.

Hart or Stag Hunting. Gesner, speaking of hart-hunting, observes, that this wild, deceitful, and subtile beast, frequently deceives its hunter by windings and turnings. Wherefore the prudent hunter must train his dogs with words of art, that he may be able to set them on and take them off again at pleasure.

First of all, he should encompass the beast in her own layer, and so unharbour her in the view of the dogs, that so they may never lose her slot or footing. Neither must he set upon every one, either of the herd or those that wander solitary alone, or a little one; but partly by sight, and partly by their footing and fumets, make a judgment of the game, and also observe the largeness of his layer.

The huntsman, having made these discoveries in order to the chase, takes off the couplings of the dogs; and some on horseback, others on foot, follow the cry, with the greatest art, observation, and speed; remembering and intercepting him in his subtile turnings and headings;

Hunting. headings; with all agility leaping hedges, gates, pales, ditches; neither fearing thorns, down-hills, nor woods, but mounting a fresh horse if the first tire. Follow the largest head of the whole herd, which must be singled out of the chase; which the dogs perceiving, must follow; not following any other. The dogs are animated to the sport by the winding of horns, and the voices of the huntsmen. But sometimes the crafty beast sends forth his little squire to be sacrificed to the dogs and hunters, instead of himself, lying close the mean time. In this case, the huntsman must sound a retreat, break off the dogs, and take them in, that is, leam them again, until they be brought to the fairer game; which riseth with fear, yet still striveth by flight, until he be wearied and breathless. The nobles call the beast *a wise hart*, who, to avoid all his enemies, runneth into the greatest herds, and so brings a cloud of error on the dogs, to obstruct their further pursuit; sometimes also bearing some of the herd into his footings, that so he may the more easily escape by amusing the dogs. Afterwards he betakes himself to his heels again, still running with the wind, not only for the sake of refreshment, but also because by that means he can the more easily hear the voice of his pursuers whether they be far from him or near to him. But at last being again discovered by the hunters and sagacious scent of the dogs, he flies into the herds of cattle, as cows, sheep, &c. leaping on a cow or ox, laying the fore parts of his body thereon, that so touching the earth only with his hinder feet, he may leave a very small or no scent at all behind for the hounds to discern. But their usual manner is, when they see themselves hard beset and every way intercepted, to make force at their enemy with their horns, who first comes upon him, unless they be prevented by spear or sword. When the beast is slain, the huntsman with his horn windeth the fall of the beast; and then the whole company comes up, blowing their horns in triumph for such a conquest; among whom, the skilfullest opens the beast, and rewards the hounds with what properly belongs to them, for their future encouragement; for which purpose the huntsmen dip bread in the skin and blood of the beast to give to the hounds.

It is very dangerous to go in to a hart at bay; of which there are two sorts, one on land and the other in water. Now, if the hart be in a deep water, where you cannot well come at him, then couple up your dogs; for should they continue long in the water, it would endanger their surbating or foundering. In this case, get a boat, and swim to him, with dagger drawn, or else with rope that has a noose, and throw it over his horns: for if the water be so deep that the hart swims, there is no danger in approaching him; otherwise you must be very cautious.

As to the land-bay, if a hart be burnished, then you must consider the place; for if it be in a plain and open place, where there is no wood nor covert, it is dangerous and difficult to come in to him; but if he be on a hedge-side, or in a thicket, then, while the hart is staring on the hounds, you may come softly and covertly behind him, and cut his throat. If you miss your aim, and the hart turn head upon you, then take refuge at some tree; and when the hart is at bay, couple up your hounds; and when you see the hart turn head to fly, gallop in roundly to him, and kill him with your sword.

Directions at the Death of a Hart or Buck. The first ceremony, when the huntsman comes in to the death of a deer, is to cry "ware haunch," that the hounds may not break into the deer; which being done, the next is the cutting his throat, and there blooding the youngest hounds, that they may the better love a deer, and learn to leap at his throat: then the mort having been blown, and all the company come in, the best person who hath not taken say before, is to take up the knife that the keeper or huntsman is to lay across the belly of the deer, some holding by the fore legs, and the keeper or huntsman drawing down the pizzle, the person who takes say, is to draw the edge of the knife leisurely along the middle of the belly, beginning near the brisket, and drawing a little upon it, enough in the length and depth to discover how fat the deer is; then he that is to break up the deer, first slits the skin from the cutting of the throat downward, making the arber, that so the ordure may not break forth, and then he paunches him, rewarding the hounds with it.

In the next place, he is to present the same person who took say, with a drawn hanger, to cut off the head of the deer. Which being done, and the hounds rewarded, the concluding ceremony is, if it be a stag, to blow a triple mort; and if a buck, a double one; and then all who have horns, blow a recheat in concert, and immediately a general whoop, whoop.

Otter-Hunting is performed with dogs, and also with a sort of instruments called *otter-spears;* with which when they find themselves wounded, they make to land, and fight with the dogs, and that most furiously, as if they were sensible that cold water would annoy their green wounds.

There is indeed craft to be used in hunting them; but they may be catched in snares under water, and by river-sides: but great care must be taken, for they bite sorely and venomously; and if they happen to remain long in the snare, they will not fail to get themselves free by their teeth.

In hunting them, one man must be on one side of the river, and another on the other, both beating the banks with dogs; and the beast not being able to endure the water long, you will soon discover if there be an otter or not in that quarter; for he must come out to make his spraints, and in the night sometimes to feed on grass and herbs.

If any of the hounds finds out an otter, then view the soft grounds and moist places, to find out which way he bent his head; if you cannot discover this by the marks, you may partly perceive it by the spraints; and then follow the hounds, and lodge him as a hart or deer. But if you do not find him quickly, you may imagine he is gone to couch somewhere farther off from the river; for sometimes they will go to feed a considerable way from the place of their rest, choosing rather to go up the river than down it. The persons that go a-hunting otters, must carry their spears, to watch his vents, that being the chief advantage; and if they perceive him swimming under water, they must endeavour to strike him with their spears, and if they miss, must pursue him with the hounds, which, if they be good and perfectly entered, will go chanting

2

ing and travelling along by the river-side, and will beat every root of a tree, and osier-bed, and tuft of bulrushes; nay, they will sometimes take water, and bait the beast, like a spaniel, by which means he will hardly escape.

Roe-buck Hunting is performed divers ways, and very easily in the woods.

When chased, they usually run against the wind, because the coolness of the air refreshes them in their course; therefore the huntsmen place their dogs with the wind: they usually, when hunted, first take a large ring, and afterwards hunt the hounds. They are also often taken by counterfeiting their voice, which a skilful huntsman knows how to do by means of a leaf in his mouth. When they are hunted, they turn much and often, and come back upon the dogs directly; and when they can no longer endure, they take foil, as the hart does, and will hang by a bough in such a manner, that nothing of them shall appear above the water but their snout, and they will suffer the dogs to come just upon them before they will stir.

The venison of a roe-buck is never out of season, being never fat, and therefore they are hunted at any time; only that some favour ought to be shown the doe while she is big with fawn, and afterwards till her fawn is able to shift for himself; but some roe-does have been killed with five fawns in their bellies.

He is not called, by the skilful in the art of hunting, a *great* roe-buck, but a *fair* roe-buck; the herd of them is called a *bevy:* and if he hath not bevy-grease upon his tail, when he is broken up, he is more fit to be dog's meat than man's meat. The hounds must be rewarded with the bowels, the blood, and feet slit asunder, and boiled altogether; this is more properly called a *dose* than a *reward.*

Hunting-Match. The first thing that is to be considered by one who designs to match his horse for his own advantage, and his horse's credit, is not to flatter himself with the opinion of his horse, by fancying that he is a swift, when he is but a slow galloper; and that he is a whole-running-horse, that is, that he will run four miles without a sob at the height of his speed, when he is not able to run two or three. Very probably some gentlemen are led into this error, by their being mistaken in the speed of their hounds, who for want of trying them against other dogs that have been really fleet, have supposed their own to be so, when in reality they are but of a middling speed; and because their horse, when trained, was able to follow them all day, and upon any hour, to command them upon deep as well as light earths, have therefore made a false conclusion, that their horse is as swift as the best; but, upon trial against a horse that has been rightly trained after hounds that were truly fleet, have bought their experience perhaps full dear. Therefore it is advisable for all lovers of hunting to procure two or three couple of tried hounds, and once or twice a-week to follow after them at train-scent; and when he is able to top them on all sorts of earth, and to endure heats and colds stoutly, then he may better rely on his speed and toughness.

That horse which is able to perform a hare-chase of five or six miles briskly and courageously, till his body be as it were bathed in sweat; and then, after the hare has been killed, in a nipping frosty morning, can endure to stand till the sweat be frozen on his back, so that he can endure to be pierced with the cold as well as the heat; and then, even in that extremity of cold, to ride another chase as briskly, and with as much courage as he did the former; that horse which can thus endure heats and colds is most valued by sportsmen. Therefore in order to make a judgment of the goodness of a horse, observe him after the death of the first hare, if the chase has been any thing brisk: if, when he is cold, he shrinks up his body, and draws his legs up together, it is an infallible sign of want of vigour and courage: the like may be done by the slackening of his girths after the first chase, and from the dulness of his teeth, and the dulness of his countenance, all which are true tokens of faintness and being tired; and such a horse is not to be relied on in case of a wager.

Here it will not be improper to take notice of the way of making matches in former times, and the modern way of deciding wagers. The old way of trial was, by running so many train-scents after hounds, as was agreed upon between the parties concerned, and a bell-course, this being found not so uncertain, but more durable than hare-hunting; and the advantage consisted in having the trains led on earth most suitable to the qualifications of the horses. But now others choose to hunt the hare till such an hour, and then to run this wild-goose chase; a method of racing that takes its name from the manner of the flight of wild geese, which is generally one after another; so the two horses after running of twelvescore yards, had liberty, which horse soever could get the leading, to ride what ground he pleased, the hindmost horse being bound to follow him, within a certain distance agreed on by articles, or else to be whipped up by the triers or judges which rode by; and whichever horse could distance the other won the match.

But this chase, in itself very inhuman, was soon found to be very destructive to good horses, especially when two good horses were matched; for neither being able to distance the other till both were ready to sink under their riders through weakness, oftentimes the match was fain to be drawn and left undecided, though both the horses were quite spoiled.

This brought up the custom of train-scents, which afterwards was changed to three heats and a straight course; and that the lovers of horses might be encouraged to keep good ones, plates have been erected in many places in Britain. The fewer of these before you come to the course, if your horse be fiery and mettled, the better; and the shorter the distance, the better. Also, above all things, be sure to make your bargain to have the leading of the first train; and then make choice of such grounds where your horse may best show his speed, and the fleetest dogs you can procure: give your hounds as much law before you as your triers will allow, and then making a loose, try to win the match with a wind; but if you fail in this attempt, then bear your horse, and save him for the course; but if your horse be slow, but well-winded, and a true spurred nag, then the more train-scents you run before you come to the straight-course, the better. But here you ought to observe to gain the leading of the first train; which in this case you must

lead

lead upon such deep earths, that it may not end near any light ground: for this is the rule received among horsemen, that the next train is to begin where the last ends, and the last train is to be ended at the starting place of the course; therefore remember to end your last on deep earths, as well as the first.

HUNTINGDON, the county-town of Huntingdonshire in England, seated upon an easy ascent, on the north side of the river Ouse. It was made a free borough by King John, consisting of a mayor, 12 aldermen, burgesses, &c. by whom the two members of parliament are chosen. It had anciently 15 parishes, and has now but two; in one of which, called *St John's*, Oliver Cromwell was born, in 1599. Here was formerly a castle, built by William the Conqueror, which afterwards belonged to David, a prince of Scotland, with the title of *earl;* but Henry VIII. gave it to George Hastings, with the earldom annexed, in whose family it still continues. It stands on the great north road; and has a bridge built of free-stone over the Ouse, which is made navigable for small vessels as high as Bedford. It is the place where the assizes are kept, and where the county-jail stands. It has a good market-place, and several convenient inns, besides a grammar-school, and contained 2397 inhabitants in 1811. W. Long. 0. 11. N. Lat. 52. 17.

HUNTINGDONSHIRE, a county of England, bounded on the south by Bedfordshire; on the west by Northamptonshire, as also on the north; and by Cambridgeshire on the east; extending 26 miles in length from north to south, 20 in breadth from east to west, and nearly 67 in circumference. This county, which is in the diocese of Lincoln, is divided into four hundreds, and contains 6 market-towns, 29 vicarages, 78 parishes, 256 villages, about 6841 houses, and in 1811, 42,208 inhabitants; but sends only four members to parliament, namely, two knights of the shire, and two members for Huntingdon. It is a good corn country; and abounds in pastures, especially on the eastern side, which is fenny. The rest is diversified by rising hills and shady groves, and the river Ouse waters the southern part.

The air of this county is in most parts pleasant and wholesome, except among the fens and meres, though they are not so bad as the hundreds of Kent and Essex. The soil is fruitful, and produces great crops of corn, and the hilly parts afford a fit pasture for sheep. They have great numbers of cattle; and plenty of water-fowl, fish, and turf for firing; which last is of great service to the inhabitants, there being but little wood, though the whole county was a forest in the time of Henry II. The only river besides the Ouse is the Nen, which runs through Whittlesey mere.

HU-QUANG, a province of the kingdom of China, in Asia, which has a great river called *Yang*, and *Tse-chiang*, which runs across it from east to west. It is divided into the north and south parts, the former of which contains eight cities of the first rank, and 60 of the second and third; and the latter, seven of the first rank, and five of the second and third. It is a flat, open country, watered everywhere with brooks, lakes, and rivers, in which there are great numbers of fish. Here is plenty of wild-fowls; the fields nourish cattle without number, and the soil produces corn, and various kinds of fruits. There is gold found in the sands of the rivers; and in the mines they have iron, tin, &c. In short, there is such a variety of all sorts of commodities, that it is called *the magazine of the empire*.

HURA, in *Botany*, a genus of plants belonging to the monœcia class; and in the natural method ranking under the 38th order, *Tricoccæ*. See BOTANY *Index*.

HURDLE, is the name of a sledge used to draw traitors to the place of execution.

HURDLES, in *Fortification*, are made of twigs of willows or osiers interwoven close together, sustained by long stakes. They are made in the figure of a long square, the length being five or six feet, and the breadth three and a half. The closer they are wattled together, the better. They serve to render the batteries firm, or to consolidate the passage over muddy ditches; or to cover traverses and lodgments for the defence of the workmen against fire-works or stones thrown against them.

The Romans had a kind of military execution for mutineers, called *putting to death under the hurdle*. The manner of it was this: The criminal was laid at his length in a shallow water, under an hurdle, upon which was heaped stones, and so pressed down till he was drowned.

HURDLES, in *Husbandry*, certain frames made either of split timber, or of hazel-rods wattled together, to serve for gates in inclosures, or to make sheep-folds, &c.

HURDS, or HORDS, of flax or hemp; the coarser parts separated in the dressings from the tear, or fine stuff. See FLAX.

HURL-BONE, in a horse, a bone near the middle of the buttock, very apt to go out of its sockets with a hurt or strain.

HURLERS, a number of large stones, set in a kind of square figure near St Clare in Cornwall, so called from an odd opinion held by the common people, that they are so many men petrified, or changed into stones, for profaning the sabbath-day by hurling the ball, an exercise for which the people of that country have been always famous.

The hurlers are oblong, rude, and unhewed. Many authors suppose them to have been trophies erected in memory of some battle: others take them for boundaries to distinguish lands. Lastly, others, with more probability, hold them to have been sepulchral monuments.

HURLY-BURLY, in vulgar language, denotes confusion or tumult, and is said to owe its origin to two neighbouring families, Hurleigh and Burleigh, which filled their part of the kingdom with contest and violence.

HURON, a vast lake of North America, situated between 80° and 84° W. Long. and between 43° and 46° of N. Lat. from whence the country contiguous to it is called *the country of the Hurons*, whose language is spoken over a great extent in the southern parts of America.

HURRICANE, a general name for any violent storm of wind; but which is commonly applied to those storms which happen in the warmer climates, and which greatly exceed the most violent storms known in this country. The ruin and desolation accompanying

ing a hurricane (says Dr Mosely *) cannot be described. Like fire, its resistless force consumes every thing in its track, in the most terrible and rapid manner. It is generally preceded by an awful stillness of the elements, and a closeness and mistiness in the atmosphere, which makes the sun appear red, and the stars larger. But a dreadful reverse succeeding—The sky is suddenly overcast and wild—The sea rises at once from a profound calm into mountains—The wind rages and roars like the noise of cannon—The rain descends in deluges—A dismal obscurity envelopes the earth with darkness—The superior regions appear rent with lightning and thunder—The earth often does and always seems to tremble—Terror and consternation distract all nature—Birds are carried from the woods into the ocean; and those whose element is the sea, seek for refuge on land—The frightened animals in the field assemble together, and are almost suffocated by the impetuosity of the wind in searching for shelter; which, when found, serves them only for destruction—The roofs of houses are carried to vast distances from their walls, which are beat to the ground, burying their inhabitants under them—Large trees are torn up by the roots, and huge branches shivered off, and driven through the air in every direction, with immense velocity—Every tree and shrub that withstands the shock, is stripped of its boughs and foliage—Plants and grass are laid flat on the earth—Luxuriant spring is changed in a moment to dreary winter.—This direful tragedy ended, when it happens in a town, the devastation is surveyed with accumulated horror; the harbour is covered with wrecks of boats and vessels; and the shore has not a vestige of its former state remaining. Mounds of rubbish and rafters in one place, heaps of earth and trunks of trees in another, deep gullies from torrents of water, and the dead and dying bodies of men, women, and children, half buried, and scattered about, where streets but a few hours before were, present the miserable survivors with a shocking conclusion of a spectacle to be followed by famine, and when accompanied by an earthquake by mortal diseases.

* *Treatise on Tropical Diseases*, &c. 8vo.

These destructive phenomena are now thought to arise from electricity, though the manner in which it acts in this case is by no means known. It seems probable, indeed, that not only hurricanes, but even the most gentle gales of wind, are produced by the action of the electric fluid; for which see WIND, WHIRLWIND, &c. METEOROLOGY *Index*.

HURST, HYRST, or HERST, are derived from the Saxon *hyrst*, i. e. *a wood*, or *grove of trees*. There are many places in Kent, Sussex, and Hampshire, which begin and end with this syllable; and the reason may be, because the great wood called *Andreswald* extended through those counties.

HURST-Castle, a fortress of Hampshire in England, not far from Limington. It is seated on the extreme point of a neck of land which shoots into the sea, towards the isle of Wight, from which it is distant two miles.

HUSBAND, a man joined or contracted with a woman in marriage. See MARRIAGE.

HUSBAND-Land, a term used in Scotland for a portion of land containing six acres of sock and scythe land; that is, of land that may be tilled with a plough, and mown with a scythe.

HUSBANDRY, as defined by some, includes not only agriculture, but several other branches connected with it, such as the rearing of cattle, the management of the dairy, making butter and cheese, raising flax, timber, &c. See AGRICULTURE.

Virgilian HUSBANDRY, a term used by authors to express that sort of husbandry, the precepts of which are so beautifully delivered in Virgil's Georgics. The husbandry in England is Virgilian in general, as is seen by the method of paring and burning the surface, of raftering or cross-ploughing, and of the care in destroying weeds, upon the same principle, and by much the same means. In those parts of England along the southern coast, where the Romans principally inhabited, not only the practice, but the expressions, are in many respects the same with those of the ancient Romans, many of the terms used by the ploughmen being of Latin origin, and the same with those used by those people on the like occasions. And on a strict observation, more of Virgil's husbandry is at this time practised in England than in Italy itself. This change in the Italian husbandry is, however, much more to the credit of that people, than the retaining the Virgilian scheme is to ours.

Tull, who has established a new method of husbandry, observes, that it is upon the whole so contradictory to this old plan, that it may be called the *anti-Virgilian husbandry*; and adds that no practice can be worse than the Virgilian.

HUSK, the same with what botanists call the *calyx* or *cup* of a flower. See CALYX, BOTANY *Index*.

HUSO. See ACCIPENSER, ICHTHYOLOGY *Index*.

HUSS, JOHN. See HUSSITES.

HUSSARS, are the national cavalry of Hungary and Croatia. Their regimentals consist in a rough furred cap, adorned with a cock's feather (the officers either an eagle's or a heron's); a doublet, with a pair of breeches to which the stockings are fastened, and yellow or red boots: besides, they occasionally wear a short upper waistcoat edged with fur, and five rows of round metal buttons; and in bad weather a cloak. Their arms are a sabre, carabine, and pistols. They are irregular troops: hence, before beginning an attack, they lay themselves so flat on the necks of their horses, that it is hardly possible to discern their force; but being come within pistol-shot of the enemy, they raise themselves with such surprising quickness, and begin the fight with such vivacity on every side, that, unless the enemy is accustomed to their method of engaging, it is very difficult for troops to preserve their order. When a retreat is necessary, their horses have so much fire, and are so indefatigable, their equipage so light, and themselves such excellent horsemen, that no other cavalry can pretend to follow them. They leap over ditches, and swim over rivers, with surprising facility. They never encamp, and consequently are not burdened with any camp-equipage, saving a kettle and a hatchet to every six men. They always lie in the woods, out-houses, or villages, in the front of the army. The emperor, queen of Hungary, and king of Prussia, have the greatest number of troops under this name in their service.

HUSSITES, in ecclesiastical history, a party of reformers, the followers of John Huss.

John Huss, from whom the Hussites take their name, Hussites.

name, was born in a little village in Bohemia, called *Huss*, and lived at Prague in the highest reputation, both on account of the sanctity of his manners and the purity of his doctrine. He was distinguished by his uncommon erudition and eloquence, and performed at the same time the functions of professor of divinity in the university, and of ordinary pastor in the church of that city. He adopted the sentiments of Wickliffe, and the Waldenses; and in the year 1407 began openly to oppose and preach against divers errors in doctrine, as well as corruptions in point of discipline, then reigning in the church. Huss likewise endeavoured to the utmost of his power to withdraw the university of Prague from the jurisdiction of Gregory XII. whom the kingdom of Bohemia had hitherto acknowledged as the true and lawful head of the church. This occasioned a violent quarrel between the incensed archbishop of Prague and the zealous reformer, which the latter inflamed and augmented from day to day, by his pathetic exclamations against the court of Rome, and the corruptions that prevailed among the sacerdotal order.

There were other circumstances that contributed to inflame the resentment of the clergy against him. He adopted the philosophical opinions of the realists, and vehemently opposed and even persecuted the nominalists, whose number and influence were considerable in the university of Prague. He also multiplied the number of his enemies in the year 1408, by procuring through his great credit, a sentence in favour of the Bohemians, who disputed with the Germans concerning the number of suffrages which their respective nations were intitled to in all matters that were carried by election in this university. In consequence of a decree obtained in favour of the former, which restored them to their constitutional right of three suffrages, usurped by the latter, the Germans withdrew from Prague, and, in the year 1409, founded a new academy at Leipsick. This event no sooner happened, than Huss began to inveigh with greater freedom than he had before done against the vices and corruptions of the clergy, and to recommend, in a public manner, the writings and opinions of Wickliffe, as far as they related to the papal hierarchy, the despotism of the court of Rome, and the corruption of the clergy. Hence an accusation was brought against him, in the year 1410, before the tribunal of John XXIII. by whom he was solemnly expelled from the communion of the church. Notwithstanding this sentence of excommunication, he proceeded to expose the Romish church with a fortitude and zeal that were almost universally applauded.

This eminent man, whose piety was equally sincere and fervent, though his zeal was perhaps too violent, and his prudence not always circumspect, was summoned to appear before the council of Constance. Secured, as he apprehended, from the rage of his enemies by the safe conduct granted him by the emperor Sigismund, for his journey to Constance, his residence in that place, and his return to his own country, John Huss obeyed the order of the council, and appeared before it to demonstrate his innocence, and to prove that the charge of his having deserted the church of Rome was entirely groundless. However, his enemies so far prevailed, that by the most scandalous breach of public faith, he was cast into prison, declared a heretic because he refused to plead guilty against the dictates of his conscience, in obedience to the council, and burnt alive in 1415; a punishment which he endured with unparalleled magnanimity and resignation.

Huss
|
Hustings.

The same unhappy fate was borne by Jerome of Prague, his intimate companion, who attended the council, in order to support his persecuted friend. Jerome, indeed, was terrified into temporary submission; but he afterwards resumed his fortitude, and maintained the opinions, which he had for a while deserted through fear, in the flames in which he expired in 1416.

The disciples of Huss adhered to their master's doctrine after his death with a zeal which broke out into an open war, that was carried on with the most savage and unparalleled barbarity. John Ziska, a Bohemian knight, in 1420, put himself at the head of the Hussites, who were now become a very considerable party, and threw off the despotic yoke of Sigismund, who had treated their brethren in the most barbarous manner. Ziska was succeeded by Procopius, in the year 1424. The acts of barbarity that were committed on both sides were shocking and horrible beyond expression: for notwithstanding the irreconcileable opposition between the religious sentiments of the contending parties, they both agreed in this one horrible principle, that it was innocent and lawful to persecute and extirpate with fire and sword the enemies of the true religion; and such they reciprocally appeared to each other. Those commotions in a great measure subsided, by the interference of the council of Basil, in the year 1433.

The Hussites, who were divided into two parties, viz. the Calixtines and Taborites, spread over all Bohemia and Hungary, and even Silesia and Poland; and there are some remains of them still subsisting in all those parts.

HUSTINGS (from the Saxon word *hustinge*, i. e. *concilium*, or *curia*), a court held in Guildhall before the lord-mayor and aldermen of London, and reckoned the supreme court of the city. Here deeds may be inrolled, outlawries sued out, and replevins and writs of error determined. In this court also is the election of aldermen, of the four members of parliament for the city, &c. This court is very ancient, as appears by the laws of Edward the Confessor. Some other cities have likewise had a court bearing the same name, as Winchester, York, &c.

HUSUM, a town of Denmark, in the duchy of Sleswick, and capital of a bailiwick of the same name, with a strong citadel and a very handsome church. It is seated near the river Ow, on the German sea; and is subject to the duke of Holstein-Gottorp. E. Long. 9. 4. N. Lat. 54. 5.

HUTCHESON, Dr Francis, a very elegant writer and excellent philosopher, was the son of a dissenting minister in the north of Ireland, and was born on the 8th of August 1694. He early discovered a superior capacity; and having gone through a school-education, began his course of philosophy at an academy, whence he removed to the university of Glasgow, where he applied himself to all the parts of literature, in which his progress was suitable to his uncommon abilities.

He

He then returned to Ireland: and entering into the ministry, was just about to be settled in a small congregation of dissenters in the north of Ireland, when some gentlemen about Dublin, who knew his great abilities and virtues, invited him to take up a private academy there. He complied with the invitation, and met with much success. He had been fixed but a short time in Dublin, when his singular merits and accomplishments made him generally known; and his acquaintance was sought by men of all ranks, who had any taste for literature, or any regard for learned men. Lord Viscount Molesworth is said to have taken great pleasure in his conversation, and to have assisted him with his criticisms and observations upon his "Inquiry into the Ideas of Beauty and Virtue," before it came abroad. He received the same favour from Dr Synge, lord bishop of Elphin, with whom he also lived in great friendship. The first edition of this performance came abroad without the author's name, but the merit of it would not suffer him to be long concealed. Such was the reputation of the work, and the ideas it had raised of the author, that Lord Granville, who was then lord lieutenant of Ireland, sent his private secretary to inquire at the bookseller's for the author; and when he could not learn his name, he left a letter to be conveyed to him: in consequence of which he soon became acquainted with his excellency, and was treated by him, all the time he continued in his government, with distinguished marks of familiarity and esteem.

From this time his acquaintance began to be still more courted by men of distinction either for station or literature in Ireland. Archbishop King, the author of the celebrated book *De origine mali*, held him in great esteem; and the friendship of that prelate was of great use to him in screening him from two different attempts made to prosecute him for daring to take upon him the education of youth, without having qualified himself by subscribing the ecclesiastical canons, and obtaining a license from the bishops. He had also a large share in the esteem of the primate Bolter, who through his influence made a donation to the university of Glasgow of a yearly fund for an exhibitioner to be bred to any of the learned professions. A few years after his Inquiry into the Ideas of Beauty and Virtue, his Treatise on the Passions was published: both these works have been often reprinted; and always admired, both for the sentiment and language, even by those who have not assented to the philosophy of them, nor allowed it to have any foundation in nature. About this time he wrote some philosophical papers accounting for laughter, in a different way from Hobbes, and more honourable to human nature: which papers were published in the collection called *Hibernicus's Letters*.

After he had taught in a private academy at Dublin for seven or eight years with great reputation and success, he was called in the year 1729, to Scotland, to be a professor of philosophy in the university of Glasgow. Several young gentlemen came along with him from the academy, and his high reputation drew many more thither both from England and Ireland. Here he spent the remainder of his life in a manner highly honourable to himself and ornamental to the university of which he was a member. His whole time was divided between his studies and the duties of his office; except what he allotted to friendship and society. A firm constitution and a pretty uniform state of good health, except some few slight attacks of the gout, seemed to promise a longer life; yet he did not exceed the 53d year of his age. He was married, soon after his settlement in Dublin, to Mrs Mary Wilson, a gentleman's daughter in the county of Longford; by whom he left behind him one son, Francis Hutcheson, doctor of medicine. By this gentleman was published, from the original manuscript of his father, "A system of Moral Philosophy, in three books, by Francis Hutcheson, LL. D. at Glasgow, 1755," in two volumes, 4to.

HUTCHINSON, John, a philosophical writer, whose notions have made no inconsiderable noise in the world, was born in 1674. He served the duke of Somerset in the capacity of steward; and in the course of his travels from place to place employed himself in collecting fossils: we are told that the large and noble collection bequeathed by Dr Woodward to the university of Cambridge was actually made by him, and even unfairly obtained from him. When he left the duke's service to indulge his studies with more freedom, the duke, then master of the horse to George I. made him his riding surveyor, a kind of sinecure place of 200l. a-year with a good house in the Meuse. In 1724 he published the first part of *Moses's Principia*, in which he ridiculed Dr Woodward's Natural History of the Earth, and exploded the doctrine of gravitation established in Newton's *Principia*: in 1727, he published a second part of *Moses's Principia*, containing the principles of the Scripture Philosophy. From this time to his death, he published a volume every year or two, which, with the MSS. he left behind, were published in 1748, in 12 vols 8vo. On the Monday before his death, Dr Mead urged him to be bled; saying pleasantly, "I will soon send you to Moses," meaning to his studies: but Mr Hutchinson taking it in the literal sense, answered in a muttering tone, "I believe, Doctor, you will;" and was so displeased, that he dismissed him for another physician; but died in a few days after, August 28. 1737. Singular as his notions are, they are not without some defenders, who have obtained the appellation of *Hutchinsonians*. The reader may find a distinct and comprehensive account of the Hutchinsonian system in a book intitled, *Thoughts concerning Religion*, &c. printed at Edinburgh 1743; and in a letter to a bishop, annexed to it, first printed in 1732.

HUTTON, Dr James, physician and naturalist, was the son of Mr William Hutton, a respectable merchant in Edinburgh. He was born on the 3d of June 1726, and lost his father while he was very young, the charge of his education devolving on his mother, who determined that it should be very liberal. Having finished his grammar-school education at the high school of Edinburgh, he entered the university at the age of 14 in the year 1740. He always considered himself as greatly indebted to Professor Stevenson's lectures on logic, not because they made him a logician, but because they accidentally gave him a predilection for chemistry which he retained and cherished to the close of life. As an illustration of some particular doctrine, the professor observed, that while the acids can singly dissolve the

Hutton. the baser metals, they must unite their strength before they can have any influence upon gold; that metal is only to be dissolved by nitro-muriatic acid, formerly denominated *aqua regia*. From this remark he found his thirst for chemical knowledge daily increase, and sought for information from every quarter.

He always evinced talents sufficient to encourage the prosecution of his studies; but it was the wish of his friends that he should turn his attention to business, with which he complied though contrary to his own inclinations. In 1743 he was put an apprentice to Mr George Chalmers, writer to the signet, where he soon discovered the ruling propensity of his mind; for when he should have been transcribing law papers, he was amusing his fellow apprentices with experiments in chemistry. Mr Chalmers perceiving this, generously freed him from his obligations to serve him, desiring him to turn his attention to some other employment more congenial to his views. He fixed his choice on the study of medicine as nearly related to his favourite pursuits, and after spending about three years at Edinburgh, he studied two years at Paris, and returning home by the Low Countries, took his degree of doctor of medicine at Leyden, in September 1749. The subject of his thesis was, *De Sanguine et Circulatione in Microcosmo*.

When he arrived in London, about the end of 1749, he conceived the design of settling in the world. He justly conjectured that Edinburgh did not hold out for him any flattering prospects in the capacity of a physician, as the principal practice was in the hands of a few eminent physicians who had been long established. He accordingly wrote to his friends in Edinburgh with much anxiety, as to the subject of his future prospects in life. To Mr James Davie, a young man nearly of his own age, with whom he contracted a friendship which death only could extinguish, he also communicated the perplexed state of his mind. Their mutual knowledge of the nature of sal ammoniac led them to establish this manufacture, which afterwards became a most lucrative concern to both. The sentiments of Mr Davie were communicated to Dr Hutton while yet in London, which probably was the chief reason why he resolved to abandon entirely the practice of physic.

On his return to Edinburgh, in the year 1750, he resolved to devote all his attention to agriculture, which might probably be occasioned by his having succeeded to a small property in Berwickshire on the death of his father. Mr Playfair of the university of Edinburgh has ascribed it, and we apprehend with great propriety, to the native simplicity of his character, and the moderation of his views, which were always free from ambition. His attachment to the life of a farmer was increased by his acquaintance with Sir John Hall of Dunglass, a gentleman who was very ingenious, a friend and lover of science, and one who well understood agriculture. Determined to make himself master of rural economy, Dr Hutton went into the county of Norfolk, where he continued for some time in the house of a farmer, who was at once his preceptor and his host. The farmer's name was John Dybold, whose practical knowledge of agriculture Dr Hutton always mentioned in terms of the highest respect.

During his residence in this county, which was to him a paradise, he made frequent excursions into different parts of England; and although information respecting rural economy was the great and primary object of his pursuit, yet it was here that he first commenced the study of mineralogy, to serve him as an amusement on the road. He acquainted his friend Sir John Hall, that he was become remarkably fond of studying the surface of the earth, and was narrowly examining every pit, or ditch, or bed of a river that fell in his way. The agricultural knowledge he acquired in Norfolk increased his desire to pay a visit to Flanders, the only place in Europe where husbandry can boast of the greatest antiquity. He set out accordingly in the spring of 1754, and returned to England during the summer of the same year. Soon after his arrival in London, he observed in a letter to Sir John Hall; "had I doubted of it before I set out, I should have returned fully convinced that they are good husbandmen in Norfolk."

About this time he returned to his native country, and was for some time at a loss what place to fix upon for the purpose of carrying into effect his agricultural improvements. His own farm at length became his choice, and a ploughman whom he had brought with him from Norfolk gave the first specimen of excellent tillage ever exhibited in that part of Scotland. To Dr Hutton the country is indebted for the introduction of the new husbandry into a county where it may be said to have made more astonishing progress than in almost any other part of the British empire. In the year 1764, he made an excursion into the north of Scotland, in company with Commissioner Clerk, who was afterwards Sir George Clerk, a man of singular worth and abilities. They went by Crieff, Dalwhinnie, Fort Augustus, and Inverness, and returned along the coast by Aberdeen to Edinburgh. To increase his knowledge of geology was Dr Hutton's chief aim in this tour, to which he was now determined to pay the most unremitting attention. About the year 1768 he devoted his whole time to scientific pursuits, and having met with a favourable opportunity of letting his farm to advantage, he took up his constant residence in Edinburgh. He now turned his attention very much to the study of chemistry, and we believe he was the first who discovered that mineral alkali is contained in zeolite. The same fact has since been confirmed by the experiments of that celebrated mineralogist M. Klaproth, as well as by those of Dr Kennedy, which have led to others of a similar nature.

Dr Hutton gave the world his first publication in 1777, which was a small pamphlet of 37 pages, entitled, *Considerations on the nature, quality, and distinctions of Coal and Culm*. It was designed to answer a question which began to be much agitated, whether the small coal of Scotland is the same with the culm of England? and whether it ought to be carried coastwise free of all duty? This created a keen contest between the proprietors and revenue officers, the one insisting that it should, and the other that it should not pay any duty. It was discussed before the board of customs in Scotland, and even occupied the attention of the privy council. The small coal of Scotland was finally exempted from the payment of duty, to which the pamphlet of Dr Hutton greatly contributed.

During a period of 30 years the attention of the doctor was turned towards geological studies, to qualify him

him for writing on his favourite topic, a new theory of the earth. Long before that theory made its appearance in the world, he had completed the great outline of it, which was only shewn to a few confidential friends. He was first induced to publish it by communicating an abridgement of it to the Royal Society of Edinburgh. Of the merits or defects of this theory (for an account of which, see GEOLOGY), our readers must judge for themselves. It has found a very able advocate in Professor Playfair of the university of Edinburgh, whose illustrations of it have received a very candid and ingenious reply from an anonymous writer, who entitles his book, *A comparative view of the Huttonian and Neptunean systems of geology*. Dr Hutton's theory did not meet with that reception from the public which the doctor's admirers expected, and which it is probable he looked for himself. Professor Playfair thinks it was in a great measure owing to the obscurity with which he wrote, so repugnant to the perspicuity of his conversation; but as the world had received so many unsatisfactory theories before, it is not improbable that men were become disgusted with every thing of the kind, and almost determined to refuse a hearing to every subsequent attempt.

A theory of rain from the same author appeared in the first volume of the Edinburgh Transactions. He had made meteorology his study for a considerable time; and his theory has been pronounced one of the few to be met with in that department of knowledge which is deserving of the name. Soon after this publication, Dr Hutton gave the world, in three volumes quarto, *An investigation of the principles of knowledge, and of the progress of reason from sense to science and philosophy*. His elements of agriculture, the result of much study and long experience, was the last work which he seemed anxious to publish, but it was left in manuscript at his death, which took place in 1796-7. On the 26th of March he was seized with a shivering, which induced him to send for his friend Mr Russel, who attended him as surgeon; but before it was possible for that gentleman to arrive, all medical aid was absolutely vain. Having with some difficulty stretched out his hand to Mr Russel, he instantly expired.

To the name of a philosopher Dr Hutton was most justly entitled, by virtue of his natural talents, acquisitions, and temper. The direction of his studies was rather uncommon and irregular; but for that very reason it was peculiarly fitted to develope his quick penetration and originality of thought, by which his intellectual character was strikingly marked. The vast acquisitions of wealth and fortune never excited more lively sensations of pleasure in the minds of men, than those which arose in the mind of Dr Hutton on hearing of a new invention, or the being made acquainted with a new truth. This pleasure, which appeared almost ridiculous to those who could not enter into his views, was not confined to any one branch of science; for in the language of Professor Playfair, "he would rejoice over Watt's improvements on the steam engine, or Cook's discoveries in the South sea, with all the warmth of a man who was to share in the honour or the profit about to accrue from them." Dr Hutton was not exclusively attached to the company of men of letters, whose conversation was entirely directed to subjects of literature; for he could occasionally unbend himself, and enjoy the innocent hilarity of promiscuous company, when he freely indulged in the gratification of his native pleasantry.

Dr Hutton was never married, but kept house with his three sisters, who were ornaments to their sex, and had the sole management of his domestic concerns. One of them, Miss Isabella, survived her worthy brother, and lived to lament a death which was certainly a loss to the literary world, as a very large share of his knowledge unavoidably perished with himself. He left no particular directions behind him as to the disposal of his collection of fossils, which was accordingly presented to Dr Black, who gave it to the Royal Society of Edinburgh, on condition that it should be completely arranged, and always kept separate, for the purpose of illustrating the Huttonian Theory of the Earth.

HUXING of pike, among fishermen, a particular method of catching that fish.

For this purpose, they take 30 or 40 as large bladders as can be got; blow them up, and tie them close and strong; and at the mouth of each tie a line, longer or shorter according to the depth of the water. At the end of the line is fastened an armed hook, artfully baited: and thus they are put into the water with the advantage of the wind, that they may gently move up and down the pond. When a master pike has struck himself, it affords great entertainment to see him bounce about in the water with a bladder fastened to him; at last, when they perceive him almost spent, they take him up.

HUY, a town of the Netherlands, in the bishopric of Liege, and capital of Condrass. It is advantageously seated on the river Maese, over which there is a bridge. E. Long. 5. 15. N. Lat. 50. 32.

HUYGENS, CHRISTIAN, one of the greatest mathematicians and astronomers of the 17th century, was the son of Constantine Huygens, lord of Zuylichem, who had served three successive princes of Orange in the quality of secretary; and was born at the Hague, in 1629. He discovered from his infancy an extraordinary fondness for the mathematics; in a little time made a great progress in them; and perfected himself in those studies under the famous professor Schooten, at Leyden. In 1649, he went to Holstein and Denmark, in the retinue of Henry count of Nassau; and was extremely desirous of going to Sweden, in order to see Des Cartes, but the count's short stay in Denmark, would not permit him. He travelled into France and England; was, in 1663, made a member of the Royal Society; and, upon his return into France, M. Colbert, being informed of his merit, settled a considerable pension upon him to engage him to fix at Paris; to which Mr Huygens consented, and staid there from the year 1666 to 1681, where he was admitted a member of the Academy of Sciences. He lived a quiet and studious manner of life, and frequently retired into the country to avoid interruption, but did not contract that moroseness which is so frequently the effect of solitude and retirement. He was the first who discovered Saturn's ring, and a third satellite belonging to that planet, which had hitherto escaped the eyes of astronomers. He discovered the means of rendering clocks exact, by applying the pendulum, and rendering all its vibrations equal by the cycloid. He brought telescopes to perfection, made many other useful discoveries, and died at the Hague in 1695. He was the author of several excellent works. The principal of these are contained in two collections; the first of which was printed at Leyden in 1682, in quarto, under the title of *Opera varia;* and the second at Amsterdam in 1728, in two volumes quarto, entitled *Opera reliqua*.

HUYSUM, the name of several Dutch painters; the most celebrated of whom was John, whose subjects were flowers, fruit, and landscapes. According to Mr Pilkington, this illustrious painter hath surpassed all who have ever painted in that style; and his works excite as much surprise by their finishing as they excite admiration by their truth. He was born at Amsterdam in 1682, and was a disciple of Justus van Huysum his father. He set out in his profession with a most commendable principle, not so much to paint for the acquisition of money as of fame; and therefore he did not aim at expedition, but at delicacy, and, if possible, to arrive at perfection in his art. Having attentively studied the pictures of Mignon, and all other artists of distinction who had painted in his own style, he tried which manner would soonest lead him to imitate the lightness and singular beauties of each flower, fruit, or plant, and then fixed on a manner peculiar to himself, which seems almost inimitable. His pictures are finished with inconceivable truth; for he painted every thing after nature; and was so singularly exact, as to watch even the hour of the day in which his model appeared in its greatest perfection. By the judicious he was accounted to paint with greater freedom than Mignon or Breughel; with more tenderness and nature than Mario da Fiori, Michael Angelo di Campidoglio, or Segers; with more mellowness than De Heem, and greater force of colouring than Baptist. His reputation rose to such a height at last, that he fixed immoderate prices on his works; so that none but princes, or those of princely fortunes, could pretend to become purchasers. Six of his paintings were sold at a public sale in Holland for prices that were almost incredible. One of them, a flower-piece, for fourteen hundred and fifty guilders; a fruit-piece for a thousand and five guilders; and the smaller pictures for nine hundred. The vast sums which Van Huysum received for his works, caused him to redouble his endeavours to excel; no person was admitted into his room while he was painting, not even his brothers; and his method of mixing the tints, and preserving the lustre of his colours, was an impenetrable secret, which he never would disclose. Yet this conduct is certainly not to his honour, but rather an argument of a low mind, fearful of being equalled or surpassed. From the same principle, he would never take any disciples, except one lady, named Haverman; and he grew envious and jealous even of her merit. By several domestic disquiets his temper became changed; he grew morose, fretful, and apt to withdraw himself from society. He had many enviers of his fame, which has ever been the severe lot of the most deserving in all professions; but he continued to work, and his reputation never diminished. It is universally agreed that he has excelled all who have painted fruit and flowers before him, by the confessed superiority of his touch, by the delicacy of his pencil, and by an amazing manner of finishing; nor does it appear probable that any future artist will become his competitor. The care which he took to purify his oils and prepare his colours, and the various experiments he made to discover the most lustrous and durable, are instances of extraordinary care and industry as well as capacity. From having observed some of his works that were perfectly finished, some only half finished, and others only begun, the principles by which he conducted himself may perhaps be discoverable. His cloths were prepared with the greatest care, and primed with white, with all possible purity, to prevent his colours from being obscured, as he laid them on very lightly. He glazed all other colours except the clear and transparent, not omitting even the white ones, till he found the exact tone of the colour; and over that he finished the forms, the lights, the shadows and the reflections, which are all executed with precision and warmth, without dryness or negligence. The greatest truth, united with the greatest brilliancy, and a velvet softness on the surface of his objects, are visible in every part of his compositions; and as to his touch, it looks like the pencil of nature. Whenever he represented flowers placed in vases, he always painted those vases after some elegant model, and the bas-relief is as exquisitely finished as any of the other parts. Through the whole he shows a delicate composition, a fine harmony, and a most happy effect of light and shadow. Those pictures which he painted on a clear ground are preferred to others of his hand, as having greatest lustre, and as they demanded more care and exactness in the finishing; yet there are some on a darkish ground, in which appears rather more force and harmony. It is observed of him, that in the grouping of his flowers, he generally designed those which were brightest in the centre, and gradually decreased the force of his colour from the centre to the extremities. The birds nests and their eggs, the feathers, insects, and drops of dew, are expressed with the utmost truth, so as even to deceive the spectator. And yet, after all this merited and just praise, it cannot but be confessed, that sometimes his fruits appear like wax or ivory, without that peculiar softness and warmth which is constantly observable in nature. Beside his merit as a flower painter, he also painted landscapes with great applause. They are well composed; and although he had never seen Rome, he adorned his scenes with the noble remains of ancient magnificence which are in that city. His pictures in that style are well coloured, and every tree is distinguished by a touch that is proper for the leafing. The grounds are well broken, and disposed with taste and judgment; the figures are designed in the manner of Lairesse, highly finished, and touched with a great deal of spirit; and through the whole composition the scene represents Italy, in the trees, the clouds, and the skies. He died in 1749, aged 67.

HUZZOOR, a Hindostan word, signifying *The presence;* applied, by way of eminence, to the Mogul's court. According to polite usage, it is now applied to the presence of every nabob or great man.

Huzzoor Nevees; the secretary who resides at court, and keeps copies of all the *firmauns*, records, or letters.

HYACINTH, in *Natural History*, a species of the zircon genus. See Zircon, Mineralogy *Index*.

HYACINTHUS, Hyacinth, a genus of plants, belonging

belonging to the hexandria class; and in the natural method ranking under the 10th order, *Coronariæ*. See BOTANY *Index*.

HYACINTHIA, in antiquity, feasts held at Sparta, in honour of Apollo, and in commemoration of his favourite Hyacinth.

This Hyacinth was the son of Amyclas king of Sparta, and was beloved both by Apollo and Zephyrus. The youth showing most inclination to the former, his rival grew jealous; and, to be revenged, one day as Apollo was playing at the discus, i. e. quoits, with Hyacinth, Zephyrus turned the direction of a quoit which Apollo had pitched full upon the head of the unhappy Hyacinth, who fell down dead. Apollo then transformed him into a flower of the same name; and as a farther token of respect, they say, commanded this feast. The Hyacinthia lasted three days; the first and third whereof were employed in bewailing the death of Hyacinth, and the second in feasting and rejoicing.

HYADES, in *Astronomy*, are seven stars in the bull's head, famous among the poets for the bringing of rain. Whence their name Ὑαδης, from the Greek ὕω, "to rain." The principal of them is in the left eye, by the Arabs called *Aldebaran*.

The poets feign them the daughters of Atlas and Pleone. Their brother Hyas being torn to pieces by a lioness, they wept his death with such vehemence, that the gods, in compassion to them, translated them into heaven, and placed them in the bull's forehead, where they continue to weep; this constellation being supposed to presage rain. Others represent the Hyades as Bacchus's nurses; and the same with the Dodonides, who fearing the resentment of Juno, and flying from the cruelty of King Lycurgus, were translated by Jupiter into heaven.

HYÆNA. See CANIS, MAMMALIA *Index*.

HYÆNIUS LAPIS, in *Natural History*, the name of a stone said to be found in the eyes of the hyæna. Pliny tells us, that those creatures were in old times hunted and destroyed for the sake of those stones, and that it was supposed they gave a man the gift of prophecy by being put under his tongue.

HYBERNACULUM, in *Botany*, WINTER-QUARTERS; defined by Linnæus to be that part of the plant which defends the embryo herb from injuries during the severities of the winter. See BULB and GEMMA.

HYBLA, in *Ancient Geography*, or MEGARA; which last name it took from the Megareans, who led thither a colony; called also *Hybla Parva* and *Galeotis*. In Strabo's time Megara was extinct; but the name *Hybla* remained on account of its excellent honey named from it. It was situated on the east coast of Sicily, between Syracuse and the Leontines. *Galeotæ* and *Megarenses*, the names of the people, who were of a prophetic spirit, being the descendants of Galeus the son of Apollo. *Hyblæus* the epithet.—The *Hyblæi colles*, small eminences at the springs of the Alabus near this place, were famous from their variety of flowers, especially thyme; the honey gathered from which was by the ancients reckoned the best in the world, excepting that of Hymettus in Attica. By the moderns it was called *Mel Passi*, for the same reason, namely, on account of its excellent honey, and extraordinary fertility, till it was overwhelmed by the lava of Ætna; and having then become totally barren, its name was changed to *Mal Passi*. In a second eruption, by a shower of ashes from the mountain, it soon reassumed its ancient beauty and fertility, and for many years was called *Bel Passi*: and, last of all, in the year 1669, it was again laid under an ocean of fire, and reduced to the most wretched sterility; since which time it is again known by the appellation of *Mal Passi*. However, the lava, in its course over this beautiful country, has left several little islands or hillocks, just sufficient to show what it formerly was. These make a singular appearance in all the bloom of the most luxuriant vegetation, surrounded and rendered almost inaccessible by large fields of black and rugged lava.

HYBLA *Major*, in *Ancient Geography*, was situated in the tract lying between Mount Ætna and the river Symethus. In Pausanius's time desolate.

HYBLA *Major*, or *Heræa*, in *Ancient Geography*, an inland town of Sicily, situated between the rivers Oanus and Herminius. Now RAGUSA.

HYBRIDA PLANTA, a monstrous production of two different species of plants, analogous to a mule among animals. The seeds of hybrid plants will not propagate.

HYBRISTICA, (of ὕβρις, *injuria*), in antiquity, a solemn feast held among the Greeks, with sacrifices and other ceremonies, at which the men attended in the apparel of women, and the women in that of men, to do honour to Venus in quality either of a god or a goddess, or both. Or, according to the account given by others, the hybristica was a feast celebrated at Argos, wherein the women being dressed like men, insulted their husbands, and treated them with all marks of superiority, in memory of the Argian dames having anciently defended their country with singular courage against Cleomenes and Demaratus.

Plutarch speaks of this feast in his treatise of the great actions of women. The name, he observes, signifies infamy; which is well accommodated to the occasion, wherein the women strutted about in men's clothes, while the men were obliged to dangle in petticoats.

HYDATIDES, in *Medicine*, little transparent vesicles or bladders full of water, sometimes found solitary, and sometimes in clusters, upon the liver and various other parts, efpecially in hydropical cases.

HYDATOSCOPIA, called also HYDROMANCY, a kind of divination or method of foretelling future events by water.

HYDE, EDWARD, earl of Clarendon, and lord high-chancellor of England, was a very eminent statesman and historian, son of Henry Hyde, a private gentleman, resident at Dinton in Wiltshire, where his lordship was born, in the month of February 1608. The first rudiments of his education he received in his father's house, the vicar of the parish being his preceptor, under whose tuition he made such rapid progress, that he was sent to Oxford at the age of 13, where he studied only for one year in Magdalen-hall, as his father entered him in the Middle Temple, that he might be trained up to the profession of the law. He repaired to London at the age of 17, being countenanced and protected by his uncle, who was afterwards chief justice of the court of king's bench. On the death of his uncle he was still a student, yet such a heavy

Hyde.

heavy misfortune did not deter him from the prosecution of his designs. As a licentiousness of manners was at that time extremely prevalent, the well-disposed part of the community considered early marriage as a commendable preservative against irregularity of conduct; and therefore in compliance with an opinion so respectable, Mr Hyde united himself in wedlock with a beautiful young lady, when he was only in the 21st year of his age, whom he had the misfortune to lose in six months after the celebration of their nuptials, she having fallen a victim to that loathsome malady the smallpox. After a widowhood of three years continuance, he married the daughter of Sir Thomas Aylesbury, with whom he lived 36 years in conjugal felicity. He considered it as a fortunate circumstance that he was made acquainted at an early period with a number of very distinguished characters, among whom we find the names of Lord Falkland, Selden, Kenelm Digby, Carew, Sheldon, May, Waller, Hales of Eton, Morley, Chillingworth, and others; of whom he has made respectable mention in memoirs written by himself; and to their instructive conversation he nobly ascribes the principal part of his literary acquisitions. His diffidence is very amiably expressed in these words; "that he never was so proud, or thought himself so good a man, as when he was the worst man in the company."

Being concerned in a cause in behalf of the merchants of London, he was thus introduced to the notice of Archbishop Laud, commissioner of the treasury, by whom he was treated with much respect, and had his advancement in the profession of the law greatly promoted. His easy circumstances and respectable connections powerfully contributed to bring him forward and increase his business as a barrister. But in the multiplicity of causes which he was employed to bring before different courts, he never lost sight of polite literature, on the study of which he bestowed indefatigable attention, and in his general deportment he exhibited more of the polished gentleman than of the mere lawyer. So great was the reputation which by this time he had acquired, that in 1640 he was chosen burgess for Wotton-Basset and Shaftesbury, in the parliament summoned by Charles I. on account of the Scotch rebellion. As public grievances first attracted the attention of this new parliament, Hyde brought forward a statement of the illegal oppressions and malpractices of the earl marshal's court; but as it was soon dissolved, a radical investigation of the conduct of that court was for a time prevented. The borough of Saltash made choice of him for the new parliament, in which he pleaded so effectually against the earl marshal's court as to procure its suppression. He now totally abandoned the profession of a barrister, and wholly confined himself to the discussion of public business; and as he was generally supposed to be attached to no particular party, he was frequently appointed chairman of committees in the transaction of the most important affairs.

Hyde was represented to his majesty in such a favourable light, that the king requested a private interview with him, in the course of which he expressed his great obligations to him for his meritorious services, and was much pleased with his zealous attachment to the church. After this interview he may be considered as devoted to the royal cause; and in order to make a proper estimate of his subsequent conduct, it will be necessary for our readers to attend to his own declaration. He informs us that he had "a very particular passion and devotion for the person of the king; and a most zealous esteem and reverence for the constitution of government, which he believed to be so equally poised, that if the least branch of the prerogative was torn off, the subject suffered by it; and he was as much troubled when the crown exceeded its just limits." He believed the church of England to be most admirably calculated for the promotion of literature, piety, and peace, perhaps of any other in the whole world, and deemed the application of any part of its revenue to civil purposes to be the most abominable sacrilege and unpardonable robbery. He also considered the removal of bishops from the house of peers as a violation of the principles of justice, which made him an enemy to every innovation in the church from conscientious motives.

When the commons published their remonstrance on the state of the nation, Hyde drew up a reply to it, merely to gratify his own personal indignation, according to his own confession, without the smallest intention of making it public, although it is more than probable that Lord Digby was made acquainted with its contents. He was, however, at length prevailed upon to allow it to appear as the king's answer with the advice of his council. This procured him an offer of the office of solicitor-general, which he thought proper to decline, although he undertook the management of the king's affairs in parliament, in conjunction with Lord Digby and Sir John Colepepper. He opposed the king's assent to the bill for depriving the bishops of their seats in the house of peers, in which the sovereign acted in direct opposition to the sentiments of his professed friend, by giving his assent. In the year 1642 his majesty sent for Hyde to York, where he contributed his assistance in drawing up various papers in the cause of the falling monarch. He was recalled by parliament, but he refused to obey the summons without the royal permission, which excluded him from pardon by a vote of the house.

Soon after the breaking out of hostilities between the king and parliament, when the court of the former was held at Oxford, Hyde was appointed chancellor of the exchequer, sworn a member of the privy council, and created a knight. He continued with his majesty till the month of March 1644, when he was appointed to accompany Prince Charles to the west, and afterwards to the island of Jersey, where Sir Edward Hyde continued during two years after the departure of the prince, prosecuting his studies with indefatigable industry, and composing a history of those memorable transactions in which he himself had borne a distinguished part. He likewise published a reply to the parliamentary declaration of February 1647, in which it was declared improper to send any more addresses to the king. In 1648 he received orders to attend the prince at Paris, who having in the mean time set out for Holland, Sir Edward took shipping for Dunkirk. The prince was at the Hague when he received the melancholy intelligence of his royal father's fate. Upon this the council of the young king determined to send ambassadors to Spain, and for this purpose made choice of Sir Edward Hyde and Lord Collington, who arrived at Madrid in 1694; and when their residence in that metropolis

Hyde.

tropolis was no longer necessary, Sir Edward returned to Paris. The king's court at the Hague was torn by dissension, which made Sir Edward apply for, and obtain leave to retire to Antwerp, the residence of his wife and children, as he clearly perceived that his personal attendance was not likely to be productive of any substantial good. This retreat afforded him literary and domestic happiness, and was better suited to the reduced state of his finances. The princess of Orange, eldest daughter of the unfortunate Charles I. having assigned Sir Edward a house at Breda free of rent, out of gratitude for his warm attachment to her father, he was prevailed upon to remove to that city.

In the year 1657 he was appointed lord high-chancellor of England; a nomination which to our readers may probably seem ridiculous, as coming from a king who was not possessed of a kingdom; but it should be remembered that the young sovereign was of an easy and too pliable a disposition, incapable of denying any request; and therefore as applications were continually made to him for contingent grants and reversions, he justly considered it as a prudent step to raise a man to that high rank, who had sufficient firmness to reject all improper requisitions.

It is but doing justice to the memory of Sir Edward Hyde to say that he was the most confidential and faithful minister of Charles II. at the time of the restoration; and by the consent of all parties, the many public and private difficulties which this event occasioned, were settled by him with much wisdom, integrity and honour. Notwithstanding he was a warm advocate for the royal prerogative, it says much for the wisdom of his head and the goodness of his heart, that he was an enemy to the extension of it beyond the limits prescribed by the constitution; for when it was proposed to raise a great standing revenue, which would have made the king independent of parliament, it met from Sir Edward the warmest opposition, and he restrained the zeal of the royalists, and their desire of revenge. His zeal for episcopacy was, however, carried to an extravagant height, as it led him to wish for the annihilation of every vestige of presbyterianism. He was chosen chancellor of the university of Oxford in 1690, and at the same time created a peer; being in the year following made Viscount Cornbury and earl of Clarendon. But as his new dignity was far superior to his fortune, the crown made several grants to him to enable him to support it. This sudden elevation, and the strictness of his moral deportment, which bordered on austerity, did not fail to create a number of enemies in such a licentious court as that of Charles II.

It would perhaps be improper to omit a remarkable circumstance respecting his daughter, who was a maid of honour to the princess of Orange, as it had every appearance of affecting his future fortune in a very material degree. The duke of York was so captivated with the charms of his lordship's daughter, that he entered with her into a private contract of marriage, when he found it impracticable to triumph over her virtue, or procure her for a mistress. Finding herself pregnant, she boldly insisted that the duke would make an open avowal of their marriage, which rendered it necessary to make the king acquainted with it; but when it reached the ears of her father, he behaved on the occasion in such a manner, as greatly to tarnish a character so illustrious. He said he would rather see his daughter the duke's mistress than his consort; advised to confine her in the Tower, and even asserted that she ought to lose her head. He was afraid of the king's indignation, from a supposition that he was privy to the marriage, which there is no good reason for believing, yet such an apprehension might bring such expressions from him as were wholly incompatible with the feelings of a parent. His extravagant notions of royalty might also have their own weight in producing such an unnatural conduct, since he would conceive the blood of majesty to be contaminated by such an alliance. To the honour of Charles he behaved on the occasion in a very commendable manner; and notwithstanding the rage of the queen-mother, the base conduct of the duke in denying his marriage, and attempting by calumny to impeach the chastity of his consort, she was at length acknowledged as the duchess of York, and became the mother of two English queens.

Earl Clarendon's influence with the crown was naturally increased by this marriage, while it as naturally procured him the envy of his fellow courtiers, and paved the way to his subsequent degradation. The sale of Dunkirk to the French was viewed as dishonourable by the nation at large, although perhaps on the score of economy and sound policy it was capable of vindication. To this we may add the unpopular measure of opposing the bill for granting liberty of conscience, as it brought on him the displeasure both of the king and of all religious sectaries. Even the unfortunate war with the Dutch was charged to his account, although he was known to be its enemy from its very commencement. Rigidly virtuous himself, the libidinous course of life pursued by his master could not fail to give him offence, and he certainly displeased the king by the freedom of his reproofs. In defiance, therefore, of all his former services, he was basely abandoned to the indignation of the people, and driven from every office of public trust in the month of August 1667. He was charged with the crime of high-treason by the house of commons, but the peers refused to commit him upon their charge; but while the dispute between the two houses was yet undetermined, Clarendon received his majesty's orders to quit the kingdom. His apology to the peers was burnt by the common executioner, and a bill of banishment was issued against him for flying from justice. While he proceeded from Calais to Rouen, the court of France sent an order to him to quit that kingdom, which bodily distress at that time rendered impracticable, upon which the cruel order was reversed. The savage rage of some Englishmen nearly deprived him of his life as he passed from Rouen to Avignon after his recovery; but the court of France punished the perpetrators of the deed. At Montpelier he met with very respectful treatment during a residence of four years, which time he devoted to the vindication of his conduct. Having spent some time at Moulins, he fixed his residence at Rouen, where he terminated his career in December 1674, in the 68th year of his age. His remains were brought to England, and interred in the abbey of Westminster.

Lord Clarendon was the author of Contemplations and Reflections on the Psalms; Animadversions on a book of Mr Cressy's in the Roman Catholic Controversy;

sy; A brief view of the Errors in Hobbes's Leviathan; History of the grand Rebellion; his own Life and a Continuation of his History, published by the university in 1759. In a literary point of view his lordship is only known as a historian; and his history of the civil war is regarded by competent judges as an important source of information. The writings of Clarendon resemble those of a man who takes a decided part, yet his representations are generally allowed to be moderate and just. His language is not devoid of beauty; but his injudicious use of the relative pronoun often renders him obscure; few however have ever excelled him in the delineation of characters.

HYDE, *Dr Thomas*, professor of Arabic at Oxford, and one of the most learned writers of the 17th century, was born in 1636; and studied first at Cambridge, and afterwards at Oxford. Before he was 18 years of age, he was sent from Cambridge to London to assist Mr Brian Walton in the great work of the Polyglot Bible; and about that period undertook to transcribe the Persian Pentateuch out of the Hebrew characters, which Archbishop Usher, who well knew the difficulty of the undertaking, pronounced to be an impossible task to a native Persian. After he had happily succeeded in this, he assisted in correcting several parts of Mr Walton's work, for which he was perfectly qualified. He was made archdeacon of Gloucester, canon of Christ-church, head-keeper of the Bodleian library, and professor both of Hebrew and Arabic in the university of Oxford. He was interpreter and secretary of the Oriental languages, during the reigns of Charles II. James II. and William III.; and was perfectly qualified to fill this post, as he could converse in the languages which he understood. There never was an Englishman in his situation of life who made so great a progress; but his mind was so engrossed by his beloved studies, that he is said to have been but ill qualified to appear to any advantage in common conversation. Of all his learned works (the very catalogue of which, as observed by Anth. Wood, is a curiosity), his *Religio Veterum Persarum* is the most celebrated. Dr Gregory Sharpe, the late learned and ingenious master of the Temple, has collected several of his pieces formerly printed, and republished them with some additional dissertations, and his life prefixed, in two elegant volumes quarto. This great man died on the 18th of February 1702. Among his other works are, 1. A Latin translation of Ulug Beig's observations on the longitude and latitude of the fixed stars; and, 2. A catalogue of the printed books in the Bodleian library.

HYDNUM, a genus of the natural order of fungi, belonging to the cryptogamia class of plants. See BOTANY *Index*.

HYDRA, in fabulous history, a serpent in the marsh of Lerna, in Peloponnesus, represented by the poets with many heads, one of which being cut off, another immediately succeeded in its place, unless the wound was instantly cauterized. Hercules attacked this monster; and having caused Iolaus to hew down wood for flaming brands, as he cut off the heads he applied the brands to the wounds, by which means he destroyed the hydra.

This hydra with many heads is said to have been only a multitude of serpents, which infested the marshes of Lerna near Mycene, and which seemed to multiply as they were destroyed. Hercules, with the assistance of his companions, cleared the country of them, by burning the reeds in which they lodged.

HYDRA, in *Astronomy*, a southern constellation, consisting of a number of stars, imagined to represent a water serpent. The stars in Hydra, in Ptolemy's catalogue, are twenty-seven; in Tycho's, nineteen; in Hevelius's, thirty-one.

HYDRA, in *Zoology*, a genus of the order of zoophyta, belonging to the class of vermes. See HELMINTHOLOGY *Index*.

HYDRAGOGUES, among physicians, remedies which evacuate a large quantity of water in dropsies. The word is formed of ὑδωρ, *water*, and αγειν, *to draw* or *lead*; but the application of the term proceeds upon a mistaken supposition, that every purgative had some particular humour which it would evacuate, and which could not be evacuated by any other. It is now, however, discovered, that all strong purgatives will prove *hydragogues*, if given in large quantity, or in weak constitutions. The principal medicines recommended as hydragogues, are the juice of elder, the root of iris, soldanella, mechoacan, jalap, &c.

HYDRANGEA, a genus of plants belonging to the decandria class, and in the natural method ranking under the 13th order, *Succulentæ*. See BOTANY *Index*.

HYDRASTIS, a genus of plants, belonging to the polyandria class, and in the natural method ranking with those of which the order is doubtful. See BOTANY *Index*.

HYDRARGYRUM, a name given to mercury, or quicksilver. The word is formed of ὑδωρ, *aqua*, "water," and αργυρος, *argentum*, "silver;" q. d. *water of silver*, on account of its resembling liquid or melted silver.

HYDRAULICS, the science of the motion of fluids and the construction of all kinds of machines relating thereto. See HYDRODYNAMICS in this work, and HYDRAULICS, SUPPLEMENT.

HYDRENTEROCELE, in *Surgery*, a species of hernia, wherein the intestines descend into the scrotum, together with a quantity of water.

HYDROCEPHALUS, a preternatural distension of the head to an uncommon size by a stagnation and extravasation of the lymph; which, when collected in the inside of the cranium, is then termed *internal*; as that collected on the outside is termed *external*. See MEDICINE *Index*.

HYDROCHARIS, the LITTLE WATER-LILY, a genus of plants belonging to the diœcia class, and in the natural method ranking under the first order, *Palmæ*. See BOTANY *Index*.

HYDROCOTYLE, WATER-NAVELWORT, a genus of plants belonging to the pentandria class, and in the natural method ranking under the 45th order, *Umbellatæ*. See BOTANY *Index*.

HYDRODYNAMICS.

HYDRODYNAMICS.

History.

Definition.

1. HYDRODYNAMICS, from Ὑδωρ, "water," and Δυναμις, "power," is properly that science which treats of the power of water, whether it acts by pressure or by impulse. In its more enlarged acceptation, however, it treats of the pressure, equilibrium, cohesion, and motion of fluids, and of the machines by which water is raised, or in which that fluid is employed as the first mover. Hydrodynamics is divided into two branches, *Hydrostatics* and *Hydraulics*. Hydrostatics comprehends the pressure, equilibrium, and cohesion of fluids, and Hydraulics their motion, together with the machines in which they are chiefly concerned.

HISTORY.

Hydrodynamics, in some respects, a modern science.

2. The science of hydrodynamics was cultivated with less success among the ancients than any other branch of mechanical philosophy. When the human mind had made considerable progress in the other departments of physical science, the doctrine of fluids had not begun to occupy the attention of philosophers; and, if we except a few propositions on the pressure and equilibrium of water, hydrodynamics must be regarded as a modern science, which owes its existence and improvement to those great men who adorned the 17th and 18th centuries.

Discoveries of Archimedes.

3. Those general principles of hydrostatics which are to this day employed as the foundation of that part of the science, were first given by Archimedes in his work *De Insidentibus Humido*, about 250 years before the birth of Christ, and were afterwards applied to experiments by Marinus Ghetaldus in his *Archimedes Promotus*. Archimedes maintained that each particle of a fluid mass, when in equilibrio, is equally pressed in every direction; and he inquired into the conditions, according to which a solid body floating in a fluid should assume and preserve a position of equilibrium. We are also indebted to the philosopher of Syracuse for that ingenious hydrostatic process by which the purity of the precious metals can be ascertained, and for the screw engine which goes by his name, the theory of which has lately exercised the ingenuity of some of our greatest mathematicians.

Inventions of Ctesibius and Hero.

4. In the Greek school at Alexandria which flourished under the auspices of the Ptolemies, the first attempts were made at the construction of hydraulic machinery. About 120 years after the birth of Christ, the fountain of compression, the syphon, and the forcing pump, were invented by Ctesibius and Hero; and though these machines operated by the elasticity and weight of the air, yet their inventors had no distinct notions of these preliminary branches of pneumatical science. The syphon is a simple instrument which is employed to empty vessels full of water or spirituous liquors, and is of great utility in the arts. The forcing pump, on the contrary, is a complicated and abstruse invention, which could scarcely have been expected in the infancy of hydraulics. It was probably suggested to Ctesibius by the *Egyptian wheel* or *Noria*, which was common at that time, and which was a kind of chain pump, consisting of a number of earthen pots carried round by a wheel. In some of these machines the pots have a valve in their bottom which enables them to descend without much resistance, and diminishes greatly the load upon the wheel; and if we suppose that this valve was introduced so early as the time of Ctesibius, it is not difficult to perceive how such a machine might have led this philosopher to the invention of the forcing pump.

Forcing pump.

Egyptian wheel.

Labours of Sextus Julius Frontinus in hydraulics.

5. Notwithstanding these inventions of the Alexandrian school, its attention does not seem to have been directed to the motion of fluids. The first attempt to investigate this subject was made by Sextus Julius Frontinus, inspector of the public fountains at Rome in the reigns of Nerva and Trajan; and we may justly suppose that his work entitled *De Aquæductibus urbis Romæ Commentarius* contains all the hydraulic knowledge of the ancients. After describing the Roman aqueducts, and mentioning the dates of their erection, he considers the methods which were at that time employed for ascertaining the quantity of water discharged from adjutages, and the mode of distributing the waters of an aqueduct or a fountain. He justly remarks that the expence of water from an orifice, depended not only on the magnitude of the orifice itself, but also on the height of the water in the reservoir; and that a pipe employed to carry off a portion of water from an aqueduct, should, as circumstances required, have a position more or less inclined to the original direction of the current. But as he was unacquainted with the true law of the velocities of running water as depending upon the depth of the orifice, we can scarcely be surprised at the want of precision which appears in his results.

6. The labours of the ancients in the science of hydrodynamics terminated with the life of Frontinus. The sciences had already begun to decline, and that night of ignorance and barbarism was advancing apace, which for more than a thousand years brooded over the nations of Europe. During this lengthened period of mental degeneracy, when less abstruse studies ceased to attract the notice, and rouse the energies of men, the human mind could not be supposed capable of that vigorous exertion, and patient industry, which are so indispensable in physical researches. Poetry and the fine arts, accordingly had made considerable progress under the patronage of the family of Medici, before Galileo began to extend the boundaries of science. This great man, who deserves to be called the father and restorer of physics, does not appear to have directed his attention to the doctrine of fluids: but his discovery of the uniform acceleration of gravity, laid the foundation of its future progress, and contributed in no small degree to aid the exertions of genius in several branches of science.

Labour of Galileo.

Of Castelli.

7. Castelli and Torricelli, two of the disciples of Galileo, applied the discoveries of their master to the science of hydrodynamics. In 1628 Castelli published a

History.

a small work, in which he gave a very satisfactory explanation of several phenomena in the motion of fluids. But he committed a great paralogism in supposing the velocity of the water proportional to the depth of the orifice below the surface of the vessel. Torricelli observing that in a *jet d'eau* where the water rushed through a small adjutage, it rose to nearly the same height with the reservoir from which it was supplied, imagined that it ought to move with the same velocity as if it had fallen through that height by the force of gravity. And hence he deduced this beautiful and important proposition, that the velocities of fluids are as the square roots of the pressures, abstracting from the resistance of the air and the friction of the orifice. This theorem was published in 1643, in his treatise *De Motu Gravium naturaliter accelerato*. It was afterwards confirmed by the experiments of Raphael Magiotti, on the expence of water discharged from different adjutages under different pressure; and though it is true only in small orifices, it gave a new turn to the science of hydraulics.

Of Torricelli.

Of Pascal.

8. After the death of the celebrated Pascal, who discovered the pressure of the atmosphere, a treatise on the equilibrism of fluids was found among his manuscripts, and was given to the public in 1662. In the hands of Pascal, hydrostatics assumed the dignity of a science. The laws of the equilibrium of fluids were demonstrated in the most perspicuous and simple manner, and amply confirmed by experiments. The discovery of Torricelli, it may be supposed, would have incited Pascal to the study of hydraulics. But as he has not treated this subject in the work which has been mentioned, it was probably composed before that discovery had been made public.

Of Mariotte.

9. The theorem of Torricelli was employed by many succeeding writers, but particularly by the celebrated Mariotte, whose labours in this department of physics deserve to be recorded. His *Traité du Mouvement des eaux*, which was published after his death in the year 1686, is founded on a great variety of well conducted experiments on the motion of fluids, performed at Versailles and Chantilly. In the discussion of some points, he has committed considerable mistakes. Others he has treated very superficially, and in none of his experiments does he seem to have attended to the diminution of efflux arising from the contraction of the fluid vein, when the orifice is merely a perforation in a thin plate; but he appears to have been the first who attempted to ascribe the discrepancy between theory and experiment to the retardation of the water's velocity arising from friction. His cotemporary Guglielmini, who was inspector of the rivers and canals in the Milanese, had ascribed this diminution of velocity in rivers, to transverse motions arising from inequalities in their bottom. But as Mariotte observed similar obstructions, even in glass pipes, where no transverse currents could exist, the cause assigned by Guglielmini seemed destitute of foundation. The French philosopher therefore regarded these obstructions as the effects of friction. He supposes that the filaments of water which graze along the sides of the pipe lose a portion of their velocity; that the contiguous filaments having on this account a greater velocity, rub upon the former, and suffer a diminution of their celerity; and that the other filaments are affected with similar retardations proportional to the distance from the axis of the pipe. In this way the medium velocity of the current may be diminished, and consequently the quantity of water discharged in a given time, must, from the effects of friction, be considerably less than that which is computed from theory.

The motion of rivers first attended to in Italy.

10. That part of the science of hydrodynamics which relates to the motion of rivers seems to have originated in Italy. This fertile country receives from the Appennines a great number of torrents, which traverse several principalities before they mingle their waters with those of the Po, into which the greater part of them fall. To defend themselves from the inundations with which they were threatened, it became necessary for the inhabitants to change the course of their rivers; and while they thus drove them from their own territories, they let them loose on those of their neighbours. Hence arose the continual quarrels which once raged between the Bolognese, and the inhabitants of Modena and Ferrara. The attention of the Italian engineers was necessarily directed to this branch of science; and hence a greater number of works were written on the subject in Italy than in all the rest of Europe.

Theory of Guglielmini.

11. Guglielmini was the first who attended to the motion of water in rivers and open canals. Embracing the theorem of Torricelli, which had been confirmed by repeated experiments, Guglielmini concluded that each particle in the perpendicular section of a current has a tendency to move with the same velocity as if it issued from an orifice at the same depth from the surface. The consequences deducible from this theory of running waters are in every respect repugnant to experience, and it is really surprising that it should have been so hastily adopted by succeeding writers. Guglielmini himself was sufficiently sensible that his parabolic theory was contradictory to fact, and endeavoured to reconcile them by supposing the motion of rivers to be obstructed by transverse currents arising from irregularities in their bed. The solution of this difficulty as given by Mariotte was more satisfactory, and was afterwards adopted by Guglielmini, who maintained also that the viscidity of water had a considerable share in retarding its motion.

Discoveries of Sir Isaac Newton.

12. The effects of friction and viscidity in diminishing the velocity of running water were noticed in the Principia of Sir Isaac Newton, who has thrown much light upon several branches of hydrodynamics. At a time when the Cartesian system of vortices universally prevailed, this great man found it necessary to investigate that absurd hypothesis, and in the course of his investigation he has shewn that the velocity of any stratum of the vortex is an arithmetical mean between the velocities of the strata which enclosed it; and from this it evidently follows, that the velocity of a filament of water moving in a pipe is an arithmetical mean between the velocities of the filaments which surround it. Taking advantage of these results, it was afterwards shewn by M. Pitot that the retardations arising from friction are inversely as the diameters of the pipes in which the fluid moves. The attention of Newton was also directed to the discharge of water from orifices in the bottom of vessels. He supposed a cylindrical vessel full of water to be perforated in its bottom with a small hole by which the water escaped, and the vessel to be supplied with water in such a mannner that it always remained full at the same height. He then supposed this cylindrical column of water to be divided into two parts; the first being a

History.

a hyperboloid generated by the revolution of a hyperbola of the fifth degree around the axis of the cylinder which should pass through the orifice; and the second the remainder of the water in the cylindrical vessel. He considered the horizontal strata of this hyperboloid as always in motion, while the remainder of the water was in a state of rest; and imagined that there was a kind of cataract in the middle of the fluid. When the results of this theory were compared with the quantity of water actually discharged, Newton concluded that the velocity with which the water issued from the orifice was equal to that which a falling body would receive by descending through half the height of water in the reservoir. This conclusion, however, is absolutely irreconcileable with the known fact, that jets of water rise nearly to the same height as their reservoirs, and Newton seems to have been aware of this objection. In the second edition of his Principia, accordingly, which appeared in 1714, Sir Isaac has reconsidered his theory. He had discovered a contraction in the vein of fluid which issued from the orifice, and found that at the distance of about a diameter of the aperture, the section of the vein was contracted in the subduplicate ratio of 2 to 1. He regarded therefore the section of the contracted vein as the true orifice from which the discharge of water ought to be deduced, and the velocity of the effluent water as due to the whole height of water in the reservoir; and by this means his theory became more conformable to the results of experience. This theory however is still liable to serious objections. The formation of a cataract is by no means agreeable to the laws of hydrostatics; for when a vessel is emptied by the efflux of water through an orifice in its bottom, all the particles of the fluid direct themselves toward this orifice, and therefore no part of it can be considered as in a state of repose.

The oscillation of waves first considered by Newton.

13. The subject of the oscillation of waves, one of the most difficult in the science of hydrodynamics, was first investigated by Sir Isaac Newton. By the 44th proposition of the 2d book of his Principia, he has furnished us with a method of ascertaining the velocity of the waves of the sea, by observing the time in which they rise and fall. If the two vertical branches of a syphon which communicate by means of a horizontal branch be filled with a fluid of known density, the two fluid columns when in a state of rest will be in equilibrio and their surfaces horizontal. But if the one column is raised above the level of the other, and left to itself, it will descend below that level, and raise the other column above it; and after a few oscillations, they will return to a state of repose. Newton occupied himself in determining the duration of these oscillations, or the length of a pendulum isochronous to their duration; and he found by a simple process of reasoning, that, abstracting from the effects of friction, the length of a synchronous pendulum is equal to one-half of the length of the syphon, that is, of the two vertical branches and the horizontal one, and hence he deduced the isochronism of these oscillations. From this Newton concluded, that the velocity of waves formed on the surface of water either by the wind or by means of a stone, was in the subduplicate ratio of their size. When their velocity therefore is measured, which can be easily done, the size of the waves will be determined by taking a pendulum which oscillates in the time that a wave takes to rise and fall.

Labours of the Marquis Poleni.

14. In the year 1718 the Marquis Poleni published at Padua his work *De Castellis per quæ derivantur Fluviorum aquæ*, &c. He found from a great number of experiments, that if A be the aperture of the orifice, and D its depth below the surface of the reservoir, the quantity of water discharged in a given time will be as $2\,AD \times \frac{0.571}{1.000}$, while it ought to be as 2 AD, if the velocity of the issuing fluid was equal to that acquired by falling through D. By adapting to a circular orifice through which the water escaped, a cylindrical tube of the same diameter, the marquis found that the quantity discharged in a determinate time was considered greater than when it issued from the circular orifice itself; and this happened whether the water descended perpendicularly or issued in a horizontal direction.

Daniel Bernouilli's theory of the motion of fluids.

15. Such was the state of hydrodynamics in 1738, when Daniel Bernouilli published his *Hydrodynamica, seu de viribus et motibus Fluidorum Commentarii.* His theory of the motion of fluids was founded on two suppositions, which appeared to him conformable to experience. He supposed that the surface of a fluid, contained in a vessel which was emptying itself by an orifice, remains always horizontal; and if the fluid mass is conceived to be divided into an infinite number of horizontal strata of the same bulk, that these strata remain contiguous to each other, and that all their points descend vertically, with velocities inversely proportional to their breadth, or to the horizontal sections of the reservoir. In order to determine the motion of each stratum, he employed the principle of the *conservatio virium vivarum*, and obtained very elegant solutions. In the opinion of the abbé Bossut, his work was one of the finest productions of mathematical genius.

Objected to by Maclaurin and John Bernouilli, who resolve the problem by more direct methods.

16. The uncertainty of the principle employed by Daniel Bernouilli, which has never been demonstrated in a general manner, deprived his results of that confidence which they would otherwise have deserved; and rendered it desirable to have a theory more certain, and depending solely on the fundamental laws of mechanics. Maclaurin and John Bernouilli, who were of this opinion, resolved the problem by more direct methods, the one in his Fluxions, published in 1742; and the other in his *Hydraulica nunc primum detecta, et directè demonstrata ex principiis purè mechanicis*, which forms the fourth volume of his works. The method employed by Maclaurin has been thought not sufficiently rigorous; and that of John Bernouilli is, in the opinion of La Grange, defective in perspicuity and precision.

D'Alembert applies his principle of dynamics to the motion of fluids.

17. The theory of Daniel Bernouilli was opposed also by the celebrated D'Alembert. When generalising James Bernouilli's Theory of Pendulums, he discovered a principle of dynamics so simple and general, that it reduced the laws of the motion of bodies to that of their equilibrium. He applied this principle to the motion of fluids, and gave a specimen of its application at the end of his Dynamics in 1743. It was more fully developed in his *Traité des Fluides*, which was published in 1744, where he has resolved, in the most simple and elegant manner, all the problems which relate

History.

late to the equilibrium and motion of fluids. He makes use of the very same suppositions as Daniel Bernouilli, though his calculus is established in a very different manner. He considers, at every instant, the actual motion of a stratum, as composed of a motion which it had in the preceding instant, and of a motion which it has lost. The laws of equilibrium between the motions lost, furnish him with equations which represent the motion of the fluid. Although the science of hydrodynamics had then made considerable progress, yet it was chiefly founded on hypothesis. It remained a desideratum to express by equations the motion of a particle of the fluid in any assigned direction. These equations were found by D'Alembert, from two principles, that a rectangular canal, taken in a mass of fluid in equilibrio, is itself in equilibrio; and that a portion of the fluid, in passing from one place to another, preserves the same volume when the fluid is incompressible, or dilates itself according to a given law when the fluid is elastic. His very ingenious method was published in 1752, in his *Essai sur la resistance des fluides.* It was brought to perfection in his *Opuscules Mathematiques*, and has been adopted by the celebrated Euler.

Before the time of D'Alembert, it was the great object of philosophers to submit the motion of fluids to general formulæ, independent of all hypothesis. Their attempts, however, were altogether fruitless; for the method of fluxions, which produced such important changes in the physical sciences, was but a feeble auxiliary in the science of hydraulics. For the resolution of the questions concerning the motion of fluids, we are indebted to the method of partial differences, a new calculus, with which Euler enriched the sciences. This great discovery was first applied to the motion of water by the celebrated D'Alembert, and enabled both him and Euler to represent the theory of fluids in formulæ restrained by no particular hypothesis.

Experiments of Michelotti.

18. An immense number of experiments on the motion of water in pipes and canals was made by Professor Michelotti of Turin, at the expence of the sovereign. In these experiments the water issued from holes of different sizes, under pressures of from five to twenty-two feet, from a tower constructed of the finest masonry. Basons built of masonry, and lined with stucco, received the effluent water, which was conveyed in canals of brickwork lined with stucco, of various forms and declivities. The whole of Michelotti's experiments were conducted with the utmost accuracy; and his results are, in every respect, entitled to our confidence.

Of the Abbe Bossut.

19. The experiments of the Abbé Bossut, whose labours in this department of science have been very assiduous and successful, have, in as far as they coincide, afforded the same results as those of Michelotti. Though performed on a smaller scale, they are equally entitled to our confidence, and have the merit of being made in cases which are most likely to occur in practice. In order to determine what were the motions of the fluid particles in the interior of a vessel emptying itself by an orifice, M. Bossut employed a glass cylinder, to the bottom of which different adjutages were fitted; and he found that all the particles descend at first vertically, but that at a certain distance from the orifice they turn from their first direction towards the aperture. In consequence of these oblique motions, the fluid vein forms a kind of truncated conoid, whose greatest base is the orifice itself, having its altitude equal to the radius of the orifice, and its bases in the ratio of 3 to 2.—It appears also, from the experiments of Bossut, that when water issues through an orifice made in a thin plate, the expence of water, as deduced from theory, is to the real expence as 16 to 10, or as 8 to 5; and, when the fluid issues through an additional tube, two or three inches long, and follows the sides of the tube, as 16 to 13.—In analyzing the effects of friction, he found, 1. That small orifices gave less water in proportion than great ones, on account of friction; and, 2. That when the height of the reservoir was augmented, the contraction of the fluid vein was also increased, and the expence of water diminished; and by means of these two laws he was enabled to determine the quantity of water discharged, with all the precision he could wish. In his experiments on the motion of water in canals and tubes, he found that there was a sensible difference between the motion of water in the former and the latter. Under the same height of reservoir, the same quantity of water always flows in a canal, whatever be its length and declivity; whereas, in a tube, a difference in length and declivity has a very considerable influence on the quantity of water discharged.—According to the theory of the resistance of fluids, the impulse upon a plane surface, is as the product of its area multiplied by the square of the fluid's velocity, and the square of the sine of the angle of incidence. The experiments of Bossut, made in conjunction with D' Alembert and Condorcet, prove, that this is sensibly true when the impulse is perpendicular; but that the aberrations from theory increase with the angle of impulsion. They found, that when the angle of impulsion was between 60° and 90°, the ordinary theory may be employed, that the resistances thus found will be a little less than they ought to be, and the more so as the angles recede from 90°. The attention of Bossut was directed to a variety of other interesting points, which we cannot stop to notice, but for which, must refer the reader to the works of that ingenious author.

Inquiries of M. Flaugergues concerning the oscillation of waves.

20. The oscillation of waves, which was first discussed by Sir Isaac Newton, and afterwards by D'Alembert, in the article *Ondes*, in the French Encyclopædia, was now revived by M. Flaugergues, who attempted to overthrow the opinions of these philosophers. He maintained, that a wave is not the effect of a motion in the particles of water, by which they rise and fall alternately, in a serpentine line, when moving from the centre where they commenced; but that it is a kind of intumescence, formed by a depression at the place where the impulse is first made, which propagates itself in a circular manner when removing from the point of impulse. A portion of the water, thus elevated, he imagines, flows from all sides into the hollow formed at the centre of impulse, so that the water being, as it were, heaped up, produces another intumescence, which propagates itself as formerly. From this theory, M. Flaugergues concludes, and he has confirmed the conclusion by experiment, that all waves, whether great or small, have the same velocity.

And of M. de la Grange.

21. This difficult subject has also been discussed by M. de la Grange, in his *Mecanique Analytique.* He found, that the velocity of waves, in a canal, is equal to that which a heavy body would acquire by falling through a height equal to half the depth of the water in

in the canal. If this depth, therefore, be one foot, the velocity of the waves will be 5.495 feet in a second; and if the depth is greater or less than this, their velocity will vary in the subduplicate ratio of the depth, provided it is not very considerable. If we suppose that, in the formation of waves, the water is agitated but to a very small depth, the theory of La Grange may be employed, whatever be the depth of the water and the figure of its bottom. This supposition, which is very plausible, when we consider the tenacity and adhesion of the particles of water, has also been confirmed by experience.

Experiments and theory of the chevalier de Buat.

22. The most successful labourer in the science of hydrodynamics, was the chevalier Buat, engineer in ordinary to the king of France. Following in the steps of the abbé Bossut, he prosecuted the inquiries of that philosopher with uncommon ingenuity; and in the year 1786, he published his *Principes d'Hydraulique*, which contains a satisfactory theory of the motion of fluids founded solely upon experiments. The chevalier du Buat considered, that if water were a perfect fluid, and the channels in which it flowed infinitely smooth, its motion would be continually accelerated, like that of bodies descending in an inclined plane. But as the motion of rivers is not continually accelerated, and soon arrives at a state of uniformity, it is evident that the viscidity of the water, and the friction of the channel in which it descends, must equal the accelerating force. M. Buat, therefore, assumes it as a proposition of fundamental importance, that when water flows in any channel or bed, the accelerating force, which obliges it to move, is equal to the sum of all the resistances which it meets with, whether they arise from its own viscidity or from the friction of its bed. This principle was employed by M. Buat, in the first edition of his work, which appeared in 1779; but the theory contained in that edition was founded on the experiments of others. He soon saw, however, that a theory so new, and leading to results so different from the ordinary theory, should be founded on new experiments more direct than the former, and he was employed in the performance of these from 1780 to 1783. The experiments of Bossut having been made only on pipes of a moderate declivity, M. Buat found it necessary to supply this defect. He used declivities of every kind, from the smallest to the greatest; and made his experiments upon channels, from a line and a half in diameter, or seven or eight square toises. All these experiments he arranged under some circumstances of resemblance, and produced the following proposition, which agrees in a most wonderful manner with the immense number of facts which he has brought together, viz. $V=\frac{307\times\sqrt{d-0.1}}{\sqrt{s}-L\sqrt{s+1.6}}-0.3\times\sqrt{d-0.1}$, where d is the hydraulic mean depth, s the slope of the pipe, or of the surface of the current, and V the velocity with which the water issues. The theory of M. Buat, with its application to practice, will be found in the articles RIVER and *WATER-Works*.

Researches of M. Venturi.

23. M. Venturi, professor of natural philosophy in the university of Modena, has lately brought to light some curious facts respecting the motion of water, in his work on the "Lateral Communication of Motion in Fluids." He observed, that if a current of water is introduced with a certain velocity into a vessel filled with the same fluid at rest, and if this current passing through a portion of the fluid is received in a curvilineal channel, the bottom of which gradually rises till it passes over the rim of the vessel itself, it will carry along with it the fluid contained in the vessel; so that after a short time has elapsed, there remains only the portion of the fluid which was originally below the aperture at which the current entered. This phenomenon has been called by Venturi, the lateral communication of motion in fluids; and, by its assistance, he has explained many important facts in hydraulics. He has not attempted to explain this principle; but has shewn, that the mutual action of the fluid particles does not afford a satisfactory explanation of it. The work of Venturi contains many other interesting discussions, which are worthy of the attention of every reader.

Experiments of Eytelwein and others.

24. The science of hydrodynamics has of late years been cultivated by M. Eytelwein of Berlin, whose practical conclusions coincide nearly with those of Bossut;— by Dr Matthew Young, late bishop of Clonfert, who has explained the cause of the increased velocity of efflux through additional tubes, and by Mr Vince, Dr T. Young, Coulomb, and Don George Juan; but the limits of this work will not permit us to give any further account of their labours at present. We must now proceed to initiate the reader into the science itself, beginning with that branch of it which relates to the pressure, equilibrium, and cohesion of non-elastic fluids.

PART I. HYDROSTATICS.

Definition of hydrostatics.

25. HYDROSTATICS is that branch of the science of hydrodynamics which comprehends the pressure and equilibrium of non-elastic fluids, as water, oil, mercury, &c.; the method of determining the specific gravities of substances, the equilibrium of floating bodies (A), and the phenomena of capillary attraction.

Definitions and Preliminary Observations.

Definition of a fluid.

26. A fluid is a collection of very minute particles, cohering so little among themselves, that they yield to the smallest force, and are easily moved among one another.

Perfect fluids.

27. Fluids have been divided into *perfect* and *imperfect*. In perfect fluids the constituent particles are supposed to be endowed with no cohesive force, and to be moved one among another by a pressure infinitely small.

Imperfect fluids.

But, in imperfect or viscous fluids, the mutual cohesion of their particles is very sensible, as in oil, varnish, melted glass, &c.; and this tenacity prevents them from yielding to the smallest pressure. Although water, mercury, alcohol, &c. have been classed among perfect fluids, yet it is evident that neither these nor any other liquid is possessed of perfect fluidity. When a glass vessel is filled with water above the brim, it assumes a convex surface; and when a quantity of it is thrown

(A) The discussion of this subject is reserved as an introduction to the article *Ship-Building*.

Hydrostatics.

thrown on the floor, it is dispersed into a variety of little globules, which can scarcely be separated from one another. Even mercury, the most perfect of all the fluids, is endowed with such a cohesive force among its particles, that if a glass tube, with a small bore, is immersed in a vessel full of this fluid, the mercury will be lower in the tube than the surface of the surrounding fluid;—if a small quantity of it be put in a glass vessel, with a gentle rising in the middle of its bottom, the mercury will desert the middle, and form itself into a ring, considerably rounded at the edges; or if several drops of mercury be placed upon a piece of flat glass, they will assume a spherical form; and if brought within certain limits, they will conglobulate and form a single drop. Now, all these phenomena concur to prove, that the particles of water have a mutual attraction for each other; that the particles of mercury have a greater attraction for one another, than for the particles of glass; and, consequently, that these substances are not entitled to the appellation of perfect fluids.

28. It was universally believed, till within the last 45 years, that water, mercury, and other fluids of a similar kind, could not be made to occupy a smaller space, by the application of any external force. This opinion was founded on an experiment made by Lord Bacon, who inclosed a quantity of water in a leaden globe, and by applying a great force attempted to compress the water into less space than it occupied at first: The water, however, made its way through the pores of the metal, and stood on its surface like dew.

Florentine experiment.

The same experiment was afterwards repeated at Florence by the academy del Cimento, who filled a silver globe with water, and hammered it with such force as to alter its form, and drive the water through the pores of the metal.

Compressibility of water first noticed by Lord Bacon.

Though these experiments were generally reckoned decisive proofs of incompressibility, yet Bacon himself seems to have drawn from his experiment a very different conclusion; for after giving an account of it, he immediately adds, that *he computed into how much less space the water was driven by this violent pressure* (B). This passage from Lord Bacon does not seem to have been noticed by any writer on hydrostatics, and appears a complete proof that the compressibility of water was fairly deducible from the issue of his experiment.

Fluids divided into compressible and incompressible.

In consequence of the reliance which was universally placed on the result of the Florentine experiment, fluids have generally been divided into *compressible* and *incompressible*, or *elastic* and *non-elastic fluids:* water, oil, alcohol, and mercury, being regarded as incompressible and non-elastic; and air, steam, and other aëriform fluids, as compressible or elastic.

Compressibility of water ascertained by Mr Canton,

29. About the year 1761, the ingenious Mr Canton began to consider this subject with attention, and distrusting the result obtained by the academy del Cimento, resolved to bring the question to a decisive issue (C). Having procured a small glass tube, about two feet long, with a ball at one end, an inch and a quarter in diameter, he filled the ball and part of the tube with mercury, and brought it to the temperature of 50° of Fahrenheit. The mercury then stood six inches and a half above the ball; but after it had been raised to the top of the tube by heat, and the tube sealed hermetically, then, upon bringing the mercury to its former temperature of 50°, it stood $\frac{32}{100}$th of an inch higher in the tube than it did before. By repeating the same experiment with water exhausted of air, instead of mercury, the water stood $\frac{43}{100}$th of an inch higher in the tube than it did at first. Hence it is evident, that when the weight of the atmosphere was removed, the water and mercury expanded, and that the water expanded $\frac{11}{100}$th of an inch more than the mercury. By placing the apparatus in the receiver of a condensing engine, and condensing the air in the receiver, he increased the pressure upon the water, and found that it descended in the tube. Having thus ascertained the fact, that water and mercury are compressible, he subjected other fluids to similar experiments, and obtained the results in the following table.

		Millionth Parts.	*Specific Gravity.*
Compression of	mercury,	3	13.595
	sea-water,	40	1.028
	rain-water,	46	1.000
	oil of olives,	48	0.918
	spirit of wine,	66	0.846

Lest it should be imagined that this small degree of compressibility arose from air imprisoned in the water, Mr Canton made the experiment on some water which had imbibed a considerable quantity of air, and found that its compressibility was not in the least augmented. By inspecting the preceding table, it will be seen that the compressibility of the different fluids is nearly in the inverse ratio of their specific gravities.

and confirmed by Zimmerman.

30. The experiments of Mr Canton have been lately confirmed by Professor Zimmerman. He found that sea-water was compressed $\frac{1}{340}$th part of its bulk when inclosed in the cavity of a strong iron cylinder, and under the influence of a force equal to a column of sea-water 1000 feet high. From those facts, it is obvious that fluids are susceptible of contraction and dilatation, and that there is no foundation in nature for their being divided into compressible and incompressible. If fluids are compressible, they will also be elastic; for when the compressing force is removed, they will recover their former magnitude; and hence their division into elastic and non-elastic is equally improper.

31. The doctrines of hydrostatics have been deduced by different philosophers from different properties of fluids. Euler has founded his analysis on the following property, "that when fluids are subjected to any pressure, that pressure is so diffused throughout the mass, that when it remains in equilibrio all its parts are equally pressed in every direction (D)." D'Alembert at first (E) deduced the principles of hydrostatics from the property which fluids have of rising to the same altitude in any number of communicating vessels; but he afterwards

Pressure, &c. of Fluids.

afterwards* adopted the same property as Euler from the foundation which it furnishes for an algebraical calculus. The same property has been employed by Bossut, Prony, and other writers, and will form the first proposition of the following chapter.

* Traité des Fluides, § 20.

CHAP. I. *On the Pressure and Equilibrium of Fluids.*

PROPOSITION I.

32. WHEN a mass of fluid, supposed without weight, is subjected to any pressure, that pressure is so diffused throughout the whole, that when it remains in equilibrio all its parts are equally pressed in every direction.

The parts of a fluid subjected to any pressure, are equally pressed in every direction.

As it is the distinguishing property of fluids that their particles yield to the smallest pressure, and are easily moved among themselves (16.), it necessarily follows, that if any particle is more pressed towards one side than towards another, it will move to that side where the pressure is least; and the equilibrium of the fluid mass will be instantly destroyed. But by the hypothesis the fluid is in equilibrio, consequently the particle cannot move towards one side, and must therefore be equally pressed in every direction.

Plate CCLXIII. fig. 1.

In order to illustrate this general law, let EF (fig. 1.) be a vessel full of any liquid, and let *m n*, *o p* be two orifices at equal depths below its surface; then, in order to prevent the water from escaping, it will be necessary to apply two pistons, A and B, to the orifices *m n*, *o p* with the same force, whether the orifice be horizontal or vertical, or in any degree inclined to the horizon; so that the pressure to which the fluid mass is subject, which in this case is its own gravity, must be distributed in every direction. But if the fluid has no weight, then the pressure exerted against the fluid at the orifice *o p*, by means of the piston B, will propagate itself through every part of the circular vessel EF, so that if the orifices *m n*, *t u* are shut, and *r s* open, the fluid would rush through this aperture in the same manner as it would rush through *m n* or *t u*, were all the other orifices shut. This proposition, however, is true only in the case of perfect fluids; for when there is a sensible cohesion between the particles, as in water, an equilibrium may exist even when a particle is less pressed in one direction than in another; but this inequality of pressure is so exceedingly trifling, that the proposition may be considered as true, even in cases of imperfect fluidity.

PROP. II.

Fig. 1.

33. If to the equal orifices *m n*, *t u*, *o p*, *r s* of a vessel, containing a fluid destitute of weight, be applied equal powers A, B, C, D, in a perpendicular direction, or if the orifices *m n*, &c. be unequal, and the powers A, B, &c. which are respectively applied to them be proportional to the orifices, these powers will be in equilibrio.

It is evident from the last proposition, that the pressure exerted by the power B is transmitted equally to the orifices *m n*, *r s*, *t u*, that the pressure of the power C is transmitted equally to the orifices *m n*, *o p*, *t u*, and so on with all the other powers. Every orifice then is influenced with the same pressure, and, consequently, none of the powers A, B, C, D, can yield to the action of the rest. The fluid mass, therefore, will neither change its form nor its situation, and the powers A, B, C, D will be in equilibrio. If the powers A, B, C, D are not equal to one another, nor the orifices *m n*, *o p*, *r s*, *t u*; but if A : B = *m n* : *o p*, and so on with the rest, the fluid will still be in equilibrio. Let A be greater than B, then *m n* will be greater than *o p*; and whatever number of times B is contained in A, so many times will *o p* be contained in *m n*. If A = 2 B, then *m n* = 2 *o p*, and since the orifice *m n* is double of *o p*, the pressure upon it must also be double; and, in order to resist that pressure, the power A must also be double of B; but, by hypothesis, A = 2B, consequently the pressures upon the orifices, or the powers A, B, will be in equilibrio. If the power A is any other multiple of B, it may be shewn in the same way that the fluid will be in equilibrio.

PROP. III.

34. The surface of a fluid influenced by the force of gravity and in equilibrio in any vessel, is horizontal, or at right angles to the direction of gravity.

The surface of fluids horizontal. Fig. 2.

Let the surface of the fluid be supposed to assume the waving form APEB. Any particle P in the surface of the fluid is influenced by the force of gravity, which may be represented by PS, and which may be decomposed into two forces P *m*, P *n* in the direction of the two elementary portions of the surface P *m*, P *n*, (see DYNAMICS, 148). But since the particle P is in a state of equilibrium, the force of gravity acting in the direction P *m*, P *n* must be destroyed by equal and opposite forces, exerted by the neighbouring particles against P in the direction *m* P, *n* P; therefore the forces P *m*, P *n* are equal to the forces *m* P, *n* P. Now the particle P being in equilibrio, must be equally pressed in every direction (32.). Wherefore the forces P *m*, P *n* are equal, and by the doctrine of the composition of forces (see DYNAMICS, 133. D), the angle *m* P *n* formed by the two elementary portions P *m*, P *n* of the surface of the fluid, must be bisected by PS, the line which represents the direction of gravity. The same may be proved of every other point of the surface of the fluid; and therefore this surface must be horizontal or perpendicular to the direction of gravity.

35. This proposition may be otherwise demonstrated. From the principles of mechanics, it is obvious, that when the centre of gravity of any body is at rest, the body itself is at rest; and that when this centre is not supported, the body itself will descend, till it is prevented by some obstacle from getting farther. In the same manner the centre of gravity of a fluid mass will descend to the lowest point possible; and it can be shewn that this centre will be in its lowest position when the surface of the fluid mass is horizontal. For let FGHI (fig. 2.) be any surface, whether solid or fluid, and C its centre of gravity, the point C is nearer the line HI when FG is parallel to HI and rectilineal, than when it has any other form or position. When the surface FGHI is suspended by the point C, or balanced upon it, it will be in equilibrio; but if the line F is made to assume any other form as F *r s t* G, by removing the portion G *o p* of the surface to *r s t*, the equilibrium

Fig. 2.

Pressure, &c. of Fluids.

equilibrium will be destroyed, and the side FG will preponderate. In order, therefore, to restore the equilibrium, the surface must be balanced on a point *c* farther from HI; that is, the centre of gravity of the surface F*rstop*IH is *c*. In the same way it may be shewn, that whatever be the form of the bounding line FG, the quantity of surface remaining the same, its centre of gravity will be nearest HI, when FG is rectilineal and parallel to it.—On the truth contained in this proposition depends the art of levelling, and the construction of the spirit level, for an account of which see LEVELLING.

36. As the direction of gravity is in lines which meet near the centre of the earth; and as it appears from this proposition, that the surface of fluids is perpendicular to that direction, their surface will be a portion of a spheroid similar to the earth. When the surface has no great extent, it may be safely considered as a plane; but when it is pretty large, the curvature of the earth must be taken into the account.

PROP. IV.

37. The surface of a fluid influenced by the force of gravity, and contained in any number of communicating vessels, however different in form and position, will be horizontal.

The surface of a fluid in any number of communicating vessels is horizontal. Fig. 3.

Let ABCDE be a system of communicating vessels into which a quantity of fluid is conveyed: It will rise to the same height in each vessel, and have a horizontal surface ABCDE. Suppose AGFE a large vessel full of water. By the last proposition, its surface ABCDE will be horizontal. Now, if any body be plunged into this vessel, the cylinder C for instance, the surface of the fluid will still be horizontal; for no reason could be assigned for the water's rising on one side of this body any more than on another. Let us now take out the cylinder C, and immerge into the fluid, successively, the solid bodies A *a*, B *b*, C *c*, D *d*, then after each immersion the surface will still be horizontal; and when all these solids are immerged, the large vessel AF will be converted into the system of communicating vessels represented in fig. 4.; in which the surface of the fluid will, of consequence, be horizontal.

Fig 4.

38. This proposition may be also demonstrated by supposing the parts A *a*, B *b*, C *c*, D *d*, converted into ice without changing their former magnitude. When this happens, the equilibrium will not be disturbed; and the fluid mass AF, whose surface was proved to be horizontal by the last proposition, will continue in the same state after the congelation of some of its parts. That is, the surface of the fluid in the communicating vessels A, B, C, D, E will be horizontal.

This proposition is not true when the communicating vessels are capillary tubes.

39. When the communicating vessels are so small that they may be regarded as capillary tubes, the surface of the fluid will not be horizontal. From the attraction which all fluids have for glass, they rise to a greater height in smaller tubes than in larger ones, and the quantity of elevation is in the inverse ratio of the diameters of the bores. In the case of mercury, and probably of melted metals, the fluid substance is depressed in capillary tubes, and the depression is subject to the same law. The subject of capillary attraction will be treated at length in a subsequent part of this article.

Pressure, &c. of Fluids.

40. This proposition explains the reason why the surface of small pools in the vicinity of rivers is always on a level with the surface of the rivers themselves, when there is any subterraneous communication between the river and the pool. The river and the pool may be considered as communicating vessels.

PROP. V.

41. If a mass of fluid contained in a vessel be in equilibrio, any particle whatever is equally pressed in every direction, with a force equal to the weight of a column of particles whose height is equal to the depth of the particle pressed below the surface of the fluid.

Immerse the small glass tube *mp*, into the vessel AB filled with any fluid; then if the tube is not of the capillary kind, the fluid will rise to *n* on the same level with the surface AB of the fluid in the vessel. Now it is evident, that the particle *p* at the bottom of the tube *mp* is pressed downwards by the superincumbent column of particles *np*, which is equal to the depth of the particle *p* below the surface of the fluid. But since the mass of fluid is in equilibrio, the particle *p* is pressed equally in every direction: Therefore, the particle *p* is pressed equally in every direction by a force equal to the superincumbent column *np*. Fig. 5.

PROP. VI.

42. A very small portion of a vessel of any form, filled with a fluid, is pressed with a force which is in the compound ratio of the number of particles contained in that surface, its depth below the surface of the fluid, and the specific gravity of the fluid.

Let D*p*EB be the vessel, and *rs* a very small portion of its surface, the pressure upon *rs* is in the compound ratio of the number of particles in *rs*, and *np* its depth below the horizontal surface DB. Suppose the glass tube *mp* to be inserted in the infinitely small aperture *p*, then, abstracting from the influence of capillary attraction, the fluid in the glass tube will ascend to *m* on a level with DB, the surface of the fluid in the vessel, and the particle *p* will be pressed with a column of particles, whose height is *np*. In the same way it may be shewn, that every other particle contained between *r* and *s* is pressed with a similar column. Then, since $p \times np$ will represent the pressure of the column *np* on the particle *p*; if N be the number of particles in the space *rs*, $N \times np$ will be the force of the column supported by the space *rs*. And as the weight of this column must increase with the specific gravity of the fluid, $S \times N \times np$ will represent its pressure, S being the specific gravity of the fluid.

PROP. VII.

43. The pressure upon a given portion of the bottom of a vessel, whether plane or curved, filled with any

Pressure, &c. of Fluids.

any fluid, is in the compound ratio of the area of that portion, and the *mean altitude* of the fluid, that is, the perpendicular distance of the centre of gravity of the given portion from the surface of the fluid; or, in other words, the pressure is equal to the weight of a column of fluid whose base is equal to the area of the given portion, and whose altitude is the mean altitude of the fluid.

Fig. 5. Let AEGB be the vessel, and AFB the surface of the fluid which it contains. Let GH be a given portion of its bottom, and C the centre of gravity of that portion: Then shall CF be the mean altitude of the fluid.—Conceive the portion GH to be divided into an infinite number of small elements Hh, Gg, &c. then (42.) the pressure sustained by the elements Hh, Gg, will be respectively $S \times Hh \times Hw$; $S \times Gg \times Gt$, &c. the specific gravity of the fluid being called S. But it follows from the nature of the centre of gravity, that the sum of all these products is equal to the product of the whole portion GH into CF the distance of its centre of gravity from the horizontal surface of the fluid (F). Therefore the pressure upon the portion GH is in the compound ratio of its surface converted into a plane, and the mean altitude of the fluid.

Hydrostatic paradox. 44. From this proposition we may deduce what is generally called the *Hydrostatic paradox*, viz. *that the pressure upon the bottoms of vessels filled with fluid does not depend upon the quantity of fluid which they contain, but upon its altitude*; or, in other words, *that any quantity of fluid, however small, may be made to balance any quantity or any weight, however great.* Fig. 6. Let ACOQRPDB be a vessel filled with water, the bottom QR will sustain the same pressure as if it supported a quantity of water equal to MQRN. It is evident (43.) that the part EF is pressed with the column of fluid ABEF, and that the part DG equal to CD is pushed upwards with the weight of a column equal to ABCD. Now, as action and reaction are equal and contrary, the part DG reacts upon FH with a force equal to the weight of the column ABCD, and FH evidently sustains the smaller column DGFH; therefore FH sustains a pressure equal to the weight of the two columns ABCD and DGFH, that is, of the column BIHF. In the same way it might be shewn, that any other equal portion of the bottom QR sustains a similar pressure; and therefore it follows, that the pressure upon the bottom QR is as great as if it supported the whole column MNQR.

Fig 1. 45. The same truth may be deduced from Prop. IV. For since the fluid in the two communicating vessels AB, CD will rise to the same level, whatever be their size, the fluid in AB evidently balances the fluid in CD; and any surface mn is pressed with the same force in the direction Bm by the small column AB, as it is pressed in the direction Dm by the larger column CD.

46. Cor. 1. From this proposition it follows that the whole pressure on the sides of a vessel which are perpendicular to its base, is equal to the weight of a rectangular prism of the fluid, whose altitude is that of the fluid, and whose base is a parallelogram, one side of which is equal to the altitude of the fluid, and the other to half the perimeter of the vessel. Corollaries.

Cor. 2. The pressure on the surface of a hemispherical vessel full of fluid, is equal to the product of its surface multiplied by its radius.

Cor. 3. In a cubical vessel the pressure against one side is equal to half the pressure against the bottom; and the pressure against the sides and bottom together, is to that against the bottom alone as three to one. Hence, as the pressure against the bottom is equal to the weight of the fluid in the vessel, the pressure against both the sides and bottom will be equal to three times that weight.

Cor. 4. The pressure sustained by different parts of the side of a vessel are as the squares of their depths below the surface; and if these depths are made the abscissa of a parabola, its ordinate will indicate the corresponding pressures.

Definition.

Definition.

47. The *centre of pressure* is that point of a surface exposed to the pressure of a fluid, to which if the total pressure were applied, the effect upon the plane would be the same as when the pressure was distributed over the whole surface: Or, it is that point to which if a force equal to the total pressure were applied in a contrary direction, the one would exactly balance the other, or, in other words, the force applied and the total pressure would be *in equilibrio*.

Prop. VIII.

48. The centre of pressure coincides with the centre of percussion.

Let AB be a vessel full of water, and CE the section of a plane whose centre of pressure is required. To find the centre of pressure. Prolong CE till it cuts the surface of the water in M. Take any point D, and draw DO, EP, CN perpendicular to the surface MP. Then if M be made the axis of suspension of the plane CE, the centre of percussion of

(F) This will be evident from the following proposition. *If every indefinitely small part of a surface be multiplied by its perpendicular distance from a given plane, the sum of the products will be equal to the product of the whole surface, multiplied by the perpendicular distance of its centre of gravity from the same plane.* In Plate CCLXIII. fig. 7. let a, c represent two weights suspended at their centre of gravity by the lines aA, cC attached to the horizontal plane of which ABC is a section, and let b be the common centre of gravity of these weights and bB the distance of this centre from the given plane, then $a \times aA + c \times cC = \overline{a+c} \times bB$.—Draw an, cm at right angles to bB. Then since b is the common centre of gravity of the weights a, c, we shall have by the similar triangles anb, cmb (Euclid VI. 4.) $nb : mb = (ba : bc =)\ c : a$ (See Mechanics, Centre of Gravity). Hence $a \times nb = c \times mb$, or $a \times \overline{nB - bB} = c \times \overline{bB - mB}$, or $a \times nb - a \times bB = c \times bB - c \times mB$; then by transposition, $a \times nb - c \times mB = a \times bB + c \times bB = \overline{a+C} + bB$. But $nB = aA$ and $mB = cC$, therefore, by substitution $a \times aA + c \times cC = \overline{a+c} \times bB$. By supposing the two weights a and c united in their common centre of gravity, the same demonstration may be extended to any number of weights.

Pressure, &c. of Fluids.

of the plane CE revolving round M will also be the centre of pressure. If MCE moves round M as a centre, and strikes any object, the percussive force of any point C is as its velocity, that is, as its distance CM from the centre of motion; therefore the percussive force of the points C, D, E, are as the lines CM, DM, EM. But the pressures upon the point C, D, E, are as the lines CN, DO, EP, and these lines are to one another as CM, DM, EM; therefore the percussive forces of the points C, D, E, are as the pressures upon these points. Consequently, the centre of pressure will always coincide with the centre of percussion.

SECT. II. *Instruments and Experiments for illustrating the Pressure of Fluids.*

Machine for illustrating the hydrostatic paradox.

49. WE have already shewn in art. 41. that the pressure upon the bottoms of vessels filled with fluids does not depend upon the quantity of fluid which they contain, but upon its particular altitude. This proposition has been called the Hydrostatical Paradox, and is excellently illustrated by the following machine. In fig. 1. AB is a box which contains about a pound of water, and *a b c d* a glass tube fixed to the end C of the beam of the balance, and the other end to a moveable bottom which supports the water in the box, the bottom and wire being of an equal weight with an empty scale hanging at the other end of the balance. If one pound weight be put into the empty scale, it will make the bottom rise a little, and the water will appear at the bottom of the tube *a*, consequently it will press with a force of one pound upon the bottom. If another pound be put into the scale, the water will rise to *b*, twice as high as the point *a*, above the bottom of the vessel. If a third, a fourth, and a fifth pound be put successively into the scale, the water will rise at each time to *c*, *d*, and *e*, the divisions *ab*, *bc*, *cd*, *de* being all equal. This will be the case, however small be the bore of the glass tube; and since when the water is at *b*, *c*, *d*, *e*, the pressures upon the bottom are successively twice, thrice, four times, and five times as great as when the water was contained within the box, we are entitled to conclude that the pressure upon the bottom of the vessel depends altogether on the altitude of the water in the glass tube, and not upon the quantity it contains. If a long narrow tube full of water, therefore, be fixed in the top of a cask likewise full of water, then though the tube be so small as not to hold a pound of the fluid, the pressure of the water in the tube will be so great on the bottom of the cask as to be in danger of bursting it; for the pressure is the same as if the cask was continued up in its full size to the height of the tube, and filled with water. Upon this principle it has been affirmed that a certain quantity of water, however small, may be rendered capable of exerting a force equal to any assignable one, by increasing the height of the column, and diminishing the base on which it presses. This, however, has its limits; for when the tube becomes so small as to belong to the capillary kind, the attraction of the glass will support a considerable quantity of the water it contains, and therefore diminish the pressure upon its base.

Plate CCLXIV. fig. 1.

The smallest quantity of water may exert a force equal to any assignable one.

Construction of the preceding machine. Fig. 2.

50. The preceding machine must be so constructed, that the moveable bottom may have no friction against the inside of the box, and that no water may get between it and the box. The method of effecting this will be manifest from fig. 2. where ABCD is a section of the box, and *a b c d* its lid, which is made very light. The moveable bottom E, with a groove round its edges, is put into a bladder *f g*, which is tied close around it in the groove, by a strong waxed thread. The upper part of the bladder is put over the top of the box at *a* and *d* all around, and is kept firm by the lid *a b c d*, so that if water be poured into the box through the aperture *l l* in its lid, it will be contained in the space *f* E *g h*, and the bottom may be raised by pulling the wire *i* fixed to it at E.

The upward pressure of fluids illustrated by the hydrostatic bellows. Figs. 3, 4, 5.

51. The upward pressure of fluids is excellently illustrated by the hydrostatic bellows. The form given to this machine by the ingenious Mr Ferguson (*Lectures*, vol. ii. p. 111.) is represented in fig. 3. where ABCD is an oblong square box, into one of whose sides is fixed the upright glass tube *a* I, which is bent into a right angle at the lower end as at *i*, fig. 4. To this bent extremity is tied the neck of a large bladder K, which lies in the bottom of the box. Over this bladder is placed the moveable board L, figs. 3. and 4. in which the upright wire M is fixed. Leaden weights NN, with holes in their centre, to the amount of 16 pounds, are put upon this wire, and press with all their weight upon the board L. The cross bar *p* is then put on, in order to keep the glass tube in an upright position; and afterwards the piece EFG for keeping the weights NN horizontal, and the wire M vertical. Four upright pins, about an inch long, are placed in the corners of the box, for the purpose of supporting the board L, and preventing it from pressing together the sides of the bladder. When the machine is thus fitted up, pour water into the tube I till the bladder is filled up to the board L. Continue pouring in more water, and the upward pressure which it will excite in the bladder will raise the board with all the weights NN, even though the base of the tube should be so small as to contain no more than an ounce of water.

Experiment for shewing that the pressure of fluids arises from their gravity, and is propagated in every direction.

52. That the pressure of fluids arises from their gravity, and is propagated in every direction, may be proved by the following experiment. Insert into an empty vessel, a number of glass tubes bent into various angles. Into their lower orifices introduce a quantity of mercury, which will rest in the longer legs on a level with these orifices. Let the vessel be afterwards filled with water; and it will be seen, while the vessel is filling, that the mercury is gradually pressed from the lower orifices towards the higher, where the water is prevented from entering. Now, in consequence of the various angles into which the glass tubes are bent, the lower orifices point to almost every direction; and therefore it follows, that the pressure of the superincumbent water is propagated in every direction. When a straight tube is employed to shew the upward pressure of fluids, the mercury which is introduced into its lower extremity must be kept in by the finger till the height of the water above the orifice is equal to fourteen times the length of the column of quicksilver: When the finger is removed the mercury will ascend in the tube.

Experiment for shewing that the superior strata press upon the inferior strata of fluids.

53. The pressure of the superior strata of fluids upon the interior strata may be shown in the following manner. Immerse two tubes of different bores, but not of the capillary kind, in a vessel of mercury. The mercury will rise in the tube on a level with its surface in

Pressure, &c. of Fluids.

in the vessel. Let water then be poured upon the mercury so as not to enter the upper orifices of the tubes, the pressure of the water upon the inferior fluid will cause the mercury to ascend in the tubes above the level of that in the vessel, but to the same height in both tubes. The columns of quicksilver in the two tubes are evidently supported by the pressure of the water on the inferior fluid. The same experiment may be made with oil and tinged water, the latter being made the inferior fluid.

Description of the syphon. *Fig. 6.*

54. The syphon is an instrument which shews the gravitation of fluids, and is frequently employed for decanting liquors. It is nothing more than a bent tube EABCF, having one of its legs longer than the other. The shorter leg BCF is immersed in the fluid contained in the vessel D; and if, by applying the mouth to the orifice E, the air be sucked out of the tube, the water in the vessel D will flow off till it be completely emptied. Now it is obvious that the atmosphere which has a tendency to raise the water in the shorter leg EB by its pressure on the surface of the water at C, has the same tendency to prevent the water from falling from the orifice E, by its pressure there, and therefore if the syphon had equal legs as AB, BC, no water could possibly issue from the orifice E. But when the leg EB is longer than BC, the column of fluid which it contains being likewise longer, will by its superior weight cause the water to flow from the orifice E, and the velocity of the issuing fluid will increase as the difference between the two legs of the syphon is made greater.

Experiment for shewing that the effect of the syphon depends on the gravitation of fluids. Fig. 7.

55. In order to shew that the effect of the syphon depends upon the gravitations of fluids, M. Pascal devised the following experiment. In the large glass vessel AB, fasten by means of bees wax two cylindrical cups *a*, *b*, containing tinged water, whose surface is about an inch higher in the one than in the other. Into the tinged water insert the legs of a glass syphon *c d*, having an open tube *e* fixed into the middle of it, and put a wooden cover on the vessel with a hole in its centre to receive the tube and keep it in a vertical position. Then through the funnel *f*, fixed in another part of the cover, pour oil of turpentine into the larger vessel till it flow into the cups *a*, *b*, and rise above the arch of the syphon. The pressure of the oil upon the tinged water in the cups will cause the water to pass through the syphon from the higher cup to the lower, till the surfaces of the water in both the cups be reduced to a level. In order to explain this, suppose a horizontal plane *e b* to pass through the legs of the syphon, and the tinged water in the cups, the parts of this plane within the legs when the syphon is full, will be equally pressed by the columns of tinged water *o e*, *d b* within the syphon; but the equal parts of this plane between the circumference of each leg of the syphon, and the circumference of each cylindrical cup, their diameters being equal, will sustain unequal pressures from their superincumbent columns, through the altitudes of these columns be equal. For since the pressure upon *e* is exerted by a column of oil *a c*, and a column of water *a e*, whereas the pressure upon *b* is exerted by a column of oil *h d*, and a column of water *h b*; the column *c e* which contains the greatest quantity of water, will evidently exert the greatest force, and by its pressure will drive the tinged water from the cup *a*, through the syphon *a c d* into the cup *b*, until a perfect equilibrium is obtained by an equality between the columns of water *a e* and *h b*.

Pressure, &c. of Fluids.

SECT. III. *Application of the Principles of Hydrostatics to the Construction of Dykes, &c. for resisting the pressure of water.*

DEFINITION.

Definition.

A dyke is an obstacle either natural or artificial, which opposes itself to the constant effort of water to spread itself in every direction.

Different ways in which a dyke may yield to the pressure of water. Fig. 8.

56. In discussing this important branch of hydraulic architecture, we must inquire into the thickness and form which must be given to the dyke in order to resist the pressure of the water. In this inquiry the dyke may be considered as a solid body which the water tends to overthrow by turning it round upon its posterior angle C; or it may be regarded as a solid, whose foundation is immoveable, but which does not resist the pressure of the water through the whole of its height, and which may be separated into horizontal sections by the efforts of the fluid. A dyke may be considered also as a solid body which can be neither broken nor overturned, but which may be pushed horizontally from its base, and can preserve its stability only by the friction of its base on the ground which supports it. On these conditions are founded the calculations in the following propositions which contain the most useful information that theory can suggest upon the construction of dykes.

PROP. I.

To find the dimensions of a dyke when the water tends to turn it round its posterior angle. Fig. 8.

57. To find the dimensions of a dyke which the water tends to overthrow by turning it round its posterior angle.

Let ABCD be the section of the dyke, considered as a continuous solid, or a piece of firm masonry, HK the level of the water which tends to overthrow it by turning it round its posterior angle C, supposed to be fixed, and let AC, BD, be right lines or known curves. It is required to determine CD the thickness which must be given to its base to prevent it from being overturned.

To the surface of the water HK draw the ordinates PM, *p m* infinitely near each other, and let fall from the points H and M the perpendiculars, HT, MX. Draw the horizontal line ML and raise the perpendicular CL, and suppose

HP	$= x$
PM	$= y$
P *p* or MV the fluxion of x	$= \dot{x}$
V *m* the fluxion of y	$= \dot{y}$
HT	$= a$
DT	$= b$
CD	$= z$
The momentum of the area ABCD, or the force with which it resists being turned round the fulcrum C	$= Z$
The specific gravity of water	$= s$
The specific gravity of the dyke	$= \sigma$

58. It is obvious from art. 41. that every element sustains a perpendicular pressure proportional to the height PM. Let RM perpendicular to M *m* represent the force

Pressure &c. of Fluids.

force exerted by the column of water $MmpP$, and let it be decomposed into two other forces, one of which RQ is horizontal, and has a tendency to turn the dyke round the point C, and the other RY is vertical and tends to press the dyke upon its base. The force RQ is evidently $= s\times y\times Mm$, (42.) and therefore the horizontal part of it will be only $sy\times Mm\times\frac{RQ}{RM}$. But the triangles RQM, MVm are evidently similar, consequently $RQ : RM = Vm : Mm$; hence $\frac{RQ}{RM}=\frac{Vm}{Mm}=\frac{\dot{y}}{Mm}$. Wherefore by substitution we have the force $RQ = sy\times Mm\times\frac{\dot{y}}{Mm}$, and dividing by Mm, we have $RQ = sy\dot{y}$. The force RQ, therefore, will always be the same as the force against Vm, whatever be the nature of the curve BD. Now the momentum of this force with relation to the fulcrum C, or its power to make the dyke revolve round C, is measured by the perpendicular CL let fall from the centre of motion to the direction in which the force is exerted (See MECHANICS), consequently this momentum will be $sy\dot{y}\times CL = sy\dot{y}\times\overline{a-y}$ (since $CL = HT - PM = a-y$) $= say\dot{y} - syy\dot{y}$, whose fluent is $\frac{sayy}{2}-\frac{sy^3}{3}$, which by supposing $y=a$ becomes $\frac{1}{6}sa^3$ for the total momentum of the horizontal effort of the water to turn the dyke round C. The vertical force RY or QM, which presses the dyke upon its base, is evidently $sy\times Mm\times\frac{MQ}{RM}$, but on account of the similar triangles $\frac{MQ}{RM}=\frac{\dot{x}}{Mm}$, consequently by substitution we shall have the force $RY = sy\times Mm\times\frac{\dot{x}}{Mm} = sy\dot{x}$, after division by Mm. The momentum, therefore, of the vertical force RY with relation to C, or its power to prevent the dyke from moving round the fulcrum C, will be $sy\dot{x}\times CX$; CX being the arm of the lever by which it acts, or the perpendicular let fall from the fulcrum upon the direction of the force. Now $CX = CD - DT + TX$ or HP, that is $CX = \overline{z-b+x}$, therefore the momentum of the force $RY = sy\dot{x}\times\overline{z-b+x}$, and the sum of the similar momenta from F to H will be the fluent $\int(\overline{z-b+x})sy\dot{x}$, the combined momentum of all the vertical forces which resist the efforts of the horizontal forces to turn the dyke round C. But the efforts of the horizontal forces are also resisted by the weight of the dyke whose momentum we have called Z, therefore σZ, σ being the specific gravity of the dyke, will be the momentum of the dyke. We have now three forces acting at once, viz. the horizontal force of the water striving to overturn the dyke, and the vertical force of the water combined with the momentum of the dyke, striving to resist its overthrow, therefore we shall have an equilibrium between these three forces, when the momentum of the horizontal forces is made equal to the momentum of the vertical forces, added to that of the dyke itself, consequently

$$\tfrac{1}{6}sa^3=\int(z-b+x)sy\dot{x}+\sigma Z.$$

59. As it is necessary, however, to give more stability to the dyke than what is just requisite to preserve its equilibrium, we must make its dimensions such as to resist a force greater than the horizontal forces, a force, for example, n times the momentum of the horizontal forces (G). The equation will therefore become

$$\text{(I.)}\quad n\times\tfrac{1}{6}sa^3=\int(z-b+x)sy\dot{x}+\sigma Z,$$

which comprehends every possible case of stability; for if we wish the stability of the dyke to have double the stability of equilibrium, we have only to make $n=2$. The preceding general equation is susceptible of a variety of applications according to the nature of the curves which form the sides of the dyke. It is at present worthy of remark that since the momentum of the horizontal forces is always the same whatever be the curvature of the sides AC, BD, and since the momentum of the vertical forces increases as the angle CDH diminishes, it follows that it will always be advantageous to diminish the angle CDH and give as much slope as possible to the sides of the dyke.

Equation containing the conditions of equilibrium on the supposition that the dyke may slide upon its base.

60. Let us now consider the conditions that may be necessary to prevent the dyke ABCD from sliding on its base CD. Since the base of the dyke is supposed horizontal, the force which the dyke opposes to the horizontal efforts of the water arises solely from the adhesion of the dyke to its base, and from the resistance of friction. These two forces, therefore, combined with the weight of the dyke, form the force which resists the horizontal efforts of the water; an equilibrium will consequently obtain when the three first forces are made equal to the last. But the force of adhesion, and the resistance of friction, being unknown, may be made equal to the weight of the dyke multiplied by the constant quantity m, which must be determined by experience. Now calling A the area of the section ABCD, we shall have σA for its weight, and $m\sigma A$ for the resistance which is opposed to the horizontal efforts of the water. But we have already seen that the horizontal forces of the water upon M are equal to $sy\dot{y}$, whose fluent $\frac{1}{2}sa^2$ (when $a=y$) is the sum of all the horizontal forces, consequently when an equilibrium takes place between these opposing forces we shall have

$$\text{(II).}\quad m\sigma A=\tfrac{1}{2}sa^2,\ \text{or}\ A=\frac{s}{\sigma}\times\frac{a^2}{2m}.$$

We might have added to the weight of the dyke the vertical pressure of the water, but it has been neglected for the purpose of having the dyke sufficiently strong to resist an additional force.

61. We

(G) The dimensions of the dyke would be sufficiently strong to resist any additional force by neglecting the term σZ, which represents the vertical pressure of the water tending to keep the dyke upon its base.

Form of the general equation when the sides of the dyke are rectilineal. Fig. 9.

61. We shall now proceed to inquire into the form which the general equation assumes when the sides of the dyke are rectilineal. Let AC, BD, fig. 9. be two lines inclined to the horizon under given angles ACD, BDC, and let AB, CD be two horizontal lines. Retaining the construction and symbols in art. 57. let fall AQ, BZ perpendicular to CD, and make $AQ=BZ=d$, $CQ=r$, and $DZ=r'$.

On account of the similar triangles HPM, FTH we shall have $a : b = y : x$, and therefore $x=\frac{by}{a}$. Substituting this value of x, instead of x in the general equation, art. 54. we have $\int(z-b+x)sy\dot{y}=\int\frac{sb}{a}\left(z-b+\frac{by}{a}\right)y\dot{y}=\frac{sbzyy}{2a}-\frac{sbbyy}{2a}+\frac{sbby^3}{3a^2}=$ (making $y=a$) $\frac{sbza}{2}-\frac{sb^2a}{6}$; now the momentum of the dyke ABCD with relation to C, is equal to the whole area of the dyke ABCD collected in its centre of gravity, and placed at the end of a lever whose length is the horizontal distance of that centre of gravity from the fulcrum C. But the area of $ABQZ=QZ\times ZB=\overline{z-r'-r}\times d$; the area of the triangle $ACQ=\frac{CQ\times QA}{2}=\frac{dr}{2}$, and the area of the triangle $BZD=\frac{DZ\times ZB}{2}=\frac{dr'}{2}$. Now the lever by which the area ABQZ collected in its centre of gravity F, acts upon the fulcrum, is evidently $=Cf=CQ+Qf=CQ+\frac{1}{2}QR=r+\frac{z-r'-r}{2}$, consequently the momentum by which the area ABCD resists the horizontal forces that conspire to give it a motion of rotation about C will be $=\overline{z-r'-r}\times d\times\overline{r+\frac{z-r'-r}{2}}$. The lever by which the triangle BZD acts, when collected in its centre of gravity I, is evidently Ci; but by the property of the centre of gravity $Di=\frac{2}{3}DZ=\frac{2r'}{3}$, hence $Ci=CD-Di=z-\frac{2r'}{3}$, consequently the energy of the triangle BZD to resist the efforts of the water acting horizontally will be $=\frac{dr'}{2}\times\overline{z-\frac{2r'}{3}}$. The lever of the triangle ACQ is plainly $Cs=\frac{2}{3}CQ=\frac{2r}{3}$, consequently the momentum of ACQ collected in its centre of gravity S will be $=\frac{dr}{2}\times\frac{2r}{3}$. Having thus found the momentum of the rectangle ABQZ, and of the triangles BZD, ACQ, the sum of these momenta will be the momentum R, with which the dyke opposes the horizontal efforts of the water, therefore we shall have

$$Z=\overline{z-r'-r}\times d\times\overline{r+\frac{z-r'-r}{2}}+\frac{dr'}{2}\times\overline{z-\frac{2r'}{3}}+\frac{dr}{2}\times\frac{2r}{3};$$

and by multiplication

$$Z=\frac{dzz}{2}-\frac{dr'z}{2}+\frac{dr'r'}{6}-\frac{drr}{6}.$$

By substituting this value of Z in the general equation in art. 54. we shall have

Resulting equation for finding the thickness of a dyke, when both its sides are rectilineal and inclined.

$$\text{(III.)}\ n\times\tfrac{1}{6}sa^3=\frac{sbza}{2}-\frac{sbba}{6}+\frac{\sigma dzz}{2}-\frac{\sigma dr'z}{2}+\frac{\sigma dr'r'}{6}-\frac{\sigma drr}{6},$$

a quadratic equation which will determine in general the base z of a dyke when its sides are rectilineal and inclined at any angle to the horizon.

Resulting equation when the posterior side of the dyke is vertical.

62. When the angle ACQ is a right angle, or when the posterior side AC of the dyke is perpendicular to the horizon, the quantity r becomes $=o$, and the last term of the preceding equation in which r appears will vanish, consequently the equation will now become

$$\text{(IV.)}\ n\times\tfrac{1}{6}sa^3=\frac{sbza}{2}-\frac{sbba}{6}+\frac{\sigma dzz}{2}-\frac{\sigma dr'z}{2}+\frac{\sigma dr'r'}{6}.$$

Resulting equation when both sides of the dyke are vertical.

63. When the angles ACQ and BDZ are both right, the dyke becomes rectangular, with its sides perpendicular to its base. In this case both r and r' become each $=o$, and therefore all the terms in which they are found will vanish. In this case too $DT=b$ becomes $=o$, and therefore the terms in which it appears will likewise vanish. The general equation will now become

$$\text{(V.)}\ n\times\tfrac{1}{6}sa^3=\frac{\sigma dzz}{2}\ \text{a pure quadratic.}$$

Application of the formulæ.

64. In order to shew the application of the preceding formulæ, and at the same time the advantages of inclining the sides of the dyke, let us suppose the depth of the water and also the height of the dyke to be 18 feet, so that B will coincide with H. Let us also suppose, what is generally the case in practice, that the declivity of the sides is $\frac{1}{6}$ of their altitude, that is $DZ=CQ=\frac{1}{6}BZ$. Let the specific gravity of the dyke be to that of water as 12 to 7; and suppose it is wished to make the stability of the dyke twice as great as the stability of equilibrium, that is, to make it capable of resisting a force twice as great as that which it really sustains. Then, upon these conditions, we shall have $BZ=HT$ or $a=d=18$ feet; $CQ=DZ=DT$, or $r'=r=b=3$ feet; $s=7$; $\sigma=12$, and $n=2$. By substituting these numerical values in the general equation N° III. it becomes

$$zz-\frac{45}{36}z=\frac{4599}{39}\ \text{feet};$$

a quadratic equation which after reduction will give $z=12$ feet nearly. When $z=12$, the area of the dyke ABCD will be 162 square feet.

Advantages of inclining the sides of the dyke.

65. Let us now suppose the sides of the dyke to be vertical, the equation N° V. will give us $z=11$ feet 2 inches, which makes the area of the dyke more than 201 square feet. The area of the dyke with inclined sides

Pressure, &c. of Fluids.

sides is therefore to its area with vertical sides nearly as 4 to 5: and hence we may conclude that a dyke with inclined sides has the same stability as a dyke with vertical sides; while it requires $\frac{1}{5}$ less materials.

Prop. II.

To find the dimensions of the dyke when the water tends to separate it into horizontal sections or laminæ.

66. To find the dimensions of a dyke which can neither slide upon its base, nor turn round its posterior angle; but which is composed of horizontal sections which may be separated from each other.

In solving this proposition we must find the curvature of the side exposed to the pressure of the water, which will make all the different sections or horizontal laminæ equally capable of resisting the different forces which tend to separate them. If the lamina NM does not resist the column PM, which partly presses it in the direction MN as powerfully as the lamina *nm* resists the horizontal pressure of the column *pm*, the lamina NM is in danger of being separated from the lamina *nm*. But if all the laminæ NM, *nm* resist with equal force the horizontal effects of the water, and if the dyke cannot be made to slide upon its base nor turn round its posterior angle T, it cannot possibly yield to the pressure of the water; for it is impossible to separate one lamina from another, unless the one opposes a less resistance than the other. To simplify the investigation as much as possible, let us suppose the posterior side of the dyke to be vertical, and the depth of the water to be equal to the height of the dyke.

Fig. 10.

67. Let ABC be the section of the dyke, AK the surface of the water, AC the curvature required, AB its posterior side; MN *nm* a horizontal lamina infinitely small, in the direction of which the dyke has a tendency to break in consequence of the efforts of the water upon AM.

If the dyke should break in the direction MN, the superior part AMN will detach itself from the inferior part MNBC, by moving from M towards N; and at the moment when the impulse takes place it will have a small motion of rotation round the point N. We must therefore determine the forces which act upon the lamina MN *nm*, and form an equation expressing their equilibrium round the point N. The forces alluded to are evidently, 1. The horizontal efforts of the water; 2. The vertical efforts of the water; 3. The weight of the part AMN; and, 4. The adhesion of the two surfaces MN, *mn*. Of these four forces the first is the only one which has a tendency to overthrow the portion AMN of the dyke; and its efforts are resisted by the three other forces. In order to find the momenta of these forces with regard to the point N let us suppose

Enumeration of the forces which act upon the dyke.

AP=NM	$=x$
PM	$=y$
The specific gravity of water	$=s$
The specific gravity of the dyke	$=r$

Then we shall have,

Momentum of these forces.

1. The momentum of the horizontal forces of the water will be $=\frac{1}{6}sy^3$, by the same reasoning that was employed in art. 57.

2. The momentum of the part AMN of the dyke will be $=r\int x\dot{y}$ the area of the surface AMN, multiplied by the distance of its centre of gravity from the fulcrum N, which is equal to $\dfrac{\frac{1}{2}\int x x\dot{y}}{\int x\dot{y}}$. See MECHANICS.

68. In order to simplify the calculus, and at the same time increase the stability of the dyke, we shall neglect the vertical force of the water, and the adhesion of the two surfaces MN, *mn*. The only forces therefore which we have to consider, are the horizontal efforts of the water acting against the momentum of the superior part AMN. By making an equilibrium between these forces we shall have the following equation

$$\frac{1}{6}sy^3 = r\int x\dot{y}\times\frac{\frac{1}{2}\int x x\dot{y}}{\int x\dot{y}} = \frac{1}{2}r\times\int x x\dot{y}$$

By taking the fluxion we have

$\frac{3}{6}sy^2\dot{y} = \frac{1}{2}r\times x x\dot{y}$. Dividing by $\dot{y}$ we have

$\frac{1}{2}sy^2 = \frac{1}{2}r\times x^2$, which by reduction becomes

$y = \sqrt{\frac{r}{s}}\times x$.

The line AMC therefore is rectilineal, and the base BC is to the altitude BA as $\sqrt{s}:\sqrt{r}$; that is, as the square root of the specific gravity of the water is to the square root of the specific gravity of the dyke.

Equation containing the conditions of equilibrium on the supposition that the dyke may slide upon its base.

69. In order to prevent the superior portion AMN from sliding on its base MN, we must procure an equilibrium between the adhesion of the surfaces MN, *mn* and the horizontal force exerted by the water. Now the sum of all the horizontal forces exerted by the water is (by art. 58.) $\frac{1}{2}sy^2$, and the adhesion may be represented by some multiple *m*, of its weight, the constant quantity *m* being determined by experience. The adhesion will therefore be $m\times r\int x\dot{y}$, and the equation of equilibrium will be

$\frac{1}{2}sy^2 = m\times r\int x\dot{y}$, the fluxion of which is

$sy\dot{y} = m\times r x\dot{y}$ Dividing by $\dot{y}$ we have

$sy = mrx$, and therefore

$x:y = s:mr$.

Hence the base BC of the dyke is to its altitude BA as the specific gravity of water is to a multiple *m* of the specific gravity of the dyke, *m* being a constant quantity which experiments alone can determine.

In a work by the Abbé Bossut and M. Viallet, entitled *Recherches sur la Construction la plus advantageuse des Digues*, the reader will find a general solution of the preceding problem, in which the vertical efforts of the water and the adhesion of the surfaces are considered. This able work, which we have followed in the preceding investigation, contains much practical information on the construction of dykes of every kind; and may be considered as a continuation of the second part of Belidor's *Architecture Hydraulique*.

CHAP.

Of Specific Gravities.

Chap. II. *Of Specific Gravities.*

Definition.

Specific gravity defined.

70. The absolute weights of different bodies of the same bulk are called their *specific gravities* or *densities*; and one body is said to be *specifically heavier*, or *specifically lighter* than another, when under the same bulk it contains a greater or less quantity of matter. Brass, for example, is said to have eight times the specific gravity of water, because one cubic inch of brass contains eight times the quantity of matter, or is eight times heavier than a cubic inch of water.

Prop. I.

71. Fluids pressing against each other into two or more communicating vessels, will be in equilibrio when the perpendicular altitudes above the level of their junction are in the inverse ratio of their specific gravities.

Plate CCLXV. fig. 1.

If a quantity of mercury be poured into the vessel FMN, it will be in equilibrio when it rises to the same level AHIB in both tubes. Take away an inch of mercury ACDH, and substitute in its room $13\frac{1}{2}$ inches of water FCDG. Then since mercury is $13\frac{1}{2}$ times heavier than water, $13\frac{1}{2}$ inches of water will have the same absolute weight as one inch of mercury, and the equilibrium will not be disturbed; for the column of water FD will exert the same pressure upon the surface CD of the mercury, as the smaller column of mercury did formerly. The surface of the mercury, therefore, will remain at IB: now, since AB, CE, are horizontal lines, AC will be equal to LK; but FC was made $13\frac{1}{2}$ times AC, therefore FC$=13\frac{1}{2}$ times IK, that is FC : IK$=13\frac{1}{2}:1$, the ratio between the specific gravities of mercury and water.

Construction of the barometer.

72. On this proposition depends the theory of the barometer. Let a quantity of mercury be introduced into the tube FMN, and let the pressure of the atmosphere be removed from the surface IB; the pressure of the air upon the other surface CD will be the same as if the tube PD were continued to the top of the atmosphere, and therefore, instead of the column of water FD we have a column of air equal to the height of the atmosphere acting against the mercury CDMIB; the mercury consequently will rise towards N, so that its height will be to the height of the atmosphere as the specific gravity of air is to the specific gravity of mercury; but as the density of the air diminishes as it recedes from the earth, we must take the specific gravity of the air at a mean height in the atmosphere. It is obvious from the proposition, that the altitude of the column of mercury which balances the column of air must be reckoned from CD the level of their junction; and that, when the specific gravity of the air is diminished, the mercury will fall, and will again rise when it regains its former density.

Prop. II.

Bodies immersed in a fluid are pressed upwards with a force equal to the weight of the quantity of fluid displaced.

73. If any body is immersed in a fluid, or floats on its surface, it is pressed upwards with a force equal to the weight of the quantity of fluid displaced.

Demonstration when a parallelopiped is immersed in the fluid. Fig. 2.

Let mH be the section of a body immersed in the vessel AB filled with a fluid. Any portion $m\,n$ of its upper surface is pressed downwards by the column of fluid C$m\,n$D (43.); but the similar portion EF of its lower surface is pressed upwards with a column of fluid equal to CEFD, therefore the part EF is pressed upwards with the difference of these forces, that is, with a force equivalent to the column of fluid mEFn, for CEFD—C$m\,n$D$=m$EFn. In the same way it may be shewn, that the remaining part FH is pressed upwards with a force equal to the weight of a column nFHo; and therefore it follows, that the rectangle mEHo is pressed upwards with a force equivalent to a column mEHo, that is, to the quantity of fluid displaced.

When the parallelopiped floats in the fluid. Fig. 3.

74. If the body floats in the fluid like CH in the vessel AB (fig. 3.) the same consequence will follow; for the body CH is evidently pressed upwards with a force equivalent to the column mEHo, that is, to the part immersed or the quantity of fluid displaced. Now as the same may be demonstrated of every other section of a solid parallelopiped, we may conclude, that the proportion is true with respect to every solid whose section is rectangular.

When the solid has any other form. Fig. 4.

75. When the solid has any other form as CD, however irregular, we may conceive its section to be divided into a number of very small rectangles $n\,o$: then (41.) the small portion of the solid at n is pressed downwards by a column of particles $m\,n$, and the small portion at o is pressed upwards by a column of particles equal to $n\,o$; therefore the differences of these forces, viz. the column $n\,o$, is the force with which the portion o is pressed upward. In the same manner it can be shewn, that every other similar portion of the lower surface of the solid CD is pressed upwards with a force equal to a column of particles whose height is equal to the vertical breadth of the solid; but all these columns of particles must occupy the same space as the solid itself, therefore any solid body immersed in a fluid, or floating on its surface, is pressed upwards with a force equal to the weight of the quantity of fluid displaced.

The weight of a floating body is equal to the weight of the quantity of fluid displaced.

76. Cor. 1. When a body floats in a fluid, the weight of the quantity of fluid displaced is equal to the weight of the floating solid. For since the solid is in equilibrium with the fluid, the force which causes it to descend must be equal to the force which presses it upward; but the force which keeps a part of the solid immerged in the fluid is the weight of the solid, and the force which presses the solid upward, and prevents it from sinking, is equivalent to the weight of the quantity of fluid displaced (73.); therefore these forces and the weights to which they are equivalent must be equal.

77. Cor. 2. A solid weighed in a fluid loses as much of its weight as is equal to the weight of the quantity of fluid displaced; for since the body is pressed upwards with a force equal to the weight of the fluid displaced (3.), this pressure acts in direct opposition to the natural gravity or absolute weight of the solid, and therefore diminishes its absolute weight by a quantity equal to the weight of the fluid displaced. The part of the weight thus lost is not destroyed: It is only sustained by a force acting in a contrary direction.

78. Cor. 3. A solid immersed in a fluid will sink, if its specific gravity exceed that of the fluid: It will

float

Of Specific Gravities.

float on the surface, partly immersed, if its specific gravity be less than that of the fluid; and it will remain wholly immersed wherever it is placed, if the specific gravities of the solid and fluid are equal. In the first case, the force with which the solid is pressed downwardly exceeds the upward pressure, and therefore it must sink. In the second case, the upward pressure exceeds the pressure downwards, and therefore the body must float; and, in the third case, the upward and downward pressures being equal, the solid will remain wherever it is placed.

79. Cor. 4. The specific gravities of two or more fluids are to one another as the losses of weight sustained by the same solid body, and specifically heavier than the fluids, when weighed in each fluid respectively. The solid in this case displaces equal quantities of each fluid; but the losses of weight are respectively as the absolute weights of the quantities displaced (Cor. 2.), therefore the specific gravities, which are as the absolute weights of equal quantities of any body (70.), must be as the losses of weight sustained by the immersed solid.

80. Cor. 5. The specific gravity of a solid is to that of a fluid as the absolute weight of the solid is to the loss of weight which it sustains when weighed in the fluid. For since the loss of weight sustained by the solid is equal to the absolute weight of the quantity of fluid displaced, or of a quantity of fluid of the same bulk as the solid, the specific gravities, which (70.) are in the ratio of the absolute weights of equal volumes, must be as the absolute weight of the solid to the less weight which it sustains.

81. Cor. 6. The specific gravity of a solid floating in a fluid, is to the specific gravity of the fluid itself, as the bulk of the part immersed is to the total bulk of the solid.

82. Cor. 7. Bodies which sustain equal losses of weight are of the same bulk. For, since the losses of weight are as the weights of the quantities of fluid displaced, and as the quantities displaced are as the bulks of the solids which displace them, the bulks must be equal when the losses of weight are equal.

The preceding corollaries deduced from an equation of equilibrium.

83. The preceding corollaries may be expressed algebraically, and may be deduced from a general equation in the following manner. Let B be the total bulk of a floating body, and C the part of it which is immersed; let S be the specific gravity of the solid, and s that of the fluid. Then it is obvious, that the absolute weight of the solid will be expressed by $B\times S$, and the absolute weight of the fluid displaced by $C\times s$; for the fluid displaced has the same bulk as the part of the solid which is immersed. In order that an equilibrium may obtain between the solid and fluid, we must have $B\times S=C\times s$: Now, when $s>S$, we have $B>C$, so that the solid will float, which is the second case of Cor. 3.—When $S=s$ we have $B=C$, which is the third case of Cor. 3.—When $S>s$ we have $C>B$, that is, the body will sink below the surface; and it will descend to the bottom, for it cannot be suspended in the fluid without some power to support it; and if such a power were necessary, we should have $B\times S>C\times s$, which is contrary to the equation of equilibrium.

84. From the equation $B\times S=C\times s$ we have (Euclid VI. 16.) $S : s=B : C$, which is Cor. 6.—When the body is completely immersed we have $B=C$, in which case the equation becomes $B\times S=B\times s$; and when the solid is specifically heavier than the fluid, it will require a counterweight to keep the solid suspended in the fluid. Let W be the counterweight necessary for keeping the solid suspended in the fluid, then in the case of an equilibrium the equation will be $B\times s+W=B\times S$, or $B\times S-W=B\times s$, or $S\times \overline{B\times S-W}=S\times B\times s$, whence (Euclid VI. 16.) $S : s=B\times S : B\times S-W$, which is Cor. 5.

85. If the same solid body is plunged in a second fluid of a different specific gravity from the first let σ be the specific gravity of the second fluid, and w the counterweight necessary to keep the solid suspended in it. The equation for the first fluid was $B\times s+W=B\times S$ (84.), and the equation for the second fluid will be $B\times\sigma+w=B\times S$; therefore we shall have, by the first equation $S\times B-W=s\times B$, and by the second $S\times B-w=\sigma\times B$, and consequently $s\times B : \sigma\times B=S\times B-W : S\times B-w$, or (Euclid V. 16.) $s : \sigma=S\times B-W : S\times B-w$, which is Cor. 4.; for the losses of weight in each fluid are evidently represented by $\overline{S\times B-W}$ and $\overline{S\times B-w}$.

86. If B and b express the bulks of two solids, S and s their specific gravities, σ the specific gravity of the fluid, and W, w the counterweights which keep them in equilibrium with the fluid. Then with the solid S the equation will be $S\times B-W=\sigma\times B$ (85.); and with the solid s the equation will be $s\times b-w=\sigma\times b$. Wherefore, if the two solids sustain equal losses of weight, we shall have $S\times B-W=s\times b-w$, since each side of the equation represents the loss of weight sustained by each solid respectively. Consequently, $\sigma\times B=\sigma\times b$, and dividing by σ, we have $B=b$, which is corollary 7.

Method of detecting adulteration in metals.

87. From the preceding proposition and its corollaries, we may deduce a method of detecting adulteration in the precious metals, and of resolving the problem proposed to Archimedes, by Hiero king of Syracuse. Take a real guinea, and a counterfeit one made of copper and gold. If the latter be lighter than the former, when weighed in a pair of scales, the imposition is instantly detected: But should their weight be the same, let the two coins be weighed in water, and let the loss of weight sustained by each be carefully observed, it will then be found that the counterfeit will lose more of its weight than the unadulterated coin. For, since the specific gravity of copper exceeds that of gold, and since the absolute weights of the coins were equal, the counterfeit guinea must be greater in bulk than the real one, and will therefore displace a greater quantity of water, that is (77.), it will lose a greater part of its weight.

Problem proposed by Hiero to Archimedes.

88. Hiero, king of Syracuse, having employed a goldsmith to make him a crown of gold, suspected that the metal had been adulterated, and inquired at Archimedes if his suspicions could be verified or disproved without injuring the crown. The particular method by which Archimedes detected the fraud of the goldsmith is not certainly known; but it is probable that he did it in the following manner. A quantity of gold, of the same absolute weight as the crown, would evidently have the same bulk also, if the crown were pure gold, and would have a greater bulk if the crown were made

Of Specific Gravities.

made of adulterated gold. By weighing, therefore, the quantity of gold and the crown in water, and observing their respective losses of weight, Archimedes found that the crown lost more of its weight than the quantity of gold; and therefore concluded, that as the crown must have displaced a greater portion of water than the piece of gold, its bulk must likewise have been greater, and the metal adulterated of which it was composed.

Prop. III.

89. If two immisceable fluids, of different specific gravities, and a solid of an intermediate specific gravity, be put into a vessel, the part of the solid in the lighter fluid will be to the whole solid, as the difference between the specific gravities of the solid and the heavier fluid, is to the difference between the specific gravities of the two fluids.

Fig. 5.

Let AB (fig. 5.) be the vessel which contains the two fluids, suppose mercury and water, and the solid CD. The mercury being heavier than water will sink to the bottom and have $m\,n$ for its surface, and the water will occupy the space AB $m\,n$. The solid having a greater specific gravity than water, will sink in the water (78.); but having a less specific gravity than mercury, it will float in the mercury. It will, therefore, be suspended in the fluids, having one portion C in the water, and the other portion D in the mercury. Now let S be the specific gravity of the mercury, s the specific gravity of the water, σ that of the solid, C the part of the solid in the water, and D the part of the mercury. Then the bulk of the solid is C+D, and its weight $\sigma \times \overline{C+D}$: The quantity of water displaced by the part C, or the loss of weight sustained by the part C, will be $C \times s$; and the quantity of mercury displaced, or the loss of weight sustained by part D, will be $D \times S$. But as the solid is suspended in the fluids, and therefore in equilibrio with them, the whole of its weight is lost. Consequently, the part of its weight which is lost in the water, added to the part lost in the mercury, must be equal to its whole weight, that is, $\overline{C \times s} + \overline{D \times S} = \sigma \times \overline{C+D}$, or $s\,C + SD = \sigma C + \sigma D$. Transposing $\sigma\,C$ and SD, we have $s\,C - \sigma\,C = SD - \sigma\,D$, or $C \times \overline{s-\sigma} = D \times \overline{S-\sigma}$, and (Euclid VI. 16.) $C : D = \overline{s-\sigma} : \overline{S-\sigma}$. Then, by inversion and composition (Euclid V. Propositions B and 18.) $C : \overline{C+D} = \overline{S-\sigma} : \overline{S-s}$. Q. E. D.

90. Cor. 1. From the analogy $C : D = \overline{s-\sigma} : \overline{S-\sigma}$, we learn that the part of the solid in the heavier fluid, is to the part in the lighter fluid, as the difference between the specific gravities of the solid and the lighter fluid, is to the difference between the specific gravities of the solid and the heavier fluid.

91. Cor. 2. When s is very small compared with S, we may use the analogy $C : C+D = \sigma : s$, though in cases where great accuracy is necessary this ought not to be done. When the specific gravity of a body, lighter than water, is determined by comparing the part immersed with the whole body, there is evidently a small error in the result; for the body is suspended partly in water and partly in air. It is in fact a solid of an intermediate specific gravity floating in two immiscible fluids, and therefore its specific gravity should be ascertained by the present proposition.

Prop. IV.

92. If two bodies, whether solid or fluid, be mixed together so as to form a compound substance, the bulk of the heavier is to the bulk of the lighter ingredient, as the difference between the specific gravities of the compound, and the lighter ingredient, is to the difference between the specific gravities of the compound and the heavier ingredient.

To find the bulk of the ingredients, their specific gravities and that of the compound being given.

Let S and s be the specific gravities of the two ingredients, σ the specific gravity of the compound, and B, b the bulks of the ingredients; then the bulk of the compound will be $B+b$, and its weight $\sigma \times \overline{B+b}$. The weight of the ingredient B will be $B \times S$, and that of the other ingredient $b \times s$; and as the weight of the compound must be equal to the weight of its ingredients, we have the following equation. $\sigma\,b + \sigma\,B = BS + b\,s$, and by transposing $\sigma\,b$ and BS, we shall have $B\,\sigma - BS = b\,s - b\,\sigma$, or $B \times \overline{\sigma - S} = b \times \overline{s-\sigma}$; therefore (Euclid VI. 16.) $B : b = \overline{s-\sigma} : \overline{\sigma - S}$. Q. E. D.

A compound mass, whether solid or fluid, is sometimes greater in bulk than the sum of the bulks of its ingredients.

93. In the preceding proposition, it has been taken for granted that the magnitude of the compound is exactly equal to the sum of the magnitudes of the two ingredients. This, however, does not obtain universally either in fluids or solids; for an increase or diminution of bulk often attends the combination of two different ingredients. A cubical inch of alcohol, for example, combined with a cubical inch of water, will form a compound which will measure less than two cubical inches; and a cubical inch of tin, when incorporated in a fluid state with a cubical inch of lead, will form a compound, whose bulk will exceed two cubical inches. The preceding proposition, however, is, even in these cases, of great use in ascertaining the increase or decrease of bulk sustained by the compound, by comparing the computed with the observed bulk. See *Specific Gravity*.

Prop. V. Problem.

94. How to determine the specific gravities of bodies whether solid or fluid.

To determine the specific gravities of solids and fluids.

The simplest and most natural way of finding the specific gravities of bodies would be to take the absolute weights of a cubic inch, or any other determinate quantity, of each substance; and the number thus found would be their specific gravities. But as it is difficult to form two bodies of the very same size, and often impossible, as in the case of precious stones, to give a determinate form to the substance under examination, we are obliged to weigh them in a fluid, and deduce their specific gravities from the losses of weight which they severally sustain. Water is a fluid which is always employed for this purpose, not only because it can be had without difficulty, but because it can be procured of the same temperature, and of the same density, in every part of the world. The specific gravity of water is always called 1.000, and with this, as a standard, the specific gravity of every other substance is compared. Thus, if a

Of Specific Gravities.

a certain quantity of water weighed four pounds, and a similar quantity of mercury 56 pounds. the specific gravity of the mercury would be called 14, because as $4 : 56 = 1 : 14$. In order, therefore, to determine the densities of bodies, we have occasion for no other instrument than a common balance with a hook fixed beneath one of its scales. When fitted up in this way, it has been called the *hydrostatic balance*, which has already been described under the article BALANCE, *Hydrostatical*.

Hydrostatic balance.

To find the specific gravity of a solid heavier than water.

95. *When the substance is heavier than its bulk of water.*—Suspend the solid by means of a fine silver wire to the hook beneath the scale, and find its weight in air. Fill a jar with pure distilled water, of the temperature of 62° of Fahrenheit's thermometer, and find the weight of the solid when immersed in this fluid. The difference of these weights is the loss of weight sustained by the solid. Then, (80.) as the loss of weight is to the weight of the solid in air, so is 1.000 the specific gravity of water to a fourth proportional, which will be the specific gravity of the solid. But as the third term of the preceding analogy is always 1.000, the fourth proportional, or density of the solid, will always be had by dividing the weight of the solid in air by its loss of weight in water. If the solid substance consists of grains of platina or metallic filings, place it in a small glass bucket. Find the weight of the bucket in air, when empty, and also its weight when it contains the substance. The difference of these weights will be the weight of the substance in air. Do the very same in water, and its weight in water will be had. Its specific gravity will then be found as formerly.—If the body is soluble in water, or so porous as to absorb it, it should be covered with varnish or some unctuous substance. When it is weighed in water, it should never touch the sides of the glass jar, and it must be carefully freed from any bubbles of air that happen to adhere to it.

To find the specific gravity of a solid lighter than water.

96. *When the substance is lighter than its bulk of water.*—Fasten to it another solid heavier than water, so that they may sink together. Find the weight of the denser body, and also of the compound body, both in air and in water; and by subtracting their weight in water from their weight in air, find how much weight they have severally lost. Then say as the difference between their losses of weight is to the weight of the light body in air, so is 1.000 to the specific gravity of the body.

To find the specific gravity of powders.

97. *When the substance is a powder which absorbs water, or is soluble in it.*—Place a glass phial in one scale, and counterpoise it by weights in the other. Fill this phial with the powder to be examined; and having rammed it as close as possible to the very top, find the weight of the powder. Remove the powder from the phial, and fill it with distilled water, and find its weight. The weight of the powder, divided by the weight of the water, will be the specific gravity of the former.

To find the specific gravity of fluids.

98. *When the substance is a fluid*, its specific gravity may be determined very accurately by the method in the preceding article, or by the following method deduced from article 79.—Take any solid specifically heavier than water, and the given fluid. Find the loss of weight which it sustains in water, and also in the given fluid. Then, since the specific gravities are as the losses of weight sustained by the same solid, the specific gravity of the fluid required will be found by dividing the loss of weight sustained by the solid in the given fluid, by the loss of weight which it sustains in water.

SECT. II. *On the Hydrometer.*

Hydrometer invented by Hypathia.

99. In order to determine, with expedition, the strength of spirituous liquors, which are inversely proportional to their specific gravities, an instrument more simple, though less accurate, than the hydrostatic balance, has been generally employed. This instrument is called a *hydrometer*, sometimes an *areometer* and *gravimeter*, and very erroneously a *hygrometer* by some foreign authors. It seems to have been invented by Hypathia, the daughter of Theon Alexandrinus, who flourished about the end of the fourth century; though there is some foundation for the opinion that the invention is due to Archimedes.

Fahrenheit's hydrometer. Fig. 6.

100. The hydrometer of Fahrenheit, which is one of the simplest that has been constructed, is represented in fig. 6. and may be formed either of glass or metal. AB is a cylindrical stem, and C, D two hollow balls appended to it. Into the lower ball D is introduced a quantity of mercury, sufficient to make the ball C sink to F, a little below the surface of distilled water. If this apparatus be plunged into a fluid lighter than water, the ball C will sink farther below the surface; and if it be immersed in a heavier fluid, it will rise nearer the surface. In this way we can tell whether one fluid is more or less dense than another. But in order to determine the real specific gravities of the fluids, the hydrometer must either be loaded with different weights, or have a scale AB engraven on its stem. The former of these methods was employed by Fahrenheit. Having placed some small weights on the top A, he marked any point E, to which the instrument sunk in distilled water. By weighing the instrument thus loaded, he found the weight of a quantity of water equal to the part immersed (76.). When the hydrometer was placed in a fluid denser than water, he loaded it with additional weights till it sunk to the same point E. The weight of the hydrometer being again found, gave him the weight of a quantity of the denser fluid equal to the part immersed; but as the part immersed was the same in both cases, the weights of the hydrometer were equal to the absolute weights of equal quantities of the two fluids; and consequently the specific gravities of the water and the other fluid were in the ratio of these weights. When the fluid, whose density is required, has less specific gravity than water, some of the weights are to be removed from the top A till the instrument sinks to E; and the density of the fluid to be determined as before.—Instead of making the weight of the hydrometer variable, it is more simple, though less accurate, to have a scale of equal parts upon the stem AB. In order to graduate this scale, immerse the hydrometer in distilled water, at the temperature of 60° Fahrenheit, so that it may sink to B near the bottom of the stem, which may be easily effected, by diminishing or increasing the quantity of mercury in the ball D. At B place the number 1.000, which shows that every fluid, in which the hydrometer sinks to B, has its specific gravity 1.000, or that of distilled water. The hydrometer is then to be plunged in another fluid less dense than water, suppose oil, whose specific gravity

Hydrometer with weights.

Hydrometer with an engraved scale.

Of Specific Gravities.

vity may be .900, and the point A marked, to which it sinks. Every fluid, therefore, in which the hydrometer sinks to A, has its specific gravity .900; and if the scale AB be divided into equal parts, every intermediate degree of specific gravity between .900 and 1.000 will be marked. If the scale AB be divided into four parts in the points E, F, G, the fluid in which the hydrometer sinks to G will have .975 for its specific gravity; the specific gravity of that in which it sinks to F will be .950, and so on with the other points of division. If it is required to extend the range of the instrument, and to make it indicate the densities of fluids specifically lighter than water, we have only to load it in such a manner as to make it sink to the middle of the scale F in distilled water; and by taking two fluids, between whose densities the specific gravity of every other fluid is contained, excepting mercury and metals in a fluid state, to determine, as before, the extremities of the scale.

Theorem for hydrometers in which the weight is variable. Fig. 6.

101. When the weight of the hydrometer is variable, let E be the point to which it sinks in two different fluids; and let W be the absolute weight necessary to make it sink to E in the denser fluid, and $W \pm p$ the weight necessary to make it sink to the same point in the lighter fluid. Let S, s be the specific gravities of the two fluids, and V the volume of the part of the hydrometer that is constantly immersed. Then (83.) $W = S \times V$, $W \pm p = s \times V$. From the first equation we have, $V = \frac{W}{S}$, and from the second equation $V = \frac{W \pm p}{s}$, consequently $\frac{W \pm p}{s} = \frac{W}{S}$, and by reduction $s = \frac{s \times \overline{W \pm p}}{W}$. Thus, by knowing W and the weight p, and also S the specific gravity of one of the fluids, which will be 1.000 if that fluid be water, we can find s the specific gravity of the other fluid.

Theorem for hydrometers in which the weight is constant.

102. When the weight of the hydrometer is constant, and the density of the fluid indicated by the depth to which it descends, let F, E be the points to which it sinks in two different fluids, whose specific gravities are S, s, W the absolute weight of the hydrometer, V the volume of the part immersed when the hydrometer has sunk to E, and v its volume when sunk to F. Then (83.), we have $W = S \times V$, and $W = s \times v$, consequently $s \times v = S \times V$, and $s = \frac{S \times V}{v}$. If the absolute weight W, therefore, of the hydrometer be known, and also the volumes V, v, and the specific gravity S of one of the fluids, which may be water, the specific gravity of the other fluid may be determined by the preceding formula. When the figure of the hydrometer is regular, the volumes V, v, may be determined geometrically; but as the instrument is generally of an irregular form, the following method should be employed.

Description of various hydrometers.

103. The hydrometers of Clarke and Desaguliers differ so little from those which have now been described, that they are not entitled to a more particular description. The hydrometer invented by Mr William Jones of Holborn, is a simple and accurate instrument, and requires only three weights to discover the strengths of spirituous liquors from alcohol to water. Like other instruments of the same kind, it is adjusted to the temperature of 60° of Fahrenheit; but as every change of temperature produces a change in the specific gravity of the spirits, Mr Jones found it necessary to attach a thermometer to the instrument, and thus make a proper allowance for every variation of temperature. Almost all bodies expand with heat and contract with cold; and as their volume becomes different at different temperatures, their specific gravities must also (70.) be variable, and will diminish with an increase of temperature. M. Homberg, and M. Eisenschmed found that the absolute weight of a cubic inch of brandy was four drams 42 grains in winter, and only four drams 32 grains in summer, and that the difference in spirits of nitre was still greater. It has been found, indeed, upon an average, that 32 gallons of spirits in winter will expand to 33 gallons in summer. As the strength of spirituous liquors is inversely as their specific gravities, they will appear much stronger in summer than in winter. This change in their strength had been formerly estimated in a rough way; but by the application of the thermometer, and by adjusting its divisions experimentally, Mr Jones has reduced it to pretty accurate computation. It has already been stated (93.) that where two substances are combined, the magnitude of the compound body is sometimes greater and sometimes less than the sum of the magnitudes of the two ingredients, and that this mutual penetration particularly happened in the mixture of alcohol and water. In strong spirits, this concentration is sometimes so great, as to produce a diminution of four gallons in the 100; for if to 100 gallons of spirit of wine found by the hydrometer to be 66 gallons in the 100 over proof, you add 66 gallons of water to reduce it to proof, the mixture will consist only of 162 gallons instead of 166 of proof spirits. This mutual penetration of the particles of alcohol and water has also been considered in Mr Jones's hydrometer, which we shall now describe with greater minuteness.

Jones's hydrometer.

Plate CCLXV. fig. 7.

104. In fig. 7. the whole instrument is represented with the thermometer attached to it. Its length AB is about $9\frac{1}{2}$ inches: the ball C is made of hard brass, and nearly oval, having its conjugate diameter about $1\frac{1}{4}$ inches. The stem AD is a parallelopiped, on the four sides of which the different strengths of spirits are engraved: the three sides which do not appear in fig. 7. are represented in fig. 8. with the three weights numbered 1, 2, 3, corresponding with the sides similarly marked at the top. If the instrument when placed in the spirits sinks to the divisions on the stem without a weight, their strength will be shewn on the side AD marked *o* at the top, and any degree of strength from 74 gallons in the 100 to 47 in the 100 above proof, will thus be indicated. If the hydrometer does not sink to the divisions without a weight, it must be loaded with any of the weights 1, 2, 3, till the ball C is completely immersed. If the weight N° 1 is necessary, the side marked 1 will show the strength of the spirits, from 46 to 13 gallons in the 100 above proof. If the weight N° 2 is employed, the corresponding side will indicate the remainder of overproof to *proof*, marked P in the instrument, and likewise every gallon in 100 under proof, down to 29. When the weight N° 3 is used, the side similarly marked will show any strength from 30 gallons in the 100 under proof, down to water; which is marked W in the scale. The small figures as 4 at 66, $3\frac{1}{2}$ at 61, $2\frac{1}{2}$ at 48 (fig. 7.) indicate the diminution

Fig. 8.

of

Of Specific Gravities.

of bulk which takes place when water is mixed with spirits of wine in order to reduce it to proof: thus, if the spirit be 61 gallons in the 100 over proof, and if 61 gallons of water are added in order to render it proof, the magnitude of the mixture will be $3\frac{1}{7}$ gallons less than the sum of the magnitudes of the ingredients, that is, instead of being 161 it will be only $157\frac{1}{7}$ gallons. The thermometer F connected with the hydrometer, has four columns engraved upon it, two on one side as seen in the figure, and two on the other side. When any of the scales upon the hydrometer, marked 0, 1, 2, 3, are employed, the column of the thermometer similarly marked must be used, and the number at which the mercury stands carefully observed. The divisions commence at the middle of each column which is marked *o*, and is equivalent to a temperature of 60 degrees of Fahrenheit; then, whatever number of divisions the mercury stands above the zero of the scale, the same number of gallons in the 100 must the spirit be reckoned weaker than the hydrometer indicates, and whatever number of divisions the mercury stands below the zero, so many gallons in the 180 must the spirit be reckoned stronger.

Dicas's hydrometer with a sliding rule.

105. The patent hydrometer invented by Mr Dicas of Liverpool, possesses all the advantages of that which has now been described, but is superior to it in regard to the accuracy with which it estimates the aberration arising from a change of temperature. It is constructed in the common form, with 36 different weights, which are valued from 0 to 370, including the divisions on the stem; but the chief improvement consists in an ivory sliding rule which accompanies the instrument. In order to understand the construction of this sliding rule the reader must have recourse to the instrument itself.

Quin's universal hydrometer.

106. Quin's universal hydrometer is constructed in such a manner, as to ascertain, with the greatest expedition, the strength of any spirit from alcohol to water, and also the concentration and specific gravity of each different strength. With the assistance of four weights, it discovers likewise the gravity of worts, and is therefore of more universal use than any other hydrometer. The instrument is represented in fig. 9. with the four sides of its stem graduated and marked at the top so as to correspond with the weights below. The side of the stem marked A, B, C, D, &c. to Z, shows the strength of any spirit from alcohol to water, and the three other sides numbered 1, 2, 3. are adapted for worts. The variation of density arising from the contraction and dilatation of the fluid is determined by means of a sliding rule, differing very little from that of Mr Dicas. In order to use this instrument, place any of the weights, if necessary, on the stem at C; find the temperature of the spirit by a thermometer, and bring the star on the sliding rule to the degree of heat on the thermometer's scale: then opposite to the number of the weight and the letter on the stem, you have the strength of the spirit pointed out on the sliding rule, which is lettered and numbered in the same way as the instrument and weights. In ascertaining the strength of worts, the weight N° 4 is always to continue on the hydrometer, and the weights, N° 1, 2, 3, are adapted to the sides N° 1, 2, 3, of the square stem, which point out the exact gravity of the worts.

Plate CCLXV. fig. 9.

Nicholson's hydrometer.

107. A considerable improvement on the hydrometer has lately been made by Mr Nicholson, who has rendered it capable of ascertaining the specific gravities both of solids and fluids. In fig. 10. F is a hollow ball of copper attached to the dish AA by a stem B, made of hardened steel. To the lower extremity of the ball is affixed a kind of iron stirrup FF, carrying another dish G of such a weight as to keep the stem vertical when the instrument is afloat. The parts of the hydrometer are so adjusted, that when the lower dish G is empty, and the upper dish AA contains 1000 grains, it will sink in distilled water at the temperature of 60° of Fahrenheit, so that the surface of the fluid may cut the stem DB at the point D. In order to measure the specific gravities of fluids, let the weight of the instrument, when loaded, be accurately ascertained. Then, this weight is equal to that of a quantity of distilled water at the temperature of 60°, having the same volume as that part of the instrument which is below the point D of the stem. If the hydrometer, therefore, is immersed to the point D in any other fluid of the same temperature, which may be done by increasing or diminishing the weights in the dish AA, the difference between this last weight and 1000 grains will express the difference between equal bulks of water and the other fluid. Now as the weight of the mass of water is equal to the weight of the instrument, which may be called W, the above-mentioned difference or D must be either added to or subtracted from W, (according as the weight in the dish AA was increased or diminished) in order to have the weight of an equal bulk of the fluid; then $W \pm D$ will be to W as the specific gravity of the given fluid is to that of water. This ratio will be expressed with considerable accuracy, as the cylindrical stem of the instrument being no more than $\frac{1}{40}$th of an inch in diameter, will be elevated or depressed nearly an inch by the subtraction or addition of $\frac{1}{10}$ of a grain, and will, therefore, easily point out any changes of weight, not less than $\frac{1}{10}$ of a grain, or $\frac{1}{81000}$ of the whole, which will give the specific gravities to five places of figures. The solid bodies whose specific gravities are to be determined by this hydrometer, must not exceed 1000 grains in weight. For this purpose, immerse the instrument in distilled water, and load the upper dish till the surface of the water is on a level with the point D of the stem. Then, if the weight required to produce this equilibrium be exactly 1000 grains, the temperature of the water will be 60° of Fahrenheit; but if they be greater or less than 1000 grains, the water will be colder or warmer. After noting down the weight necessary for producing an equilibrium, unload the upper dish, and place on it the body whose specific gravity is required. Increase the weight in the upper dish, till the instrument sinks to the point D, and the difference between this new weight and the weight formerly noted down will be the weight of the body in air. Place the body in the lower dish G, and add weights in the upper dish till the hydrometer again sinks to D. This weight will be the difference between 1000 grains and the weight of the body in water; and since the weight of the body in air, and its weight in water, are ascertained, its loss of weight will be known, and consequently its specific gravity (80.).

Fig. 10.

De Parcieux's areometer.

108. The areometer or hydrometer of M. de Parcieux consists of a small glass phial EG, about two inches in diameter

Plate CCLXVI. fig. 6.

Of Specific Gravities.

diameter and seven inches long, having its bottom as flat as possible. The mouth is closed with a cork stopper, into which is inserted a straight iron or brass wire EF, about a line in diameter, and 30 inches long. When two fluids are to be compared, the bottle is loaded in such a manner by the introduction of small shot, that the instrument, when plunged in the lightest of the fluids, sinks so deep as to leave only the extremity of the wire above its surface, while in the heaviest fluid, the wire is some inches below the surface. The same effect may be produced by fixing a little dish F to the top of the wire, and varying the weights, or by altering the thickness of the wire. The areometer thus constructed, will indicate the smallest differences of specific gravity, and such minute variations of density, arising from a change of temperature, which would be imperceptible by any other hydrometer. The motion of an instrument of this kind, says Montucla, was so sensible, that when immersed in water of the usual temperature, it sunk several inches while the rays of the sun fell upon the water, and instantly rose when his rays were intercepted. In one of the areometers used by Deparcieux, an interval of six lines in the stem corresponded to a change of density about $\frac{1}{15043}$ of the whole. (*Mem. de l'Acad. Paris* 1766, p. 158.).

Plate CCLXVI. fig. 1.

Wilson's hydrometer.

109. In order to determine the strength of spirits with the greatest expedition, Professor Wilson of Glasgow employed a very simple method. His hydrometer consists of a number of glass beads, the specific gravities of each of which vary in a known ratio. When the strength of any spirit is to be tried, the glass beads, which are all numbered, are to be thrown into it. Some of those whose specific gravity exceeds that of the spirit, will sink to the bottom, while others will swim on the top, or remain suspended in the fluid. That which neither sinks to the bottom nor swims on the surface, will indicate by its number the specific gravity of the spirits (78.). For an account of the Patent Beads constructed by Mrs Lovi of Edinburgh, in all respects the most accurate apparatus for this purpose, see note under *Spirituous Liquors*.

Sect. III. *On Tables of Specific Gravities.*

Table of specific gravities.

110. As the knowledge of the specific gravities of bodies is of great use in all the branches of mechanical philosophy, we have given the following table, published in the enlarged edition of Ferguson's Lectures, 2d edition. It comprehends the greater part of Brisson's tables, and is one of the most extensive that has yet been published. The names of the minerals, as given in Kirwan's Mineralogy, have in general been adopted; and such as have been discovered since the publication of that work will be found in later works. When the specific gravities of any substance, as determined by different authors, seem to be at variance, the different results are frequently given, and the names of the chemists prefixed by whom these results were obtained. The substances in the table have, contrary to the usual practice, been disposed in an alphabetical order. This was deemed more convenient for the purposes of reference, than if they had been divided into classes, or arranged according to the order of their densities.

Table of Specific Gravities.

Chap. III. *On Capillary Attraction, and the Cohesion of Fluids.*

Fluids do not rise to the same level in a system of communicating vessels when their diameters are very minute.

111. We have already seen, when discussing the equilibrium of fluids, that when water or any other fluid is poured into a vessel, or any number of communicating vessels, its surface will be horizontal, or it will rise to the same height in each vessel, whatever be its form or position. This proposition, however, only holds true when the diameter of these vessels or tubes exceeds the fifteenth of an inch: for if a system of communicating vessels be composed of tubes of various diameters, the fluid will rise to a level surface in all the tubes which exceed one-fifteenth of an inch in diameter; but in the tubes of a smaller bore, it will rise above that level to altitudes inversely proportional to the diameters of the tubes. The power by which the fluid is raised above its natural level is called *capillary attraction*, and the glass tubes which are employed to exhibit its phenomena are named *capillary tubes*. These appellations derive their origin from the Latin word *capillus*, signifying a hair, either

2

Capillary Attraction, &c.

either because the bores of these tubes have the fineness of a hair, or because that substance is itself supposed to be of a tubular structure.

112. When we bring a piece of clean glass in contact with water or any other fluid, except mercury and fused metals, and withdraw it gently from its surface, a portion of the fluid will not only adhere to the glass, but a small force is necessary to detach this glass from the fluid mass, which seems to resist any separation of its parts. Hence it is obvious that there is an attraction of cohesion between glass and water, and that the constituent particles of water have also an attraction for each other. The suspension of a drop of water from the lower side of a plate of glass is a more palpable illustration of the first of these truths; and the following experiment will completely verify the second. Place two large drops of water on a smooth metallic surface, their distance being about the tenth of an inch. With the point of a pin unite these drops by two parallel canals, and the drops will instantly rush to each other through these canals, and fill the dry space that intervenes. This experiment is exhibited in fig. 2. where AB is the metallic plate, C, D the drops of water, and m, n the two canals.

There is an attraction of cohesion between glass and water, and between the particles of water.

Plate CCLXVI. fig. 2.

113. Upon these principles many attempts have been made to account for the elevation of water in capillary tubes; but all the explanations which have hitherto been offered, are founded upon hypothesis, and are very far from being satisfactory. Without presuming to substitute a better explanation in the room of those which have been already given, and so frequently repeated, we shall endeavour to illustrate that explanation of the phenomena of capillary attraction which seems liable to the fewest objections. For this purpose let E be a drop of water laid upon a clean glass surface AB. Every particle of the glass immediately below the drop E, exerts an attractive force upon the particles of water. This force will produce the same effect upon the drop as a pressure in the opposite direction, the pressure of a column of air, for instance, on the upper surface of the drop. The effect of the attractive force, therefore, tending to press the drop to the glass will be an enlargement of its size, and the water will occupy the space FG; this increase of its dimensions will take place when the surface AB is held downwards; and that it does not arise from atmospheric pressure may be shown by performing the experiment *in vacuo*. Now let AB (fig. 2.) be a section of the plate of glass AB (fig. 3.) held vertically, part of the water will descend by its gravity, and form a drop B, while a small film of the fluid will be supported at m by the attraction of the glass. Bring a similar plate of glass CD into a position parallel to AB, and make them approach nearer and nearer each other. When the drops B and D come in contact, they will rush together from their mutual attraction, and will fill the space op. The gravity of the drops B and D being thus diminished, the film of water at m and n which was prevented from rising by their gravity will move upwards. As the plates of glass continue to approximate, the space between them will fill with water, and the films at m and n being no longer prevented from yielding to the action of the glass immediately below them (by the gravity of the water at op, which is diminished by the mutual action of the fluid particles) will rise higher in proportion to the approach of the plates. Hence it may be easily understood how the water rises in capillary tubes, and how its altitude is inversely as their internal diameters. For let A, a be the altitudes of the fluid in two tubes of different diameters D, d; and let C, c be the two cylinders of fluid which are raised by virtue of the attraction of the glass. Now, as the force which raises the fluid must be as the number of attracting particles, that is, as the surface of the tube in contact with the water, that is, as the diameter of the tubes, and as this same force must be proportional to its effects on the cylinder of water raised, we shall have $D : d = C : c$. But (GEOMETRY, Sect. VIII. Theor. XI. Sect. IX. Theor. II.) $C : c = D^2A : d^2a$, therefore $D^2A : d^2a = D : d$; hence $D^2A\,d = d^2aD$, and $DA = \frac{d^2aD}{Dd}$, or $DA = da$, that is, $D : d = a : A$, or the altitudes of the water are inversely as the diameters of the tubes. Since $DA = d\,a$, the product of the diameter by the altitude of the water will always be a constant quantity. In a tube whose diameter is 0.01, or $\frac{1}{100}$ of an inch, the water has been found to reach the altitude of 5.3 inches; hence the constant quantity $5.3 \times 0.1 = 0.053$ may fitly represent the attraction of glass for water. According to the experiments of Muschenbroek, the constant quantity is 0.039; according to Weitbrecht 0.0428; according to Monge 0.042, and according to Atwood 0.0530. When a glass tube was immersed in melted lead, Gellert found the depression multiplied by the bore to be 0.0054.

Attempt to account for the rise of water in capillary tubes. Fig. 2.

Fig. 5.

Capillary Attraction, &c.

The altitudes of fluids in capillary tubes are inversely as their diameters.

114. Having thus attempted to explain the causes of capillary action, we shall now proceed to consider some of its most interesting phenomena. In fig. 4. MN is a vessel of water in which tubes of various forms are immersed. The water will rise in the tubes A, B, C to different altitudes m, n, o, inversely proportional to their diameters. If the tube B is broken at a, the water will not rise to the very top of it at a, but will stand at b, a little below the top, whatever be the length of the tube or the diameter of its bore. If the tube be taken from the fluid and laid in a horizontal position, the water will recede from the end that was immersed. These two facts seem to countenance the opinion of Dr Jurin * and other philosophers, that the water is elevated in the tube by the attraction of the annulus, or ring of glass, *immediately above* the cylinder of water. This hypothesis is sufficiently plausible; but supposing it to be true, the ring of glass immediately below the surface of the cylinder of fluid should produce an equal and opposite effect, and therefore the water instead of rising should be stationary, being influenced by two forces of an equal and opposite kind.

Phenomena of capillary attraction. Fig. 4.

Jurin's hypothesis.

* Phil. Trans. N° 363. art. 2.

115. If a tube D composed of two cylindrical tubes of different bores be immersed in water with the widest part downwards, the water will rise to the altitude p, and if another tube E of the same size and form be plunged in the fluid with the smaller end downwards, the water will rise to the same height q as it did in the tube D. This experiment seems to be a complete refutation of the opinion of Dr Jurin, that the water is raised by the action of the annulus of glass above the fluid column; for since the annular surface is the same at q as at p, the same quantity of fluid ought to be supported in both tubes, whereas the tube E evidently raises

Phenomena of capillary attraction.

Capillary Attraction, &c.

raises much less water than D. But if we admit the supposition in art. 113. that the fluid is supported by the whole surface of glass in contact with the water, the phenomenon receives a complete explanation; for since the surface of glass in contact with the fluid in the tube E is much less than the surface in contact with it in the tube D, the quantity of fluid sustained in the former ought to be much less than the quantity supported in the latter.

Phenomena of capillary attraction.

116. When a vessel F $v w$ is plunged in water, and the lower part $t u v w$ filled by suction till the fluid enter the part F t, the water will rise to the same height as it does in the capillary tube G, whose bore is equal to the bore of the part F t. In this experiment the portions of water $t v x$ and $u x w$ on each side of the column F x are supported by the pressure of the atmosphere on the surface of the water in the vessel MM; for if this vessel be placed in the exhausted receiver of an air-pump, these portions of water will not be sustained. Dr Jurin, indeed, maintains that these portions will retain their position *in vacuo*, but in his time the exhausting power of the air-pump was not sufficiently great to determine a point of so great nicety. The column $t u x$, which is not sustained by atmospherical pressure, is kept in its position by the attraction of the water immediately around and above it, and the column F $t u$ is supported by the attraction of the glass surface with which it is in contact. According to Dr Jurin's hypothesis, the column $t u x$ is supported by the ring of glass immediately above r, which is a very unlikely supposition.

Fig. 4.

Hypothesis of Dr Hamilton and Dr Matthew Young.

117. The preceding experiment completely overturns the hypothesis of Dr Hamilton, afterwards revived by Dr Matthew Young. These philosophers maintained that the fluid was sustained in the tube by the lower ring of glass contiguous to the bottom of the tube, that this ring raises the portion of water immediately below it, and then other portions successively till the portion of water thus raised be in equilibrium with the attraction of the annulus in question. But if the elevation of the fluid were produced in this way, the quantity supported would be regulated by the form and magnitude of the orifice at the bottom of the tube; whereas it is evident from every experiment, that the cylinder of fluid sustained in capillary tubes has no reference whatever to the form of the lower annulus, but depends solely upon the diameter of the tube immediately above the elevated column of water.

The capillary phenomena take place in the exhausted receiver of an air-pump.

118. If the experiments which we have now explained be performed in the exhausted receiver of an air-pump, the water will rise to the same height as when they are performed in air. We may therefore conclude, that the ascent of the water is not occasioned, as some have imagined, by the pressure of the atmosphere acting more freely upon the surface of the water in the vessel than upon the column of fluid in the capillary tube.

Experiments of Mr B. Martin on the ascent of different fluids in capillary tubes.

119. It appears from the following table constructed by Mr B. Martin, that different fluids rise to very different heights in capillary tubes, and that spirituous liquors, whose specific gravity is less than that of water, are not raised to the same altitude. Mr Martin's experiments were made with a tube about $\frac{1}{25}$ of an inch in diameter. He found that when capillary tubes charged with different fluids were suspended in the sun for months together, the enclosed fluid was not in the least degree diminished by evaporation.

120. To the preceding table as given by Mr Martin we have added the constant number for each fluid, or the product of the altitude of the liquid, and the diameter of the tube (art. 115.). By this number, therefore, we can find the altitude to which any of the preceding fluids will rise in a tube of a given bore, or the diameter of the bore when the altitude of the fluid is known; for since the constant number $C=DA$ (art. 113.) we shall have $D=\frac{C}{A}$ and $A=\frac{C}{D}$. Since the constant number, however, as deduced from the experiments of Martin, may not be perfectly correct, it would be improper to derive from it the diameter of the capillary bore when great accuracy is necessary. The following method, therefore, may be adopted as the most correct that can be given. Put into the capillary tube a quantity of mercury, whose weight in troy grains is W, and let the length L of the tube which it occupies be accurately ascertained; then if the mercury be pure and at the temperature of 60° of Fahrenheit, the diameter of the tube $D=\sqrt{\frac{W}{L}}\times 0.019241$, the specific gravity of mercury being 13.580. The weight of a cubic inch of mercury being 3438 grains, and the solid content of the mercurial column being $D^2L\times 0.7854$, we shall have $1:3438=D^2L\times 0.7854:W$. Hence (GEOMETRY, Sect. IV. Theor. VIII.) $D^2L\times 0.7854\times 3438=W$, and dividing we have $D^2=\frac{W}{L\times 0.7854\times 3438}$

Method of measuring the internal diameter of a capillary tube.

$$\text{or } D=\sqrt{\frac{W}{L\times 0.7854\times 3438}} \text{ or } D=\sqrt{\frac{W}{L}}\times 0.019241.$$

If the whole tube be filled with mercury, and if W be the difference in troy grains between its weight when empty, *Capillary Attraction, &c.*

empty, and when filled with mercury, the same theorem will serve for ascertaining the diameter of the tube. Should the temperature of the mercury happen to be 32° of Fahrenheit, its specific gravity will be 13.619, which will alter a very little the constant multiplier 0.019241.

The motion of water in capillary tubes accelerated by electricity and by heat.

121. When water is made to pass through a capillary tube of such a bore that the fluid is discharged only by successive drops; the tube, when electrified, will furnish a constant and accelerated stream, and the acceleration is proportional to the smallness of the bore. A similar effect may be produced by employing warm water. Mr Leslie found that a jet of warm water rose to a much greater height than a jet of cold water, though the water in both cases moved through the same aperture, and was influenced by the same pressure. A syphon also which discharged cold water only by drops, yielded warm water in an invariable stream.

On the ascent of fluids between two inclined plates of glass.

122. Such are the leading phenomena of capillary tubes. The rise of fluids between two plates of glass remains to be considered; and while it furnishes us with a very beautiful experiment, it confirms the reasoning by which we have accounted for the elevation of fluids in cylindrical canals. Let ABEF and CDEF be two pieces of plate glass with smooth and clean surfaces, having their sides EF joined together with wax, and their sides AB, CD kept a little distance by another piece of wax W, so that their interior surfaces, whose common intersection is the line EF, may form a small angle. When this apparatus is immersed in a vessel MN full of water, the fluid will rise in such a manner between the glass panes as to form the curve D $q\,o\,m$ E, which represents the surface of the elevated water. By measuring the ordinates $m\,n$, $o\,p$, &c. of this curve, and also its abscissæ F n, F p, &c. Mr Hawksbee found it to be the common Apollonian hyperbola, having for its assymptotes the surface DF of the fluid, and EF the common intersection of the two planes. To the very same conclusion we are led by the principles already laid down; for as the distance between the plates diminishes at every point of the curve D $q\,o\,m$ E from D towards E, the water ought to rise higher at o than at q, still higher at m, and highest of all at E, where the distance between the plates is a minimum. To illustrate this more clearly, let ABEF and CDEF be the same plates of glass, (inclined at a greater angle for the sake of distinctness) and let E $m\,q$ D, and E $o\,s$ B be the curves which bound the surface of the elevated fluid. Then, since the altitudes of the water in capillary tubes are inversely as their diameters or the distances of their opposite sides, the altitudes of the water between two glass plates, should at any given point be inversely as the distances of the plates at that point. Now, the distance of the plates at the point m is obviously $m\,o$, or its equal $n\,p$, and the distance at q is $q\,s$ or $r\,t$; and since $m\,n$ is the altitude of the water at m, and $q\,r$ its altitude at q, we have $m\,n : q\,r = n\,p : r\,t$; but (Geometry, Sect. IV. Theor. XVII.) $\mathrm{F}\,n : \mathrm{F}\,r = n\,p : r\,t$; therefore $m\,n : q\,r = \mathrm{F}\,n : \mathrm{F}\,r$, that is, the altitudes of the fluid at the points m, q, which are equal to the abscissæ F n, F r (fig. 5.) are proportional to the ordinates $q\,r$, $m\,n$, equal to F n, F r, in fig. 5. But in the Apollonian hyperbola the ordinates are inversely proportional to their respective abscissæ, therefore the curve D $q\,o\,m$ E is the common hyperbola.—As the plates are infinitely near each other at the apex E, the water will evidently rise to that point, whatever be the height of the plates.

Plate CCLXVI. fig. 5.

Fig. 6.

123. The phenomena which we have been endeavouring to explain, are all referable to one simple fact, that the particles of glass have a stronger attraction for the particles of water than the particles of water have for each other. This is the case with almost all other fluids except mercury, the particles of which have a stronger attraction for each other than for glass. When capillary tubes therefore are plunged in this fluid, a new series of phenomena present themselves to our consideration. Let MN (fig. 7.) be a vessel full of mercury. Plunge into the fluid the capillary tube CD, and the mercury, instead of rising in the tube, will remain stationary at E, its depression below the level surface AB being inversely proportional to the diameter of the bore. This was formerly ascribed to a repulsive force supposed to exist between mercury and glass, but we shall presently see that it is owing to a very different cause.

Mercury descends in capillary tubes.

Fig. 7.

Mercury has a stronger attraction for its own particles than for glass.

124. That the particles of mercury have a very strong attraction for each other, appears from the globular form which a small portion of that fluid assumes, and from the resistance which it opposes to any separation of its parts. If a quantity of mercury is separated into a number of minute parts, all these parts will be spherical; and if two of these spheres be brought into contact, they will instantly rush together, and form a single drop of the same form. There is also a very small degree of attraction existing between glass and mercury; for a globule of the latter very readily adheres to the lower surface of a plate of glass. Now suppose a drop of water laid upon a surface anointed with grease, to prevent the attraction of cohesion from reducing it to a film of fluid, this drop, if very small, will be spherical. If its size is considerable, the gravity of its parts will make it spheroidal, and as the drop increases in magnitude, it will become more and more flattened at its poles, like AB in fig. 8. The drop, however, will still retain its convexity at the circumference, however oblate be the spheroid into which it is moulded by the force of gravity. Let two pieces of glass o A m, p B n, be now brought in contact with the circumference of the drop; the mutual attraction between the particles of water which enabled it to preserve the convexity of its circumference, will yield to their superior attraction for glass; the space m, n, o, p, will be immediately filled; and the water will rise on the sides of the glass, and the drop will have the appearance of A B in fig. 9. If the drop AB fig. 8. be now supposed mercury instead of water, it will also, by the gravity of its parts, assume the form of an oblate spheroid; but when the pieces of glass o A m, p B n are brought close to its periphery, their attractive force upon the mercurial particles is not sufficient to counteract the mutual attraction of these particles; the mercury therefore retains its convexity at the circumference, and assumes the form of AB in fig. 10. The small spaces o, p being filled by the pressure of the superincumbent fluid, while the spaces m, n, still remain between the glass and the mercury. Now if the two plates of glass, A, B be made to approach each other, the depressions m, n will still continue, and when the distance of the plates is so small that these depressions or indentations meet, the mercury will

Cause of the depression of mercury in capillary tubes.

Fig. 8.

Fig. 9.

Fig. 10.

Capillary Attraction, &c.

will sink between the plates, and its descent will continue as the pieces of glass approach. Hence the depression of the mercury in capillary tubes becomes very intelligible.—If two glass planes forming a small angle, as in fig. 5. be immersed in a vessel of mercury, the fluid will sink below the surface of the mercury in the vessel, and form an Apollonian hyperbola like D o E, having for its assymptotes the common intersection of the planes and the surface of mercury in the vessel.

Fig. 5.

The depression of mercury in glass tubes, owing ultimately to an imperfect contact between the solid and the fluid.

125. The depression of mercury in capillary tubes is evidently owing to the greater attraction that subsists between the particles of mercury, than between the particles of mercury and those of glass. The difference between these two attractions, however, arises from an imperfect contact between the mercury and the capillary tube, occasioned by the interposition of a thin coating of water which generally lines the interior surface of the tube, and weakens the mutual action of the glass and mercury; for this action always increases as the thickness of the interposed film is diminished by boiling. In the experiments which were made by Laplace and Lavoisier on barometers, by boiling the mercury in them for a long time, the convexity of the interior surface of the mercury was often made to disappear. They even succeeded in rendering it concave, but could always restore the convexity by introducing a drop of water into the tube. When the ebullition of the mercury is sufficiently strong to expel all foreign particles, it often rises to the level of the surrounding fluid, and the depression is even converted into an elevation.

Capillary attraction does not seem to act at any perceptible distance.

126. Newton, Clairaut, and other geometers, have maintained, that the action of the capillary tube is sensible at a small distance, and that it is extended to the particles of fluid in the axis of the tube. Laplace and other philosophers who have lately attended to this subject, suppose capillary attraction to be like the refractive force, and all the chemical affinities, which are not sensible except at imperceptible distances; and it must be allowed that this opinion is consistent with many of the phenomena. It has been often observed that water rises to the same height in glass tubes, of the same bore, whether they be very thin or very thick. The zones of the glass tube therefore, which are at a small distance from the interior surface, do not contribute to the ascent of the water, though in each of these zones, taken separately, the water would rise above its level. When the interior surface of a capillary tube is lined with a very thin coating of an unctuous substance, the water will no longer ascend. Now if the attraction of the glass tube were similar to the attraction of gravity, of electricity, or magnetism, it ought to act through bodies of all kinds, and, notwithstanding the thin coating of grease, should elevate the fluid in which it is immersed. But as the intervention of an attenuated film of grease destroys capillary action, there is reason to conclude, that it does not extend to sensible distances. The same conclusion is deducible from the fact in the preceding paragraph.

Opinion of Laplace.

127. From these facts Laplace concludes, that the attraction of capillary tubes has not any influence on the elevation or depression of the fluids which they contain, except by determining the inclination of the first planes of the surface of the interior fluid, which are extremely near the sides of the tube. He supposes that when the attraction of the tube upon the fluid exceeds the attraction of the fluid upon itself, the fluid will in that case attach itself to the tube, and form an anterior tube, which alone will raise the fluid.

128. 'It is interesting, says Laplace, to ascertain the radius of curvature of the surface of water included in capillary tubes of glass. This may be known by a curious experiment, which shews at the same time the effects of the concavity and convexity of surfaces. It consists in plunging in water, to a known depth, a capillary tube of which the diameter is likewise known. The lower extremity of the tube is then to be closed with the finger, and the tube being taken out of the water, its external surface must be gently wiped. Upon withdrawing the finger in this last situation, the water is seen to subside in the tube and form a drop at its lower base; but the height of the column is always greater than the elevation of the water in the tube above the level in the common experiment of plunging it in water. This excess in the height is owing to the action of the drop upon the column on account of its convexity; and it is observable that the increase in the elevation of the water is more considerable, the smaller the diameter of the drop beneath. The length of the fluid column which came out by subsidence to form the drop, determines its mass; and as its surface is spherical as well as that of the interior fluid, if we know the height of the fluid above the summit of the drop, and the distance of this summit from the plane of the interior bore of the tube, it will be easy to deduce the radii of these two surfaces. Some experiments lead me to conclude that the surface of the interior fluid approaches very nearly to the figure of an hemisphere.'

129. 'The theory which I have adopted, observes the same philosopher, likewise gives the explanation and measure of a singular phenomenon presented by experiment. Whether the fluid be elevated or depressed between two vertical planes, parallel to each other, and plunged in the fluid at their lower extremities, the planes tend to come together. Analysis shews us, that if the fluid be raised between them, each plane will undergo from without inwards a pressure equal to that of a column of the same fluid, of which the height would be half the sum of the elevations above the level of the points of contact of the interior and exterior surfaces of the fluids with the plane, and of which the base should be the parts of the plane comprised between the two horizontal lines drawn through those points. If the fluid be depressed between the planes, each of them will in like manner undergo from without inwards, a pressure equal to that of a column of the same fluid, of which the height would be half the sum of the depressions below the level of the points of contact of the interior and exterior surfaces of the fluid with the plane, and of which the base should be the part of the plane comprised between the two horizontal lines drawn through those points.'

130. As most philosophers seem to agree in thinking that all the capillary phenomena are referable to the cohesive attraction of the superficial particles only of the fluid, a variety of experiments has been made in order to determine the force required to raise a horizontal solid surface from the surface of a fluid. Mr Achard found that a disc of glass, $1\frac{1}{2}$ French inches in diameter, required a weight of 91 French grains to raise it

Capillary Attraction, &c.

it from the surface of the water at 69° of Fahrenheit, which is only 37 English grains for each square inch. At $44\frac{1}{2}$ of Fahrenheit the force was $\frac{1}{12}$ greater, or $39\frac{1}{2}$ grains, the difference being $\frac{1}{243}$ for each degree of Fahrenheit. From these experiments Dr Young concludes that the height of ascent in a tube of a given bore, which varies in the duplicate ratio of the height of adhesion, is diminished about $\frac{1}{180}$ for every degree of Fahrenheit that the temperature is raised above 50°; and he conjectures that there must have been some considerable source of error in Achard's experiments, as he never found this diminution to exceed $\frac{1}{1000}$. According to the experiments of Dutour, the force necessary to elevate the solid, or the quantity of water raised, is equal to 44.1 grains for every square inch.

Morveau's experiments on the force necessary to raise metals from the surface of mercury.

131. According to the experiments of Morveau, the force necessary to elevate a circular inch of gold from the surface of mercury is 446 grains; a circular inch of silver, 429 grains; a circular inch of tin, 418 grains; a circular inch of lead, 397 grains; a circular inch of bismuth, 372 grains; a circular inch of zinc, 204 grains; a circular inch of copper, 142 grains; a circular inch of metallic antimony, 126; a circular inch of iron, 115 grains; and a similar surface of cobalt required 8 grains. The order in which these metals are arranged is the very order in which they are most easily amalgamated with mercury.

On the apparent attraction of floating bodies.

132. The approach of two floating bodies has been ascribed by some to their mutual attraction, and by others to the attraction of the portions of fluid that are raised round each by the attraction of cohesion. Dr Young, however, observes that the approach of the two floating bodies is produced by the excess of the atmospheric pressure on the remote sides of the solids, above its pressure on their neighbouring sides; or, if the experiments are performed in a vacuum, by the equivalent hydrostatic pressure or suction derived from the weight and immediate cohesion of the intervening fluid. This force varies alternately in the inverse ratio of the square of the distance; for when the two bodies approach each other, the altitude of the fluid between them is increased in the simple inverse ratio of the distance; and the mean action, or the negative pressure of the fluid on each particle of the surface, is also increased in the same ratio. When the floating bodies are surrounded by a depression, the same law prevails, and its demonstration is still more simple and obvious.

Experiments of Count Rumford on the adhesion of fluids.

133. A number of experiments on the adhesion of fluids have been lately made by Count Rumford, which authorise him to conclude, that on account of the mutual adhesion of the particles of fluid, a pellicle or film is formed at the superior and inferior surfaces of water, and that the force of the film to resist the descent of bodies specifically heavier than the fluid increases with the viscidity of the water. He poured a stratum of sulphuric ether upon a quantity of water, and introduced a variety of bodies specifically heavier than water into this compound fluid. A sewing needle, granulated tin, and small globules of mercury, descended through the ether, but floated upon the surface of the water. When the eye was placed below the level of the aqueous surface, the floating body, which was a spherule of mercury, seemed suspended in a kind of bag a little below the surface. When a larger spherule of mercury was employed, about the 40th or 50th of an inch in diameter, it broke the pellicle and descended to the bottom. The same results were obtained by using essential oil of turpentine or oil of olives instead of ether. When a stratum of alcohol was incumbent upon the water, a quantity of very fine powder of tin thrown upon its surface, descended to the very bottom, without seeming to have met with any resistance from the film at the surface of the water. This unexpected result Count Rumford endeavours to explain by supposing that the aqueous film was destroyed by the chemical action of the alcohol. In order to ascertain with greater accuracy the existence of a pellicle at the surface of the water, Count Rumford employed a cylindrical glass vessel 10 inches high and $1\frac{1}{2}$ inch in diameter, and filled it with water and ether as before. A number of small bodies thrown into the vessel descended through the ether and floated on the surface of the water. When the whole was perfectly tranquil, he turned the cylinder three or four times round with considerable rapidity in a vertical position. The floating bodies turned round along with the glass, and stopped when it was stopped; but the liquid water below the surface did not at first begin to turn along with the glass; and its motion of rotation did not cease with the motion of the vessel. From this Count Rumford concludes that there was a real pellicle at the surface of the water, and that this pellicle was strongly attached to the sides of the glass, so as to move along with it. When this pellicle was touched by the point of a needle, all the small bodies upon its surface trembled at the same time. The apparatus was allowed to stand till the ether had entirely evaporated, and when the pellicle was examined with a magnifier, it was in the same state as formerly; and the floating bodies had the same relative positions.

134. In order to shew that a pellicle was formed at the inferior surface of water, Count Rumford poured water upon mercury, and upon that a stratum of ether. He threw into a vessel a spherule of mercury about one-third of a line in diameter, which being too heavy to be supported by the pellicle at the superior surface of the water, broke it, and descending through that fluid, was stopped at its inferior surface. When this spherule was moved, and even compressed with a feather, it still preserved its spherical form, and refused to mix with the mass of mercury. When the viscidity of the water was increased by the infusion of gum-arabic, much larger spherules were supported by the pellicle. From the very rapid evaporation of ether, and its inability to support the lightest particles of a solid upon its surface, Count Rumford very justly concludes, that the mutual adhesion of its particles is very small.

References to works on the cohesion of fluids.

135. Those who wish to extend their inquiries concerning the cohesion of fluids, may consult an ingenious paper on Capillary Action by Professor Leslie, in the Phil. Mag. for 1802; Dr Thomas Young's Essay on the Cohesion of Fluids, in the Phil. Trans. 1805; an Abstract of a Memoir of Laplace, in Nicholson's Journal, N° 57.; and an Account of Rumford's Experiments in the same Journal, N° 60, 61, and 62.

PART

PART II. HYDRAULICS.

Definition. 136. HYDRAULICS is that branch of the science of hydrodynamics which relates to fluids in motion. It comprehends the theory of running water, whether issuing from orifices in reservoirs by the pressure of the superincumbent mass, or rising perpendicularly in *jets d'eaux* from the pressure of the atmosphere; whether moving in pipes and canals, or rolling in the beds of rivers. It comprehends also the resistance or the percussion of fluids, and the oscillation of waves.

CHAP. I. *Theory of Fluids issuing from Orifices in Reservoirs, either in a Lateral or a Vertical direction.*

Preliminary observations. 137. IF water issues from an orifice either in the bottom or side of a reservoir, the surface of the fluid in the reservoir is always horizontal till it reaches within a little of the bottom. When a vesse therefore is emptying itself, the particles of the fluid descend in vertical lines, as is represented in fig. 1.; but when they have reached within three or four inches of the orifice *m n*, the particles which are not immediately above it change the direction of their motion, and make for the orifice in directions of different degrees of obliquity. The velocities of these particles may be decomposed into two others, one in a horizontal direction, by which they move parallel to the orifice, and the other in a vertical direction by which they approach that orifice. Now, as the particles about C and D move with greater obliquity than those nearer E, their horizontal velocities must also be greater, and their vertical velocities less. But the particles near E move with so little obliquity that their vertical are much greater than their horizontal velocities, and very little less than their absolute ones. The different particles of the fluid, therefore, will rush through the orifice *m n* with very different velocities, and in various directions, and will arrive at a certain distance from the orifice in different times. On account of the mutual adhesion of the fluid particles, however, those which have the greatest velocity drag the rest along with them; and as the former move through the centre of the orifice, the breadth of the issuing column of fluid will be less at *o p* than the width of the orifice *m n*.

Plate CCLXVII. fig. 1.

Cause of the vena contracta,

138. That the preceding phenomena really exist when a vessel of water is discharging its contents through an aperture, experience sufficiently testifies. If some small substances specifically heavier than water be thrown into the fluid when the vessel is emptying itself, they will at first descend vertically, and when they come within a few inches of the bottom they will deviate from this direction, and describe oblique curves similar to those in the figure. The contraction of the vein or column of fluid at *o p* is also manifest from observation. It was first discovered by Sir Isaac Newton, and denominated the *vena contracta*. The greatest contraction takes place at a point *o* whose distance from the orifice is equal to half its diameter, so that $o\,m = \frac{m\,n}{2}$; and the breadth of the vein or column of fluid at *o* is to the width of the orifice as 5 to 8 according to Bossut, or as 5.197 to 8 according to the experiments of Michelotti, the orifice being perforated in a thin plate. But when the water is made to issue through a short cylindrical tube, the same contraction, though not obvious to the eye, is so considerable, that the diameter of the contracted vein is to that of the orifice as 6.5 to 8. If A therefore be the real size of the orifice in a thin plate, its corrected size, or the breadth of the contracted vein, will be $\frac{5.197 \times A}{8}$, and when a cylindrical tube is employed it will be $\frac{13 \times A}{16}$. In the first case the height of the water in the reservoir must be reckoned from the surface of the fluid to the point *o*, where the vein ceases to contract; and when a cylindrical tube is employed, it must be reckoned from the same surface to the exterior aperture of the tube.

which was discovered by Newton.

Description of the vena contracta.

139. Suppose the fluid ABCD divided into an infinite number of equal *strata* or *laminæ* by the horizontal surfaces MN, *g h* infinitely near each other; and let *m n o p* be a small column of fluid which issues from the orifice in the same time that the surface MN descends to *g h*. The column *m n o p* is evidently equal to the lamina MN *g h*, for the quantity of fluid which is discharged during the time that MN descends to *gh*, is evidently MN *hg*; and to the quantity discharged in that time, the column *m n o p* was equal by hypothesis. Let A be the area of the base MN, and B the area of the base *m n*; let *x* be the height of a column equal to MN *g h*, and having A for its base, and let *y* be the height of the column *m n o p*. Then, since the column *m n o p* is equal to the lamina MN *g h*, we shall have $Ax = By$, and (GEOMETRY, Sect. IV. Theor. IX.) $x : y = A : B$; but as the surface MN descends to *g h* in the same time that *m n* descends to *o p*, *x* will represent the mean velocity of the lamina MN *g h*, and *y* the mean velocity of the column *m n o p*. The preceding analogy, therefore, informs us, that the mean velocity of any lamina is to the velocity of the fluid issuing from the orifice reciprocally as the area of the orifice is to the area of the base of the lamina MN *g h*. Hence it follows, that, if the area of the orifice is infinitely small, with regard to the area of the base of the lamina into which the fluid is supposed to be divided, the mean velocity of the fluid at the orifice will be infinitely greater than that of the laminæ; that is, while the velocity at the orifice is finite, that of the laminæ will be infinitely small.

Relation between the velocity of the fluid at the orifice, and that of the interior laminæ.

140. Before applying these principles to the theory of hydraulics, it may be proper to observe, that several distinguished philosophers have founded the science upon the same general law from which we have deduced the principles of hydrostatics (32.). In this way they have represented the motion of fluids in general formulæ; but these formulæ are so complicated from the very

very nature of the theory, and the calculations are so intricate, and sometimes impracticable from their length, that they can afford no assistance to the practical engineer.

Definition.

Fig. 1. 141. If the water issues at $m\,n$ with the same velocity V that a heavy body would acquire by falling freely through a given height H, this velocity is said to be due to the height H, and inversely the height H is said to be due to the velocity V.

Prop. I.

142. The velocity of a fluid issuing from an infinitely small orifice in the bottom or side of a vessel, is equal to that which is due to the height of the surface of the fluid above that orifice, the vessel being supposed constantly full.

Fig. 2. Let AB be the vessel containing the fluid, its velocity when issuing from the aperture $m\,n$ will be that which is due to the height $D\,m$, or equal to that which a heavy body would acquire by falling through that height. Because the orifice $m\,n$ is infinitely small, the velocity of the laminæ into which the fluid may be supposed to be divided, will also be infinitely small (art. 138.). But since all the fluid particles, by virtue of their gravity, have a tendency to descend with the same velocity; and since the different laminæ of the fluid lose this velocity, the column $m\,n\,s\,t$ must be pressed by the superincumbent column $D\,m\,n$; and calling S the specific gravity of the fluid, the moving force which pushes out the column $m\,n\,s\,t$ will be $S \times Dm \times m\,n$ (art. 42.). Now let us suppose, that, when this moving force is pushing out the column $m\,n\,s\,t$, the absolute weight of the column $m\,n\,o\,p$, which may be represented by $S \times m\,n \times n\,p$, causes itself to fall through the height np. Thus, if V, U be the velocities impressed upon the columns $m\,n\,s\,t$, and $m\,n\,o\,p$, by the moving forces $S \times Dm \times m\,n$, and $S \times m\,n \times n\,p$; these moving forces must be proportional to their effects, or to the quantities of motion which they produce, that is, to $V \times m\,n\,s\,t$ and $U \times m\,n\,o\,p$, because the quantity of motion is equal to the velocity and mass conjointly; hence we shall have $S \times Dm \times mn^2 : S \times mn \times np = V \times mnst : U \times mnop$. But since the volumes $m\,n\,s\,t$, $m\,n\,o\,p$ are to one another as their heights $m\,o$, $o\,s$, and as their heights are run through in equal times, and consequently represent the velocity of their motion, $m\,n\,s\,t$ may be represented by $V \times m\,n$ and $m\,n\,o\,p$ by $U \times m\,n$; therefore we shall have $S \times Dm \times mn : S \times m\,n \times n\,p = V \times V \times mn : U \times U \times m\,n$, and dividing by $m\,n$, $S \times Dm : np = V^2 : U^2$. Now let v be the velocity due to the height $D\,m$, then (see Mechanics) $np : U^2 = Dm : v^2$; but since $S \times Dm : S \times n\,p = V^2 : U^2$; then by (Euclid V. 15.), and by permutation $D\,m : V^2 = n\,p : U^2$, therefore by substitution (Euclid V. 11.) $D\,m : V^2 = D\,m : v^2$, and (Euclid V. 9.) $V^2 = v^2$ or $V = v$. But V is the velocity with which the fluid issues from the orifice $m\,n$, and v is the velocity due to the height Dm; therefore, since the velocities are equal, the proposition is demonstrated.

143. Cor. 1. If the vessel AB empties itself by the small orifice $m\,n$, so that the surface of the fluid takes successively the positions DP, QR, ST, the velocities with which the water will issue when the surfaces have these positions will be those due to the heights $E\,n$, $F\,n$, $G\,n$, for in these different positions the moving forces are the columns $E\,m\,n$, $F\,m\,n$, $G\,m\,n$.

144. Cor. 1. Since the velocities of the issuing fluid when its surface is at E, F, G, are those due to the heights $E\,n$, $F\,n$, $G\,n$, it follows from the properties of falling bodies (see Mechanics), that if these velocities were continued uniformly, the fluid would run through spaces equal to $2\,E\,n$, $2\,F\,n$, $2\,G\,n$ respectively, in the same time that a heavy body would fall through $E\,n$, $F\,n$, $G\,n$, respectively.

145. Cor. 3. As fluids press equally in all directions, the preceding proposition will hold true, when the orifices are at the sides of vessels, and when they are formed to throw the fluid upwards, either in a vertical or an inclined direction, provided that the orifices are in these several cases at an equal distance from the upper surface of the fluid. This corollary holds also in the case mentioned in Cor. 1.

146. Cor. 4. When the fluid issues vertically, it will rise to a height equal to the perpendicular distance of the orifice from the surface of the fluid; for (see Mechanics), this is true of falling bodies in general, and must therefore be true in the case of water: owing to the resistance of the air, however, and the friction of the issuing fluid upon the sides of the orifice, jets of water do not exactly rise to this height.

147. Cor. 5. As the velocities of falling bodies are as the square roots of the heights through which they fall (see Mechanics), the velocity V of the effluent water when the surface is at E, will be to its velocity v when the surface is at G, as $\sqrt{E\,n} : \sqrt{G\,n}$, (Cor. 1.) that is, the velocities of fluids issuing from a very small orifice are as the square roots of the altitude of the water above these orifices. As the quantities of fluids discharged are as the velocities, they will also be as the square roots of the altitude of the fluid. This corollary holds true of fluids of different specific gravities, notwithstanding Belidor (*Architec. Hydraul.* tom. i. p. 187.) has maintained the contrary; for though a column of mercury $D\,m\,n$ presses with 14 times the force of a similar column of water, yet the column $m\,n\,o\,p$ of mercury which is pushed out is also 14 times as heavy as a similar column of water; and as the resistance bears the same proportion to the moving force, the velocities must be equal. Fig. 2.

148. Cor. 6. When a vessel is emptying itself, if the area of the laminæ into which we may suppose it divided, be everywhere the same, the velocity with which the surface of the fluid descends, and also the velocity of efflux, will be uniformly retarded. For (art. 138.) as the velocity V with which the surface descends is to the velocity v at the orifice, as the area a of the orifice to the area A of the surface, then $V : v = a : A$; but the ratio of $a : A$ is constant, therefore V varies as v, that is, $V : V' = v : v'$; but, (Cor. 1.) $v : v' = \sqrt{h} : \sqrt{h'}$, h being the height of the surface above the orifice, therefore $V : V' = \sqrt{h} : \sqrt{h'}$. But this is the property of a body projected vertically from the earth's surface, and as the retarding force is uniform in the one case (see Mechanics), it must also be uniform in the other.

149. Cor. 7. If a cylindrical vessel be kept constantly full, twice the quantity contained in the vessel will run out during the time in which the vessel would have emptied,

Motion of Fluids, &c.

tied itself. For (Cor. 2. and 6.) the space through which the surface of the fluid at D would descend if its velocity continued uniform being $2Dm$, double of Dm the space which it actually describes in the time it empties itself, the quantity discharged in the former case will also be double the quantity discharged in the latter: because the quantity discharged when the vessel is kept full, may be measured by what the descent of the surface would be, if it could descend with its first velocity.

Fig. 2.

Scholium.

150. The reader will probably be surprised when he finds in some of our elementary works on hydrostatics, that the velocity of the water at the orifice is only equal to that which a heavy body would acquire by falling through *half* the height of the fluid above the orifice. This was first maintained by Sir Isaac Newton, who found that the diameter of the *vena contracta* was to that of the orifice as 21 to 25. The area therefore of the one was to the area of the other as 21^2 to 25^2, which is nearly the ratio of 1 to $\sqrt{2}$. But by measuring the quantity of water discharged in a given time, and also the area of the *vena contracta*, Sir Isaac found that the velocity at the *vena contracta* was that which was due to the *whole* altitude of the fluid above the orifice. He therefore concluded, that since the velocity at the orifice was to that at the *vena contracta* as (H) $1 : \sqrt{2}$, and in the latter velocity was that which was due to the whole altitude of the fluid, the former velocity, or that at the orifice, must be that which is due to only *half* that altitude, the velocities being as the square roots of the heights. Now the difference between this theory and that contained in the preceding proposition may be thus reconciled. The velocity found by the preceding proposition is evidently the vertical velocity of the filaments at E, which being immediately above the centre of the aperture mn are not diverted from their course, and have therefore their vertical equal to their absolute velocity. But the vertical velocity of the particles between C and E, and E and D, is much less than their absolute velocity, on account of the obliquity of their motion, and also on account of their friction on the sides of the orifice. The mean vertical velocity, consequently, of the issuing fluid will be much less than the vertical velocity of the particles at E, that is, than the velocity found by the above proposition, or that due to the height Dm. Now the velocity found by Sir Isaac Newton from measuring the quantity of water discharged, was evidently the mean velocity, which ought to be less than the velocity given by the preceding proposition, the two velocities being as $1 : \sqrt{2}$ or as $1 : 1.414$. The theorem of Newton therefore may be considered as giving the mean velocity at the orifice, while our proposition gives the velocity of the particles at D, or the velocity at the *vena contracta*.

Fig. 2.

Prop. II.

151. To find the quantity of water discharged from a very small orifice in the side or bottom of a reservoir, the time of discharge, and the altitude of the fluid, the vessel being kept constantly full, and any two of these quantities being given.

Plate CCLXVII. fig. 2.

Let A be the area of the orifice mn; W the quantity of water discharged in the time T; H the constant height Dm of the water in the vessel, and let 16.087 feet be the height through which a heavy body descends in a second of time. Now, as the times of description are proportional to the square roots of the heights described, the time in which a heavy body will fall through the height H, will be found from the following analogy, $\sqrt{16.087} : \sqrt{H} = 1 : \frac{\sqrt{H}}{16.087}$, the time required. But as the velocity at the orifice is uniform, a column of fluid whose base is mn and altitude $2H$ (Prop. I. Cor. 2.) will issue in the time $16.087\sqrt{H}$, or since A is the area of the orifice mn, $A \times 2H$ or $2HA$ will represent the column of fluid discharged in that time. Now since the quantities of fluid discharged in different times must be as the times of discharge, the velocity at the orifice being always the same, we shall have $\frac{\sqrt{H}}{16.087} : T = 2HA : W$, and (Geometry, Sect. IV. Theor. VIII.) $\frac{W\sqrt{H}}{16.087} = 2HAT$ or $W = \frac{2HAT \times 16.087}{\sqrt{H}}$, and since $\frac{H}{\sqrt{H}} = \sqrt{H}$ we shall have $W = 2AT\sqrt{H} \times 16.087$, an equation from which we deduce the following formulæ, which determine the quantity of water discharged, the time of discharge, the altitude of the fluid, and the area of the orifice, any three of these four quantities being given:

$$W = 2AT\sqrt{H \times 16.087} \qquad A = \frac{W}{2T\sqrt{H} \times 16.087}$$

$$H = \frac{W^2}{4A^2T^2 \times 16.887} \qquad T = \frac{W}{2A\sqrt{H} = 16.087}$$

152. It is supposed in the preceding proposition that the orifice in the side of the vessel is so small that every part of it is equally distant from the surface of the fluid. But when the orifice is large like M (fig. 3.), the depths of different parts of the orifice below the surface of the fluid are very different, and consequently the preceding formulæ will not give very accurate results. Fig. 3.

(H) When a fluid runs through a conical tube kept continually full, the velocities of the fluid in different sections will be inversely as the area of the sections. For as the same quantity of fluid runs through every section in the same time, it is evident that the velocity must be greater in a smaller section, and as much greater as the section is smaller, otherwise the same quantity of water would not pass through each section in the same time. Now the area of the *vena contracta* is to the area of the orifice, as $1 : \sqrt{2}$, therefore the velocity at the *vena contracta* must be to the velocity at the orifice as $\sqrt{2} : 1$.

sults. If we suppose the orifice M divided into a number of smaller orifices a, b, c, it is evident that the water will issue at a, with a velocity due to the height Da, the water at b, with a velocity due to the height Eb, and the water at c, with a velocity due to the height Fc. When the whole orifice, therefore, is opened, the fluid will issue with different velocities at different parts of its section. Consequently, in order to find new formulæ expressing the quantity of water discharged, we must conceive the orifice to be divided into an infinite number of areas or portions by horizontal planes; and by considering each area as an orifice, and finding the quantity which it will discharge in a given time, the sum of all these quantities will be the quantity discharged by the whole orifice M.

Prop. III.

153. To find the quantity of water discharged by a rectangular orifice in the side of a vessel kept constantly full.

Plate CCLXVII. Let ABD be the vessel with the rectangular orifice GL, and let AB be the surface of the fluid. Draw the lines MNOP, $m\,n\,o\,p$ infinitely near each other, and from any point D draw the perpendicular DC meeting the surface of the fluid in C. Then regarding the infinitely small rectangle MO$m\,o$ as an orifice whose depth below the surface of the fluid is H, we shall have by the first of the preceding formulæ, the quantity of water discharged in the time T, or $W = T\sqrt{16.087}\times\sqrt{CN}\times\overline{2MO\times Nn}$, CN being equal to H and $\overline{MO\times Nn}$ to the area. As the preceding formula represents the quantity of fluid discharged by each elementary rectangular orifice, into which the whole orifice GL is supposed to be divided, we must find the sum of all the quantities discharged in the time T, in order to have the total quantity afforded by the finite orifice in the same time. Upon DC as the principal axis, describe the parabola CHE, having its parameter P equal to 4DC. Continue FG and DK to H and E. The area NPpn may be expressed by $NP\times Nn$. But (Conic Sections, Part I. Prop. X.) $\overline{NP^2}=CN\times P$ (P being the parameter of the parabola) therefore $NP=\sqrt{CN\times P}$, and multiplying by Nn we have $NP\times Nn = Nn\sqrt{CN\times P}$, which expresses the area NPpn. Now this expression of the elementary area being multiplied by the constant quantity $T\sqrt{16.087}\times\frac{MO}{\sqrt{\frac{1}{4}P}}$ gives for a product $T\sqrt{16.087}\times\sqrt{CN}\times\overline{2MO\times Nn}$, for $\sqrt{\frac{1}{4}P}=\frac{1}{2}\sqrt{P}$ and $\frac{MO\times\sqrt{P}}{\frac{1}{2}\sqrt{P}}=2MO$. But that product is the very same formula which expresses the quantity of water discharged in the time T by the orifice MOom. Therefore since the elementary area MPpm multiplied by the constant quantity $T\sqrt{16.087}\times\frac{MO}{\sqrt{\frac{1}{4}P}}$ gives the quantity of water discharged by the orifice MOom in a given time, and since the same may be proved of every other orifice of the same kind into which the whole orifice is supposed divided, we may conclude that the quantity of water discharged by the whole orifice GL will be found by multiplying the parabolic area FHED by the same constant quantity $T\sqrt{16.087}\times\frac{MO}{\sqrt{\frac{1}{4}P}}$. Now the area FHED is equal to the difference between the areas CDE and CFH. But (Conic Sections, Part I. Prop. X.) the area $CDE=\frac{2}{3}CD\times DE$; and since $P=4CD$, and (Conic Sections, Part I. Prop. X.) $\overline{DE^2}=CD\times P$ we have $\overline{DE^2}=CD\times 4CD=4CD^2$, that is $DE=2CD$, then by substituting this value of DE in the expression of the area CDE, we have $CDE=\frac{4}{3}CD^2$. The area $CFH=\frac{2}{3}CF\times FH$, consequently the area $FHED=\frac{4}{3}CD^2-\frac{2}{3}CF\times FH$, which multiplied by the constant quantity, gives for the quantity of water discharged, ($\frac{1}{3}P^2$ being substituted instead of its equal $\frac{4}{3}CD^2$,)

$$W=\frac{T\sqrt{16.087}\times MO\times\overline{\frac{1}{3}P^2-\frac{2}{3}CF\times FH}}{\sqrt{\frac{1}{4}P}}.$$

But by the property of the parabola $FH^2=CF\times P$ and $FH=\sqrt{CF\times P}$, therefore substituting this value of FH in the preceding formula, and also $\frac{1}{2}\sqrt{P}$ for its equal $\sqrt{\frac{1}{4}P}$, we have

$$W=\frac{T\sqrt{16.087}\times MO\times\overline{\frac{1}{3}P^2-\frac{2}{3}CF\times\sqrt{CF\times P}}}{\frac{1}{2}\sqrt{P}}$$

and dividing by $\frac{1}{2}\sqrt{P}$ gives us

$$W=T\sqrt{16.087}\times MO\times\overline{\frac{2}{3}P\sqrt{P}-\frac{4}{3}CF\times\sqrt{CF}};$$

hence

$$T=\frac{W}{\sqrt{16.087}\times MO\times\overline{\frac{2}{3}P\sqrt{P}-\frac{4}{3}CF\times\sqrt{CF}}};$$

$$MO=\frac{W}{T\sqrt{16.087}\times\overline{\frac{2}{3}P\sqrt{P}-\frac{4}{3}CF\times\sqrt{CF}}},$$

$$P=\overline{\frac{9\,W}{4T\sqrt{16.087}}+3\,CF\sqrt{CF}}\Big|^{\frac{2}{3}},$$

and since $P=4CD$

$$CD=\overline{\frac{9\,W}{16T\sqrt{16.087}}+12\,CF\times\sqrt{CF}}\Big|^{\frac{2}{3}}$$

$$CF=\overline{\frac{9\,W}{16T\sqrt{16.087}}+\frac{1}{8}P\sqrt{P}}\Big|^{\frac{2}{3}}$$

In these formulæ W represents the quantity of water discharged, T the time of discharge, MO the horizontal width of the rectangular orifice, P the parameter of the parabola $=4CD$, CD the depth of the water in the vessel or the altitude of the water above the bottom of the orifice, and CF the altitude of the water above the top of the orifice. The vertical breadth of the orifice is equal to CD—CF.

154. Let x be the mean height of the fluid above the orifice, or the height due to a velocity, which, if communicated to all the particles of the issuing fluid, would make the same quantity of water issue in the time T as if all the particles moved with the different velocities due to their different depths below the surface, then by Prop. II. the quantity discharged or $W=2T\times MO\times\overline{CD-CF}\times\sqrt{x\times 16.087}$, the area of the orifice being $MO\times\overline{CD-CF}$,

Motion of Fluids, &c.

$\times\overline{CD-CF}$, and by making this value of W equal to its value in the preceding article, we have the following equation.

$$2T\times MO\times\overline{CD-CF}\times\sqrt{x\times 16.087}=T\sqrt{16.087}\times MO\times\tfrac{2}{3}P\sqrt{P}-\tfrac{4}{3}CF\sqrt{CF},$$

which by division and reduction, and the substitution of $\frac{1}{4}P$ instead of CD its equal, becomes

$$x=\frac{\frac{4}{9}(P\sqrt{P}-\frac{4}{3}CF\sqrt{CF})^2}{4(\frac{1}{4}P-CF)^2}.$$

Now this value of x is evidently different from the distance of the centre of gravity of the orifice from the surface of the fluid, for this distance is $\frac{CD+CF}{2}$ or $\frac{\frac{1}{4}P+CF}{2}$. But in proportion as CE increases, the other qualities remaining the same, the value of x will approach nearer the distance of the centre of gravity of the orifice from the surface of the fluid; for when CF becomes infinite, the parabolic arch CHE will become a straight line, and consequently the mean ordinate of the curve, which is represented by the mean velocity of the water, will pass through the middle of FD or the centre of gravity of the orifice.

Prop. IV.

155. To find the time in which a quantity of fluid equal to ABRT, will issue out of a small orifice in the side or bottom of the vessel AB, that is, the time in which the surface AB will descend to RT.

Plate CCLXVII. fig. 5.

Draw DE, de at an infinitely small distance and parallel to AB. The lamina of fluid $DdeE$ may be represented by $DE\times ob$; DE expressing the area of the surface. When the surface of the water has descended to DE, the quantity of fluid which will be discharged by an uniform velocity in the time T, will be $T\sqrt{16.087}\times 2A\times\sqrt{om}$, A being the area of the orifice, as in Prop. II. But as the variation in the velocity of the water will be infinitely small, when the surface descends from DE to de, its velocity may be regarded as uniform. The time, therefore, in which the surface describes the small height ob will be found by the following analogy; $T\sqrt{16.087}\times 2A\times\sqrt{om} : T=DE\times ob : \frac{DE\times ob}{\sqrt{16.087}\times 2A\times\sqrt{om}}$. Now as this formula expresses the time in which the surface descends from DE to de, and as the same may be shewn of every other elementary portion of the height CS, the sum of all these elementary times will give us the value of T, the time in which the surface AB falls down to RT. For this purpose, draw GP equal and parallel to Cn, and upon it as an axis, describe the parabola PVQ, having its parameter P equal to 4 GP. Continue the lines AB, DE, de, RT, so as to form the ordinates HF, hf, UV, of the parabola. Upon GP as an axis describe a second curve, so that the ordinate GM may be equal to the area of the surface at AB, divided by the corresponding ordinate GQ of the parabola, and that the ordinate H may be the quotient of the area of the surface at DE divided by the ordinate HF. Now (Conic Sections, Part I. Prop. X.) $\overline{HF}^2=HP\times P$, or $HF=\sqrt{HP}\times\sqrt{P}$, that is $\sqrt{HP}=\frac{HF}{\sqrt{P}}$; and since $om=HP$; $\frac{DE}{\sqrt{om}}=\frac{DE\times\sqrt{P}}{HF}$. But by the construction of the curve MN, we have $\frac{DE}{HF}=Hr$, consequently $\frac{DE}{\sqrt{om}}=Hr\times\sqrt{P}$. The elementary time therefore, expressed by $\frac{DE\times ob}{\sqrt{16.087}\times 2A\times\sqrt{om}}$ will, by the different substitutions now mentioned, be $\frac{Hr\times ob\sqrt{P}}{2A\sqrt{16.087}}$ or $\frac{\sqrt{P}}{2A\sqrt{16.087}}\times Hr\times ob$. But the factor $\frac{\sqrt{P}}{2A\sqrt{16.087}}$ consisting of constant quantities is itself constant, and the other factor $Hr\times ob$ represents the variable curvilineal area $Hrsh$. Now as the same may be shown of every other element of the time T, compared with the corresponding elements of the area GUtM, it follows that the time T required, will be found by multiplying the constant quantity $\frac{\sqrt{P}}{2A\sqrt{16.087}}$ by the curvilineal area GUtM; therefore $T=\frac{\sqrt{P}}{\sqrt{16.087}}\times\frac{GUtM}{2A}$, and the time in which the surface descends to mn, or in which the vessel empties itself, will be equal to $\frac{\sqrt{P}}{\sqrt{16.087}}\times\frac{GPNM}{2A}$.

Cor. The quantity of fluid discharged in the given time T may be found by measuring the contents of the vessel AB between the planes AB, and RT, the descent of the surface AB, viz. the depth CS, being known.

Prop. V.

156. To find the time in which a quantity of fluid equal to ABRT will issue out of a small orifice in the side or bottom of the *cylindrical* vessel AB, that is, the time in which the surface AB will descend to RT.

Let us suppose that a body ascends through the height mC with a velocity increasing in the same manner as if the vessel AB were inverted, and the body fell from m to C. The velocity of the ascending body at different points of its path being proportional to the square roots of the heights described, will be expressed by the ordinates of the parabola PVQ. The line DE being infinitely near to de, as soon as the body arrives at b it will describe the small space bo or hH in a portion of time infinitely small, with a velocity represented by the ordinate HF. Now the time in which the body will ascend through the space mC or its equal PG will be $\frac{\sqrt{PG}}{\sqrt{16.087}}$, because $\sqrt{16.087}:\sqrt{PG}=\frac{\sqrt{PG}}{\sqrt{16.087}}$ (See Mechanics); and if the velocity

Plate CCLXVII. fig. 6.

impressed

impressed upon the body when at C were continued uniformly, it would run through a space equal to 2 GP or GQ in the time $\frac{\sqrt{PG}}{\sqrt{16.087}}$. But (DYNAMICS, 22.) the times of description are as the spaces described directly, and the velocities inversely, and therefore the time of describing the space 2 GP or GQ uniformly, viz. the time $\frac{\sqrt{PG}}{\sqrt{16.087}}$ will be to the time of describing the space h H uniformly, as, $\frac{GQ}{GQ} : \frac{Hh}{HF}$, that is, as $\frac{GQ}{GQ}$ or $1 : \frac{\sqrt{PG}}{\sqrt{16.087}} = \frac{Hh}{HF} : \frac{\sqrt{PG}}{\sqrt{16.087}} \times \frac{Hh}{HF}$ the time in which the ascending body will describe H h uniformly; but PG being equal to $\frac{1}{4}$ P, the parameter of the parabola, we shall have $\sqrt{PG} = \sqrt{\frac{1}{4}P} = \frac{1}{2}\sqrt{P}$. Substituting this value of $\sqrt{PG}$ in the last formula, we shall have for the expression of the time of describing Hh uniformly $\frac{\frac{1}{2}\sqrt{P}}{\sqrt{16.087}} \times \frac{Hh}{HF}$. But by Prop. IV. the time in which the surface DH descends into the position dh, that is, in which it describes H h, is represented by $\frac{\sqrt{P}}{2A\sqrt{16.087}} \times Hr \times ob$ or $\frac{\sqrt{P}}{\sqrt{16.087}} \times \frac{Hr \times Hh}{2A}$. Therefore the time in which the ascending body moves through hH, is to the time in which the descending surface moves through Hh as $\frac{\frac{1}{2}\sqrt{P}}{\sqrt{16.087}} \times \frac{Hh}{HF} : \frac{\sqrt{P}}{\sqrt{16.087}} \times \frac{Hr \times Hh}{2A}$, which expressions after being multiplied by 2, and after substituting in the latter $\frac{DE}{HF}$ instead of H r, which is equal to it by construction, will become $\frac{\sqrt{P}}{\sqrt{16.087}} \times \frac{Hh}{HF} : \frac{\sqrt{P}}{\sqrt{16.087}} \times \frac{DE \times Hh}{A \times HF}$, DE representing, in this and in the following proposition, the area of the surface of the fluid at D. Now, if we multiply the first of these expressions by DE, and the second by A, we shall find the two products equal; consequently (Euclid VI. 16.) the first expression is to the second, or the time of the body's ascent through h H is to the time of the surface's descent through H h, as the area A of the orifice is to the area DE of the base of the cylindrical vessel; and as the same may be demonstrated of every elementary time in which the ascending body and the descending surface describe equal spaces, it follows that the whole time in which the ascending body will describe the height m C or PG, is to the whole time in which the surface AB will descend to mn, or in which the vessel will empty itself, as the area A of the orifice is to the area of the surface DE, that is $A : DE = \sqrt{\frac{PG}{16.087}} : \sqrt{\frac{PG}{16.087}} \times \frac{DE}{A}$, the time in which the vessel AB will empty itself. If RT mn be the vessel, it may be shewn in the same manner, that the time in which it will empty itself will be $\sqrt{\frac{PU}{16.087}} \times \frac{DE}{A}$, DE being equal to RT. But the difference between the time in which the vessel AB mn empties itself, and the time in which the vessel RT mn empties itself, will be equal to the time required in the proposition, during which the surface AB descends to RT. This time therefore will be

$$T = \sqrt{\frac{PG}{16.087}} \times \frac{DE}{A} \sqrt{\frac{PU}{16.087}} \times \frac{DE}{A} = \frac{DE\sqrt{PG} - DE\sqrt{PU}}{A\sqrt{16.087}}$$

$$T = \frac{DE \times \overline{\sqrt{PG} - \sqrt{PU}}}{A\sqrt{16.087}}.\ \text{Hence}$$

$$PU = \left(\frac{T, A\sqrt{16.087}}{DE} - \sqrt{PG}\right)^2$$

$$PG = \left(\frac{T, A\sqrt{16.087}}{DE} + \sqrt{PU}\right)^2$$

$$PG - PU \text{ or } UG = \frac{2T, A \times DE\sqrt{PG \times 16.087} - T^2A^2 \times 16.807}{\overline{DE}^2}$$

As the quantity of fluid discharged while the surface AB descends to RT is equal to DE $\times$ UG, we shall have

$$W = DE \times \frac{2T, A \times DE\sqrt{PG \times 16.087} - T^2A^2 \times 16.087}{\overline{DE}^2}$$

$$A = \frac{\overline{DE} \times \sqrt{PG \times PU}}{T\sqrt{16.087}}$$

$$DE = \frac{T, A\sqrt{16.087}}{\sqrt{PG} - \sqrt{PU}}.$$

Prop. VI.

Figs. 6. and 7.

157. If two cylindrical vessels are filled with water, the time in which their surfaces will descend through similar heights will be in the compound ratio of their bases, and the difference between the square roots of the altitudes of each surface at the beginning and end of its motion, directly, and the area of the orifices inversely.

Let AB mn, A′ B′, $m'n'$ be the two vessels; then, by the last proposition, the time T, in which the surface AC of the first descends to RT, will be to the time T′ in which the surface A′ B′ of the second descends to R′T′ as $\frac{DE \times \overline{\sqrt{PG} \times \sqrt{PU}}}{A\sqrt{16.087}}$ to $\frac{D'E' \times \overline{P'G' - \sqrt{P'U'}}}{A'\sqrt{16.087}}$, or, by dividing by $\sqrt{16.087}$, as $\frac{DE \times \overline{\sqrt{PG} - \sqrt{PU}}}{A}$ to $\frac{D'E' \times \overline{\sqrt{PG} - \sqrt{PU}}}{A}$. Q. E. D.

158. Cor. Hence the time in which two cylindrical vessels full of water will empty themselves, will be in the compound ratio of their bases and the square roots of their altitudes directly, and the area of the orifices inversely; for in this time the surfaces AB, A′B′ descend to mn, $m'n'$ respectively, and therefore $\sqrt{PG} - PU = \sqrt{PG}$; since PU vanishes, the times will be as $\frac{DE \times \sqrt{PG}}{A}$ to $\frac{D'E' \times \sqrt{P'G}}{A}$.

Prop. VII.

Theory of clepsydræ or water-clocks.

159. To explain the theory and construction of clepsydræ or water-clocks.

A clepsydra or water-clock, is a machine which, filled with water, measures time by the descent of the fluid surface. See Part III. on *Hydraulic Machinery*.

It has already been demonstrated in Prop IV. that the times in which the surface AB descends to DE and RT, &c. are as the areas GM r H, GM t U, &c. If such a form therefore is given to the vessel that the areas GM r H, GM t U, &c. increase uniformly as the times, or are to one another as the numbers 1, 2, 3, 4, 5, &c. the time in which the surface AB descends to DE, and RT, &c. will be in the same ratio, and the vessel will form a machine for measuring time. If the vessel is cylindrical and empties itself in 12 hours, its altitude may be divided in such a manner that the fluid surface may take exactly an hour to descend through each division. Let the cylindrical vessel, for example, be divided into 144 equal parts, then the surface of the water, when the twelve hours begins to run, will be 144 parts above the bottom of the vessel; when one hour is completed, the surface will be 121 parts above the bottom, and so on in the following manner.

Hours.	0	1	2	3	4	5	6	7	8	9	10	11	12
Distance of each Hour above the bottom.	144	121	100	81	64	49	36	25	16	9	4	1	0
Number of Parts in each Hour.	23	21	19	17	15	13	11	9	7	5	3	1	

For since the velocity with which the surface AB descends, the area of that surface being always the same, is as the square roots of its altitude above the orifice (Prop. I. Cor. 6.); and since the velocities are as the times of description, the times will also be as the square roots of the altitudes, that is, when

12	11	10	9	&c. are the times
144	121	100	81	will be the altitudes of the surface. Q. E. D,

Prop. VIII.

Lateral communication of motion in fluids. Fig. 9.

160. To explain the lateral communication of motion in fluids.

This property of fluids in motion was discovered by M. Venturi, professor of natural philosophy in the university of Modena, who has illustrated it by a variety of experiments in his work on the lateral communication of motion in fluids. Let a pipe AC, about half an inch in diameter and a foot long, proceeding from the reservoir AB, and having its extremity bent into the form CD, be inserted into the vessel CDG, whose side DG gradually rises till it passes over the rim of the vessel. Fill this vessel with water, and pour the same fluid into the reservoir AB, till, running down the pipe AC, it forms the stream EGH. In a short while, the water in the vessel CDG will be carried off by the current EG, which communicates its motion to the adjacent fluid. In the same way, when a stream of water runs through air, it drags the air along with it, and produces wind. Hence we have the water blowing machine which conveys a blast to furnaces, and which shall be described in a future part of this article. The lateral communication of motion, whether the surrounding fluid be air or water, is well illustrated by the following beautiful experiments of Venturi's. In the side of the reservoir AB insert the horizontal line P about an inch and a half in diameter, and five inches long. At the point o of this pipe, about seven-tenths of an inch from the reservoir, fasten the bent glass tube $o\,n\,m$, whose cavity communicates with that of the pipe, whilst its other extremity is immersed in coloured water contained in the small vessel F. When water is poured into the reservoir AB, having no connection with the pipe C, so that it may issue from the horizontal pipe, the red liquor will rise towards m in the incurvated tube $o\,n\,m$. If the descending leg of this glass syphon be six inches and a half longer than the other, the red liquor will rise to the very top of the syphon, enter the pipe P, and running out with the other water will in a short time leave the vessel F empty. Now the cause of this phenomenon is evidently this: When the water begins to flow from the pipe P, it communicates with the air in the syphon $o\,n\,m$, and drags

Water blowing machine.

drags a portion along with it. The air in the syphon is therefore rarefied, and this process of rarefaction is constantly going on as long as the water runs through the horizontal pipe. The equilibrium between the external air pressing upon the fluid in the vessel F, and that included in the syphon, being thus destroyed, the red liquor will rise in the syphon, till it communicates with the issuing fluid, and is dragged along with it through the orifice of the pipe P, till the vessel F is emptied.

Prop. IX.

161. To find the horizontal distance to which fluids will spout from an orifice perforated in the side of a vessel, and the curve which it will describe.

Theory of vertical and oblique jets. Plate CCLXVIII fig. 1.

Let AB be a vessel filled with water, and C an orifice in its side, so inclined to the horizon as to discharge the fluid in the direction CP. If the issuing fluid were influenced by no other force except that which impels it out of the orifice, it would move with an uniform motion in the direction CP. But immediately upon its exit from the orifice C it is subject to the force of gravity, and is therefore influenced by two forces, one of which impels it in the direction CP, and the other draws it downwards in vertical lines. Make CE equal to EG, and CP double of CS the altitude of the fluid. Draw PL parallel to CK and join SL. Draw also EF, GH parallel to CN, and FM, HN parallel to CG, and let CM, CN represent the force of gravity, or the spaces through which it would cause a portion of fluid to descend in the time that this portion would move through CE, CG respectively by virtue of the impulsive force. Now, it follows from the composition of forces, (Dynamics, 135.) that the fluid at C, being solicited in the direction CE by a force which would carry it through CE in the same time that the force of gravity would make it fall through CM, will describe the diagonal CF of the parallelogram CEFM, and will arrive at F in the same time that it would have reached E by its impulsive force, or M by the force of gravity; and for the same reason the portion of the fluid will arrive at H in the same time that it would have reached G by the one force, and N by the other. The fluid therefore being continually deflected from its rectilineal direction CP by the force of gravity, will describe a curve line CEHP, which will be a parabola: for since the motion along CP must be uniform, CE, CG will be to one another as the times in which they are described; and may therefore represent the times in which the fluid would arrive at E and G, if influenced by no other force. But in the time that the fluid has described CE gravity has made it fall through EF, and in the time that it would have described CG, gravity has caused it to fall through GH. Now, since the spaces are as the squares of the times in which they are described, (Dynamics, 37. 2.) we shall have EF : GH $=\overline{CE}^2 : \overline{CG}^2$. But on account of the parallelograms CEFM, CGHN, EF and GH are equal to CM and CN respectively, and MF, NH to CE, CG respectively; therefore CM : CN $=\overline{MF}^2 : \overline{NH}^2$, which is the property of the parabola, CM, CN being the abscissæ, and ME, NH the ordinates (Conic Sections, Part I. Prop. IX. Cor.).

162. On account of the parallels LP, CX, LC, GX, the triangles LCP, GCX are similar, and therefore (Geom. Sect. IV. Theor. XX.) CG : CX = PC : PL and GX : CX = CL : PL. Hence $CG=\frac{CX\times PC}{PL}$, and $GX=\frac{CX\times CL}{PL}$, but since PC = 2 CS, we have $CG=\frac{CX\times 2\,CS}{PL}$, and since GX=GX—HX, we shall have $GH=\frac{CX\times CL}{PL}-HX$. But as the parameter of the parabola CRK is equal to 4 CS (1), we have, by the property of this conic section, $\overline{NH}^2=CN\times 4\,CS$, or $\overline{CG}^2=4\,GH\times CS$; therefore, by substituting in this equation the preceding values of CG and GH, we shall have $\overline{CX}^2\times CS=CX\times CL\times PL-HX\times\overline{PL}^2$. Now, it is evident, from this equation, that HX is nothing, or vanishes when CX=0, or when $CX=\frac{CL\times PL}{CS}$, for HX being =0, $HX\times\overline{PL}^2$, will also be =0, and the equation will become $\overline{CX}^2\times CS=CX\times CL\times PL$, or dividing by CX and CS, it becomes $CX=\frac{CL\times PL}{CS}$. But when HX vanishes towards K, CX is equal to CK, consequently $CK=\frac{CL\times PL}{CS}$. Bisect CK in T, then $CT=\frac{CK}{2}$, and $CT=\frac{CL\times PL}{2\,CS}$. Draw TR perpendicular to CK, and TR will be found $=\frac{\overline{CL}^2}{4\,CS}$. Then if H*m* be drawn at right angles to HX, we shall have $CX=CT-Hm=\frac{CL\times PL}{2\,CS}-Hm$ and $HX=RT-Rm=\frac{\overline{CL}^2}{4\,CS}-Rm$. After substituting these values of CX and HX in the equation $\overline{CX}^2\times CS=CX\times CL\times PL-HX\times\overline{PL}^2$, it will become, after the necessary reductions, $\overline{Hm}^2=\frac{\overline{PL}^2}{CS}\times Rm$. The curve CRK is

(1) The parameter of the parabola described by the issuing fluid, is equal to *four times* the altitude of the fluid above the orifice. For since the fluid issues at C with a velocity equal to that acquired by falling through SC, if this velocity were continued uniform, the fluid would move through 2 CS or CP, in the same time that a heavy body would fall through SC. Draw PQ parallel to CS, and QW to CP; then since Q is in the parabola, the fluid will describe CP uniformly in the same time that it falls through CW by the force of gravity, therefore CW=CS. Now CP=2 CS, and $\overline{CP}^2=4\,\overline{CS}^2=4\times CS\times CS=4\times CS\times CW$; but it is a property of the parabola, that the square of the ordinate WQ or CP is equal to the product of the abscissa CW and the parameter, therefore 4 CS is the parameter of the parabola.

is therefore a parabola whose vertex is R, its axis RT and its parameter $\frac{\overline{PL}^2}{CS}$, R$m$ being an abscissa of the axis, and H m its correspondent ordinate. Now, making a=CS, the altitude of the reservoir; R = radius; m=PL the sine of the angle PCL; and n=CL, the cosine of the same angle, CP being radius. Then CP : PL=R : m, therefore PL×R=CP×m, and dividing by R and substituting $2a$ or 2 CS instead of its equal CP, we have $PL=\frac{2am}{R}$, and by the very same reasoning, we have $CL=\frac{2an}{R}$. Hence $RT\times\frac{\overline{CL}^2}{4\,CS}$ will be $=\frac{4a^2n^2}{R^2}$ divided by $4a$, or $RT=a\times\frac{n^2}{R^2}$, and $CT=\frac{CL\times PL}{2\,CS}=\frac{4a^2mn}{2a\times R^2}=2a\times\frac{mn}{R^2}$, and the parameter of the parabola $=\frac{PL^2}{CS}=\frac{4a^2m^2}{a\times R^2}=4a\times\frac{m^2}{R^2}$.

Fig. 2. 163. Hence we have the following construction. With ½CS as radius, describe the semicircle SGC, which the direction CR of the jet or issuing fluid meets in G. Draw GN perpendicular to CS, and having prolonged it towards R, make GR equal to GN. From R let fall RT perpendicular to CK and meeting it in T, and upon RT, CT describe the parabola CRK having its vertex in R, this parabola shall be the course of the issuing fluid. For by the construction NR or CT=2 GN, and on account of the similar triangles SGC, CGN, SC : SG=CG : GN; hence SC × GN = SG × CG, or 2 GN, or $CT=\frac{2\,SG\times CG}{SC}$. But from the similarity of triangles CS : CG=SG : GN and CS : CG=CG : CN, consequently, when CG is radius or =R, GN will be the sine m of the angle GCS, and CN its cosine n; and we shall then have, by Euclid VI. 16. and reduction $SG=\frac{CS\times m}{R}$, and $CG=\frac{CS\times n}{R}$. But substituting these values of SG and CG in the equation $CT=\frac{2\,SG\times CG}{SC}$, we have $CT=\frac{2}{SC}\times\frac{CS\times m}{R}\times\frac{CS\times n}{R}=\frac{2\,CS\times m\times CS\times n}{CS\times R\times R}=\frac{2\,CS\times mn}{R^2}=2a\times\frac{mn}{R^2}$. But the parameter P of the parabola CRK is equal to $\frac{\overline{CT}^2}{RT}$, because it is a third proportional to the abscissa and its ordinate, therefore $P=\frac{4a^2\times m^2n^2}{R^4\times RT}$. Now RT=CN, and $CN=\frac{NG\times n}{m}$, because CN : NG=m : n, or CN $=RT=a\times\frac{n^2}{R^2}$ by substituting the preceding value of NG. Therefore the parameter $P=\left(\frac{4a^2\times m^2n^2}{R^4}\div\left(\frac{a\times n^2}{R^2}\right)\right.$ $=4a\times\frac{m^2}{R^2}$, which is the same value of the parameter as was found in the preceding article, and therefore verifies the construction.

164. Cor. 1. Since NG=GR and CT=TK, the amplitude or distance CK, to which the fluid will reach on a horizontal plane, will be 4 NG, or quadruple the sine of the angle formed by the direction of the jet and a vertical line, the chord of the arch CG being radius.

165. Cor. 2. If S n be made equal to CN, and ng be drawn parallel to CT, and gr be made equal to ng; then if the direction of the jet be Cg, the fluid will describe the parabola C r K whose vertex is r, and will meet the horizontal line in K, because ng=NG, and $4\,ng$=4 NG=CK. The same may be shewn of every other pair of parabolas whose vertices R r are equidistant from $a\,c$ a horizontal line passing through the centre of the circle.

166. Cor. 3. Draw the ordinate $a\,b$ through the centre a, and since this is the greatest ordinate that can be drawn, the distance to which the water will spout, being equal to $4a$, will be the greatest when its line of direction passes through b, that is, when it makes an angle of 45° with the horizon.

167. Cor. 4. If an orifice be made in the vessel AB at N, and the water issues horizontally in the direction NG, it will describe the parabola NT, and CT will be equal to 2 NG. For (by Prop. IX. note) the parameter of the parabola NT is equal to 4 NS, and by the property of the parabola $\overline{CT}^2$= NC × 4 NS, or ½CT= $2\sqrt{NC\times NS}$; but by the property of the circle (Geom. Sect. IV. Theor. XXVIII.) $\overline{NG}^2$=NC×NS, and NG=$\sqrt{NC\times NS}$, hence CT=2NG. If the fluid is discharged from the orifice at n, so that Sn=CN, ng, will be =NG, and it will spout to the same distance CT.

Prop. X.

168. To determine the pressure exerted upon pipes by the water which flows through them.

Let us suppose the column of fluid CD divided into an infinite number of laminæ EFfe. Then friction being abstracted, every particle of each lamina will move with the same velocity when the pipe CD is horizontal. Now the velocity at the vena contracta $m\,n$ may be expressed by $\sqrt{A}$, A being the altitude of the fluid in the reservoir. But the velocity at the *vena contracta* is to the velocity in the pipe, as the area of the latter is to the area of the former. Therefore δ being the diameter of the *vena contracta*, and d that of the pipe CD, the area of the one will be to the area of the other, as $\delta^2 : d^2$, (Geometry, Sect. VI. Prop. IV.) consequently we shall have $d^2 : \delta^2=\sqrt{A} : \frac{\delta^2\sqrt{A}}{d^2}$, the velocity of the water in the pipe. But since the velocity $\sqrt{A}$ is due to the altitude A, the velocity $\frac{\delta^2\sqrt{A}}{d^2}$ will be due to the altitude $\frac{\delta^4 A}{d^4}$. Now as each particle of fluid which successively reaches the extremity DH of the pipe, has a tendency to move with the velocity $\sqrt{A}$, while it moves only with the velocity $\frac{\delta^2\sqrt{A}}{d^2}$, the extremity D n of the pipe will sustain a pressure equal to the difference of the pressures produced by the velocities $\sqrt{A}$ and $\frac{\delta^2\sqrt{A}}{d^2}$, that is, by

Fig. 3.

Experiments on the Motion of Fluids.

by a pressure $A-\frac{\delta^4 A}{d^4}$, A representing the pressure which produces the velocity $\sqrt{A}$, and $\frac{\delta^4 A}{d^4}$ the pressure which produces the velocity $\frac{\delta^2\sqrt{A}}{d^2}$. But this pressure is distributed through every part of the pipe CD, consequently the pressure sustained by the sides of the pipe will be $A-\frac{\delta^4 A}{d^4}$.

169. Cor. 1. If a very small aperture be made in the side of the pipe, the water will issue with a velocity due to the height $A-\frac{\delta^4 A}{d^4}$. When the diameter δ of the orifice is equal to the diameter d of the pipe, the altitude becomes A—A or nothing; and if the orifice is in this case below the pipe, the water will descend through it by drops. Hence we see the mistake of those who have maintained, that when a lateral orifice is pierced in the side of a pipe, the water will rise to a height due to the velocity of the included water.

170. Cor. 2. Since the quantities of water, discharged by the same orifice, are proportional to the square roots of the altitudes of the reservoir, or to the pressures exerted at the orifice, the quantity of water discharged by a lateral orifice may be easily found. Let W be the quantity of water discharged in a given time by the proposed aperture under the pressure A, and let w be the quantity discharged under the pressure $A-\frac{\delta^4 A}{\delta^4}$. Then $W : w = \sqrt{A} : \sqrt{A-\frac{\delta^4 A}{d^4}}$, consequently, $w\times\sqrt{A} = W\times\sqrt{A-\frac{\delta^4 A}{d^4}}$ and $w = \frac{W\times\sqrt{A-\frac{\delta^4 A}{d^4}}}{\sqrt{A}} = W\sqrt{\frac{d^4-\delta^4}{d^2}}$.

Therefore, since W may be determined by the experiments in the following chapter, w is known.

Chap. II. *Account of Experiments on the Motion of Water discharged from vessels, either by Orifices or additional Tubes, or running in Pipes or open Canals.*

Ratio between the area of the vena contracta and the orifice.

171. In the preceding chapter, we have taken notice of the contraction produced upon the vein of fluid issuing from an orifice in a tin plate, and have endeavoured to ascertain its cause. According to *Sir Isaac Newton*, the diameter of the *vena contracta* is to that of the orifice as 21 to 25. *Polenus* makes it as 11 to 13; *Bernouilli* as 5 to 7; the *Chevalier de Buat* as 6 to 7; *Bossut* as 41 to 50; *Michelotti*, as 4 to 5; and *Venturi*, as 4 to 5. This ratio, however, is by no means constant. It varies with the form and position of the orifice, with the thickness of the plate in which the orifice is made, and likewise with the form of the vessel and the weight of the superincumbent fluid. But these variations are too trifling to be regarded in practice.—We shall now lay before the reader an account of the results of the experiments of different philosophers, but particularly those of the Abbé Bossut, to whom the science is deeply indebted both for the accuracy and extent of his labours.

Sect. I. *On the Quantity of Water discharged from Vessels constantly full by Orifices in thin Plates.*

Experiments on the Motion of Fluids.

Quantities of water discharged by orifices in thin plates, according to the experiments of Bossut.

172. In the following experiments, which were frequently repeated in various ways, the orifice was pierced in a plate of copper about half a line thick. When the orifice is in the bottom of the vessel, it is called a *horizontal* orifice, and when it is in the side of it, it is called a *lateral* orifice.

Table I. *Shewing the Quantity of Water discharged in one minute, by orifices differing in form and position.*

Altitude of the fluid above the centre of the orifice.	Form and position of the orifice.	The orifice's diameter.	N° of cub. in. discharged in a minute.
Ft. In. Lin.	Circular and Horizontal	6 lines	2311
11 8 10	Circular and Horizontal	1 inch	9281
	Circular and Horizontal	2 inches	37203
	Rectangular and Horizontal	1 inch by 3 lines	2933
	Horizontal and Square	1 inch, side	11817
	Horizontal and Square	2 inch, side	47361
9 0 0	Lateral and Circular	6 lines	2018
	Lateral and Circular	1 inch	8135
4 0 0	Lateral and Circular	6 lines	1353
	Lateral and Circular	1 inch	5436
5 0 7	Lateral and Circular	1 inch	628

173. From the results contained in the preceding table, we may draw the following conclusions.

1. That the quantities of water discharged in equal times by different apertures, the altitudes of the fluid being the same, are very nearly as the areas of the orifices. That is, if A or a represent the areas of the orifices, and W, w the quantities of water discharged,

$$W : w = A : a.$$

2. The quantities discharged in equal times by the same aperture, the altitude of the fluid being different, are to one another very nearly as the square roots of the altitudes of the water in the reservoir, reckoning from the centres of the orifices. That is, if H, h be the different altitudes of the fluid, we shall have $W : w = \sqrt{H} : \sqrt{h}$.

3. Hence we may conclude in general that the quantities discharged in the same time by different apertures, and under different altitudes in the reservoir, are in the compound ratio of the areas of the orifices, and the square roots of the altitudes.—Thus, if W, w be the quantities discharged in the same time from the orifices A, a, under the same altitude of water; and if W′, w be the quantities discharged in the same time by the same aperture a under different altitudes, H, h: then by the first of the two preceding articles.

$W : w = A : a$, and by the second

$w : W' = \sqrt{H} : \sqrt{h}$. Multiplying these analogies together, gives us

$W w : W' w = A\sqrt{H} : a\sqrt{h}$, and dividing by w,

$W : W' = A\sqrt{H} : a\sqrt{h}$.

This

Experiments on the Motion of Fluids.

This rule is sufficiently correct in practice; but when great accuracy is required, the following remarks must be attended to.

4. Small orifices discharge less water in proportion than great ones, the altitude of the fluid being the same. The circumference of the small orifices being greater in proportion to the issuing column of fluid than the circumferences of greater ones, the friction, which increases with the area of the rubbing surfaces, will also be greater, and will therefore diminish the velocity, and consequently the quantity discharged.

5. Hence of several orifices whose areas are equal, that which has the smallest circumference will discharge more water than the rest under the same altitude of fluid in the reservoir, because in this case the friction will be least.—Circular orifices, therefore, are the most advantageous of all, for the circumference of a circle is the shortest of all lines that can be employed to inclose a given space.

6. In consequence of a small increase which the contraction of the vein of fluid undergoes, in proportion as the altitude of the water in the reservoir augments, the quantity discharged ought also to diminish a little as that altitude increases.

By attending to the preceding observations, the results of theory may be so corrected, that the quantities of water discharged in a given time may be determined with the greatest accuracy possible.

Comparison between the theoretical and the real discharges from a circular orifice.

174. The abbé Bossut has given the following table containing a comparison of the theoretical with the real discharges, for an orifice one inch diameter, and for different altitudes of the fluid in the reservoir. The real discharges were not found immediately by experiment, but were determined by the precautions pointed out in the preceding articles, and may be regarded to be as accurate as if direct experiments had been employed. The fourth column was computed by M. Prony.

TABLE II. *Comparison of the Theoretic with the Real discharges from an orifice one inch in diameter.*

Constant altitude of the water in the reservoir above the centre of the orifice.	Theoretical discharges through a circular orifice *one* inch in diameter.	Real discharges in the same time through the same orifice.	Ratio of the theoretical to the real discharges.
Paris Feet.	Cubic Inches.	Cubic Inches.	
1	4381	2722	1 to 0.62133
2	6196	3846	1 to 0.62073
3	7589	4710	1 to 0.62064
4	8763	5436	1 to 0.62034
5	9797	6075	1 to 0.62010
6	10732	6654	1 to 0.62000
7	11592	7183	1 to 0.61965
8	12392	7672	1 to 0.61911
9	13144	8135	1 to 0.61892
10	13855	8574	1 to 0.61883
11	14530	8990	1 to 0.61873
12	15180	9384	1 to 0.61819
13	15797	9764	1 to 0.61810
14	16393	10130	1 to 0.61795
15	16968	10472	1 to 0.61716
1	2	3	4

175. It is evident from the preceding table, that the theoretical, as well as the real discharges, are nearly proportional to the square roots of the altitudes of the fluid in the reservoir. Thus, if we take the altitudes 1 and 4, whose square roots are as 1 to 2, the real discharges taken from the table are 2722, 5436, which are to one another very nearly as 1 to 2, their real ratio being as 1 to 1.997.

The fourth column of the preceding table also shows us that the theoretical are to the real discharges nearly in the ratio of 1 to 0.62, or more accurately, as 1 to 0.61938; therefore 0.62 is the number by which we must multiply the discharges as found by the formulæ in the preceding chapter, in order to have the quantities of water actually discharged.

176. In order to find the quantities of fluid discharged by orifices of different sizes, and under different altitudes of water in the reservoir, we must use the table in the following manner. Let it be required, for example, to find the quantity of water furnished by an orifice three inches in diameter, the altitude of the water in the reservoir being 30 feet. As the real discharges are in the compound ratio of the area of the orifices, and the square roots of the altitudes of the fluid, (art. 173. N°3.) and as the theoretical quantity of water discharged by an orifice one inch in diameter, is by the second column of the table 16918 cubic inches in a minute, we shall have this analogy, $1\sqrt{15} : 9\sqrt{30} = 16968 : 215961$ cubic inches, the quantity required. This quantity being diminished in the ratio of 1 to .62, being the ratio of the theoretical to the actual discharges, gives 133896 for the real quantity of water discharged by the given orifice. But (by N° 5. of art. 173.) the quantity discharged ought to be a little greater than 133896, because greater orifices discharge more than small ones; and by N° 6. the quantity ought to be less than 133896, because the altitude of the fluid is double that in the table. These two causes therefore having a tendency to increase and diminish the quantity deduced from the preceding table, we may regard 133896 as very near the truth. Had the orifice been less than one inch, or the altitude less than 15 feet, it would have been necessary to diminish the preceding answer by a few cubic inches. Since the velocities of the issuing fluid are as the quantities discharged, the preceding results may be employed also to find the real velocities from those which are deduced from theory.

177. As the velocity of falling bodies is 16.087 feet per second, the velocity due to 16.087 feet will be 32.174 feet per second, and as the velocities are as the square roots of the height, we shall have $\sqrt{16.087} : \sqrt{H} = 32.174 : V$ the velocity due to any other height, consequently $V = \frac{32.174\sqrt{H}}{\sqrt{16.087}} = \frac{32.174\sqrt{H}}{4.011} = 8.016\sqrt{H}$, so that 8.016 is the coefficient by which we must always multiply the altitude of the fluid in order to have its theoretical velocity.

178. According to the experiments of M. Eytelwein, published at Berlin in 1801, in his treatise *Handbuch der Mechanik und der Hydraulik*, the following are the ratios between the theoretical and actual discharges, and the coefficients by which the height may be multiplied in order to find the velocities of the issuing fluid.

5 TABLE

Experiments on the Motion of Fluids.

TABLE III. *Results of Eytelwein's Experiments.*

N°	Nature of the orifices employed.	Ratio between the theoretical and real discharges.	Coefficients for finding the velocities.
1	When the orifice has the form of the contracted stream	1 to 0.973	7.8
2	For wide openings whose bottom is on a level with that of the reservoir	1 to 0.961	7.7
3	For sluices with walls in a line with the orifice	1 to 0.961	7.7
4	For bridges with pointed piers	1 to 0.961	7.7
5	For narrow openings whose bottom is on a level with that of the reservoir	1 to 0.861	6.9
6	For smaller openings in a sluice with side walls	1 to 0.861	6.9
7	For abrupt projections and square piers of bridges	1 to 0.861	6.9
8	For openings in sluices without side walls	1 to 0.635	5.1
9	For orifices in a thin plate	1 to 0.625	5.0

179. M. Eytelwein has likewise shown, that the quantity of water discharged from rectangular orifices in the side of a reservoir extending to the surface, may be found by taking two-thirds of the velocity due to the mean height, and allowing for the contraction according to the form of the orifice.

SECT. II. *On the Quantity of Water discharged from Vessels constantly full, by small Tubes adapted to Circular Orifices.*

Quantities of water discharged by small tubes.

180. The difference between the natural discharges, and those deduced from theory, arises from the contraction of the fluid vein, and from the friction of the water against the circumference of the orifice. If the operation of any of these causes could be prevented, the quantities of water actually discharged would approach nearer the theoretical discharges. There is no probability of diminishing friction in the present case by the application of unguents; but if a short cylindrical tube be inserted in the orifice of the vessel, the water will follow the sides of the tube, the contraction of the fluid vein will be in a great measure prevented, and the actual discharges will approximate much nearer to these deduced from theory, than when the fluid issues through a simple orifice.

When the cylindrical tube is two inches long and two in diameter, the fluid vein is contracted as in simple orifices.

181. If a cylindrical tube two inches long, and two inches in diameter, be inserted in the reservoir, and if this orifice is stopped by a piston till the reservoir is filled with water, the fluid, when permitted to escape, will not follow the sides of the tube, that is, the tube will not be filled with water, and the contraction in the vein of fluid will take place in the same manner as if the orifice were pierced in a thin plate. When the cylindrical tube was one inch in diameter, and two inches long, the water followed the sides of the tube, and the vein of fluid ceased to contract. While M. Bossut was repeating this experiment, he prevented the escape of the fluid by placing the instrument MN, consisting of a handle and a circular head, upon the interior extremity of the tube, and found, to his great surprise, that when he withdrew the instrument MN, to give passage to the water, it sometimes followed the sides of the tube, and sometimes detached itself from them, and produced a contraction in the fluid vein similar to that which took place when the first tube was employed. After a little practice, he could produce either of these effects at pleasure. The same phenomenon was exhibited when the length of the tube was diminished to one inch six lines; only it was more difficult to make the fluid follow the circumference of the tube. This effect was still more difficult to produce when its length was reduced to one inch; and when it was so small as half an inch, the water uniformly detached itself from its circumference, and formed the *vena contracta*.

Plate CCLXVIII fig. 4.

182. TABLE IV. *Shewing the Quantities of Water discharged by Cylindrical Tubes one inch in diameter with different lengths.*

Quantities of fluid discharged from cylindrical tubes of the same diameters but different lengths.

•		Variable lengths of the tubes expressed in lines.	Cubic inches discharged in a minute.
Constant altitude of the fluid above the superior base of the tube being 11 feet 8 inches and 10 lines.	The tube being filled with the issuing fluid	48	12274
		24	12188
		18	12168
	The tube not filled with the issuing fluid	18	9282

The experiments in the preceding table were made with tubes inserted in the bottom of the vessel. When the tubes were fixed horizontally in the side of the reservoir, they furnished the very same quantities of fluid, their dimensions and the altitude of the fluid remaining the same.

It appears from the preceding results, that the quantities of water discharged increase with the length of the tube, and that these quantities are very nearly as the square roots of the altitudes of the fluid above the interior orifice of the vertical tube.

We have already seen that the theoretical are to real discharges, as 1 to 0.62, or nearly as 16.1 to 10. But by comparing the two last experiments in the preceding table, it appears that the quantity of fluid discharged by a cylindrical tube where the water follows its sides, is to the quantity discharged by the same tube when the *vena contracta* is formed, as 13 to 10; and since the same quantity must be discharged by the latter method as by a simple orifice, we may conclude

Experiments on the Motion of Fluids.

clude that the quantity discharged according to theory, and that which is discharged by a cylindrical tube and by a simple orifice, are to one another very nearly as the numbers 16, 13, 10. Though the water therefore follows the sides of the cylindrical tube, the contraction of the fluid vein is not wholly destroyed; for the difference between the quantity discharged in this case, and that deduced from theory, is too great to be ascribed to the increase of friction which arises from the water following the circumference of the tube.

183. In order to determine the effect of tubes of different diameters, under different altitudes of water in the reservoir, M. Bossut instituted the experiments, the results of which are exhibited in the following table.

TABLE V. *Shewing the Quantities of Water discharged by Cylindrical Tubes two inches long, with different diameters.*

Quantities of water discharged by cylindrical tubes of the same length but different diameters.

Constant altitude of the water above the orifice.		Diameter of the tube.		Quantity of water discharged in a minute.
Feet.	Inches.		Lines.	Cubic inches.
3	10	The tube being filled with the issuing fluid.	6	1689
			10	4703
		The tube not filled with the issuing fluid.	6	1293
			10	3598
2	0	The tube being filled with the issuing fluid.	6	1222
			10	3402
		The tube not filled with the issuing fluid.	6	935
			10	2603

184. By comparing the different numbers in this table we may conclude,

1. That the quantities of water discharged by different cylindrical tubes of the same length, the altitude of the fluid remaining the same, are nearly as the areas of the orifices, or the squares of their diameter.

2. That the quantities discharged by cylindrical tubes of the same diameter and length, are nearly as the square roots of the altitude of the fluid in the reservoir.

3. Hence the quantities discharged during the same time, by tubes of different diameters, under different altitudes of fluid in the reservoir, are nearly in the compound ratio of the squares of the diameters of the tube, and the square roots of the altitudes of the water in the reservoir.

4. By comparing these results with those which were deduced from the experiments with simple orifices, it will be seen that the discharges follow the same laws in cylindrical tubes as in simple orifices.

185. The following table is deduced from the foregoing experiments, and contains a comparative view of the quantities of water discharged by a simple orifice, according to theory, and those discharged by a cylindrical tube of the same diameter under different altitudes of water. The numbers might have been more accurate by attending to some of the preceding remarks; but they are sufficiently exact for any practical purpose. The fourth column, containing the ratio between the theoretical and actual discharges, was computed by M. Prony.

TABLE VI. *Comparison of the Theoretical with the Real Discharges from a Cylindrical Tube one inch in Diameter and two inches Long.*

Constant altitude of the water in the reservoir above the centre of the orifice.	Theoretical discharges through a circular orifice one inch in diameter.	Real discharges in the same time by a cylindrical tube one inch in diameter and two inches long.	Ratio of the theoretical to the real discharges.
Paris Feet.	Cubic inches.	Cubic inches.	
1	4381	3539	1 to 0.81781

15	16968	13620	1 to 0.80270
1	2	3	4

By comparing the preceding table with that in art. 174. we shall find that cylindrical tubes discharge a much greater quantity of water than simple orifices of the same diameter, and that the quantities discharged are as 81 to 62 nearly. This is a curious phenomenon, and will be afterwards explained.

186. The application of this table to other additional tubes under different altitudes of the fluid, not contained in the first column, is very simple. Let it be required, for example, to find the quantity of water discharged by a cylindrical tube, 4 inches in diameter, and 8 inches long, the altitude of the fluid in the reservoir being 25 feet. In order to resolve this question, find (by art. 176.) the theoretical quantity discharged which in the present instance will be 350490 cubic inches, and this number diminished in the ratio of 1 to 0.81 will give 284773 for the quantity required. The length of the tube in this example was made 8 inches, because, when the length of the tube is less than twice its diameter, the water does not easily follow its interior circumference. If the tube were longer than 8 inches, the quantity of fluid discharged would have been greater, because it uniformly increases with the length of the tube; the greatest length of the tube being always small, in comparison with the altitude of the fluid in the reservoir.

187. Hitherto we have supposed the tube to be exactly cylindrical. When its interior surface, however, is conical, the quantities discharged undergo a considerable variation, which may be estimated from the following experiments of the marquis Poleni, published in his work *De Castellis per quæ derivantur fluviorum aquæ*, &c. which appeared at Padua in 1718.

TABLE

Experiments on the Motion of Fluids.

Quantities of water discharged by conical tubes according to the experiments of M. Poleni.

Table VII. *Shewing the Quantities of Water discharged by Conical Tubes of different Diameters.*

		Apertures employed.	Interior diameter.	Exterior diameter.	Quantity discharged in a min. in cubic ft.	Time in which 73035 cub. inches were discharged.
Constant altitude of the water in the reservoir, 256 lines, or 1 foot 9 inches and 4 lines.	Length of each tube 92 lines, or 7 inches 8 lines.	Orifice in a thin plate,	26 lines	26 lines	15877	4′ 36″
		Cylindrical tube,	26	26	23434	3′ 7″
		1st Conical tube,	33	26	24758	2′ 57″
		2d Conical tube,	42	26	24619	2′ 58″
		3d Conical tube,	60	26	24345	3′ 0″
		4th Conical tube,	118	26	23687	3′ 5″

From these experiments we are authorised to conclude, 1. That the real discharges are less than those deduced from theory, which in the present case is 27425 cubic inches in a minute, and 2. That when the interior orifice of the tube is enlarged to a certain degree, the quantity discharged is increased; but that when this enlargement is too great, a contraction takes place without the exterior orifice, and the quantity discharged suffers a diminution. If the smallest base of the conical tube be inserted in the side of the reservoir, it will furnish more water than a cylindrical tube whose diameter is equal to the smallest diameter of the conical tube; for the divergency of its sides changes the oblique motion which the particles would otherwise have had, when passing from the reservoir into the tube.

Experiments of Venturi with tubes of various forms. Plate CCLXVIII. fig. 4.

188. The experiments of Poleni and Bossut having been made only with tubes of a conical and cylindrical form, M. Venturi was induced to institute a set of experiments, in which he employed tubes of the various forms exhibited in fig. 4. The results of his researches are contained in the following table, for which we have computed the column containing the number of cubic inches discharged in one minute, in order that the experiments of the Italian philosopher may be more easily compared with those which are exhibited in the preceding tables. The constant altitude of the water in the reservoir was 32.5 French inches, or 34.642 English inches. The quantity of water which flowed out of the vessel in the times contained in the first column was 4 French cubic feet, or 4.845 English cubic feet. The measures in the table are all English, unless the contrary be expressed.

Table VIII. *Shewing the Quantities of Water discharged from Orifices of various forms, the constant Altitude of the Fluid being 32.5 French, or 34.642 English inches.*

N°	Nature and dimensions of the tubes and orifices.	Time in which 4 Paris cub. ft. were discharged.	Paris cubic inches discharged in a minute
		Seconds.	
1	A simple circular orifice in a thin plate, the diameter of the aperture being 1.6 inches,	41	10115
2	A cylindrical tube 1.6 inches in diameter, and 4.8 inches long,	31	13378
3	A tube similar to B, figure 4. which differs from the preceding only in having the contraction in the shape of the natural contracted vein,	31	13378

10	The tube F, consisting of a cylindrical tube 3.2 inches long, and 1.376 inches in diameter, interposed between the two conical parts of the preceding,	28.5.	14516

Important facts deducible from Venturi's experiments. Fig. 4.

189. These experiments of Venturi inform us of a curious fact, extremely useful to the practical hydraulist. They incontestably prove, that when water is conveyed through a straight cylindrical pipe of an unlimited length, the discharge of water may be increased only by altering the form of the terminations of the pipe, that is, by making the end of the pipe A of the same form as the *vena contracta*, and by forming the other extremity BC into a truncated one, having its length BC about 9 times the diameter of the cylindrical tube AB, and the aperture at C to that at B, as 18 to 10. By giving this form to the pipe, it will discharge more than twice as much water in a given time, the quantity discharged by the cylindrical pipe being to the

Experiments on the Motion of Fluids.

the quantity discharged by the pipe of the form ABC, as 10 to 24.

190. M. Venturi also found, that the quantities of water discharged out of a straight tube, a curved tube forming a quadrantal arc, and an elbowed tube with an angle of 90°, each branch having a horizontal position, are to one another nearly as the numbers 70, 50, 45. Hence we see the disadvantages of sinuosities and bendings in conduit pipes. In the construction of hydraulic machines, any variation in the internal diameter of the pipe ought to be carefully avoided, excepting those alterations at the extremities which we have recommended in the preceding paragraph.

Results of Eytelwein's experiments on additional tubes.

191. It appears from the researches of Eytelwein, that when the shortest tube that will make the water follow its sides is applied to the reservoir, the quantity discharged will be to that deduced from theory, as 0.810 to 1.000, and the multiplier for finding the velocity will be 6.5. When the lengths of the tubes are increased from *two* to *four* times their diameter, the ratio of the actual and theoretical discharge will be 0.822 to 1.000, and the constant multiplier for finding the velocity will be 6.6. In employing a conical tube approaching to the figure of the *vena contracta*, the ratio of the discharges was as 0.92 to 1.00, and when its edges were rounded off, as 0.98 to 1.00 computing from its least section. He found also that the smallest quantity of water was discharged, when the interior extremity of the tube projected within the reservoir, the quantity furnished in this case being reduced to one half of what was discharged when the tube had its proper position.

Reason why cylindrical tubes furnish more water than orifices of the same diameter.

192. When a cylindrical tube is applied to an orifice, the oblique motion of the particles which enter it is diminished; the vertical velocity of the particles, therefore, is increased, and consequently the quantity of water discharged. M. Venturi maintains that the pressure of the atmosphere increases the expence of water through a simple cylindrical tube, and that in conical tubes, the pressure of the atmosphere increases the expenditure in the ratio of the exterior section of the tube to the section of the contracted vein, whatever be the position of the tube.

Best form for tubes employed to discharge water.

193. Of all the tubes that can be employed for discharging water, that is the most advantageous which has the form of a contracted vein. Hence, it will be a truncated cone with its greatest base next the reservoir, having its length equal to half the diameter of that base, and the area of the two orifices as 8 to 5, or their diameters in the subduplicate ratio of these numbers, viz. as $\sqrt{8} : \sqrt{5}$.

Sect. III. *Experiments on the Exhaustion of Vessels.*

Difficulty in determining the time when a vessel is completely exhausted.

194. It is almost impossible to determine the exact time in which any vessel of water is completely exhausted. When the surface of the fluid has descended within a few inches of the orifice, a kind of conoidal funnel is formed immediately above the orifice. The pressure of the superincumbent column being therefore removed, the time of exhaustion is prolonged. The water falls in drops; and it is next to impossible to determine the moment when the vessel is empty. Instead, therefore, of endeavouring to ascertain the time in which vessels are completely exhausted, the abbé Bossut has determined the times in which the superior surface of the fluid descends through a certain vertical height, and his results will be found in the following table.

Table IX. *Shewing the times in which Vessels are partly exhausted.*

Primitive altitude of the water in the vessel.	Constant area of a horizontal section of the vessel.	Diameter of the circular orifice.	Depression of the upper surface of the fluid.	Time in which this depression takes place.

11.6666	9	1	4	7 $25\frac{1}{2}$
		2	4	1 52
		1	9	20 $24\frac{1}{2}$
		2	9	5 6
PG	DE	$\sqrt{\frac{A}{.7854}}$	PG—PU	T

Experiments compared with theory. Plate CCLXI fig. 5.

195. In order to compare these experimental results with those deduced from theory, we must employ the formula (in Prop. V. 156.) where the time in which the surface descends through any height is $T=\frac{DE\times\sqrt{PG}-\sqrt{PU}}{A\sqrt{16.087}}$, in which DE is the area of a section of the vessel, PG the primitive altitude of the surface above the centre of the orifice, PU the altitude of the surface after the time T is elapsed, A the area of the orifice, and 16.087 the space through which a heavy body descends in one second of time. That the preceding formula may be corrected, we must substitute 0.62 A or $\frac{5A}{8}$, instead of A, in the formula, 0.62 A being the area of the *vena contracta*; and as the measures in the preceding table are in Paris feet, we must use 15.085 instead of 16.087, the former being the distance in Paris feet, and the latter the distance in English feet, which falling bodies describe in a second. The formula, therefore, will become $T=\frac{DE\times\sqrt{PG-PU}}{0.62A\sqrt{15.085}}$, and when the computations are made for the different diameters of the orifices and the different depressions of the fluid surface, the results will be had, which are exhibited in the last column of the following table, containing the values of T, according to theory and experience.

Table X. *Comparison of the results of Theory with those of Experience.*

It

Experiments on the Motion of Fluids.

It appears from this table that the times of discharge, by experiment, differ very little from those deduced from the corrected formula; and that the latter always err in defect. This may arise from 0.62 being too great a multiplier for finding the corrected diameter of the orifice.—When the orifices are in the sides of the reservoir, the altitude PG, PU of the surface may be reckoned from the centre of gravity of the orifice, unless when it is very large.

Experiments on the Motion of Fluids.

Sect. IV. *Experiments on Vertical and Oblique Jets.*

Vertical jets do not rise to the same altitude as that of their reservoirs.

196. We have already seen, that, according to theory, vertical jets should rise to the same altitude as that of the reservoirs from which they are supplied. It will appear, however, from the following experiments of Bossut, that jets do not rise exactly to this height. This arises from the friction at the orifice, the resistance of the air, and other causes which shall afterwards be explained.

Table XI. *Containing the Altitudes to which Jets rise through Adjutages of different forms, the Altitude of the Reservoir being Eleven Feet, reckoning from the upper surface of the horizontal Tubes* m n P, o p R.

Plate CLXVIII. fig. 6.

Diameter of the horizontal tubes *m*P, *n*R, each being six feet long.		Form of the orifices.	References to Fig. 6.	Diameter of the orifice.	Altitude of the jet when rising vertically, reckoning from *m*.			Altitude of the jet when inclined a little to the vertical.			Description of the jets.

0	9½	———	L	4	9	7	10	—	—	—	The jet much deformed, and very much enlarged at top.
0	9½	———	K	8	7	10	0	—	—	—	The column much broken; and the successive jets are detached from each other.

Ratio between the diameters of the tube and the adjutage for producing a maximum height to the jet.

197. It appears, from the three first experiments of the preceding table, that *great jets rise higher than small ones;* and from the three last experiments, that *small jets rise higher than great ones when the horizontal tube is very narrow.* There is therefore a certain proportion between the diameter of the horizontal tube and that of the adjutage or orifice, which will give a maximum height to the jet. This proportion may be found in the following manner. Let D be the diameter of the tube, *d* that of the adjutage, *a* the altitude B *m* of the reservoir, *b* the velocity along the tube; and as the velocity at the adjutage is constant, it may be expressed by $\sqrt{a}$. Now (art. 150. note) the velocity in the tube is to the velocity at the adjutage as the area of their respective sections, that is, as the square of the diameter of the one is to the square of the diameter of the other. Therefore, $\sqrt{g} : b = D^2 : d^2$, and consequently $b = \frac{d^2\sqrt{a}}{D^2}$. If there is another tube and another adjutage, the corresponding quantities may be the same letters in the Greek character, viz. Δ, δ, α, β, and we shall have the equation $\beta = \frac{\delta^2\sqrt{\alpha}}{\Delta^2}$. If we wish, therefore, that the two jets be furnished in the same manner, then if the velocity in the first tube leaves to the first jet all the height possible, the velocity in the second tube leaves also to the second jet all the height possible, and we shall have $b = \beta$, or $\frac{d^2\sqrt{a}}{D^2} = \frac{\delta^2\sqrt{\alpha}}{\Delta^2}$. Hence $D^2 : \Delta^2 = dd\sqrt{a} : \delta\delta\sqrt{\alpha}$, that is, *the squares of the diameters of the horizontal tubes ought to be to one another in the compound ratio of the squares of the diameters of the adjutages, and the square roots of the altitudes of the reservoir.*

Experiments on the Motion of Fluids.

voir. Now, it appears from the experiments of Mariotte (*Traité de mouvement des eaux*), that when the altitude of the reservoir is 16 feet, and the diameter of the adjutage six lines, the diameter of the horizontal tube ought to be 28 lines and a half. By taking this as a standard, therefore, the diameters of the horizontal tube may be easily found by the preceding rule, whatever be the altitude of the reservoir and the diameter of the adjutage.

It results from the three last experiments, that the jets rise to the smaller height when the adjutage is a cylindrical tube (see D fig. 6.), that a conical adjutage throws the fluid very much higher, and that when the adjutage is a simple orifice the jet rises highest of all.

Fig. 6.

198. By comparing the preceding experiments with those of Mariotte, it appears, that *the differences between the heights of vertical jets, and the heights of the reservoir, are nearly as the squares of the heights of the jets.* Thus, $ab : cd = \overline{Eb}^2 : \overline{Fd}^2$; therefore, if ab be known by experiment, we shall have $cd = \frac{ab \times \overline{Fd}^2}{\overline{Eb}^2}$, and by adding cd to Fd, we shall have the altitude of the reservoir. But if Fc were given, and it were required to find Fd, the height of the jet, we have, by the preceding analogy, $\overline{Fd}^2 = \frac{\overline{Eb}^2 \times cd}{ab}$. But cd is an unknown quantity, and is equal to $Fc - Fd$, therefore, by substitution, $\overline{Fd}^2 = \frac{\overline{Eb}^2 \times \overline{Fc - Fd}}{ab}$, or $\overline{Fd}^2 \times \frac{\overline{Eb}^2}{ab} \times \overline{Fd} = \frac{Eb^2 \times Fc}{ab}$, which is evidently a quadratic equation, which, after reduction, becomes $Fd = \sqrt{\frac{\overline{Eb}^2 \times Fc}{ab} + \frac{\overline{Eb}^4}{4}} - \frac{Eb^2}{2}$.

A small inclination of the jet increases its altitude.

199. From a comparison of the 5th and 6th columns of the table, it appears that a small inclination of the jet, to a vertical line, makes it rise higher than when it ascends exactly vertical (K); but even then it still falls short of the height of the reservoir. When the water first escapes from the adjutage, it generally springs higher than the reservoir; but this effect is merely momentary, as the jet instantly subsides, and continues at the altitudes exhibited in the foregoing tables. The great size of the jet at its first formation, and its subsequent diminution, have been ascribed by some philosophers to the elasticity of the air which follows the water in its passage through the orifice; but it is obvious, that this air, which moves along with the fluid, can never give it an impulsive force. In order to explain this phenomenon, let us suppose the adjutage to be stopped; then the air which the water drags along with it, will lodge itself at the extremity of the adjutage, so that there will be no water contiguous to the body which covers the orifice. As soon as the cover is removed from the adjutage, the imprisoned air escapes; the water immediately behind it rushes into the space which it leaves, and thus acquires in the tube a certain velocity which increases at the orifice in the ratio of the area of the section of the tube to the area of the section of the orifice (art. 150. note). When the orifice is small in comparison with the tube, the velocity of the issuing fluid must be considerable, and will raise it higher than the reservoir. But as the jet is resisted by the air, and retarded by the descending fluid, its altitude diminishes, and the simple pressure of the fluid becomes the only permanent source of its velocity. The preceding phenomenon was first noticed by Torricellius *, who seems to ascribe the diminution in the altitude of the jet to the gravity of the descending particles.

The jet rises higher than the reservoir at its commencement.

200. The following table exhibits all that is necessary in the formation of jets. The two first columns are taken from Mariotte †, and shew the altitude of the reservoir requisite to producing a jet of a certain height. The third column contains, in Paris pints, 36 of which are equal to a cubic foot, the quantity of water discharged in a minute by an orifice six lines in diameter. The fourth column, computed from the hypothesis in art. 197. contains the diameters of the horizontal tubes for an adjutage six lines in diameter, relative to the altitudes in the second column. The thickness of the horizontal tubes will be determined in a subsequent section.

TABLE XII. *Containing the Altitudes of Reservoirs, the Diameters of the Horizontal Tubes, &c. for Jets of different heights.*

201. We have already seen that jets do not rise to the heights of their reservoirs; and have remarked that the difference between theory and experiment arises from the friction at the orifice, and the resistance of the air. The diminution of velocity produced by friction is very small, and the resistance of the air is a very inconsiderable

(K) This was also observed by Wolfius, *Opera Mathematica*, tom. i. p. 802. Schol. iv.

Experiments on the Motion of Fluids.

considerable source of retardation, unless when the jet rises to a great altitude. We must seek therefore for another cause of obstruction to the rising jet, which, when combined with these, may be adequate to the effect produced. Wolfius * has very properly ascribed the diminution in the altitude of the jet to the gravity of the falling water. When the velocity of the foremost particles is completely spent, those immediately behind by impinging against them lose their velocity, and, in consequence of this constant struggle between the ascending and descending fluid, the jet continues at an altitude less than that of the reservoir. Hence we may discover the reason why an inclination of the jet increases its altitude; for the descending fluid falling a little to one side does not encounter the rising particles, and therefore permits them to reach a greater altitude, than when their ascension is in a vertical line. Wolfius observes, in proof of his remark that the diminution is occasioned also by the weight of the *ascending* fluid, that mercury rises to a less height than water: but this cannot be owing to the greater specific gravity of mercury; for though the weight of the mercurial particles is greater than that of water, yet the momentum with which they ascend is proportionally greater, and therefore the resistance which opposes their tendency downwards, has the same relation to their gravity, as the resistance in the case of water has to the weight of the aqueous particles.

* *Wolfii Opera Mathemat.* tom. i. p. 802. schol. 4.

Experiments on oblique jets Plate CCLXVIII. fig 2.

202. The theory of oblique jets has already been discussed in Prop. IX. art. 161. The two following experiments of Bossut contain all that is necessary to be known in practice. When the height NS of the reservoir AB was 9 feet, and the diameter of the adjutage at N, 6 lines, a vertical abscissa CN of 4 feet 3 inches and 7 lines, answered to a horizontal ordinate CT of 11 feet 3 inches and 3 lines. When the altitude NS of the reservoir was 4 feet, the adjutage remaining the same, a vertical abscissa CN of 4 feet 3 inches, and 7 lines, corresponded with a horizontal ordinate CT of 8 feet 2 inches and 8 lines. The real amplitudes, therefore, are less than those deduced from theory; and both are very nearly as the square roots of the altitudes of the reservoirs. Hence, to find the amplitude of a jet when the height of the reservoir is 10 feet, and the vertical abscissa the same, we have $\sqrt{9}$ feet : $\sqrt{16}$ feet = 11 feet 3 inches 3 lines : 15 feet 4 lines, the amplitude of the jet required. This rule, however, will apply only to small reservoirs; for when the jets enlarge, the curve which they describe cannot be determined by theory, and therefore the relation between the amplitudes and the heights of the reservoirs must be uncertain.

SECT. V. *Experiments on the Motion of Water in Conduit Pipes.*

203. The experiments of the chevalier de Buat, will be given at great length in the article *WATER-Works*, for which we have been indebted to the late learned Dr Robison. That the reader, however, may be in possession of every thing valuable on a subject of such public importance, we shall at present give a concise view of the experiments of Couplet and Bossut, and of the practical conclusions which they authorize us to form.

204. It must be evident to every reader, that, when water is conducted from a reservoir by means of a long horizontal pipe, the velocity with which the water enters the pipe will be much greater than the velocity with which it issues from its farther extremity; and, that if the pipe has various flexures or bendings, the velocity with which the water leaves the pipe will be still farther diminished. The difference, therefore, between the initial velocity of the water, and the velocity with which it issues, will increase with the length of the pipe and the number of its flexures. By means of the theory, corrected by the preceding experiments, it is easy to determine with great accuracy the initial velocity of the water, or that with which it enters the pipe; but on the obstructions which the fluid experiences in its progress through the pipe, and on the causes of these obstructions, theory throws but a feeble light. The experiments of Bossut afford much instruction on this subject; and it is from them that we have arranged the following table, containing the quantities of water discharged by pipes of different lengths and diameters, compared with the quantities discharged from additional tubes.

TABLE

Experiments on the Motion of Fluids.

TABLE XIII.—*Containing the Quantities of Water discharged by Conduit Pipes of different lengths and diameters, compared with the Quantities discharged from additional tubes inserted in the same Reservoir.*

Constant altitude of the water in the reservoir above the axis of the tube.	Length of the conduit Pipes.	Quantity of water discharged in a minute by an additional tube.	Quantity of water discharged by the conduit pipe in a minute.	Ratio between the quantities of water furnished by the tube and the pipe of 16 lines diameter.	Quantity of water discharged by an additional tube in a minute	Quantity of water discharged by the conduit pipe in a minute.	Ratio between the quantities of water furnished by the tube and the pipe of 24 lines diameter.

Deductions from the preceding table.

205. The third column of the preceding table contains the quantity of water discharged through an additional cylindrical tube 16 lines in diameter, or the quantity discharged from the reservoir into a conduit pipe of the same diameter; and the fourth column contains the quantity discharged by the conduit pipe. The fifth column, therefore, which contains the ratio between these quantities, will also contain the ratio between the velocity of the water at its entrance into the conduit pipe, which we shall afterwards call its initial velocity, and its velocity when it issues from the pipe, which shall be denominated its final velocity; for the velocities are as the quantities discharged, when the orifices are the same. The same may be said of the 6th, 7th, and 8th columns, with this difference only, that they apply to a cylindrical tube and a conduit pipe 24 lines in diameter.

Cause of the retardation of water in moving pipes.

206. By examining some of the experiments in the foregoing table, it will appear, that the water sometimes loses $\frac{8}{10}$ths of its initial velocity. The velocity thus lost is consumed by the friction of the water on the sides of the pipe, as the quantities discharged, and consequently the velocities, diminish when the length of the pipe is increased. In simple orifices, the friction is in the inverse ratio of their diameter; and it appears from the table, that the velocity of the water is more retarded in the pipe 16 lines in diameter, than in the other, which has a diameter of 24 lines. But though the velocity decreases when the length of the tube is increased, it by no means decreases in a regular arithmetical progression, as some authors have maintained. This is obvious from the table, from which it appears, that the differences between the quantities discharged, which represent also the differences between the velocities, always *decrease*, whereas the differences would have been *equal*, had the velocities decreased in an arithmetical progression. The same truth is capable of a physical explanation. If every filament of the fluid rubbed against the sides of the conduit pipe, then, since in equal times they all experience the same degree of friction, the velocities must diminish in the direct ratio of the lengths of the tubes, and will form a regular arithmetical progression, of which the first term will be the final, and the last the initial velocity of the water. But it is only the lateral filaments that are exposed to friction. This retards their motion; and the adjacent filaments which do not touch the pipe, by the adhesion to those which do touch it, experience also a retardation, but in a less degree, and go on with the rest, each filament sustaining a diminution of velocity inversely proportional to its distance from the sides of the pipe. The lateral filaments alone, therefore, provided they always remain in contact with the sides of the pipe, will have their velocities diminished in arithmetical progression, while the velocities of the central filaments will not decrease in a much slower progression; consequently, the mean velocity of the fluid, or that to which the quantities discharged are proportional, will decrease *less* rapidly than the terms of an arithmetical progression.

207. When the altitude of the reservoir was two feet, the diminution of discharge, and consequently of velocity, was greater than when the height of the reservoir was only one foot. The cause of this is manifest. Friction increases with the velocity, because a greater number of obstructions are encountered in a certain time, and the velocities are as the square roots of the altitudes; therefore friction must also be as the square roots of the altitudes of the reservoir. On some occasions Coulomb found that the friction of solid bodies diminished with an augmentation of velocity, but there is no ground for

Experiments on the Motion of Fluids.

for supposing that this takes place in the case of fluids.

In inclined pipes the velocity of the fluid is increased by its relative gravity. Plate CCLXVIII. fig. 7.

208. When the pipe is inclined to the horizon, as CGF, the water will move with a greater velocity than in the horizontal tube CG *hf*. In the former case, the relative gravity of the water, which is to its absolute gravity as F*f* to C*f*, or as the height of the inclined plane to its length, accelerates its motion along the tube. But this acceleration takes place only when the inclination is considerable; for if the angle which the direction of the pipe forms with the horizon were no more than one degree, the retardation of friction would completely counterbalance the acceleration of gravity. Thus when the pipe CF, 16 lines in diameter, was 177 feet, and was divided into three equal parts in the points D and E, so that CD was 59 feet, CE 118 feet; and when CF was to F*f* as 2124 to 241, the quantity of water discharged at F was 5795 cubic inches in a minute, the quantity discharged at E was 5801 cubic inches in a minute, and the quantity at D 5808 cubic inches. The quantities discharged therefore, and consequently the velocities, decreased from C to F; whereas if there had been no friction, and no adhesion between the aqueous particles, the velocities would have increased along the line CF in the subduplicate ratio of the altitudes CB, D *m*, E *n*, and F *o*; AB being the surface of the water in the resesvoir. The preceding numbers, representing the quantities discharged at F, E, and D, decrease very slowly; consequently by increasing the relative gravity of the water, that is, by inclining the tube more to the horizon, the effects of friction may be exactly counterbalanced. This happens when the angle *f*CF is about 6° 31′, or when F*f* is the eighth or ninth part of CF. The quantities discharged at C, D, E, and F, will be then equal, and friction will have consumed the velocity arising from the relative gravity of the included water.

Friction destroys this increase of velocity when the inclination of the pipe is 6° 31′.

209. In order to determine the effects produced by flexures or sinuosities in conduit pipes, M. Bossut made the following experiments.

Table XIV. *Shewing the Quantities of Water discharged by rectilineal and curvilineal Pipes 50 Feet long, and 1 Inch in Diameter.*

Experiments with curvilineal pipes.

0	4	The same tube placed as in fig. 9. where ABCD is a vertical section, the parts A, B, C, D rising above a horizontal plane, and the parts *a*, *b*, *c* lying upon it,	520
1	0	The same tube similarly placed,	1028

210. 1. The two first experiments of the foregoing table shew, that the quantities discharged diminish as the altitude of the reservoir. This arises from an increase of velocity, which produces an increase of friction.

2. The four first experiments shew, that a curvilineal pipe, in which the flexures lie horizontally, discharges less water than a rectilineal pipe of the same length. The friction being the same in both cases, this difference must arise from the impulse of the fluid against the angles of the tube; for if the tube formed an accurate curve, it is demonstrable that the curvature would not diminish the velocity of the water.

3. By comparing the 1st and 5th, and the 2d and 6th experiments, it appears, that when the flexures are vertical, the quantity discharged is diminished. This also arises from the imperfection of curvature.

4. It appears from a comparison of the 3d and 5th, with the 4th and 6th experiments, that when the flexures are vertical, the quantity discharged is less than when they are horizontal. In the former case, the motion of the fluid arises from the central impulsion of the water, retarded by its gravity in the ascending parts of the pipe, and accelerated in the descending parts; whereas the motion, in the latter case, arises wholly from the central impulsion of the fluid. To these points of difference the diminution of velocity may somehow or other be owing.

When a large pipe has a number of contrary flexures, the air sometimes mixes with the water, and occupies the highest parts of each flexure as at B and C, fig. 9. Fig. 9.
By this means the velocity of the fluid is greatly retarded, and the quantities discharged much diminished. This ought to be prevented by placing small tubes at B and C, having a small valve at their top.

Experiments of Couplet.

211. A set of valuable experiments on a large scale were made by M. Couplet upon the motion of water in conduit pipes, and are detailed in the Memoirs of the Academy for 1732, in his paper entitled *Des Recherches sur le mouvement des eaux dans les tuyaux de conduite.* These experiments are combined with those of the Abbé Bossut in the following table, which gives a distinct view of all that they have done on this subject, and will be of great use to the practical hydraulist.

Experiments on the Motion of Fluids.

Experiments on the Motion of Fluids.

20	3	0	14040	144	Conduit pipe made of iron, with several flexures both horizontal and vertical,	1 to 0.0517

Application and use of the preceding table.

212. In order to shew the application of the preceding results, let us suppose, that a spring, or number of springs combined, furnishes 40,000 cubic inches of water in one minute; and that it is required to conduct it to a given place 4 feet below the level of the spring, and so situated that the length of the pipe must be 2400 feet. It appears from Table VI. art. 185. that the quantity of water furnished in a minute by a short cylindrical tube, when the altitude of the fluid in the reservoir is 4 feet, is 7070 cubic inches; and since the quantities furnished by two cylindrical pipes under the same altitude of water are as the squares of their diameters, we shall have by the following analogy the diameter of the tube necessary for discharging 40,000 cubic inches in a minute; $\sqrt{70720} : \sqrt{40000} = 12$ lines or 1 inch : $28.\frac{1}{2}$ lines, the diameter required. But by comparing some of the experiments in the preceding table, it appears, that when the length of the pipe is nearly 2400 feet, it will admit only about one-eighth of the water, that is, about 5000 cubic inches. That the pipe, however, may transmit the whole 40000 cubic inches, its diameter must be increased. The following analogy, therefore, will furnish us with this new diameter; $\sqrt{5000} : \sqrt{40000} = 28.54$ lines : 80.73 lines, or 6 inches $8\frac{7}{15}$

Experiments on the Motion of Fluids.

$8\frac{7}{10}$ lines, the diameter of the pipe which will discharge 40000 cub. inches of water when its length is 2400 feet.

SECT. VI. *Experiments on the Pressure exerted upon Pipes by the water which flows through them.*

Experiments on the pressure sustained by pipes.

213. The pressure exerted upon the sides of conduit pipes by the included water, has been already investigated theoretically in Prop. X. Part II. The only way of ascertaining by experiment the magnitude of this lateral pressure is to make an orifice in the side of the pipe, and find the quantity of water which it discharges in a given time. This lateral pressure is the force which impels the water through the orifice; and therefore the quantity discharged, or the effect produced, must be always proportional to that pressure as its producing cause, and may be employed to represent it. The following table, founded on the experiments of Bossut, contains the quantities of water discharged from a lateral orifice about $3\frac{1}{4}$ lines in diameter, according to theory and experiment.

TABLE XVI. *Containing the Quantities discharged by a Lateral Orifice, or the Pressures on the Sides of Pipes, according to Theory and Experiment.*

Altitude of the Water in the Reservoir.	Length of the Conduit Pipe.	Quantities of Water discharged in 1 Minute, according to Theory.	Quantities of Water discharged in 1 Minute according to Experiment.
Feet.	Feet.	Cubic Inches.	Cubic Inches.
1	30	176	171
1	60	186	186
1	90	190	190
1	120	191	191
1	150	192	193
1	180	193	194
2	30	244	240
2	60	259	256
2	90	264	261
2	120	267	264
2	150	268	265
2	180	269	266

It appears from the preceding table, that the real lateral pressure in conduit pipes differs very little from that which is computed from the formula; but in order that this accordance may take place, the orifice must be so perforated, that its circumference is exactly perpendicular to the direction of the water, otherwise a portion of the water discharged would be owing to the direct motion of the included fluid.

SECT. VII. *Experiments on the Motion of Water in Canals.*

Experiments on the velocity of water in horizontal canals.

214. AMONG the numerous experiments which have been made on this important subject, those of the Abbé Bossut seem entitled to the greatest confidence. His experiments were made on a rectangular canal 105 feet long, 5 inches broad at the bottom, and from 8 to 9 inches deep. The orifice which transmitted the water from the reservoir into the canal was rectangular, having its horizontal base constantly 5 inches, and its vertical height sometimes half an inch, and at other times an inch. The sides of this orifice were made of copper, and rising perpendicularly from the side of the reservoir they formed two vertical planes parallel to each other. This projecting orifice was fitted into the canal, which was divided into 5 equal parts of 21 feet each, and also into 3 equal parts of 35, and the time was noted which the water employed in reaching these points of division. The arrival of the water at these points was signified by the motion of a very small water wheel placed at each, and impelled by the stream. When the canal was horizontal, the following results were obtained.

TABLE XVII. *Containing the Velocity of Water in a Rectangular Horizontal Canal 105 Feet long, under different Altitudes of Fluid in the Reservoir.*

Altitude of the water in the reservoir.	*Ft. In.* 11 8	*Ft. In.* 7 8	*Ft. In.* 3 8	*Ft. In.* 11 8	*Ft. In.* 7 8	*Ft. In.* 3 8	Space run through by the water.

Time in which the number of feet in column seventh are run through by the water.	2"	3"—	3"+	2"	2"+	3"	21
	5—	7	9	4	5	6+	42
	10—	13—	17+	7	9	11+	63
	16—	20—	27+	11	14	18+	84
	23+	28+	38+	16½	20	26	105

Deductions from the preceding experiments.

215. It appears from column 1st, that the times successively employed to run through spaces of 21 feet each, are as the numbers 2, 3—, 5, 6, 7+, which form nearly an arithmetical progression, whose terms differ nearly by 1, so that by continuing the progression, we may determine very nearly the time in which the fluid would run through

Experiments on the Motion of Fluids.

through any number of feet not contained in the 7th column. The same may be done with the other columns of the table.

If we compute theoretically the time which the water should employ in running through the whole length of the canal, or 105 feet, we shall find, that under the circumstances for each column of the preceding table the times, reckoning from the first column, are 6″.350, 7″.834, 11″.330, 6″.350, 7″.834, 11″.330. It appears, therefore, by comparing these times with those found by experiment, that the velocity of the stream is very much retarded by friction, and that this retardation is less as the breadth of the orifice is increased; for since a greater quantity of water issues in this case from the reservoir, it has more power to overcome the obstacles which obstruct its progress. The signs + and — affixed to the numbers in the preceding table indicate, that these numbers are a little too great or too small.

216. The following experiments were made on inclined canals with different declivities, and will be of great use to the practical hydraulist. The inclination of the canal is the vertical distance of one of its extremities from a horizontal line which passes through its other extremity.

Experiments on the Motion of Fluids.

The velocity of the first portion of water that issues from the reservoir is less than that of the established current.

Bossut ascribes this difference to a diminution of friction.

217. In the preceding experiments the velocity of the first portion of water that issues from the reservoir was only observed; but when the current is once established, and its velocity permanent, it moves with greater rapidity, and there is always a fixed proportion between the velocity of the first portion of water and the permanent velocity of the established current. The cause of this difference Bossut does not seem to have thoroughly comprehended, when he ascribes it to a diminution of friction when the velocity becomes permanent. The velocity of the first portion of water that issues from the reservoir was measured by its arrival at certain divisions of the canal, consequently the velocity thus determined was the *mean* velocity of the water. The velocity of the established current, on the contrary, was measured by light bodies floating upon its surface, at the centre of the canal, therefore the velocity thus determined was the *superficial* velocity of the stream. But the velocity of the superficial central filaments must be the greatest of all, because being at the greatest distance from the sides and bottom of the canal they are less affected by friction than any of the adjacent or inferior filaments, and are not retarded by the weight of any superincumbent fluid. The *superficial* velocity of the current must of consequence be greater than its *mean* velocity, or, in other words, the velocity of the established current must exceed the velocity of the first portion of water. The following table contains the experiments of Bossut on this subject; the canal being of the same size as in the former experiments, but 600 feet long, and its inclination one-tenth of the whole, or 59.702 feet.

Experiments on the Motion of Fluids.

It is owing to a different cause: the *superficial* velocity having been measured in the one case, and only the mean velocity in the other.

The common theory of the motion of fluids defective in not considering the temperature of the water employed.

218. In all the experiments related in this chapter, and in those of the Chevalier Buat, which are given in the article *WATER-Works*, the temperature of the water employed has never been taken into consideration. That the fluidity of water is increased by heat can scarcely admit of a doubt. Professor Leslie, in his ingenious paper on Capillary Action, has proved by experiment that a jet of warm water will spring much higher than a jet of cold water, and that a syphon which discharges cold water only by drops, will discharge water of a high temperature in a continued stream. A similar fact was observed by the ancients. Plutarch (L) in particular assures us, that the clepsydræ or water clocks went slower in winter than in summer, and he seems to attribute this retardation to a diminution of fluidity. It is therefore obvious, that warm water will issue from an aperture with greater velocity than cold water, and that the quantities of fluid discharged from the same orifice, and under the same pressure, will increase with the temperature of the fluid. Hence we may discover the cause of the great discrepancy between the experiments of different philosophers on the motion of fluids.

Warm water moves faster than cold water.

On the Resistance of Fluids.

fluids. Their experiments were performed in different climates and at different seasons of the year; and, as the temperature of the water would be variable from these and from other causes, a variation in their results was the inevitable consequence.

Experiments for determining the effects of heat on the motion of fluids.

219. The writer of this article has a set of experiments in view, by which he expects to determine the precise effects of heat upon the motion of fluids, and to furnish the practical hydraulist with a more correct formula than that of the Chevalier Buat, for finding, under any given circumstances, the velocity of water and the quantities discharged. He hopes also to be able to determine whether or not the friction of water in conduit pipes varies, as in the case of solid bodies, with the nature of the substances of which the pipes are formed; and to ascertain the effects of different unguents in diminishing the resistance of friction. The result of these experiments will probably be communicated in a subsequent article of this work.

CHAP. III. *On the Resistance of Fluids.*

Reference to the article RESISTANCE *of Fluids.*

220. IN the article RESISTANCE *of Fluids*, the reader will find that important subject treated at great length, and with great ability, by the late learned Dr Robison. The researches of preceding philosophers are there given in full detail; their different theories are compared with experiments, and the defects of these minutely considered. Since that article was composed, this intricate subject has been investigated by other writers, and though they have not enriched the science of hydraulics with a legitimate theory of the resistance of fluids, the results of their labours cannot fail to be interesting to every philosopher.

Researches of Coulomb.

221. The celebrated Coulomb has very successfully employed the principle of torsion, to determine the cohesion of fluids, and the laws of their resistance in very slow motions. His experiments are new, and were performed with the greatest accuracy; and the results which he obtained were perfectly conformable to the deductions of theory. We shall therefore endeavour to give the reader some idea of the discoveries which he has made.

222. When a body is struck by a fluid with a velocity exceeding eight or nine inches per second, the resistance has been found proportional to the square of the velocity, whether the body in motion strikes the fluid at rest, or the body is struck by the moving fluid. But when the velocity is so slow as not to exceed four-tenths of an inch in a second, the resistance is represented by two terms, one of which is proportional to the simple velocity, and the other to the square of the velocity. The first of these sources of resistance arises from the cohesion of the fluid particles which separate from one another, the number of particles thus separated being proportional to the velocity of the body. The other cause of resistance is the inertia of the particles, which when struck by the fluid, acquire a certain degree of velocity proportional to the velocity of the body; and as the number of these particles is also proportional to that velocity, the resistance generated by their inertia must be proportional to the square of the velocity.

223. When Sir Isaac Newton * was determining the resistance which the air opposed to the oscillatory motion of a globe in small oscillations, he employed a formula of three terms, one of them being as the square of the velocity, the second the $\frac{3}{2}$ power of the velocity, and the third as the simple velocity; and in another part of the work he reduces the formula to two terms, one of which is as the square of the velocity, and the other constant. D. Bernouilli (*Comment. Petropol.* tom. iii. and v.) also supposes the resistance to be represented by two terms, one as the square of the velocity, and the other constant. M. Gravesende (*Elements of Nat. Phil.* art. 1911), has found that the pressure of a fluid in motion against a body at rest, is partly proportional to the simple velocity, and partly to the square of the velocity. But when the body moves in a fluid at rest, he found (art. 1975) the resistance proportional to the square of the velocity, and to a constant quantity.—When the *body in motion, therefore, meets the fluid at rest*, these three philosophers have agreed, that the formula which represents the resistance of fluids consists of two terms, one of which is as the square of the velocity, and the other constant. The experiments of Coulomb, however, incontestably prove, that the pressure which the moving body in this case sustains, is represented by two terms, one proportional to the simple velocity, and the other to its square, and that if there is a constant quantity, it is so very small as to escape detection.

* *Principia* lib. ii. prop. xi.

Opinions of Newton, Bernouilli, and Gravesende.

Apparatus employed by Coulomb in his experiments.

224. In order to apply the principle of torsion to the resistance of fluids, M. Coulomb made use of the apparatus represented in fig. 1. On the horizontal arm LK, which may be supported by a vertical stand, is fixed the small circle $f e$, perforated in the centre, so as to admit the cylindrical pin $b\ a$. Into a slit in the extremity of this pin is fastened, by means of a screw, the brass wire $a\ g$, whose force of torsion is to be compared with the resistance of the fluid; and its lower extremity is fixed in the same way into a cylinder of copper $g\ d$, whose diameter is about four-tenths of an inch. The cylinder $g\ d$ is perpendicular to the disc DS, whose circumference is divided into 480 equal parts. When this horizontal disc is at rest, which happens when the torsion of the brass wire is nothing, the index RS is placed upon the point o, the zero of the circular scale. The small rule R m may be elevated or depressed at pleasure round its axis n, and the stand GH which supports it may be brought into any position round the horizontal disc. The lower extremity of the cylinder $g\ d$ is immersed about two inches in the vessel of water MNOP, and to the extremity d is attached the planes, or the bodies whose resistance is to be determined when they oscillate in the fluid by the torsion of the brass wire. In order to produce these oscillations, the disc DS, supported by both hands, must be turned gently round to a certain distance from the index, without deranging the vertical position of the suspended wire. The disc is then left to itself; the force of torsion causes it to oscillate, and the successive diminutions of these oscillations are carefully observed. A simple formula gives in weights the force of torsion that produces the oscillations; and another formula well known to geometers, determines (by an approximation sufficiently accurate in practice), by means of the successive diminution of the oscillations compared with their amplitude, what is the law of the resistance, relative to the velocity, which produces these diminutions.

Plate CCLXII fig. 1.

Method of using it.

225.

On the Resistance Of Fluids.

The method adopted by Coulomb resembles that employed by Newton and other philosophers who observed the oscillations of a pendulum in resisting media.

225. The method employed by Coulomb, in reducing his experiments, is similar to that adopted by Newton and other mathematicians, when they wished to determine the resistance of fluids, from the successive diminutions of the oscillations of a pendulum moving in a resisting medium; but it is much better fitted for detecting the small quantities which are to be estimated in such researches. When the pendulum is employed, the specific gravity of the body, relative to that of the fluid, must be determined; and the least error in this point leads to very uncertain results. When the pendulum is in different points of the arc in which it oscillates, the wire or pendulum rod is plunged more or less in the fluid; and the alterations which may result from this are frequently more considerable than the small quantities which are the object of research. It is only in small oscillations, too, that the force which brings the pendulum from the vertical, is proportional to the angle which the pendulum rod, in different positions, forms with this vertical line; a condition which is necessary before the formulæ can be applied. But small oscillations are attended with great disadvantages; and their successive diminutions cannot be determined but by quantities which it is difficult to estimate exactly, and which are changed by the smallest motion either of the fluid in the vessel, or of the air in the chamber. In small velocities, the pendulum rod experiences a greater resistance at the point of floatation than at any other part. This resistance, too, is very changeable; for the water rises from its level along the pendulum rod to greater or less heights, according to the velocity of the pendulum.

Disadvantages of a pendulum.

Advantages of comparing the resistance of fluids with the force of torsion.

226. These and other inconveniences which might be mentioned, are so inseparable from the use of the pendulum, that Newton and Bernouilli have not been able to determine the laws of the resistance of fluids in very slow motions. When the resistance of fluids is compared with the force of torsion, these disadvantages do not exist. The body is in this case entirely immersed in the fluid; and as every point of its surface oscillates in a horizontal plane, the relation between the densities of the fluid and the oscillating body has no influence whatever on the moving force. One or two circles of amplitude may be given to the oscillations; and their duration may be increased at pleasure, either by diminishing the diameter of the wire, or increasing its length; or, which may be more convenient, by augmenting the momentum of the horizontal disc. Coulomb, however, found that when each oscillation was so long as to continue about 100 seconds, the least motion of the fluid, or the tremor occasioned by the passing of a carriage, produced a sensible alteration on the results. The oscillations best fitted for experiments of this kind, continued from 20 to 30 seconds, and the amplitude of those that gave the most regular results, was comprehended between 480 degrees, the entire division of the disc, and 8 or 10 divisions reckoned from the zero of the scale. From these observations it will be readily seen, that it is only in very slow motions that an oscillating body can be employed for determining the resistance of fluids. In small oscillations, or in quick circular motions, the fluid struck by the body is continually in motion; and when the oscillating body returns to its former position, its velocity is either increased or retarded by the motion communicated to the fluid, and not extinguished.

When the velocity is very small, the part of the resistance proportional to the square of the velocity disappears.

227. In the first set of experiments made by Coulomb, he attached to the lower extremity of the cylinder $g\,d$ a circular plate of white iron, about 195 millimetres in diameter, and made it move so slowly, that the part of the resistance proportional to the square of the velocity, wholly disappeared. For if, in any particular case, the portion of the resistance proportional to the simple velocity, should be equal to the portion that is proportional to the square of the velocity when the body has a velocity of one-tenth of an inch per second; then, when the velocity is 100 tenths of an inch per second, the part proportional to the square of the velocity will be a hundred times greater than that proportional to the simple velocity; but if the velocity is only the 100dth part of the tenth of an inch per second, then the part proportional to the simple velocity will be 100 times greater than the part proportional to the square of the velocity.

Result of Coulomb's experiments on the resistance of water to a horizontal plate moving round its centre in the plane of its superficies.

228. When the oscillations of the white iron plate were so slow, that the part of the resistance which varies with the second power of the velocity was greatly inferior to the other part, he found, from a variety of experiments, that the resistance which diminished the oscillations of the horizontal plate was uniformly proportional to the simple velocity, and that the other part of the resistance, which follows the ratio of the square of the velocity, produced no sensible change upon the motion of the white iron disc.—He found also, in conformity with theory, that the momenta of resistance in different circular plates moving round their centre in a fluid, are as the fourth power of the diameters of these circles; and that, when a circle of 195 millimetres (6.677 English inches) in diameter, moved round its centre in water, so that its circumference had a velocity of 140 millimetres (5.512 English inches) per second, the momentum of resistance which the fluid opposed to its circular motion was equal to one-tenth of a gramme (1.544 English troy grains) placed at the end of a lever 143 millimetres (5.63 English inches) in length.

Similar result obtained in clarified oil.

Ratio between the mutual cohesion of the particles of oil, and the mutual cohesion of the particles of water.

229. M. Coulomb repeated the same experiments in a vessel of clarified oil, at the temperature of 16 degrees of Reaumur. He found, as before, that the momenta of the resistance of different circles, moving round their centre in the plane of their superficies, were as the fourth power of their diameters; and that the difficulty with which the same horizontal plate, moving with the same velocity, separated the particles of oil, was to the difficulty with which it separated the particles of water, as 17.5 to 1, which is therefore the ratio that the mutual cohesion of the particles of oil has to the mutual cohesion of the particles of water.

The resistance not influenced by the nature of the surface of the moving body.

230. In order to ascertain whether or not the resistance of a body moving in a fluid was influenced by the nature of its surface, M. Coulomb anointed the surface of the white iron plate with tallow, and wiped it partly away, so that the thickness of the plate might not be sensibly increased. The plate was then made to oscillate in water, and the oscillations were found to diminish in the same manner as before the application of the unguent. Over the surface of the tallow upon the plate, he afterwards scattered, by means of a sieve, a

quantity

On the Resistance of Fluids.

quantity of coarse sand which adhered to the greasy surface; but when the plate, thus prepared, was caused to oscillate, the augmentation of resistance was so small, that it could scarcely be appreciated. We may therefore conclude, that the part of the resistance which is proportional to the simple velocity, is owing to the mutual adhesion of the particles of the fluid, and not to the adhesion of these particles to the surface of the body.

Experiments for finding if the resistance is increased by increasing the superincumbent fluid.

231. If the part of the resistance varying with the simple velocity were increased when the white iron plate was immerged at greater depths in the water, we might suppose it to be owing to the friction of the water on the horizontal surface, which, like the friction of solid bodies, should be proportional to the superincumbent pressure. In order to settle this point, M. Coulomb made the white iron plate oscillate at the depth of two centimetres (.787 English inches), and also at the depth of 50 centimetres (19.6855 English inches), and found no difference in the resistance; but as the surface of the water was loaded with the whole weight of the atmosphere, and as an additional load of 50 centimetres of water could scarcely produce a perceptible augmentation of the resistance, M. Coulomb employed another method of deciding the question. Having placed a vessel full of water under the receiver of an air-pump, the receiver being furnished with a rod and collar of leather at its top, he fixed to the hook, at the end of the rod, a harpsichord wire, numbered 7 in commerce, and suspended to it a cylinder of copper, like *gd*, fig. 1. which plunged in the water of the vessel, and under this cylinder he fixed a circular plane, whose diameter was 101 millimetres (3.976 English inches). When the oscillations were finished, and consequently the force of torsion nothing, the zero of torsion was marked by the aid of an index fixed to the cylinder. The rod was then made to turn quickly round through a complete circle, which gave to the wire a complete circle of torsion, and the successive diminutions of the oscillations were carefully observed. The diminution for a complete circle of torsion was found to be nearly a fourth part of the circle for the first oscillation, but always the same whether the experiment was made in a vacuum or in the atmosphere. A small pallet 50 millimetres long (1.969 English inches) and 10 millimetres broad, (0.3937 English inches) which struck the water perpendicular to its plane, furnished a similar result. We may therefore conclude, that when a submerged body moves in a fluid, the pressure which it sustains, measured by the altitude of the superior fluid, does not perceptibly increase the resistance; and consequently, that the part of this resistance proportional to the simple velocity, can in no respect be compared with the friction of solid bodies, which is always proportional to the pressure.

On the resistance of cylinders moving perpendicular to their axes.

232. The next object of M. Coulomb was to ascertain the resistance experienced by cylinders that moved very slowly, and perpendicular to their axes; but as the particles of fluid struck by the cylinder necessarily partook of its motion, it was impossible to neglect the part of the resistance proportional to the square of the velocity, and therefore he was obliged to perform the experiments in such a manner that both parts of the resistance might be computed. The three cylinders which he employed were 249 millimetres (.9803 English inches) long. The first cylinder was 0,87 millimetres (0.0342 English inches or $\frac{1}{29}$ of an inch) in circumference, the second 11.2 millimetres (0.4409 English inches), and the third 21.1 millimetres (.88307 English inches). They were fixed by their middle under the cylindrical piece *dg*, so as to form two horizontal radii, whose length was 124.5 millimetres (.4901 English inches) or half the length of each cylinder. After making the necessary experiments and computations, he found that the part of the resistance proportional to the simple velocity, which, to avoid circumlocution we shall call *r*, did not vary with the circumferences of the cylinders. The circumferences of the first and third cylinders were to one another as 24 : 1, whereas the resistances were in the ratio of 3 : 1. The same conclusion was deduced by comparing the experiments made with the first and second cylinder.

233. In order to explain these results, M. Coulomb very justly supposes, that in consequence of the mutual adhesion of the particles of water, the motion of the cylinder is communicated to the particles at a small distance from it. The particles which touch the cylinder have the same velocity as the cylinder, those at a greater distance have a less velocity, and at the distance of about one-tenth of an inch the velocity ceases entirely, so that it is only at that distance from the cylinder that the mutual adhesion of the fluid molecules ceases to influence the resistance. The resistance *r* therefore should not be proportional to the circumference of the real cylinder, but to the circumference of a cylinder whose radius is greater than the real cylinder by one-tenth of an inch. It consequently becomes a matter of importance to determine with accuracy the quantity which must be added to the real cylinder in order to have the radius of the cylinder to which the resistance *r* is proportional, and from which it must be computed. Coulomb found the quantity by which the radius should be increased, to be 1.5 millimetres ($\frac{59}{1000}$ of an English inch) so that the diameter of the augmented cylinder will exceed the diameter of the real cylinder by double that quantity, or $\frac{118}{1000}$ of an inch.

234. The part of the resistance varying with the square of the velocity, or that arising from the inertia of the fluid, which we shall call R, was likewise not proportional to the circumferences of the cylinder; but the augmentation of the radii amounts in this case only to $\frac{11}{1000}$ of an inch, which is only one-fifth of the augmentation necessary for finding the resistance *r*. The reason of this difference is obvious; all the particles of the fluid when they are separated from each other oppose the same resistance, whatever be their velocity; consequently as the value of *r* depends only on the adhesion of the particles, the resistances due to this adhesion will reach to the distance from the cylinder where the velocity of the particles is 0. In comparing the different values of R, the part of the resistance which varies as the square of the velocity, all the particles are supposed to have a velocity equal to that of the cylinder; but as it is only the particles which touch the cylinder that have this velocity, it follows that the augmentation of the diameter necessary for finding R must be less than the augmentation necessary for finding *r*.

235. In determining experimentally the part of the momentum of resistance proportional to the velocity, by two cylinders of the same diameter, but of different lengths, M. Coulomb found that this momentum was proportional

On the Resistance of Fluids.

proportional to the third power of their lengths. The same result may be deduced from theory; for supposing each cylinder divided into any number of parts, the length of each part will be proportional to the whole length. The velocity of the corresponding parts will be as these lengths, and also as the distance of the same parts from the centre of rotation. The theory likewise proves, that the momentum of resistance depending on the square of the velocity, in two cylinders of the same diameter but of different lengths, is proportional to the fourth power of the length of the cylinder.

Real resistance of a given cylinder.

236. When the cylinder 0.9803 inches in length, and 0.04409 inches in circumference, was made to oscillate in the fluid with a velocity of 5.51 inches per second, the part of the resistance *r* was equal to 58 milligrammes, or .8932 troy grains. And when the velocity was 0.3937 inches per second, the resistance *r* was 0.00414 grammes, or 0.637 troy grains.

Result of the preceding experiments when made in oil.

237. The preceding experiments were also made in the oil formerly mentioned; and it likewise appeared, from their results, that the mutual adhesion of the particles of oil was to the mutual adhesion of the particles of water as 17 to 1. But though this be the case, M. Coulomb discovered that the quantity by which the radii of the cylinder must be augmented in order to have the resistance *r*, is the very same as when the cylinder oscillated in water. This result was very unexpected, as the greater adhesion between the particles of oil might have led us to anticipate a much greater augmentation. When the cylinders oscillated both in oil and water with the same velocity, the part of the resistance R produced by the inertia of the fluid particles which the cylinder put in motion, was almost the same in both. As this part of the resistance depends on the quantity of particles put in motion, and not on their adhesion, the resistances due to the inertia of the particles will be in different fluids as their densities.

Coulomb promises to extend his researches on the resistance of fluids.

238. In a subsequent memoir Coulomb proposes to determine numerically the part of the resistance proportional to the square of the velocity, and to ascertain the resistance of globes with plain, convex, and concave surfaces. He has found in general that the resistance of bodies not entirely immersed in the fluid is much greater than that of bodies which are wholly immersed; and he promises to make farther experiments upon this point. We intended on the present occasion to have given the reader a more complete view of the researches of this ingenious philosopher; but these could not well be understood without a knowledge of his investigations respecting the force of torsion, which we have not yet had an opportunity of communicating. In the article MECHANICS, however, we shall introduce the reader to this interesting subject; and may afterwards have an opportunity of making him farther acquainted with those researches of Coulomb, of which we have at present given only a general view.

Researches of Dr Hutton.

239. The subject of the resistance of fluids has been recently treated by the learned Dr Hutton of Woolwich. His experiments were made in air, with bodies of various forms, moving with different velocities, and inclined at various angles to the direction of their motion. The following table contains the results of many interesting experiments. The numbers in the 9th column represent the exponents of the power of the velocity which the resistances in the 8th column bear to each other.

From

Results of the preceding experiments.

240. From the preceding experiments we may draw the following conclusions: 1. That the resistance is nearly proportional to the surfaces, a small increase taking place when the surfaces and the velocities are great. 2. The resistance to the same surface moving with different velocities, is nearly as the square of the velocity; but it appears from the 9th column that the exponent increases with the velocity. 3. The round and sharp ends of solids sustain a greater resistance than the flat ends of the same diameter. 4. The resistance to the base of the hemisphere is to the resistance on the convex side, or the whole sphere, as $2\frac{1}{5}$ to 1, instead of 2 to 1, as given by theory. 5. The resistance on the base of the cone is to the resistance on the vertex nearly as $2\frac{3}{10}$ to 1; and in the same ratio is radius to the sine of half the angle at the vertex. Hence in this case the resistance is directly as the sine of the angle of incidence, the transverse section being the same. 6. The resistance of the base of a hemisphere, the base of a cone, and the base of a cylinder, are all different, though these bases be exactly equal and similar.

241. The following table contains the resistance sustained by a globe 1.965 inches in diameter. The fourth column is the quotient of the resistance by experiment, divided by the theoretical resistance.

Experiments with a globe 1.965 inches in diameter.

242. It appears from a comparison of the 2d, 3d, and 4th columns, that when the velocity is small the resistance by experiment is nearly equal to that deduced from theory; but that as the velocity increases, the former gradually exceeds the latter till the velocity is 1300 feet per second, when it becomes twice as great. The difference between the two resistances then increases, and reaches its maximum between the velocities of 1600 and 1700 feet. It afterwards decreases gradually as the velocity increases, and at the velocity of 2000 the resistance by experiment is again double of the theoretical resistance.—By considering the numbers in column 5th it will be seen, that in slow motions the resistances are nearly as the squares of the velocities; that this ratio increases gradually, though not regularly, till at the velocity of 1500 or 1600 feet it arrives at its maximum. It then gradually diminishes as the velocity increases.

Conclusions similar to these were deduced from experiments made with globes of a larger size.

243. The following table contains the resistance of a plane inclined at various angles, according to experiment, and according to a formula deduced from the experiments.

TABLE III. *Containing the Resistances to a Plane inclined at various Angles to the Line of its Motion.*

244. The plane with which the preceding experiments were performed was 32 square inches, and always moved with a velocity of 12 feet per second. The resistances which this plane experienced are contained in column 2d. From the numbers in that column Dr Hutton deduced the formula $.84s^{1.842}c$, where s is the sine, and c is the cosine of the angles of inclination in the first column. The resistances computed from this formula are contained in column 3d, and agree very nearly

On the Resistance of Fluids.

ly with the resistances deduced from experiment. The 4th column contains the sines of the angles in the first column to a radius .84, in order to compare them with the resistances which have obviously no relation either to the sines of the angles or to any power of the sines. From the angle of 0 to about 60° the resistances are less than the sines; but from 60° to 90° they are somewhat greater.

Researches of Mr Vince.

245. The experiments of Mr Vince were made with bodies at a considerable depth below the surface of water; and he determined the resistance which they experienced, both when they moved in the fluid at rest, and when they received the impulse of the moving fluid. In the experiments contained in the following table, the body moved in the fluid with a velocity of 0.66 feet in a second. The angles at which the planes struck the fluid are contained in the first column. The second column shews the resistance by experiment in the direction of their motion in troy ounces. The third column exhibits the resistance by theory, the perpendicular distance being supposed the same as by experiment. The fourth column shews the power of the sine of the angle to which the resistance is proportional, and was computed in the following manner. Let s be the sine of the angle, radius being 1, and r the resistance at that angle. Suppose r to vary as s^m, then we have $r^m : s^m = 0.2321 : r$; hence $s^m = \frac{1}{0.2321}$, and therefore $m = \frac{\text{Log. } r - \text{Log. } 0.2321}{\text{Log. } s}$, and by substituting their corresponding values, instead of r and s we shall have the values of m or the numbers in the fourth column.

Determination of the resistance when the body moved in the fluid.

TABLE IV. *Containing the Resistance of a Plane Surface moving in a Fluid, and placed at different Angles to the Path of its Motion.*

Angle of inclination.	Resistance by experiment.	Resistance by theory.	Power of the sine of the angle to which the resistance is proportional.
Degrees.	Troy ounces.	Troy ounces.	Exponents.
10	0.0112	0.0012	1.73
20	0.0364	0.0093	1.73
30	0.0769	0.0290	1.54
40	0.1174	0.0616	1.54
50	0.1552	0.1043	1.51

80	0.2237	0.2217	2.41
90	0.2321	0.2321	
1	2	3	4

246. According to the theory the resistance should vary as the cube of the sine, whereas from an angle of 90° it decreases in a less ratio, but not as any constant power, nor as any function of the sine and cosine. Hence the actual resistance always exceeds that which is deduced from theory, assuming the perpendicular resistance to be the same. The cause of this difference is partly owing to our theory neglecting that part of the force which after resolution acts parallel to the plane, but which according to experiments is really a part of the force which acts upon the plane.

Oscillation of Fluids, &c.

247. Mr Vince made also a number of experiments on the resistance of hemispheres, globes, and cylinders, which moved with a velocity of 0.542 feet per second. He found that the resistance to the spherical side of a hemisphere was to the resistance on its base as 0.034 is to 0.08339; that the resistance of the flat side of a hemisphere was to the resistance of a cylinder of the same diameter, and moving with the same velocity, as 0.08339 is to 0.07998; and that the resistance to a complete globe is to the resistance of a cylinder of the same diameter, and with the same velocity, as 1 : 2.23.

Experiments with hemispheres, globes, and cylinders.

248. The following results were obtained, when the plane was struck by the moving fluid. The 2d column of the following table contains the resistance by experiment, and the 3d column the resistance by theory from the perpendicular force, supposing it to vary as the sine of the inclination.

Determination of the resistance when the body is struck by the moving fluid.

TABLE V. *Containing the Resistance of a Plane struck by the Fluid in Motion, and inclined at different Angles to the direction of its Path.*

Angle of inclination.	Resistance by experiment.			Resistance by theory.

20	0	12	12	0	12	19
10	0	6	4	0	6	12
1	2			3		

249. It appears from the preceding results, that the resistance varies as the sine of the angle at which the fluid strikes the plane, the difference between theory and experiment being such as might be expected from the necessary inaccuracy of the experiments.

By comparing the preceding table with Table IV. it will be found that the resistance of a plane moving in a fluid is to the resistance of the same plane when struck by the fluid in motion as 5 to 6. In both these cases the actual effect on the plane must be the same, and therefore the difference in the resistance can arise only from the action of the fluid behind the body in the former case.

CHAP. IV. *On the Oscillation of Fluids, and the Undulation of Waves.*

PROP. I.

On the oscillation of water in a syphon.

250. The oscillations of water in a syphon, consisting of two vertical branches and a horizontal one, are isochronous, and have the same duration

Oscillation of Fluids, &c.

tion as the oscillations of a pendulum, whose length is equal to half the length of the oscillating column of water.

Plate CCLXIX. fig. 2.

Into the tube MNOP, having its internal diameter everywhere the same, introduce a quantity of water. When the water is in equilibrio, the two surfaces AB, CD will be in the same horizontal line AD. If this equilibrium be disturbed by making the syphon oscillate round the point y, the water will rise and fall alternately in the vertical branches after the syphon is at rest. Suppose the water to rise to EF in the branch MO, it will evidently fall to GH in the other branch, so that CG is equal to AE. Then it is evident, that the force which makes the water oscillate, is the weight of the column EFKL, which is double the column EABF; and that this force is to the whole weight of the water, as 2AE is to AOPD.

Fig. 3.

Now, let P be a pendulum, whose length is equal to half the length of the oscillating column AOPD, and which describes to the lowest point S arches PS, equal to AE; then 2AE : AOPD=AE : QP, because AE is one-half of 2AE, and QP one-half of AOPD. Consequently, since AOPD is a constant quantity, the force which makes the water oscillate is always proportional to the space which it runs through, and its oscillations are therefore isochronous. The force which makes the pendulum describe the arch PS, is to the weight of the pendulum as PS is to PQ, or as AE is to PQ, since AE=PS; but the force which makes the water oscillate, is to the weight of the whole water in the same ratio; consequently, since the pendulum P, and the column AOPD, are influenced by the very same force, their oscillations must be performed in the same time. Q. E. D.

251. Cor. As the oscillations of water and of pendulums are regulated by the same laws, if the oscillating column of water is increased or diminished, the time in which the oscillations are performed will increase or diminish in the subduplicate ratio of the length of the pendulum.

Scholium.

252. This subject has been treated in a general manner, by Newton and different philosophers, who have shewn how to determine the time of an oscillation, whatever be the form of the syphon. See the *Principia*, lib. ii. Prop. 45, 46. Bossut's *Traité d'Hydrodynamique*, tom. i. *Notes sur le Chap. II. Part II. Bernouilli Opera*, tom. iii. p. 125. and *Encyclopedie*, art. *Ondes*.

Prop. II.

On the undulation of waves.

253. The undulations of waves are performed in the same time as the oscillations of a pendulum whose length is equal to the breadth of a wave, or to the distance between two neighbouring cavities or eminences.

Fig. 4.

In the waves ABCDEF, the undulations are performed in such a manner, that the highest parts A, C, E become the lowest; and as the force which depresses the eminences A, C, E, is always the weight of water contained in these eminences, it is obvious, that the undulations of waves are of the same kind as the undulations or oscillations of water in a syphon. It follows, therefore, from Prop. I. that if we take a pendulum, whose length is one-half BM, or half the distance between the highest and lowest parts of the wave, the highest parts of each wave will descend to the lowest parts during one oscillation of the pendulum, and in the time of another oscillation will again become the highest parts. The pendulum, therefore, will perform two oscillations in the time that each wave performs one undulation, that is, in the time that each wave describes the space AC or BD, between two neighbouring eminences or cavities, which is called *the breadth of the wave*. Now if a pendulum, whose length is one-half BM, performs two oscillations in the above time, it will require a pendulum four times that length to perform only one oscillation in the same time, that is, a pendulum whose length is AC or BD, since $4\times\frac{1}{2}$ BM=2BM=AC or BD. Q. E. D.

Scholium.

254. The explanation of the oscillation of waves contained in the two preceding propositions, was first given by Sir Isaac Newton, in his *Principia*, lib. ii. Prop. 44. He considered it only as an approximation to the truth, since it supposes the waves to rise and fall perpendicularly like the water in the vertical branches of the syphon, while their real motion is partly circular. The theory of Newton was, nevertheless, adopted by succeeding philosophers, and gave rise to many analogous discussions respecting the undulation of waves. Very lately, however, an attempt has been made by M. Flaugergues, to overturn the theory of Newton. From a number of experiments on the motion and figure of waves, an account of which may be seen in the *Journal des Sçavans*, for October 1789, M. Flaugergues concludes, that a wave is not the result of a motion in the particles of water, by which they ascend and descend alternately in a serpentine line, when moving from the place where the water received the shock; but that it is an intumescence which this shock occasions around the place where it is received, by the depression that is there produced. This intumescence afterwards propagates itself circularly, while it removes from the place where the shock first raised it above the level of the stagnant water. A portion of the stagnant water then flows from all sides into the hollow formed at the place where the shock was received; this hollow is thus heaped with fluid, and the water is elevated so as to produce all around another intumescence, or a new wave, which propagates itself circularly as before. The repetition of this effect produces on the surface of the water a number of concentric rings, successively elevated and depressed, which have the appearance of an undulatory motion. This interesting subject has also been discussed by M. La Grange, in his *Mechanique Analytique*, to which we must refer the reader for farther information. See also some excellent remarks on this subject, in Mr Leslie's Essay on Heat, p. 223. and note 29.

New theory of the formation of waves by M. Flaugergues.

PART

PART III. ON HYDRAULIC MACHINERY.

Hydraulic machines.

255. TO describe the various machines in which water is the impelling power, would be an endless and unprofitable task. Those machines which can be driven by wind, steam, and the force of men or horses, as well as they can be driven by water, do not properly belong to the science of hydraulics. By hydraulic machinery, therefore, we are to understand those various contrivances by which water can be employed as the impelling power of machinery; and those machines which are employed to raise water, or which could not operate without the assistance of that fluid.

CHAP. I. *On Water-Wheels.*

Different kinds of water-wheels.

256. WATER-WHEELS are divided into three kinds, overshot-wheels, breast-wheels, and undershot-wheels, which derive their names from the manner in which the water is delivered upon their circumferences.

SECT. I. *On Overshot-Wheels.*

Description of an overshot-wheel. Plate CCLXIX. fig. 1.

257. An overshot-wheel is a wheel driven by the weight of water, conveyed into buckets disposed on its circumference. It is represented in fig. 5. where ABC is the circumference of the wheel furnished with a number of buckets. The canal MN conveys the water into the second bucket from the top A *a*. The equilibrium of the wheel is therefore destroyed; and the power of the bucket A *a*, to turn the wheel round its centre of motion O, is the same as if the weight of the water in the bucket were suspended at *m*, the extremity of the lever O *m*, *c* being the centre of gravity of the bucket, and O *m* a perpendicular let fall from the fulcrum O to the direction *c m*, in which the force is exerted. In consequence of this destruction of equilibrium, the wheel will move round in the direction AB, the bucket A *a* will be at *d*, and the empty bucket *b* will take the place of A *a*, and receive water from the spout N. The force acting on the wheel is now the water in the bucket *d* acting with a lever *n* O, and the water in the bucket A *a* acting with a lever *m* O. The velocity of the wheel will therefore increase with the number of loaded buckets, and with their distance from the vertex of the wheel; for the lever by which they tend to turn the wheel about its axis, increases as the buckets approach to *c*, where their power, represented by *e* O, is a maximum. After the buckets have passed *c*, the lever by which they act gradually diminishes, they lose by degrees a small portion of their water; and as soon as they reach B it is completely discharged. When the wheel begins to move, its velocity will increase rapidly till the quadrant of buckets *b e* is completely filled. While these buckets are descending through the inferior quadrant *e* P, and the buckets on the left hand of *b* are receiving water from the spout, the velocity of the wheel will still increase; but the increments of velocity will be smaller and smaller, since the levers by which the inferior buckets act are gradually diminishing. As soon as the highest bucket A *c* has reached the point B where it is emptied, the whole semicircumference nearly of the wheel is loaded with water; and when the bucket at B is discharging its contents, the bucket at A is filling, so that the load in the buckets, by which the wheel is impelled, will be always the same, and the velocity of the wheel will become uniform.

Method of computing the momentum of the water in the loaded arch.

258. In order to find the power of the loaded arch to turn the wheel, or, which is the same thing, to find a weight which suspended at the opposite extremity C, will balance the loaded arch or keep it in equilibrio, we must multiply the weight of water in each bucket by the length of the virtual lever by which it acts, and take the sum of all these momenta for the momentum of the loaded arch. It will be much easier, however, and the result will be the same, if we multiply the weight of all the water on the arch AB, by the distance of its centre of gravity G, from the fulcrum or centre of motion O. Now, by the property of the centre of gravity (see MECHANICS), the distance of the centre of gravity of a circular arch from its centre, is a fourth proportional to half the arch, the radius, and the sine of half the arch. Since the vertical bucket *b* has no power to turn the wheel if it were filled, and since two or three buckets between B and P are always empty, we may safely suppose that the loaded arch never exceeds 160°, so that if R = radius of the wheel in feet, we shall have the length of half the loaded arch, or $80° = 2R \times 3.1416 \times \frac{80}{360} = R \times 1.396$; and the distance of the centre of gravity from the fulcrum O, $= GO = \frac{R \times \text{Sin. } 80°}{R \times 1.396}$. Now, if N be the number of buckets in the wheel $\frac{160\,N}{360}$, or $\frac{4\,N}{9}$, will be the number of buckets in the loaded arch; and if G be the number of ale gallons contained in each bucket, the weight of the water in each bucket will be $1.02 \times G$ pounds avoirdupois. The weight of the water, therefore, in the loaded arch, will be $\frac{4\,N}{9} \times 10.2\,G$, and consequently the momentum of the loaded arch will be $= \frac{4\,N}{9} \times 10.2\,G \times \frac{R \times \text{Sin. } 80°}{R \times 1.396} = \frac{4\,N}{9} \times 10.2G \times 0.6338 = \frac{4\,N}{9} \times 6.465\,G$ pounds avoirdupois. Hence, we have the following rule: Multiply the constant number 6.465 by $\frac{4}{9}$ of the number of buckets in the wheel, and this product by the number of ale gallons in each bucket; and the result will be the effective weight, or momentum of the water in the loaded arch. For a description of the best form that can be given to the buckets, see the article *WATER-Works*. Dr Robison has there recommended a mode of constructing the buckets invented by Mr Burns, who divided each bucket into two by means of a partition; but the writer of this article is assured, on the authority of an ingenious millwright, who wrought with Mr Burns at the time when wheels of this kind were constructed, that the inner bucket is never filled with water, and that much of the power is thus lost. The partition prevents the introduction

On Water-Wheels.

introduction of the fluid, and the water is driven backwards by the escape of the included air.

On the diameter of overshot-wheels relatively to the height of the fall.

259. In the construction of overshot-wheels, it is of great importance to determine what should be the diameter of the wheel relatively to the height of the fall. It is evident that its diameter cannot exceed the height of the fall. Some mechanical writers have demonstrated that, in theory, an overshot-wheel will produce a maximum effect when its diameter is two-thirds of that height, the water being supposed to fall into the buckets with the velocity of the wheel. But this rule is palpably erroneous, and directly repugnant to the results of experiment. For if the height of the fall be 48 feet, the diameter of the wheel will, according to this rule, be 32 feet; and the water having to fall through 16 feet before it reaches the buckets, will have a velocity of 32 feet per second, which, according to the hypothesis, must also be the velocity of the wheel's circumference. But Smeaton has proved, that a maximum effect is produced by an overshot-wheel of any diameter, when its velocity is only *three* feet per second. The chevalier de Borda has shewn, that overshot-wheels will produce a maximum effect when their diameter is equal to the height of the fall; and this is completely confirmed by Mr Smeaton's experiments. From a great number of trials, Mr Smeaton has concluded, "that the higher the wheel is in proportion to the whole descent, the greater will be the effect." Nor is it difficult to assign the reason of this. The water which is conveyed into the buckets can produce very little effect by its impulse, even if its velocity be great; both on account of the obliquity with which it strikes the buckets, and in consequence of the loss of water occasioned by a considerable quantity of the fluid being dashed over their sides. Instead, therefore, of expecting an increase of effect from the impulse of the water occasioned by its fall through one-third of the whole height, we should allow it to act through this height by its gravity, and therefore make the diameter of the wheel as great as possible. But a disadvantage attends even this rule; for if the water is conveyed into the buckets without any velocity, which must be the case when the diameter of the wheel equals the height of the fall, the velocity of the wheel will be retarded by the impulse of the buckets against the water, and much power would be lost by the water dashing over them. In order, therefore, to avoid all inconveniences, the distance of the spout from the receiving bucket should, in general, be about two or three inches, that the water may be delivered with a velocity a little greater than that of the wheel; or, in other words, the diameter of an overshot-wheel should be two or three inches less than the greatest height of the fall; and yet it is no uncommon thing to see the diameters of these wheels scarcely one-half of that height. In such a construction the loss of power is prodigious.

On the proper velocity of overshot-wheels. Experiments of Deparcieux on the velocity of overshot-wheels.

260. The proper velocity of overshot-wheels is a subject on which mechanical writers have entertained different sentiments. While some have maintained that there is a certain velocity which produces a maximum effect, Deparcieux has endeavoured to prove by a set of ingenious experiments that most work is performed by an overshot-wheel when it moves slowly, and that the more its motion is retarded by increasing the work to be performed, the greater will be the performance of the wheel. In these experiments he employed a small wheel, 20 inches in diameter, having its circumference furnished with 48 buckets. On the centre or axle of this wheel were placed 4 cylinders of different diameters, the first being 1 inch in diameter, the second 2 inches, the third 3 inches, and the fourth 4 inches. When the experiments are made, a cord is attached to one of the cylinders, and after passing over a pulley a weight is suspended at its other extremity. By moving the wheel upon its axis, the cord winds round the cylinder and raises the weight. In order to diminish the friction, the gudgeons of the wheel are supported by two friction rollers, and before the wheel, a little higher than its axis, is placed a small table which supports a vessel filled with water, having an orifice in the side next the wheel. Above this vessel is placed a large bottle full of water and inverted, having its mouth immersed a few lines in the water, so that it empties itself in proportion as the water in the vessel is discharged from the orifice. The quantity of water thus discharged is always the same, and is conveyed from the orifice by means of a canal to the buckets of the wheel. With this apparatus he obtained the following results.

Diameters of the Cylinders.	Altitude through which 12 ounces were elevated.		Altitude through which 24 ounces were elevated.	
Inches.	Inches.	Lines.	Inches.	Lines.
1	69	9	40	0
2	80	6	43	6
3	85	6	44	6
4	87	9	45	3

261. When the large cylinders were used, the velocity of the wheel was smaller, because the resistances are proportional to their diameter, the weight being the same. Hence, it appears, by comparing the four results in column 2d with one another, and also the four results in column 3d, that when the wheel turns more slowly, the effect, which is in this case measured by the elevation of the weight, always increases. When the weight of 24 ounces was used, the resistance was twice as great, and the velocity twice as slow, as when the 12 ounce weight was employed. But by comparing the results in column 2d with the corresponding results in column 3d, it appears, that when the 24 ounce weight was employed, and the velocity was only one-half of what it was when the 12 ounce weight was used, the effect was *more than one-half*, the numbers in the 3d column being more than one-half the numbers in the 2d. Hence we may conclude, that the slower an overshot-wheel moves, the greater will be its performance.

262. These experiments of Deparcieux presented such unexpected results, as to induce other philosophers to examine them with care. The chevalier d'Arcy, in particular, considered them attentively. He maintained that there was a determinate velocity when the effect of the wheel reached its maximum; and he has shewn, by comparing the experiments of Deparcieux with his own formulæ, that the overshot-wheel which Deparcieux employed never moved with such a small velocity as corresponded with the maximum effect, and that if

On Water-Wheels.

if he had increased the diameter of his cylinders, or the magnitude of the weights, his own experiments would have exhibited the degree of velocity, when the effect was the greatest possible.

His opinion confirmed by the experiments of Smeaton.

263. The reasoning of the chevalier d'Arcy is completely confirmed by the experiments of Smeaton. This celebrated engineer concludes with Deparcieux that, *cæteris paribus*, the less the velocity of the wheel, the greater will be its effect. But he observes, on the contrary, that when the wheel of his model made about 30 turns in a minute, the effect was nearly the greatest; when it made 30 turns, the effect was diminished about one-twentieth part; and that when it made 40 it was diminished about one-fourth; when it made less than $18\frac{1}{4}$ turns, its motion was irregular, and when it was loaded so that it could not make 18 turns, the wheel was overpowered by its load. Mr Smeaton likewise observes, that when the circumferences of overshot wheels, whether high or low, move with the velocity of three feet per second, and when the other parts of the work are properly adapted to it, they will produce the greatest possible effect. He allows, however, that high wheels may deviate farther from this rule before losing their power than low ones can be permitted to do; and assures us that he has seen a wheel 24 feet high moving at the rate of six feet per second, without losing any considerable part of its power, and likewise a wheel 33 feet high moving very steadily and well with a velocity but little exceeding two feet.

And also by the experiments of Bossut.

264. The experiments of the abbé Bossut may also be brought forward in support of the same reasoning. He employed a wheel 3 feet in diameter, furnished with 48 buckets, having each three inches of depth, and four inches of width. The canal which conveyed the water into the buckets was perfectly horizontal, and was five inches wide. It furnished uniformly 1194 cubic inches of water in a minute. The resistance to be overcome was a variety of weights fixed to the extremity of a cord, which, after passing over a pulley as in Deparcieux's experiments, winded round the cylindrical axle of the wheel. The diameter of this cylinder was two inches and seven lines, and that of the gudgeons or pivots of the wheel two lines and a half. The number of turns which the wheel made in a minute was not reckoned till its motion became uniform, which always happened when it had performed five or six revolutions. When the wheel was unloaded it made $40\frac{1}{4}$ turns in a minute.

Number of pounds raised.	Number of seconds in which the load was raised.	Number of revolutions performed by the wheel.	Effect of the wheel, or the product of the number of turns multiplied by the load.
11	60″	$11\frac{46}{48}$	$131\frac{22}{48}$
12	60	$11\frac{11}{48}$	$134\frac{16}{48}$
13	60	$10\frac{25}{48}$	$136\frac{19}{48}$
14	60	$9\frac{40}{48}$	$137\frac{12}{48}$
15	60	$9\frac{10}{48}$	$138\frac{6}{48}$
16	60	$8\frac{31}{48}$	$138\frac{16}{48}$
17	60	$8\frac{9}{48}$	$139\frac{9}{48}$
18	60	$7\frac{32}{48}$	138
19	The wheel turned but exceedingly slow.		
20	The wheel stopped though first put in motion by the hand to make it catch the water.		

265. It appears evidently from the last column, which we have computed on purpose, that the effect increases as the velocity diminishes; but that the effect is a maximum when the number of turns is $8\frac{9}{48}$ in a minute, being then $139\frac{9}{48}$. When the velocity was farther diminished by adding an additional pound to the resistance, the effect was diminished to 138, and when the velocity was still less, the wheel ceased to move.

Now since the wheel was three feet in diameter, and 9.42 feet in circumference, the velocity of its circumference will be about one foot four inches per second, when it performs $8\frac{9}{48}$ turns in a minute, or when the maximum effect is produced. With Mr Smeaton's model, the maximum effect was produced when the velocity of the wheel's circumference was two feet per second. So that the experiments both of Smeaton and Bossut concur to prove, that the power of overshot wheels increases as the velocity diminishes; but that there is a certain velocity, between one and two feet per second, when the wheel produces a maximum effect. Since when the wheel was unloaded it turned $40\frac{1}{4}$ times in a minute, and performed only $8\frac{9}{48}$ revolutions when its power was a maximum, the velocity of the wheel when unloaded will be to its velocity when the effect is the greatest, as five to one, nearly.

On the effect of overshot-wheels.

266. The chevalier de Borda maintains that an overshot wheel will raise through the height of the fall a quantity of water equal to that by which it is driven, and Albert Euler has shewn that the effect of these wheels is very much inferior to the momentum or force which impels them. It appears, however, from Mr Smeaton's experiments, that when the work performed was a maximum, the ratio of the power to the effect was as four to three, when the height of the fall

On Water-Wheels.

fall and the quantities of water expended were the least; but that it was as four to two when the heights of the fall and the quantities discharged were the greatest. By taking a mean between these ratios, we may conclude, in general, that in overshot wheels the power is to the effect as three to one. In this case the power is supposed to be computed from the whole height of the fall; because the water must be raised to that height in order to be in a condition of producing the same effect a second time. When the power of the water is estimated only from the height of the wheel, the ratio of the power to the effect was more constant, being nearly as five to four.

Investigations of Albert Euler.

267. The theory of overshot wheels has been ably discussed by Albert Euler, and Lambert. The former of these philosophers has shown that the altitude of the wheel should be made as great as possible: that the buckets should be made as capacious as other circumstances will permit; that their form should be such as to convey the water as near the lowest point of the wheel as can be conveniently done; and that the motion of the wheel should be slow, that the buckets may be completely filled. He has likewise shown that the effect of the wheel increases as its velocity is diminished; and that overshot wheels should be used only when there is a sufficient height of fall. The results of Lambert's investigations are less consonant with the experiments of Smeaton. By examining the following table, which contains these results, it will appear at once that he makes the diameter of the wheel much smaller than it ought to be.

SECT. II. *On Breast Wheels.*

Description of breast-wheels.

Plate CCLXIX. fig. 6.

268. A breast wheel partakes of the nature both of an overshot and an undershot wheel, and is driven partly by the impulse, but chiefly by the weight of the water. A water wheel of this kind is represented in fig. 6. where MC is the stream of water falling on the floatboard *o*, with a velocity corresponding to the altitude *m n*, and afterwards acting by its weight on the floatboards between *o* and B. The mill course *o* B is made concentric with the wheel, which is fitted to it in such a manner that very little water is allowed to escape at the sides and extremities of the floatboards. According to Mr Smeaton, the effect of a wheel driven in this manner is equal "to the effect of an undershot wheel whose head of water is equal to the difference of level between the surface of water in the reservoir, and the point where it strikes the wheel, added to that of an overshot whose height is equal to the difference of level between the point where it strikes the wheel and the level of the tail water (M)." That is, the effect of the wheel A is equal to that of an undershot wheel driven by a fall of water equal to *m n*, added to that of an overshot wheel whose height is equal to *n* D.

Results of the investigations of Lambert.

269. Mr Lambert of the academy of sciences at Berlin (N) has shewn that when the floatboards arrive at the position *o p*, they ought to be horizontal: the point *p* should be lower than *o*, in order that the whole space between any two adjacent floatboards may be filled with water; and that C *m* should be equal to the depth of the floatboards. He observes also, that a breast wheel should be used when the fall of water is above four feet in height, and below ten. The following table is calculated from Lambert's formulæ, and exhibits at one view the results of his investigations.

TABLE

(M) Smeaton on Mills, schol. p. 36.

1	2	3	4	5	6	7	8	9	10	11

270. It appears from the preceding table, that when the altitude of the fall of water is below three feet, there is such an unsuitable proportion between the depth and width of the floatboards, that a breast wheel cannot well be employed. It is also evident, on the other hand, that when the height of the fall approaches to ten feet, the depth of the floatboards is too small in relation to their width. These two extremes, therefore, ought to be avoided in practice. The eleventh column of the table contains the quantity of water necessary to drive the wheel; but the total quantity of water should always exceed this, by the quantity, at least, that escapes between the mill course and the sides and extremities of the floatboards (o).

Dimensions of a breast wheel. Plate CCLXIX.

271. The following are the dimensions of an excellent breast water wheel, differing very little from that which is represented in fig. 6. The water, however, instead of falling through the height *cn* which is 16 inches, is delivered on the floatboard *op*, through an adjutage six inches and a half high.—The height *n* D is four feet two inches; and therefore the whole height CD must be five feet and a half. The radius of the wheel AB is six feet and a half, the breadth of each floatboard six inches and a half, and their depth 28 inches. The point P of the wheel moves with the velocity of 7.588 feet in a second. The quantity of water discharged in a second is 3.266 cubic feet, and the force of impulsion upon the floatboards 356 pounds avoirdupois. On some occasions buckets have been used in breast wheels instead of floatboards; but this is evidently a disadvantage, as the height through which the water acts is diminished by the number of inches through which the water must fall in order to acquire the velocity of the wheel, and also by the versed sine of the arch above the lowest point of the wheel which may be considered as not loaded with water.

SECT. III. *On Undershot Wheels.*

Description of an undershot wheel. Plate CCLXX. fig. 1.

272. AN undershot wheel is a wheel with a number of floatboards disposed on its circumference, which receive the impulse of the water conveyed to the lowest point of the wheel by an inclined canal. It is represented in fig. 1. where WW is the water wheel, and ABDFHKMV the canal or mill course, which conveys the water to K, where it strikes the plane floatboards *no*, &c. and makes the wheel revolve about its axis.

Construction of the mill course.

273. In order to construct the mill course to the greatest advantage, we must give but a very small declivity to the canal which conducts the water from the river. It will be sufficient to make AB slope about one inch in 200 yards, making the declivity, however, about half an inch for the first 48 yards, in order that the water may have sufficient velocity to prevent it from falling back into the river. The inclination of the fall, represented by the angle GCR, should be 25° 50′, or CR the radius should be to GR, the tangent of this angle, as 100 to 28, or as 25 to 12; and since the surface of the water S*b* is bent from *ab* into *ac* before it is precipitated down the fall, it will be necessary to incurvate the upper part BCD of the course into BD, that the water in the bottom may move parallel to the water at the surface of the stream. For this purpose take the points B, D about 12 inches distant from C, and raise the perpendiculars BE, DE. The point of intersection E will be the centre from which the arch BD is to be described; the radius being about $10\frac{1}{10}$ inches. Now, in order that the water may act more advantageously upon the floatboards of the wheel WW, it must assume a horizontal direction, with the same velocity which it would have acquired when it came to the point G. But, if the water were allowed to fall from C to G, it would dash upon the horizontal part HG, and thus

(o) See Appendix to Ferguson's Lectures, vol. ii. p. 189. edit. 2d.

On Water-Wheels.

thus lose a great part of its velocity. It will be necessary, therefore, to make it move along FH, an arch of a circle to which DF and KH are tangents in the points F and H. For this purpose make GF and GH each equal to three feet; and raise the perpendiculars HI, FI which will intersect one another in the point I, distant about four feet nine inches from the points F and H, and the centre of the arch FH will be determined. The distance HK, through which the water runs before it acts upon the wheel, should not be less than two or three feet, in order that the different filaments of the fluid may have attained a horizontal direction. If HK were too large, the steam would suffer a diminution of velocity by its friction on the bottom of the course. That no water may escape between the bottom of the course KH and the extremities of the floatboards, KL should be about three inches, and the extremity *o* of the floatboard *n o* ought to reach below the line HKX, sufficient room being left between *o* and M for the play of the wheel; or KLM may be formed into the arch of a circle KM concentric with the wheel. The line LMV, which has been called the course of impulsion, should be prolonged so as to support the water as long as it can act upon the floatboards, and should be about nine inches distant from OP, a horizontal line passing through O the lowest point of the fall; for if OL were much less than nine inches, the water having spent the greatest part of its force in impelling the floatboard, would accumulate below the wheel, and retard its motion. For the same reason another course, which has been called the course of discharge, should be connected with LMV by the curve VN to preserve the remaining velocity of the water, which would otherwise be discharged by falling perpendicularly from V to N. The course of discharge, which is represented by the line VZ, sloping from the point O, should be about 16 yards long, having an inch of declivity for every two yards. The canal which reconducts the water from the course of discharge to the river should slope about four inches in the first 200 yards, three inches in the second 200 yards, decreasing gradually till it terminates in the river. But if the river to which the water is conveyed should, when swelled by the rains, force the water back upon the wheel, the canal must have a greater declivity to prevent this from taking place. Hence it is evident that very accurate levelling is requisite to the proper formation of the mill course.

Plate CCLXX. fig. 2.

As it is of great importance that none of the water should escape either below the floatboards, or at their sides, without contributing to turn the wheel, the course of impulsion KV should be wider than the course at K, as represented in fig. 2. where CD the course of impulsion corresponds with LV in fig. 1. AB corresponds with HK and BC with KL. The breadth of the floatboards therefore should be wider than *m n*, and their extremities should reach a little below B, like *n o* in fig. 1. When these precautions are properly taken, no water can escape without exerting its force upon the floatboards.

273. It has been disputed among philosophers, whether the wheel should be furnished with a small or a great number of floatboards. M. Pitot has shewn, that when the floatboards have different degrees of obliquity, the force of impulsion upon the different surfaces will be reciprocally as their breadths: Thus in fig. 3. the force of impulsion upon *h c* will be to the force upon DO, as DO to *h c* (P). Hence he concludes that the distance between the floatboards should be equal to one-half of the immersed arch, or that when one floatboard is at the bottom of the wheel, and perpendicular to the current, as DE, the preceding floatboard BC should be just leaving the stream, and the succeeding one FG just immerging into it. For when the three floatboards FG, DE, BC have the same position as in the figure, the whole force of the current NM will act upon DE when it is in the most advantageous position for receiving it, whereas, if another floatboard *d c* were inserted between FG and DE, the part *i g* would cover DO, and by thus substituting an oblique for a perpendicular surface, the effect would be diminished in the proportion of DO to *i g*. Hence it is evident that, upon this principle, the depth of the floatboard DE should be always equal to the versed sine of the arch EG (Q).

274. Notwithstanding the plausibility of this reasoning, it will not be difficult to shew that it is destitute of foundation. It is evident from fig. 3. that when one of the floatboards DE is perpendicular to the stream, it receives the whole impulse of the water in the most advantageous manner. But when it arrives at the position *d e*, and the succeeding one FG at the position *f g*, so that the angle *e A g* may be bisected by the perpendicular AE; the situation of these floatboards will be the most disadvantageous, for a great part of the water will escape between the extremities *g* and *e* of the floatboards without striking them, and the part *i g* of the floatboard, which is really impelled, is less than DE, and oblique to the current. The wheel, therefore, must move irregularly, sometimes quick and sometimes slow, according to the position of the floatboards with respect to the stream: and this inequality will increase with the arch plunged in the water. The reasoning of M. Pitot, indeed, is founded on the supposition, that if another floatboard *f g* were placed between FG and DF it would annihilate the force of the water that impels it, and prevent any of the fluid from striking the corresponding part DO of the preceding floatboard. But this is not the case. For when the water has acted upon *f g*, it still retains a part of its motion, and after bending round the extremity *g* strikes DE with its remaining force. We are entitled, therefore, to conclude that advantage must be gained by using more floatboards than are recommended by Pitot.

275. It is evident from the preceding remarks, that in order to remove any inequality of motion in the wheel, and prevent the water from escaping below the extremities of the floatboards, the wheel should be furnished with the greatest possible number of floatboards, without loading it too much, or enfeebling the rim on which they are

(P) *Mem. de l'Acad. Paris*, 1729, 8vo. p. 359.

(Q) A table containing the number of floatboards for wheels of different diameters, and founded on this principle, has been computed by Mr Brewster. See *Appendix to Ferguson's Lectures*, vol. ii. p. 149. 2d Edit.

on Water-Wheels.

are fixed. This rule was first given by M. Dupetit Vandin (R); and it is easily perceived, that if the millwright should err in using too many floatboards, this error in excess will be perfectly trifling, and that a much greater loss of power would be occasioned by an error in defect.

Form of the floatboards. Fig. 3.

276. The section of the floatboards ought not to be rectangular like *a b n c* in fig. 3. but should be bevelled like *a b m c*. For if they were rectangular, the extremity *b n* would interrupt a portion of the water which would otherwise fall on the corresponding part of the preceding floatboard. In order to find the angle *a b m*, subtract from 180 degrees the number of degrees contained in the immersed arch CEG, and the half of the remainder will be the angle required.

Position of the floatboards.

277. It has been maintained by M. Pitot and other philosophers, that the floatboards should be a continuation of the radius, or perpendicular to the rim, as in fig. 1. This indeed is true in theory, but it appears from the most unquestionable experiments, that they should be inclined to the radius. This important fact was discovered by Deparcieux in 1753, and proved by several experiments. When the floatboards are inclined, the water heaps up on their surface, and acts not only by its impulse but also by its weight. The same truth has also been confirmed by the abbé Bossut, the most accurate of whose experiments are contained in the following table. The wheel that was employed was immersed four inches vertically in the water, and it was furnished with 12 floatboards.

Inclination of the floatboard.	Number of pounds raised.	Time in which the load was raised in seconds.	Number of turns made by the wheel.
0	40	40	$13\frac{17}{48}$
15	40	40	$14\frac{21}{48}$
30	40	40	$14\frac{32}{48}$
37	40	40	$14\frac{15}{48}$
1	2	3	4

278. It is obvious, from the preceding table, that the wheel made the greatest number of turns, or moved with the greatest velocity, when the number of floatboards was between 15 and 30. When the water-wheels are placed on canals that have little declivity, and in which the water can escape freely after its impulse upon the floatboards, it would be proper to make the floatboards a continuation of the radius. But when they move in an inclined mill-course, an augmentation of velocity may be expected from an inclination of the floatboards.

On the proper velocity of undershot wheels when the effect is a maximum.

279. Having thus pointed out the most scientific method of constructing the wheel, and delivering the water upon its floatboards, we have now to determine the velocity with which it should move. It is evident, that the velocity of the wheel must be always less than that of the water which impels it, even when there is no work to be performed; for a part of the impelling power is necessarily spent in overcoming the inertia of the wheel and the resistance of friction. It is likewise obvious, that when the wheel has little or no velocity, its performance will be very trifling. There is, consequently, a certain proportion between the velocity of the water and the wheel, when its effect is a maximum. By the reasoning which is employed in the section on undershot wheels in the article *WATER-Works*, Parent and Pitot found, that a maximum effect was produced when the velocity of the wheel was one-third of the velocity of the water; and Desaguliers (S) Maclaurin (T), Lambert (U), and Atwood (X), have adopted their conclusions. In the calculus from which this result was deduced, it was taken for granted, that the momentum or force of water upon the wheel is in the duplicate ratio of the relative velocity, or as the square of the difference between the velocity of the water and that of the wheel. This supposition, indeed, is perfectly correct when the water impels a single floatboard; for as the number of particles which strike the floatboard in a given time, and also the momentum of these, are each as the relative velocity of the floatboards, the momentum must be as the square of the relative velocity, that is, $M \div R^2$, M being the momentum, and R the relative velocity. But we have seen, in some of the preceding paragraphs, that the water acts on more than one floatboard at a time. Now the number of floatboards acted upon in a given time will be as the velocity of the wheel, or inversely as the relative velocity; for if you increase the relative velocity, the velocity of the water remaining the same, you must diminish the velocity of the wheel. Consequently, we shall have $M \div \frac{R^2}{R}$ or $M \div R$; that is, the momentum of the water acting upon the wheel, is directly as the relative velocity.

The force of a current impelling an undershot wheel is as the relative velocity.

280. Let V be now the velocity of the stream, and F the force with which it would strike the floatboard at rest, and v the velocity of the wheel. Then the relative velocity will be $V - v$; and since the velocity of the water will be to its momentum, or the force with which it would strike the floatboard at rest, as the relative velocity is to the real force which the water exerts against the moving floatboards, we shall have $V : V - v = F : F \times \frac{\overline{V - v}}{V} = \frac{F}{V} \times \overline{V - v}$. But the effect of the wheel is measured by the product of the momentum of the water and the velocity of the wheel, consequently the effect of the undershot wheel will be $v \times \overline{\frac{F}{V} \times V - v} = \frac{F}{V} \times \overline{Vv - v^2}$. Now this effect is to be a maximum, and therefore its fluxion must be equal to 0, that is, v, being the variable quantity, $V\dot{v} - 2v\dot{v} = 0$, or $2v\dot{v} = V\dot{v}$. Dividing by $\dot{v}$, we have $2v = V$,

On Water-Wheels.

V, and $v=\frac{V}{2}$, that is, the velocity of the wheel will be *one half* the velocity of the fluid when the effect is a maximum.

Confirmed by Smeaton's experiments,

281. This result, which was first obtained by the chevalier de Borda, has been amply confirmed by the experiments of Mr Smeaton. "The velocity of the stream (says he) varies at the maximum between one-third and one-half that of the water; but in all the cases in which most work is performed in proportion to the water expended, and which approach the nearest to the circumstances of great works, when properly executed, the maximum lies much nearer *one-half* than *one-third*, one half seeming to be the true maximum, if nothing were lost by the resistance of the air, the scattering of the water carried up by the wheel, &c."

and by the experiments of Bossut.

282. A result, nearly similar to this, was deduced from the experiments of Bossut. He employed a wheel whose diameter was three feet. The number of floatboards was at one time 48, and at another 24, their width being five inches, and their depth six. The experiments with the wheel, when it had 48 floatboards, were made in an inclined canal, supplied from a reservoir by an orifice two inches deep, the velocity being 300 feet in 27 seconds. The experiments with the wheel, when it had 24 floatboards, were made in a canal, contained between two vertical walls, 12 or 13 feet distant. The depth of the water was about seven or eight inches, and its mean velocity about 2740 inches in 40 seconds. The floatboards of the wheel were immersed about four inches in the stream.

Time in which the load is raised.	No. of pounds raised.	Number of turns made by the wheel.	No. of pounds raised.	Number of turns made by the wheel.
Seconds	48 Floatboards.		48 Floatboards.	
40	$30\frac{1}{2}$	$22\frac{12}{48}$	30	$17\frac{22}{48}$
40	31	$22\frac{4}{48}$	35	$16\frac{25}{48}$
40	$31\frac{1}{2}$	$21\frac{42}{48}$	40	$15\frac{28}{48}$
40	32	$21\frac{12}{48}$	45	$14\frac{11}{48}$
40	$32\frac{1}{2}$	$21\frac{20}{48}$	50	$13\frac{34}{48}$
40	33	$21\frac{8}{48}$	55	$12\frac{37}{48}$
40	$33\frac{1}{2}$	$20\frac{44}{48}$	56	$12\frac{28}{48}$
40	34	$20\frac{12}{48}$	57	$12\frac{10}{48}$
40	$34\frac{1}{2}$	$20\frac{21}{48}$	58	$12\frac{10}{48}$
40	35	$19\frac{44}{48}$	59	$12\frac{1}{48}$
40	$35\frac{1}{2}$	$19\frac{15}{48}$	60	$11\frac{40}{48}$
40	36	$18\frac{28}{48}$	61	$11\frac{30}{48}$
40			62	$11\frac{10}{48}$
			63	$11\frac{7}{48}$
			64	$10\frac{41}{48}$
			65	$10\frac{25}{48}$
			66	$10\frac{5}{48}$

283. As the effect of the machine is measured by the product of the load raised, and the time employed, it will appear, by multiplying the second and third columns, that the effect was a maximum when the load was $34\frac{1}{2}$ pounds, the wheel performing $20\frac{21}{48}$ revolutions in 40 seconds. By comparing the velocity of the centre of impression computed from the diameter of the wheel, and the number of turns which it makes in 40 seconds, with the velocity of the current, it will be found, that the velocity of the wheel, when its effect is the greatest possible, is nearly two-fifths that of the stream. From the two last columns of the table, where the effect is a maximum when the load is 60 pounds, the same conclusion may be deduced.

Method of constructing a mill-wright's table.

284. The proper velocity of the wheel being thus established, we shall proceed to point out the method of constructing a mill-wright's table for undershot wheels, taking it for granted, that the velocity of the wheel should be one-half the velocity of the stream, and that water moves with the same velocity as falling bodies.

1. Find the perpendicular height of the fall of water above the bottom of the mill-course, and having diminished this number by one-half the depth of the water at K, call that the height of the fall. Fig. 1.

2. Since bodies acquire a velocity of 32.174 feet, by falling through the height of 16.087 feet; and as the velocities of falling bodies are as the square roots of the heights through which they fall, the square root of 16.087 will be to the square root of the height of the fall as 32.174 to a fourth number, which will be the velocity of the water. Therefore the velocity of the water may be always found by multiplying 32.174 by the square root of the height of the fall, and dividing that product by the square root of 16.087. Or it may be found more easily by multiplying the height of the fall by the constant quantity $64.348=2\times 32.174$, and extracting the square root of the product. This root, abstracting from the effects of friction, will be the velocity of the water required.

3. Take *one-half* the velocity of the water, and it will be the velocity which must be given to the floatboards, or the number of feet they must move through in a second, in order to produce a maximum effect.

4. Divide the circumference of the wheel by the velocity of its floatboards per second, and the quotient will be the number of seconds in which the wheel revolves.

5. Divide 60 by the number last found, and the quotient will be the number of turns made by the wheel in a minute.—Or the number of revolutions performed by the wheel in a minute may be found, by multiplying the velocity of the floatboards by 60, and dividing the product by the circumference of the wheel.

6. Divide 90, the number of revolutions which a millstone, five feet diameter, should make in a minute, by the number of revolutions made by the wheel in a minute; and the quotient will be the number of turns which the millstone ought to make for one revolution of the wheel.

7. Then as the number of revolutions of the wheel in a minute, is to the number of revolutions of the millstone in a minute, so must the number of staves in the trundle be to the number of teeth in the wheel, in the nearest whole numbers that can be found.

8. Multiply the number of revolutions performed by the wheel in a minute, by the number of revolutions made by the millstone for one of the wheel, and the product will be the number of revolutions made by the millstone in a minute.

285. By these rules, the following table has been computed

On Water-Wheels.

computed for a water wheel fifteen feet in diameter, which is a good medium size, the millstone being seven feet in diameter, and revolving 90 times in a minute.

TABLE I. *A New Mill-Wright's Table, in which the Velocity of the Wheel is one-half the Velocity of the Stream, the effects of Friction not being considered.*

Height of the fall of water.	Velocity of the water per second, friction not being considered.	Velocity of the wheel per second, being one-half that of the water.	Revolutions of the wheel per minute, its diameter being 15 feet.	Revolutions of the millstone for one of the wheel.	Teeth in the wheel and staves in the trundle.		Revolutions of the millstone per minute by these staves and teeth.

286. The preceding table, computed by Mr Brewster (Appendix to Ferguson's Lectures, vol. ii. p. 174.) supposes, according to theory, that the velocity of the wheel, at the maximum effect, is one-half that of the stream, which is nearly the case in practice, when the quantities of water discharged by the stream are considerable. "When we consider, however, (observes the "editor of the work now quoted), that after every "precaution has been observed, a small quantity of "water will escape between the mill course and the "extremities of the floatboards, and that the effect is "diminished by the resistance of the air and the dis-"persion of water carried up by the wheel, the pro-"priety of making the wheel move with three-sevenths "the velocity of the water will appear. The chevalier "de Borda supposes it never to exceed three-eighths; "and Mr Smeaton and the abbé Bossut found two-fifths "to be the proper medium (Y). With three-sevenths, "therefore, as the best medium, which differs only "$\frac{1}{35}$th from $\frac{2}{5}$ths, the numbers in the following table "have been computed. In Table I. the water was sup-"posed to move with the same velocity as falling bo-"dies, but owing to its friction on the mill-course, &c. "this is not exactly the case. We have therefore "deduced the velocity of the water in column second, "from the following formula, $V=\sqrt{\frac{172}{3}\times Rb-\frac{Hh}{2}}$, Fig. 1. "in which V is the velocity of the water, Rb the ab-"solute height of the fall, and Hh the depth of the "water at the bottom of the course. The formula is "founded on the experiments of Bossut, from which it "appears, that if a canal be inclined one-tenth part of "its length, this additional declivity will restore that ve-"locity to the water which was destroyed by friction."

TABLE II. *A New Mill-Wright's Table, in which the Velocity of the Wheel is three-sevenths of the Velocity of the Water, and the effects of Friction on the Velocity of the stream reduced to computation.*

Height of the fall of water.	Velocity of the water per second, friction being considered.	Velocity of the wheel per second, being 3-7ths that of the water.	Revolutions of the wheel per minute, its diameter being 15 feet.	Revolutions of millstone for one of the wheel.	Teeth in the wheel and staves in the trundle.		Revolutions of the millstone per minute, by these staves and teeth.
Feet.	Feet. 100 parts of a foot.	Feet. 100 parts of a foot.	Revol. 100 parts of a revol.	Revol. 100 parts of a revol.	Teeth.	Staves.	Revol. 100 parts of a revol.

287.

(Y) The great hydraulic machine at Marly was found to produce a maximum effect, when its velocity was two-fifths that of the stream.

On Water-Wheels.

Method of using the table.

287. In order that the wheel may move with a velocity duly adjusted to that of the current, we would not advise the mechanic to trust to the second column of Table II. for the true velocity of the stream, or to any theoretical results, even when deduced from formulæ founded on experiments. Bossut, with great justice, remarks, that "it would not be exact in practice to compute the velocity of a current from its declivity. This velocity ought to be determined by immediate experiment in every particular case." Let the velocity of the water, therefore, where it strikes the wheel, be determined by the method in the following paragraph. With this velocity, as an argument, enter column second of either of these tables, according as the velocity of the wheel is to be one-half or three-sevenths that of the stream, and take out the other numbers from the table.

Different methods of measuring the velocity of the stream.

288. Various methods have been proposed by different philosophers for measuring the velocity of running water; the method, by floating bodies, which Mariotte (Z) employed, the bent tube of Pitot (A), the regulator of Guglielmini (B), the quadrant (C), the little wheel (D), and the method proposed by the Abbé Mann (E), have each their advantages and disadvantages. The little wheel was employed in the experiments of Bossut. It is the most convenient mode of determining the superficial velocity of the water; and, when constructed in the following manner, will be more accurate, it is hoped, than any instrument that has hitherto been used. The small wheel WW should be formed of the lightest materials. It should be about 10 or 12 inches in diameter, and furnished with 14 or 16 floatboards. This wheel moves upon a delicate screw aB, passing through its axle Bb; and when impelled by the stream it will gradually approach towards D, each revolution of the wheel coresponding with a thread of the screw. The number of revolutions performed in a given time are determined upon the scale ma, by means of the index Oh fixed at O, and moveable with the wheel, each division of the scale being equal to the breadth of a thread of the screw, and the extremity h of the index Oh coinciding with the beginning of the scale, when the shoulder b of the wheel is screwed close to a. The parts of a revolution are indicated by the bent index mn pointing to the periphery of the wheel, which is divided into 100 parts. When this instrument is to be used, take it by the handles C, D, or when great accuracy is required, make it rest on the handles C, D; and screw the shoulder n of the wheel close to a, so that the indices may both point to o the commencement of the scales. Then, by means of a stop-watch or pendulum, find how many revolutions of the wheel are performed in a given time. Multiply the mean circumference of the wheel (or the circumference deduced from the mean radius, which is equal to the distance of the centre of impulsion or impression from the axis bB) by the number of revolutions, and the product will be the number of feet through which the water moves in the given time. On account of the friction of the screw, the resistance of the air, and the weight of the wheel, its centre of impression will revolve with a little less velocity than that of the stream; but the diminution of velocity, arising from these causes, may be estimated with sufficient precision for all the purposes of the practical mechanic. (*Appendix to Ferguson's Lectures*, vol. ii. p. 177.)

Simple instrument for this purpose. Plate CCLXX. fig. 4.

Results of Smeaton's experiments.

289. It appears, from a comparison of the numerous and accurate experiments of Mr Smeaton, that, in undershot wheels, the power employed to turn the wheel is to the effect produced as 3 to 1; and that the load which the wheel will carry at its maximum, is to the load which will totally stop it, as 3 to 4. The same experiments inform us, that the impulse of the water on the wheel, in the case of a maximum, is more than double of what is assigned by theory, that is, instead of four-sevenths of the column, it is nearly equal to the whole column. In order to account for this, Mr Smeaton observes, that the wheel was not, in this case, placed in an open river, where the natural current, after it had communicated its impulse to the float, has room on all sides to escape, as the theory supposes; but in a conduit or race, to which the float being adapted, the water could not otherwise escape than by moving along with the wheel. He likewise remarks, that when a wheel works in this manner, the water, as soon as it meets the float, receives a sudden check, and rises up against it like a wave against a fixed object; insomuch, that when the sheet of water is not a quarter of an inch thick before it meets the float, yet this sheet will act upon the whole surface of a float, whose height is three inches. Were the float, therefore, no higher than the thickness of the sheet of water, as the theory supposes, a great part of the force would be lost by the water dashing over it. In order to try what would be the effect of diminishing the number of floatboards, Mr Smeaton reduced the floatboards, which were originally 24, to 12. This change produced a diminution of the effect, as a greater quantity of water escaped between the floats and the floor. But when a circular sweep was adapted to the floor, and made of such a length that one float entered the curve before the preceding one quitted it, the effect came so near to the former, as to afford no hopes of increasing it by augmenting the number of floats beyond 24 in this particular wheel. Mr Smeaton likewise deduced, from his experiments, the following maxims.

1. That the virtual or effective head being the same, the effect will be nearly as the quantity of water expended.

2. That

On Water-Wheels.

2. That the expence of water being the same, the effect will be nearly as the height of the virtual or effective head.

3. That the quantity of water expended being the same, the effect is nearly as the square of the velocity.

4. The aperture being the same, the effect will be nearly as the cube of the velocity of the water.

Undershot wheels with floatboards inclined to the plane of the wheel, Plate CCLXX. fig. 5.

290. We have hitherto supposed the floatboards, though inclined to the radius, to be perpendicular to the plane of the wheel. Undershot-wheels, however, have sometimes been constructed with floatboards inclined to the plane of the wheel. A wheel of this kind is represented in fig. 5. where AB is the wheel, and CDEFGH the oblique floatboards. The horizontal current MN is delivered on the floatboards, so as to strike them perpendicularly. On account of the size of the floatboards, every filament of the water contributes to turn the wheel; and therefore its effect will be greater than in undershot wheels of the common form. Albert Euler imagines that the effect will be twice as great, and observes, that in order to produce such an effect, the velocity of the centre of impression should be to the velocity of the water, as radius is to triple the sine of the angle by which the floatboards are inclined to the plane of the wheel. If this inclination, therefore, be 60°, the velocity of the wheel at the centre of impression ought to be to the velocity of the impelling fluid as 1 to $\frac{3\sqrt{3}}{2}$, that is, as 5 to 13 nearly, because Sin. $60^\circ = \frac{\sqrt{3}}{2}$. When the inclination is 30°, the ratio of the velocities will be found to be as 2 to 3.

and also to the radius.

291. In wheels of this kind, the floats may also be advantageously inclined to the radius. In this case, the stream, which still strikes them perpendicularly, is inclined to the horizon. If the angle formed by the common section of the wheel and floatboards with the radius of the wheel, be $= m$; and if the angle by which the floatboards are inclined to the plane of the wheel be $= n$, then the angle which the floatboards should form with the direction in which the wheel moves, will be $= \text{Cos. } m \times \text{Sin. } n$. In order, therefore, that the stream may strike the floatboards with a perpendicular impulse, its inclination to the horizon must be $= m$, and its inclination to the plane of the wheel $= 90^\circ - n$. The less that the velocity of the water is, the greater should be the angle m; for there is, in this case, no danger that the celerity of the wheel be too great. The area of the floatboards ought to be much greater than the section of the current; and the interval between two adjacent floatboards should be so great, that before the one completely withdraws itself from the action of the water, the other should begin to receive its impulse.

On horizontal water-wheels Fig. 6.

292. Horizontal water-wheels have been much used on the continent, and are strongly recommended to our notice by the simplicity of their construction. In fig. 6. AB is the large water-wheel which moves horizontally upon its arbor CD. This arbor passes through the immoveable millstone EF at D, and being fixed to the upper one GH, carries it once round for every revolution of the great wheel. The mill-course is constructed in the same manner for horizontal as for vertical wheels, with this difference only, that the part mBnC, fig. 2. of which KL in fig. 1. is a section, instead of being rectilineal like mn, must be circular like mP, and concentric with the rim of the wheel, sufficient room being left between it and the tips of the floatboards for the play of the wheel. In this construction, where the water moves in a horizontal direction before it strikes the wheel, the floatboards should be inclined about 25° to the plane of the wheel, and the same number of degrees to the radius, so that the lowest and outermost sides of the floatboards may be farthest up the stream.

293. Instead of making the canal horizontal before it delivers the water on the floatboards, they are frequently inclined in such a manner as to receive the impulse perpendicularly, and in the direction of the declivity of the mill-course. When this construction is adopted, the maximum effect will be produced when the velocity of the floatboards is not less than $\frac{5.67\sqrt{H}}{2 \text{ Sin. A}}$, where H represents the height of the fall, and A the angle which the direction of the fall makes with a vertical line. But as the quantity $\frac{5.67\sqrt{H}}{2 \text{ Sin. A}}$ evidently increases as the sine of A decreases, it follows, that without lessening the effect of these wheels, we may diminish the angle A, and thus augment considerably the velocity of the floatboards, according to the nature of the machinery employed; whereas, in vertical wheels, there is only one determinate velocity which produces a maximum effect.

With curvilineal floatboards.

294. In the southern provinces of France, where horizontal wheels are generally employed, the floatboards are made of a curvilineal form, so as to be concave towards the stream. The Chevalier de Borda observes, that in theory a double effect is produced when the floatboards are concave; but that the effect is diminished in practice, from the difficulty of making the fluid enter and leave the curve in a proper direction. Notwithstanding this difficulty, however, and other defects which might be pointed out, horizontal wheels with concave floatboards are always superior to those in which the floatboards are plane, and even to vertical wheels, when there is a sufficient fall of water. When the floatboards are plane, the wheel is driven merely by the impulse of the stream; but when they are concave, a part of the water acts by its weight and increases the velocity of the wheel. If the fall of water be 5 or 6 feet, a horizontal wheel with concave floatboards may be erected, whose maximum effect will be to that of the ordinary vertical wheels as 3 to 2.

295. An advantage attending horizontal wheels is, that the water may be divided into several canals, and delivered upon several floatboards at the same time. Each stream will heap up on its corresponding floatboard, and produce a greater effect than if the force of the water had been concentrated on a single floatboard. Horizontal wheels may be employed with greatest advantage when a small quantity of water falls through a considerable height.

Overshot wheels superior to undershot ones.

296. It has been disputed among mechanical philosophers, whether overshot or undershot wheels produce the greatest effect. M. Belidor maintained that the former were inferior to the latter, while a contrary opinion was

Machines driven by the Reaction of Water.

was entertained by Desaguliers. It appears, however, from Mr Smeaton's experiments, that in overshot wheels the power is to the effect nearly as 3 to 2 or as 5 to 4 in general, whereas in undershot wheels, it is only as 3 to 1. The effect of overshot wheels therefore is nearly double that of undershot wheels, other circumstances being the same. In comparing the relative effects of water-wheels, the Chevalier de Borda remarks that overshot wheels will raise through the height of the fall, a quantity of water equal to that by which they are driven; that undershot vertical wheels will produce only three-eighths of this effect; that horizontal wheels will produce a little less than one half of it when the floatboards are plain, and a little more than one-half of it when the floatboards have a curvilineal form.

Besant's Undershot Wheel.

Description of Besant's water-wheel. Plate CCLXXI. fig. 1.

297. The water-wheel invented by Mr Besant of Brompton is constructed in the form of a hollow drum, so as to resist the admission of the water. The floatboards are fixed obliquely in pairs on the periphery of the wheel, so that each pair may form an acute angle open at its vertex, while one of the floatboards extends beyond the vertex of the angle. A section of the water-wheel is represented in fig. 1. where AB is the wheel, CD its axis, *m n*, *o p* the position of the floatboards. The motion of common undershot wheels is greatly retarded by the resistance which the tail-water and the atmosphere oppose to the ascending floatboards; but in Besant's wheel this resistance is greatly diminished, as the floats emerge from the stream in an oblique direction. Although this wheel is much heavier than those of the common construction, yet it revolves more easily upon its axis, as the stream has a tendency to make it float.

Conical Horizontal Wheel with Spiral Floatboards.

Description of a conical horizontal wheel with spiral floatboards. Fig. 2.

298. In Guyenne and Languedoc, in the south of France, a kind of conical horizontal wheel is sometimes employed for turning machinery. It is constructed in the form of an inverted cone AB, with spiral floatboards winding round its surface. The wheel moves on a vertical axis AB, in the building DD, and is driven chiefly by the impulse of the water conveyed by the canal B to the oblique floatboards, the direction of the current being perpendicular to the floatboards at the place of impact. When the impulsive force of the water is annihilated, it descends along the spirals, and continues to act by its weight till it reaches the bottom, when it is carried off by the canal M.

Chap. II. *On Machines driven by the Reaction of Water.*

Water produces greater effects by its reaction than by its impulse or weight.

299. We have hitherto considered the mechanical effects of water as the impelling power of machinery, when it acts either by its impulse or by its gravity. The reaction of water may be employed to communicate motion to machinery; and though this principle has not yet been adopted in practice, it appears from theory, and from some detached experiments on a small scale, that a given quantity of water, falling through a given height, will produce greater effects by its reaction than by its impulse or its weight.

Sect. I. *On Dr Barker's Mill.*

Description of Dr Barker's mill. Plate CCLXXII fig. 3.

300. This machine, which is sometimes called Parent's mill, is represented in fig. 3. where A is the canal that conveys the water into the upright tube B, which communicates with the horizontal arm C. The water will therefore descend through the upright tube into this arm, and will exert upon the inside of it a pressure proportioned to the height of the fall. But if two orifices *d* and *e* be perforated at the extremities of the arm, and on contrary sides, the pressure upon these orifices will be removed by the efflux of the water, and the unbalanced pressure upon the opposite sides of the arm will make the tube and the horizontal arm revolve upon the spindle D as an axis. This will be more easily understood, if we suppose the orifices to be shut up, and consider the pressure upon a circular inch of the arm opposite to the orifice, the orifice being of the same size. The pressure upon this circular inch will be equal to a cylinder of water whose base is one inch in diameter, and whose altitude is the height of the fall; and the same force is exerted upon the shut-up orifice. These two pressures, therefore, being equal and opposite, the arm C will remain at rest. But as soon as you open the orifice, the water will issue with a velocity due to the height of the fall: the pressure upon the orifice will of consequence be removed; and as the pressure upon the circular inch opposite to the orifice still continues, the equilibrium will be destroyed, and the arm C will move in a retrograde direction.

301. The upright spindle D, on which the arm revolves, is fixed in the bottom of the arm, and screwed to it below by the nut *g*. It is fixed to the upright tube by two cross bars at *f*, so as to move along with it. If a corn mill is to be driven, the top of the spindle is fixed into the upper millstone H. The lower quiescent millstone I rests upon the floor K, in which is the hole L, to let the meal pass into a trough about M. The bridgetree GF, which supports the millstone, tube, &c. is moveable on a pin at *h*, and its other end is supported by an iron rod fixed into it, the top of the rod going through the fixed bracket o, furnished with a nut *o*. By screwing this nut, the millstone may be raised or lowered at pleasure. If any other kind of machinery is to be driven, the spindle D must be prolonged to X, and a small wheel W fixed to its extremity, which will communicate its motion to any species of mechanism. An improvement on this machine by M. Mathon de la Cour, and some excellent observations on the subject by Professor Robison, will be found in the article *Water-Works*.

302. Mr Waring of the American Philosophical Society, has given a theory of Barker's mill with the improvement of M. Mathon de la Cour, which he has strangely ascribed to a Mr Rumsey about 20 years after it was published in *Rozier's Journal de Physique*, Jan. and August 1775. Contrary to every other philosopher, he makes the effect of the machine equal only to that of a good undershot-wheel, moved with the same quantity of water, falling though the same height. The following

Machines driven by the Reaction of Water.

lowing rules, however, deduced from his calculus may be of use to those who may wish to make experiments on the effect of this interesting machine.

Practical rules.

1. Make the arm of the rotatory tube or arm C, from the centre of motion to the centre of the aperture, of any convenient length, not less than one-third (one-ninth according to Mr Gregory (F), who has corrected some of Waring's numbers) of the perpendicular height of the water's surface above their centres.

2. Multiply the length of the arm in feet by .614, and take the square root of the product for the proper time of a revolution in seconds, and adapt the other parts of the machinery to this velocity; or, if the time of a revolution be given, multiply the square of this time by 1.63 for the proportional length of the arm.

3. Multiply together the breadth, depth, and velocity per second, of the race, and divide the last product by 18.47 times (14.27 according to Mr Gregory) the square root of the height, for the area of either aperture.

4. Multiply the area of either aperture by the height of the fall of water, and the product by $41\frac{2}{7}$ pounds (55.775 according to Mr Gregory), for the moving force estimated at the centres of the apertures in pounds avoirdupois.

5. The power and velocity at the aperture may be easily reduced to any part of the machinery by the simplest mechanical rules.

Form given to Barker's mill by Professor Segner.

303. Long after the preceding machine had been described in several of our English treatises on machines, Professor Segner published in his hydraulics, as an invention of his own, the account of a machine, differing from this only in form. MN was the axis of the machine, corresponding with DX in Barker's mill, and a number of tubes AB were also so arranged round this axis that their higher extremities A formed a circular superficies into which the water flowed from a reservoir. When the machine has this form, it has been shewn by Albert Euler that the maximum effect is produced when the velocity is infinite, and that the effect is equal to the power. As a considerable portion of the power, however, must be consumed in communicating to the fluid the circular motion of the tubes; and as the portion thus lost must increase with the velocity of the tube, the effect will in reality sustain a diminution from an increase of velocity.

Fig. 4.

Machines driven by the Reaction of Water.

Sect. II. *Description of Albert Euler's Machine driven by the Reaction of the Water.*

Plate CCLXXI. Fig. 5.

304. This machine consists of two vessels, the lowest of which EEFF is moveable round the vertical axis OO, while the higher vessel remains immoveable. The form of the lowest vessel, which is represented by itself in fig. 6. is similar to that of a truncated bell, which is fastened by the cross beams *m*, *n* to the axis O so as to move along with it. The annular cavity *h h h h* terminates at *e e* in several tubes *e f*, *e f*, *e f*, diverging from the axis. Through the lower extremities of these tubes, which are bent into a right angle, the water flowing from the cavity *h h h h* issues with a velocity due to the altitude of its surface in *h*, *h*, and produces by its reaction a rotatory and retrograde motion round the axis OO. The cavity of the ring *h*, *h* receives the water from the superior vessel GGHH, similar to the inferior vessel in fig. 6. but not connected with the axis OO. This vessel has also an annular cavity PP, into which the water is conveyed from a reservoir by the canal R. Around the lower part HH of the cavity, this vessel is divided into several apertures I *i*, placed obliquely that the water may descend with proper obliquity into the inferior vessel. The width of the higher vessel at HH ought to be equal to the width of the lower vessel at EE, that the water which issues from the former may exactly fill the annular cavity *h*, *h*, *h*, *h*.

Fig. 6.

When the machine is constructed in this way, its maximum effect will be equal to the power, provided all its parts be proportioned and adjusted according to the results in the following table, computed from the formulæ of Albert Euler. In the table,

Q = the quantity of water, or number of cubic feet of water furnished in a second.
T = the time, or number of seconds in which the lower vessel revolves.
B = the breadth of the annular orifice in inches.

(F) Gregory's Mechanics, vol. ii. p. 111.

Machines driven by the Reaction of Water.

Table for mills driven by the reaction of water.

TABLE *for Mills driven by the Reaction of Water.*

Height of the fall of water.	Sum of the areas of all the orifices at *f, f, f*, &c.	Sum of the areas of all the orifices at *f, f, f*, &c.	Mean radius of the annular orifice HH.	Difference between the altitude of the two vessels.	Tangent of the inclination of the tubes to the horizon.

Explanation of the table.

The determinations in the preceding table are exhibited in a general manner, that the machine may be accommodated to local circumstances. The time of a revolution T, for instance, is left undetermined, because upon this time depends the magnitude of the machine; and T may be assumed of such a value that the dimensions of the machine may be suitable to the given place, or to the nature of the work to be performed.

Example.

305. In order to shew the application of the preceding table, let it be required to construct the machine when the height of the fall is five feet, and when the reservoir furnishes one cubic foot of water in a second. In this case Q=1, and therefore, by column 3d, the sum of the areas of the orifices will be 11.52 square inches. Consequently, if there are twelve orifices, the area of each orifice will be $\frac{11.52}{12}$=0.96 of a square inch. Suppose the time of a revolution to be =1 second or T=1, then the 4th column will give the mean radius of the annular orifice =1.9894 feet, or nearly two feet. Let the breadth of the annular orifice or B=$\frac{1}{2}$ an inch, then the difference between the altitude of

On Machines for raising Water.

of each vessel will be $0.3539 \times \frac{QQ}{TTBB} = 0.3539 \times \frac{1 \times 1}{\frac{1}{2} \times \frac{1}{2} \times 1 \times 1} = 0.3539 \times \frac{1}{\frac{1}{4}} = 0.3539 \times 4 = 1.4156$ inches. Now as the sum of the heights of the vessels must be always equal to the height of the fall, half that sum will in the present case be two feet six inches; and since half the difference of their altitudes is 7-tenths of an inch, the altitude of the superior vessel will be two feet six inches and seven-tenths, and that of the inferior vessel two feet five inches and three-tenths. It appears from the last column of the table, that the tangent of the inclination of the tubes is 0.1536, which corresponds with an angle of 8° 44′.

Reference to the researches of Leonhard Euler.

306. The theory of this machine has also been discussed by Leonhard Euler in the *Mem. de l'Acad. Berlin*, vol. vi. p. 311.; and its application to all kinds of work has been pointed out in a subsequent paper, entitled, *Application de la Machine Hydraulique de M. Segner à toutes sorts d'ouvrage, et de ses avantages sur les autres Machines Hydrauliques dont on se sert ordinairement*, *Mem. Acad. Berlin*, tom. vii. 1752, p. 271. The results of Euler's analysis are not sufficiently practical for the use of the general reader. But it appears from his investigations, as well as from those of John Bernouilli and other philosophers, that the reaction of water is the most powerful way in which the force of that fluid can be employed.

New kind of water-wheel suggested. Plate CCLXXI.

307. It has often occurred to the writer of this article, that a very powerful hydraulic machine might be constructed by combining the impulse with the reaction of water. If the spout *a*, for example, instead of delivering the water into the higher vessel, were to throw it upon a number of curvilineal floatboards fixed on its circumference, and so formed as to convey the water easily into the spiral canals, we should have a machine something like the conical horizontal wheel in fig. 2. with spiral channels instead of spiral floatboards; and which would in some measure be moved both by the impulse, weight, and reaction of the water.

Fig. 2.

Chap. III. *On Machines for raising Water.*

Sect. I. *On Pumps.*

Reference to the article Pump.

308. The subject of pumps has been fully and ably discussed by Dr Robison under the article Pump, to which we must refer the reader for a complete view of the theory of the machine. In that article, however, a reference is made to the present for a description of the ancient pump of Ctesibius, and of those in common use to which it has given rise. To these subjects, therefore, we must now confine our attention.

Description of the original pump of Ctesibius. Plate CCLXXII. Fig. 1.

309. The pump was invented by Ctesibius, a mathematician of Alexandria, who flourished under Ptolemy Psychon, about 120 years before Christ. In its original state it is represented in fig. 1. where ABCD is a brass cylinder with a valve L in its bottom. It is furnished with a piston MK made of green wood, so as not to swell in water, and adjusted to the bore of the cylinder by the interposition of a ring of leather. The tube CI connects the cylinder ABCD with another tube NH, the bottom of which is furnished with a valve I opening upwards. Now when the extremity DC of the cylinder is immersed in water, and the piston MK elevated, the pressure of the water upon the valve L from below will be proportioned to the depth below the surface (41). The valve will therefore open and admit the water into the cylinder. But when the piston is depressed, it will force the water into the tube CH, and through the valve I into the tube NH. As soon as the portion of water that was admitted into the cylinder ABCD, is thus impelled into the tube NH, the valve I will close. A second elevation of the piston will admit another quantity of fluid into the cylinder, and a second depression will force it into the tube NH; so that, by continuing the motion of the piston, the water may be elevated to any altitude in the tube. From this pump of Ctesibius are derived the three kinds of pumps now commonly used, the sucking, the forcing, and the lifting pump.

Description of the sucking pump. Fig. 2.

310. The common sucking pump is represented in fig. 2. where ICBL is the body of the pump immersed in the water at A. The moveable piston DG is composed of the piston rod D *d*, the piston or bucket G, and the valve *a*: The bucket H, which is fixed to the body of the pump, is likewise furnished with a valve *b*, which, like the valve *a*, should by its own weight lie close upon the hole in the bucket till the working of the engine commences. The valves are made of brass, and have their lower surface covered with leather, in order to fit the holes in the bucket more exactly. The moveable bucket G is covered with leather, so as to suit exactly the bore of the cylinder, and to prevent any air from escaping between it and the pump. The piston DG may be elevated or depressed by the lever DQ, whose fulcrum is *r*, the extremity of the bent arm R *r*.

Mode of operation.

311. Let us now suppose the piston G to be depressed so that its inferior surface may rest upon the valve *b*. Then if the piston G be raised to C, there would have been a vacuum between H and G if the valve *b* were immoveable. But as the valve *b* is moveable, and as the pressure of the air is removed from its superior surface, the air in the tube HL will, by its elasticity, force open the valve *b*, and expand itself through the whole cavity LC. This air, however, will be much rarer than that of the atmosphere; and since the equilibrium between the external air and that in the tube LH is destroyed by the rarefaction of the latter, the pressure of the atmosphere on the surface of the water in the vessel K will predominate, and raise the water to about *e* in the suction pipe HL, so that the air formerly included in the space LC will be condensed to the same state as that of the atmosphere. The elasticity of the air both above and below the valve *b* being now equal, that valve will fall by its own weight.—Let the piston DG be now depressed to *b*. The air would evidently resist its descent, did not the valve *a* open and give a free exit to the air in the space CH, for it cannot escape through the inferior valve *b*. When the piston reaches *b*, the valve *a* will fall by its weight; and when the piston is again elevated, the incumbent air will press the valve *a* firmly upon its orifice. During the second ascent of the piston to C the valve *b* will rise, the air between *e* H will rush into HC; and in consequence of its rarefaction, and inability to counteract the pressure of the atmosphere, the water will rise to *f*. In the same way it may be shewn, that at the next stroke of the piston the water will rise through the box H to B, and

On Machines for raising Water.

and then the valve b which was raised by it will fall when the bucket G is at C. Upon depressing the bucket G again, the water cannot be driven through the valve b, which is pressed to its orifice by the water above it. At the next ascent of the piston a new quantity of water will rise through H, and follow the piston to C. When the piston again descends, the valve a will open; and as the water between C and H cannot be pushed through the valve b, it will rise through a, and have its surface at C when the piston G is at b; but when the piston rises, the valve a being shut by the water above it, this water will be raised up towards I, and issue at the pipe F. A new quantity of water will rush through H and fill the space HC; consequently, the surface of the fluid will always remain at C, and every succeeding elevation of the piston from b to C will make the column of water CH run out at the pipe F.

The sucking pump will not raise water higher than 33 feet.

312. As the water rises in the pipe CL solely by the pressure of the atmosphere; and as a column of water, 33 feet high, is equal in weight to a column of air of the same base, reaching from the earth's surface to the top of the atmosphere, the water in the vessel K will not follow the piston G to a greater altitude than 33 feet; for when it reaches this height, the column of water completely balances, or is in equilibrium with, the atmosphere, and therefore cannot be raised higher by the pressure of the external air.

Description of the forcing pump. Plate CCLXXII. fig. 3.

313. The forcing pump is represented in fig. 3. where D d is the piston attached to a solid plunger g, adjusted to the bore of the pipe BC by the interposition of a ring of leather. The rectangular pipe MMN communicates with the tube BC by the cavity round H; and its upper extremity P is furnished with a valve a opening upwards. An air-vessel KK is fastened to P, and the tube FGI is introduced into it so as to reach as near as possible to the valve a.—Let us now suppose the plunger Dg to be depressed to b. As soon as it is elevated to C the air below it will be rarefied, and the water will ascend through the valve b in the same way as in the sucking pump, till the pipe is filled to C. The valve b will now be shut by the weight of the incumbent water; and therefore when the plunger Dg is depressed, it will force the water between C and b through the rectangular pipe MMN, into the air vessel KK. Before the water enters the air vessel, it opens the valve a, which shuts as soon as the plunger is again raised, because the pressure of the water upon its under side is removed. In this way the water is driven into the air vessel by repeated strokes of the plunger, till its surface is above the lower extremity of the pipe IG. Now, as the air in the vessel KK has no communication with the external air when the water is above I, it must be condensed more and more, as new quantities of water are injected. It will therefore endeavour to expand itself, and by pressing upon the surface H of the water in the air vessel, it will drive the water through the tube IG, and make it issue at F in a continued stream, even when the plunger is rising to C. If the pipe GHI were joined to the pipe MMN at P, without the intervention of an air vessel, the stream of water would issue at F only when the plunger was depressed.

Mode of its operation.

Description of the lifting pump. Fig. 4.

314. The lifting pump, which is only a particular modification of the forcing pump, is represented in fig. 4. The barrel AB is fixed in the immoveable frame KILM, the lower part of which is immersed in the water to be raised. The frame GEQHO consists of two strong iron rods EQ, GH which move through holes in IK and LM, the upper and lower ends of the pump. To the bottom GH of this frame is fixed an inverted piston with its bucket and valve uppermost at D. An inclined branch KH, either fixed to the top of the barrel, or moveable by a ball and socket, as represented at F, must be fitted to the barrel so exactly as to resist the admission both of air and water. The branch KH is furnished with a valve C opening upwards. Let the pump be now plunged in the water to the depth of D. Then if the piston frame be thrust down into the fluid, the piston will descend, and the water by its upward pressure will open the valve at D and gain admission above the piston. When the piston frame is elevated, it will raise the water above D along with it, and forcing it through the valve, it will be carried off by the spout.

Mode of its operation.

De la Hire's pump. Fig. 5.

315. An ingenious pump, invented by De la Hire, is represented in fig. 5. It raises water equally quick by the descent as by the ascent of the piston. The pipes B, C, E, F, all communicate with the barrel MD, and have each a valve at their top, viz. at b, S, e, f. The piston rod LM and plunger K never rise higher than K, nor descend lower than D, KD being the length of the stroke. When the plunger K is raised from D to K, the pressure of the atmosphere forces the water through the valve b, and fills the barrel up to the plunger, in the very same way as in the forcing pump. When the plunger K is depressed to D, it forces the water between K and b up the pipe E and through the valve e into the box G, where it issues at the orifice O. During the descent of the plunger K the valve f falls, and covers the top of the pipe F; and as the piston rod LM moves in a collar of leather at M, and is air-tight, the air above the plunger, between Q and M, will be rarefied, and likewise the air in the pipe CS, which communicates with the rarefied air by the valve S. The pressure of the air therefore will raise the water in CS, force it through the valve S, and fill the space above the plunger, expelling the rarefied air through the valve f. When the piston is raised from D to K, it will force the water through the bent pipe F into the box G, so that the same quantity of water will be discharged at O through the pipe F, during the ascent of the piston, as was discharged through the pipe E during the piston's descent. Above the pipe O is a close air-vessel P, so that when the water is driven above the spout O, it compresses the air in the vessel P, and this air acting by its elasticity on the surface of the water, forces it out at O in a constant and nearly equal stream. As the effect of the machine depends on a proper proportion between the height O of the spout above the surface of the well, and the diameter of the barrel, the following table will be of use to the practical mechanic.

Height

On Machines for raising Water.

Height of the spout O above the well.	Diameter of the barrel D	Height of the spout O above the well.	Diameter of the barrel D.
Feet.	Inches.	Feet.	Inches.
10	6.9	60	2.8
15	5.6	65	2.7
20	4.9	70	2.6
25	4.4	75	2.5
30	4.0	80	2.5
35	3.7	85	2.4
40	3.5	90	2.3
45	3.3	95	2.2
50	3.1	100	2.1

When the proportions in the preceding table are observed, a man of common strength will raise water much higher than he could do with a pump of the common construction.

Noble's pump. Fig. 6.

316. A very simple pump which furnishes a continued stream is represented in fig. 6. It was invented by a Mr Noble, and consists of a working barrel AB with two pistons C and B, which are moved up and down alternately by the rods fixed to the lever EMN. The rod of the piston B passes through the piston C, and the piston C moves upon the rod AB. When the piston rod B is depressed and elevated, it will make the water rise in the barrel A, in the same way as in the sucking pump, whether the valve C be moveable or not. Let us now suppose that the water is raised to A. Then if the piston B is elevated by depressing the extremity N of the lever, the water at A will be raised higher in the barrel, and issue at the spout P, and when the same piston B is depressed by elevating the end N of the lever, the piston C is evidently raised, and the water above it will be expelled at P. This pump, therefore, will give a continued stream, for as the pistons ascend and descend alternately, one of them must always be forcing the water out at P. The pistons are elevated and depressed by means of toothed arches, *c* and *d*, working in the teeth of a rack, at the extremities *a*, *b* of the piston rod.

Buchanan's pump. Fig. 7.

317. The pump invented by Mr Buchanan is shewn in fig. 7. In the vertical section DGA, A is the suction barrel, D the working barrel, E the piston, G the spout, B the inner valve, and C the outer valve. These valves are of the kind called clack valves, and have their hinges generally of metal. It is easily seen that when the piston E is raised, the water will rise through the suction barrel A, into the working barrel D, in the same way as in the sucking pump; and that when the piston E is depressed, it will force the water between it and the valve B, through the valve C, and make it issue at G. The points of difference between this pump and those of the common form, are,—that it discharges the water below the piston, and has its valves lying near each other. Hence the sand or mud which may be in the water, is discharged without injuring the barrel or the piston leathers; and as the valves B, C may be of any size, they will transmit, without being choked, any rubbish which may rise in the suction barrels. If any obstruction should happen to the valves, they are within the reach of the workman's hand, and may be cleared without taking the pump to pieces. This simple machine may be quickly converted into a fire engine, by adding the air-vessel H, which is screwed like a hosepipe, and by fixing in the spout G a perforated stopple fitted to receive such pipes as are employed in fire engines. When these additions are made, the water, as in the case of the forcing pump, will be driven into the air vessel H, and repelled through the perforated stopple G, by the elasticity of the included air.

Balance-pump. Figs. 8 & 9.

318. A simple method of working two pumps at once by means of a balance, is exhibited in fig. 8. where AB is the balance, having a large iron ball at each end, placed in equilibrium on the two spindles C, see fig. 9. The person who works the pump stands on two boards I, I, nailed to two cross pieces fastened to the axis of the machine, and supports himself by a cross bar D *d* joined to the two parts D, E. At the distance of ten inches on each side of the axis are suspended the iron rods M, N, to which the pistons are attached. The workman, by bearing alternately on the right and left foot, puts the balance in motion. The pistons M, N are alternately elevated and depressed, and the water raised in the barrel of each, is driven into the pipe HH, in which it is elevated to a height proportional to the diameter of the valves, and the power of the balance. In order to make the oscillations of the balance equal, and prevent it from acquiring too great a velocity, iron springs F, G are fixed to the upright posts, which limit the length of its oscillations.

Chain-pump. Plate CCLXXIII. fig. 1.

319. The chain pump is represented in fig. 1. It consists of a chain MTHG, about 30 feet long, carrying a number of flat pistons M, N, O, P, Q, which are made to revolve in the barrels ABCD and GH, by driving the wheel F. When the flat pistons are at the lower part of the barrel T, they are immersed in the water RR, and as they rise in the barrel GH, they bring up the water along with them into the reservoir MG, from which it is conveyed by the spout S. The teeth of the wheel F are so contrived as to receive one-half of the flat pistons, and let them fold in; and sometimes another wheel like F is fixed at the bottom D. The distance of the pistons from the side of the barrel is about half an inch; but as the machine is generally worked with great velocity, the ascending pistons bring along with them into the reservoir as much water as fills the cavity GH. Sometimes chain pumps are constructed without the barrels ABCD and GH. In this case, the flat pistons are converted into buckets connected with a chain, which dip in the water with their mouths downwards, and convey it to the reservoir. The buckets are moved by hexagonal axles, and the distance between each is nearly equal to the depth of the buckets. Chain pumps are frequently in an inclined position, and in this position they raise the greatest quantity of water when the distance of the flat pistons is equal to their breadth, and when the inclination of the barrels is about 24° 21′.

Hair-rope machine of the Sieur Vera. Fig. 2.

320. The hair-rope machine, invented by the Sieur Vera, operates on the same principle as the chain pump. Instead of a chain of pistons moving round the wheel F, a hair rope is substituted. The part of the rope at T that is lowest always dips in the water, which adhering to the rope is raised along with it. When the rope reaches the top at G and M, it passes through two small tubes, which being fixed in the bottom of the reservoir

On Machines for raising Water.

servoir prevent the water from returning into the well. Sometimes a common rope is employed, having a number of stuffed cushions fixed to it instead of the flat pistons in the chain pump. These cushions carry the water along with them through the barrel HG, and deliver it into the reservoir.—For the description of other pumps, see the article PUMP; and for pump mills, see the article MILL.

Machine with cushions instead of flat pistons.

SECT. II. *On Engines for Extinguishing Fire.*

Common squirting engine. Fig. 2.

321. The common fire engine which discharges water in successive jets is represented in fig. 2. and is only a modification of the lifting pump. In the vessel AB full of water, is immersed the frame DC of a common lifting pump. This frame, and consequently the piston N, is elevated and depressed by means of the levers E, F, and the water which is raised is forced through the pipe G, which may be moved in any direction by means of the elastic leather pipe H, or by a ball and socket screwed on the top of the pump. While the piston N is descending, the stream at G is evidently discontinued, and issues only at each elevation of the piston. The vessel AB is supplied with water by buckets, and the pump is prevented from being choked by the strainer LK which separates from the water any mud that it may happen to contain.

Improved fire engine. Fig. 3.

322. As this fire engine does not afford a continued stream, it is not so useful in case of accidents as when the stream is uninterrupted. An improved engine of this sort is represented in fig. 3. where D, E, are two forcing pumps connected with the large vessel OG, and wrought by the levers F, G, moving upon H as a fulcrum. This apparatus is plunged and fastened in the vessel AB partly filled with water, and by means of the forcing pump DE, the operation of which has already been described, the water is driven through the valves I, L into the large vessel OG, where the included air is condensed. Into this vessel is inserted the tube PO communicating with the leathern pipe ORQS. The elasticity of the condensed air in the vessel OG pressing upon the surface of the water in that vessel, forces it up through the tube PO into the leathern pipe, from whose extremity S, it issues with great force and velocity; and as the condensed air is continually pressing upon the water in the vessel OG, the stream at S will be constant and uniform.

Newsham's fire-engine. Fig. 4.

323. A section of the fire engine, as improved by Mr Newsham, is represented in fig. 4. where TU and WX are the forcing pumps corresponding with D and C in fig. 3. YZ the large vessel corresponding with GO, and *e f* the tube corresponding with PO. The vessels TU, WX, YZ, the horizontal canals ON, QP, ML, and the vertical canal EE, all communicate with each other by means of four valves O, I, K, P opening upwards, and the vertical pipe is immersed in the water to be raised. When the piston R is raised by means of the double lever $\alpha\beta$, a vacuum would be made in the barrel TU, if the water at R were prevented from rising; but as this barrel communicates with the vessel of water below EF, on the surface of which the pressure of the atmosphere is exerted, the water will rise through EF, force open the valve H, and follow the piston R. By depressing the piston R, however, the water is driven down the barrel, closes the valve H, and rushes through the valve I into the air vessel YZ. The very same operation is going on with the pump WX, which forces the water into the air vessel through the valve K. By these means the air vessel is constantly filling with water, and the included air undergoing continual condensation. The air thus compressed, reacts upon the surface YZ of the water, and forces it through the tube *e f* to the stop-cock *e g*, whence after turning the cock, the water passes into the tube *h*, fixed to a ball and socket, by which it may be discharged in any direction.

Reference to the improvements

324. The fire engine has undergone various alterations and improvements from Bramah, Dickenson, Simpkin, Raventree, Philips and Furst, an account of whose engines may be seen in the Repertory of Arts, &c. A very simple and cheap fire engine has been invented by Mr B. Dearborn, and is described in the American Transactions for 1794, and in Gregory's Mechanics, vol. ii. p. 177.

SECT. III. *On Whitehurst's Machine, and Montgolfier's Hydraulic Ram.*

* Phil. Trans. 1775.

The idea of raising water by its own momentum first suggested by Mr Whitehurst.

325. MR Whitehurst * was the first who suggested the ingenious idea of raising water by means of its momentum. A machine upon the same principle as Mr Whitehurst's, but in an improved form, has lately made its appearance in France, and excited considerable attention both on the continent and in this country. Whatever credit, therefore, has been given to the inventor of the hydraulic ram, justly belongs to our countryman Mr Whitehurst, and Montgolfier is entitled to nothing more than the merit of an improver.

Description of Mr Whitehurst's machine. Plate CCLXXIV. fig. 1.

326. Mr Whitehurst's machine, which was actually erected at Oulton in Cheshire, is represented in fig. 1. where AM is the original reservoir having its surface in the same horizontal line with the bottom of the reservoir BN. The diameter of the main pipe AE is one inch and a half, and its length about 200 yards; and the branch pipe EF is of such a size that the height of the surface M of the reservoir is nearly 16 feet above the cock F. In the valve box D is placed the valve *a*, and into the air vessel C are inserted the extremities *m*, *n* of the main pipe, bent downwards to prevent the air from being driven out, when the water is forced into it. Now as the cock F is 16 feet below the reservoir AM, the water will issue from F with a velocity of nearly 30 feet per second. As soon as the cock F therefore is opened, a column of water 200 yards long is put in motion, and though the aperture of the cock F be small, this column must have a very considerable momentum. Let the cock F be now suddenly stopped, and the water will rush through the valve *a* into the air vessel C, and condense the included air. This condensation must take place every time the cock is shut, and the imprisoned air being in a state of high compression, will react upon the water in the air vessel, and raise it into the reservoir BN.

Description of Montgolfier's hydraulic ram. Fig. 2.

327. A section of the hydraulic ram of Montgolfier is exhibited in fig. 2. where R is the reservoir, RS the height of the fall, and ST the horizontal canal which conveys the water to the engine ABHTC. E and D are two valves, and FG a pipe reaching within a very little of the bottom CB. Let us now suppose that water

On Machines for raising Water.

ter is permitted to descend from the reservoir. It will evidently rush out at the aperture $m\,n$ till its velocity is such as to force up the valve E. The water being thus suddenly checked, and unable to find a passage at $m\,n$, will rush forwards to H and raise the valve D. A portion of water being thus admitted into the vessel ABC, the impulse of the column of fluid is spent, the valves D and E fall, and the water issues at $m\,n$ as before; when its motion is again checked, and the same operation repeated, which has now been described. Whenever, therefore, the valve E closes, a portion of water will force its way into the vessel ABC, and condense the air which it contains, for the included air has no communication with the atmosphere after the bottom of the pipe FG is beneath the surface of the injected water. This condensed air will consequently react upon the surface of the water, and raise it in the pipe FG to an altitude proportioned to the elasticity of the included air. The external appearance of the engine, drawn from one in the possession of Professor Leslie, is represented in fig. 3. where ABC is the air vessel, F the valve box, G the extremity of the valve, and M, N screws for fixing the horizontal canal to the machine. When the engine is employed to form a jet of water, a piece of brass, A, with a small aperture, is screwed upon the top of the tube FG, which, in that case, rises no higher than the top of the air vessel. From this description it will be seen, that the only difference between the engines of Montgolfier and Whitehurst, is, that the one requires a person to turn the cock, while the other has the advantage of acting spontaneously. Montgolfier (G) assures us, that the honour of this invention does not belong to England, but that he is the sole inventor, and did not receive a hint from any person whatever. We leave the reader to determine the degree of credit to which these assertions are entitled.—It would appear from some experiments made by Montgolfier, that the effect of the water ram is equal to between a half and three-fourths of the power expended, which renders it superior to most hydraulic machines. *Appendix to Ferguson's Lectures*, p. 19.

Fig. 3.

Sect. IV. *On Archimedes's Screw Engine.*

Description of Archimedes's screw-engine.

328. The screw engine invented by Archimedes is represented in fig. 4. where AB is a cylinder with a flexible pipe, CEHOGF, wrapped round its circumference like a screw. The cylinder is inclined to the horizon, and supported at one extremity by the bent pillar IR, while its other extremity, furnished with a pivot, is immersed in the water. When, by means of the handle K, the cylinder is made to revolve upon its axis, the water which enters the lower orifice of the flexible pipe is raised to the top, and discharged at D. On some occasions, when the water to be raised moves with a considerable velocity, the engine is put in motion by a number of floatboards fixed at L, and impelled by the current; and if the water is to be raised to a great height, another cylinder is immersed in the vessel D, which receives the water from the first cylinder, and is driven by a pinion fixed at I. In this way, by having a succession of screw engines, and a succession of reservoirs, water may be raised to any altitude. An engine of this kind is described in Ferguson's Lectures, vol. ii. p. 113.

Fig. 4.

Operation of the screw engine.

329. In order to explain the reason why the water rises in the spiral tube, let AB be a section of the engine, BCdDE the spiral tube, BF a horizontal line or the surface of the stagnant water which is to be raised, and ABF the angle which the axis of the cylinder makes with the horizon. Then, the water which enters the extremity B of the spiral tube will descend to C, and remain there as long as the cylinder is at rest. But if a motion of rotation be communicated to the cylinder, so that the lowest part C of the spiral BCD move towards B, and the points d, D, E towards C, and become successively the lowest parts of the spiral, the water must occupy successively the points d, D, E, and therefore rise in the tube; or, which is the same thing, when the point C moves to c, the point d will be at C; and as the water at C cannot rise along with the point C to c, on account of the inclination of C c to the horizon, it must occupy the point d of the spiral, when C has moved to c; that is, the water has a tendency to occupy the lower parts of the spiral, and the rotatory motion withdraws this part of the spiral from the water, and causes it to ascend to the top of the tube. By wrapping a cord round the cylinder, and inclining it to the horizon, so that the angle ABC may be greater than the angle ABF, and then making it revolve upon its axis, the preceding remarks will be clearly illustrated.—If the direction of the spiral BC should be horizontal, that is, if it should coincide with the line BF, the water will have no tendency to move towards C, and therefore cannot be raised in the tube. For a similar reason, it will not rise when the point C is above the horizontal line BF. Consequently, in the construction of this engine, the angle ABC, which the spiral forms with the side of the cylinder, must always be greater than the angle ABF, at which the cylinder is inclined to the horizon. In practice, the angle of inclination ABF should generally be about 50°, and the angle ABC about 65°.

Fig. 5.

330. The theory of this engine is treated at great length by Hennert, in his *Dissertation sur la vis d'Archimede*, Berlin 1767; by Pitot, in the Memoirs of the French Academy, and by Euler in the *Nov. Comment. Petrop.* tom. v. An account of Pitot's investigations may be seen in Gregory's Mechanics, vol. ii. p. 348.

Sect. V. *On the Persian Wheel.*

Description of the Persian wheel.

331. The Persian wheel is an engine which raises water to a height equal to its diameter. It is shewn in fig. 6. where CDE is the wheel driven by the stream AB acting upon floatboards fixed on one side of its rim. A number of buckets, a, a, a, a, are disposed on the opposite side of the rim, and suspended by strong pins, b, b, b, b, &c. When the wheel is in motion, the descending buckets immerge into the stream, and ascend full

Fig. 6.

(G) *Cette invention n'est point originaire d'Angleterre, elle appartient toute entiere à la France. Je declare que j'en suis le seul inventeur, et que l'idée ne m'en a été fournie par personne.* Journal des Mines, vol. xiii. N° 73.

On Machines for raising Water.

full of water till they reach the top K, where they strike against the extremity *n* of the fixed reservoir M, and being overset, discharge their contents into that reservoir. As soon as the bucket quits the reservoir, it resumes its perpendicular position by its own weight, and descends as before. On each bucket is fixed a spring *r*, which moves over the top of the bar *m*, fastened to the reservoir. By this means the bottom of the bucket is raised above the level of its mouth, and its contents completely discharged.

332. On some occasions the Persian wheel is made to raise water only to the height of its axle. In this case, instead of buckets, its spokes *c, d, e, f, g, h*, are made of a spiral form, and hollow within, so that their inner extremities all terminate in the box N on the axle, and their outer extremities in the circumference of the wheel. When the rim CDEF, therefore, is immersed in the stream, the water runs into the tubes C, D, E, F, &c. rises in the spiral spokes *c, d*, &c. and is discharged from the orifices at O into the reservoir Q, from which it may be conveyed in pipes.

Sect. VI. *On the Zurich Machine.*

333. This machine is a kind of pump invented and erected by H. Andreas Wirtz, an ingenious tin-plate worker in Zurich, and operates on a principle different from all other hydraulic engines. The following description of it, written by Dr Robison, is transferred to this part of the work for the sake of uniformity.

Plate LXXIV. fig. 7.

334. Fig. 7. is a sketch of the section of the machine, as it was first erected by Wirtz at a dye-house in Limmat, in the suburbs or vicinity of Zurich. It consists of a hollow cylinder, like a very large grindstone, turning on a horizontal axis, and partly plunged in a cistern of water. The axis is hollow at one end, and communicates with a perpendicular pipe CBZ, part of which is hid by the cylinder. This cylinder or drum is formed into a spiral canal by a plate coiled up within it like the main spring of a watch in its box; only the spires are at a distance from each other, so as to form a conduit for the water of uniform width. This spiral partition is well joined to the two ends of the cylinder, and no water escapes between them. The outermost turn of the spiral begins to widen about three-fourths of a circumference from the end, and this gradual enlargement continues from Q to S nearly a semicircle: this part may be called the Horn. It then widens suddenly, forming a Scoop or shovel SS′. The cylinder is supported so as to dip several inches into the water, whose surface is represented by VV′.

335. When this cylinder is turned round its axis in the direction ABEO, as expressed by the two darts, the scoop SS′ dips at V′ and takes up a certain quantity of water before it immerges again at V. This quantity is sufficient to fill the taper part SQ, which we have called the Horn; and this is nearly equal in capacity to the outermost uniform spiral round.

336. After the scoop has emerged, the water passes along the spiral by the motion of it round the axis, and drives the air before it into the rising-pipe, where it escapes.—In the mean time, air comes in at the mouth of the scoop; and when the scoop again dips into the water, it again takes in some. Thus there is now a part filled with water and a part filled with air. Continuing this motion, we shall receive a second round of water and another of air. The water in any turn of the spiral will have its two ends on a level; and the air between the successive columns of water will be in its natural state; for since the passage into the rising pipe or Main is open, there is nothing to force the water and air into any other position. But since the spires gradually diminish in their length, it is plain that the column of water will gradually occupy more and more of the circumference of each. At last it will occupy a complete turn of some spiral that is near the centre; and when sent farther in, by the continuance of the motion, some of it will run back over the top of the succeeding spiral. Thus it will run over at K 4 into the right-hand side of the third spiral. Therefore it will push the water of this spire backwards, and raise its other end, so that it also will run over backwards *before* the next turn be completed. And this change of disposition will at last reach the first or outermost spiral, and some water will run over into the horn and scoop, and finally into the cistern.

337. But as soon as water gets into the rising pipe, and rises a little in it, it stops the escape of the air when the next scoop of water is taken in. Here are now two columns of water acting against each other by hydrostatic pressure and the intervening column of air. They must compress the air between them, and the water and air-columns will now be unequal. This will have a general tendency to keep the whole water back, and cause it to be higher on the left or rising side of each spire than on the right descending side. The excess of height will be just such as produces the compression of the air between that and the preceding column of water. This will go on increasing as the water mounts in the rising pipe; for the air next to the rising pipe is compressed at its inner end with the weight of the whole column in the main. It must be as much compressed at its outer end. This must be done by the water column without it; and this column exerts this pressure partly by reason that *its* outer end is higher than its inner end, and partly by the transmission of the pressure on its outer end by air, which is similarly compressed from without. And thus it will happen that each column of water, being higher at its outer than at its inner end, compresses the air on the water column beyond or within it, which transmits this pressure to the air beyond it, adding to it the pressure arising from its own want of levels at the ends. Therefore the greatest compression, viz. that of the air next the main, is produced by *the sum of all the transmitted pressures*; and these are the sum of all the differences between the elevations of the inner ends of the water columns above their outer ends: and the height to which the water will rise in the main will be just equal to this sum.

338. Draw the horizontal lines K′K 1, K′K 2, K′K 3, &c. and *mn, mn, mn*, &c. Suppose the left-hand spaces to be filled with water, and the right-hand spaces to be filled with air. There is a certain gradation of compression which will keep things in this position. The spaces evidently decrease in arithmetical progression; so do the hydrostatic heights and pressures of the water columns. If therefore the air be dense in the same progression, all will be in hydrostatical equilibrium. Now

On Machines for raising Water.

Now this is evidently producible by the mere motion of the machine; for since the density and compression in each air column is supposed inversely as the bulk of the column, the absolute quantity of air is the same in all; therefore the column first taken in will pass gradually inwards, and the increasing compression will cause it to occupy precisely the whole right-hand side of every spire. The gradual diminution of the water columns will be produced during the motion by the water running over backwards at the top, from spire to spire, and at last coming out by the scoop.

Plate CCLXXIV fig. 7.

339. It is evident that this disposition of the air and water will raise the water to the greatest height, because the hydrostatic height of each water column is the greatest possible, viz. the diameter of the spire. This disposition may be obtained in the following manner: Take CL to CB as the density of the external air to its density in the last column next the rising-pipe or main; that is, make CL to CB as 33 feet (the height of the column of water which balances the atmosphere), to the sum of 33 feet and the height of the rising-pipe. Then divide BL into such a number of turns, that the sum of their diameters shall be equal to the height of the main; then bring a pipe straight from L to the centre C. The reason of all this is very evident.

340. But when the main is very high, this construction will require a very great diameter of the drum, or many turns of a very narrow pipe. In such cases it will be much better to make the spiral in the form of a cork-screw, as in fig. 1. instead of this flat form like a watch spring. The pipe which forms the spiral may be lapped round the frustum of a cone, whose greatest diameter is to the least (which is next to the rising pipe) in the same proportion that we assigned to CB and CL. By this construction the water will stand in every round so as to have its upper and lower surfaces tangents to the top and bottom of the spiral, and the water columns will occupy the whole ascending side of the machine, while the air occupies the descending side.

Plate CCLXXV. fig. 1.

341. This form is vastly preferable to the flat: it will allow us to employ many turns of a large pipe, and therefore produce a great elevation of a large quantity of water.

The same thing will be still better done by lapping the pipe on a cylinder, and making it taper to the end, in such a proportion that the contents of each round may be the same as when it is lapped round the cone. It will raise the water to a greater height (but with an increase of the impelling power) by the same number of turns, because the vertical or pressing height of each column is greater.

Nay, the same thing may be done in a more simple manner, by lapping a pipe of uniform bore round a cylinder. But this will require more turns, because the water columns will have less differences between the heights of their two ends. It requires a very minute investigation to show the progress of the columns of air and water in this construction, and the various changes of their arrangement, before one is attained which will continue during the working of the machine.

342. We have chosen for the description of the machine that construction which made its principle and manner of working most evident, namely, which contained the same material quantity of air in each turn of the spiral, more and more compressed as it approaches to the rising pipe. We should otherwise have been obliged to investigate in great detail the gradual progress of the water, and the frequent changes of its arrangement, before we could see that one arrangement would be produced which would remain constant during the working of the machine. But this is not the best construction. We see that, in order to raise water to the height of a column of 34 feet, which balances the atmosphere, the air in the last spire is compressed into half its bulk; and the quantity of water delivered into the main at each turn is but half of what was received into the first spire, the rest flowing back from spire to spire, and being discharged at the spout.

343. But it may be constructed so as that the quantity of water in each spire may be the same that was received into the first; by which means a greater quantity (double in the instance now given) will be delivered into the main, and raised to the same height by very nearly the same force.—This may be done by another proportion of the capacity of the spires, whether by a change of their caliber or of their diameters. Suppose the bore to be the same, the diameter must be made such that the constant column of water, and the column of air, compressed to the proper degree, may occupy the whole circumference. Let A be the column of water which balances the atmosphere, and h the height to which the water is to be raised. Let A be to $A+h$ as 1 to m.

344. It is plain that m will represent the density of the air in the last spire, if its natural density be 1, because it is pressed by the column $A+h$, while the common air is pressed by A. Let 1 represent the constant water column, and therefore nearly equal to the air column in the first spire. The whole circumference of the last spire must be $1+\frac{1}{m}$, in order to hold the water 1, and the air compressed into the space $\frac{1}{m}$ or $\frac{A}{A+h}$.

345. The circumference of the first spire is $1+1$ or 2. Let D and d be the diameters of the first and last spires; we have $2:1+\frac{1}{m}=D:d$, or $2m:m+1=D:d$. Therefore if a pipe of uniform bore be lapped round a cone, of which D and d are the end diameters, the spirals will be very nearly such as will answer the purpose. It will not be quite exact, for the intermediate spirals will be somewhat too large. The conoidal frustum should be formed by the revolution of a curve of the logarithmic kind. But the error is very trifling.

With such a spiral, the full quantity of water which was confined in the first spiral will find room in the last, and will be sent into the main at every turn. This is a very great advantage, especially when the water is to be much raised. The saving of power by this change of construction is always in proportion to the greatest compression of the air.

The great difficulty in the construction of any of

On Machines for raising Water.

of these forms is in determining the form and position of the horn and the scoop; and on this greatly depends the performance of the machine. The following instructions will make it pretty easy.

Plate CCLXXV. fig. 2.

346. Let ABEO (fig. 2.) represent the first or outermost round of the spiral, of which the axis is C. Suppose it immerged up to the axis in the water VV, we have seen that the machine is most effective when the surfaces KB and O n of the water columns are distant the whole diameter BO of the spiral. Therefore let the pipe be first supposed of equal calibre to the very mouth E e, which we suppose to be just about to dip into the water. The surface O n is kept there, in opposition to the pressure of the water column BAO, by the compressed air contained in the quadrant OE, and in the quadrant which lies behind EB. And this compression is supported by the columns behind, between this spire and the rising pipe. But the air in the outermost quadrant EB is in its natural state, communicating as yet with the external air. When, however, the mouth E e has come round to A, it will not have the water standing in it in the same manner, leaving the half space BEO filled with compressed air; for it took in and confined only what filled the quadrant BE. It is plain, therefore, that the quadrant BE must be so shaped as to take in and confine a much greater quantity of air; so that when it has come to A, the space BEO may contain air sufficiently dense to support the column AO. But this is not enough: For when the wide mouth, now at A a, rises up to the top, the surface of the water in it rises also, because the part AO o a is more capacious than the cylindric part OEe o which succeeds it, and which cannot contain all the water that it does. Since, then, the water in the spire rises above A, it will press the water back from O n to some other position m' n', and the pressing height of the water-column will be diminished by this rising on the other side of O. In short, the horn must begin to widen, not from B, but from A, and must occupy the whole semicircle ABE; and its capacity must be to the capacity of the opposite cylindrical side as the sum of BO, and the height of a column of water which balances the atmosphere to the height of that column. For then the air which filled it, when of the common density, will fill the uniform side BEO, when compressed so as to balance the vertical column BO. But even this is not enough; for it has not taken in enough of water. When it dipped into the cistern at E, it carried air down with it, and the pressure of the water in the cistern caused the water to rise into it a little way; and some water must have come over at B from the other side, which was drawing narrower. Therefore when the horn is in the position EOA, it is not full of water. Therefore when it comes into the situation OAB, it cannot be full nor balance the air on the opposite side. Some will therefore come out at O, and rise up through the water. The horn must therefore, 1st, Extend at least from O to B, or occupy half the circumference; and, 2dly, It must contain at least twice as much water as would fill the side BEO. It will do little harm though it be much larger; because the surplus of air which it takes in at E will be discharged, as the end E e of the horn rises from O to B, and it will leave the precise quantity that is wanted. The overplus water will be discharged as the horn comes round to dip again into the cistern. It is possible, but requires a discussion too intricate for this place, to make it of such a size and shape, that while the mouth moves from E to B, passing through O and A, the surface of the water in it shall advance from E s to O n, and be exactly at O when the beginning or narrow end of the horn arrives there.

347. We must also secure the proper quantity of water. When the machine is so much immersed as to be up to the axis in water, the capacity which thus secures the proper quantity of air will also take in the proper quantity of water. But it may be erected so as that the spirals shall not even reach the water. In this case it will answer our purpose if we join to the end of the horn a scoop or shovel QRSB (fig. 3.), which is so formed as to take in at least as much water as will fill the horn. This is all that is wanted in the beginning of the motion along the spiral, and more than is necessary when the water has advanced to the succeeding spire; but the overplus is discharged in the way we have mentioned. At the same time, it is needless to load the machine with more water than is necessary, merely to throw it out again. We think that if the horn occupies fully more than one-half of the circumference, and contains as much as will fill the whole round, and if the scoop lifts as much as will certainly fill the horn, it will do very well.

Plate CCLXXV. fig. 3.

N. B. The scoop must be very open on the side next the axis, that it may not confine the air as soon as it enters the water. This would hinder it from receiving water enough.

348. The following dimensions of a machine erected at Florence, and whose performance corresponded extremely well with the theory, may serve as an example.

The spiral is formed on a cylinder of 10 feet diameter, and the diameter of the pipe is six inches. The smaller end of the horn is of the same diameter; it occupies three-fourths of the circumference, and is $7\frac{8}{10}$ths inches wide at the outer end. Here it joins the scoop, which lifts as much water as fills the horn, which contains 4340 Swedish cubic inches, each $=1.577$ English. The machine makes six turns in a minute, and raises 1354 pounds of water, or 22 cubic feet, 10 feet high in a minute.

349. The above account will, we hope, sufficiently explain the manner in which this singular hydraulic machine produces its effect. When every thing is executed by the maxims which we have deduced from its principles, we are confident that its performance will correspond to the theory; and we have the Florentine machine as a proof of this. It raises more than ten-elevenths of what the theory promises, and it is not perfect. The spiral is of equal caliber, and is formed on a cylinder. The friction is so inconsiderable in this machine, that it need not be minded: but the great excellency is, that whatever imperfection there may be in the arrangement of the air and water columns, this only affects the elegance of the execution, causing the water to make a few more turns in the spiral before it can mount to the height required; but wastes no power, because the power employed is always in proportion to the sum of the vertical columns of water in the rising side of the machine; and the height to which the water is raised by it is in the very same proportion. It should be

On Machines for raising Water.

be made to move very slow, that the water be not always dragged up by the pipes, which would cause more to run over from each column, and diminish the pressure of the remainder.

350. If the rising-pipe be made wide, and thus room be made for the air to escape freely up through the water, it will rise to the height assigned; but if it be narrow, so that the air cannot get up, it rises almost as slow as the water, and by this circumstance the water is raised to a much greater height mixed with air, and this with hardly any more power. It is in this way that we can account for the great performance of the Florentine machine, which is almost triple of what a man can do with the finest pump that ever was made: indeed the performance is so great, that one is apt to suspect some inaccuracy in the accounts. The entry into the rising-pipe should be no wider than the last part of the spiral; and it would be advisable to divide it into four channels by a thin partition, and then to make the rising-pipe very wide, and to put into it a number of slender rods, which would divide it into slender channels that would completely entangle the air among the water. This will greatly increase the height of the heterogeneous column. It is surprising that a machine that is so very promising should have attracted so little notice. We do not know of any being erected out of Switzerland, except at Florence in 1778. The account of its performance was in consequence of a very public trial in 1779, and honourable declaration of its merit, by Sig. Lorenzo Ginori, who erected another, which fully equalled it. It is shortly mentioned by Professor Sulzer of Berlin, in the *Sammlungen Vermischlen Schristen* for 1754. A description of it is published by the Philosophical Society at Zurich in 1766, and in the descriptions published by the Society in London for the encouragement of Arts in 1776. The celebrated Daniel Bernouilli has published a very accurate theory of it in the Petersburgh Commentaries for 1772, and the machines at Florence were erected according to his instructions. Baron Alstromer in Sweden caused a glass model of it to be made, to exhibit the internal motions for the instruction of artists, and also ordered an operative engine to be erected; but we have not seen any account of its performance. It is a very intricate machine in its principles; and an ignorant engineer, nay the most intelligent, may erect one which shall hardly do any thing; and yet by a very trifling change, may become very powerful. We presume that failures of this kind have turned the attention of engineers from it; but we are persuaded that it may be made very effective, and we are certain that it must be very durable.

Plate CCLXXV. fig. 4.

Fig. 4. is a section of the manner in which the author has formed the communication between the spiral and the rising pipe. P is the end of the hollow axis which is united with the solid iron axis. Adjoining to P, on the under side, is the entry from the last turn of the spiral. At Q is the collar which rests on the supports, and turns round in a hole of bell-metal. *ff* is a broad flanch cast in one piece with the hollow part. Beyond this the pipe is turned somewhat smaller, very round and smooth, so as to fit into the mouth of the rising-pipe, like the key of a cock. This mouth has a plate *ee* attached to it. There is another plate *dd*, which is breader than *ee*, and is not fixed to the cylindrical part, but moves easily round it. In this plate are four screws, such as *gg*, which go into holes in the plate *ff*, and thus draw the two plates *ff* and *dd* together, with the plate *ee* between them. Pieces of thin leather are put on each side of *ee*; and thus all escape of water is effectually prevented, with a very moderate compression and friction.

Water Blowing Machine.

Chap. IV. *On Machines in which Water is the chief Agent.*

Sect. I. *On the Water Blowing Machine.*

Description of the water blowing machine.

Plate CCLXXV. fig. 5.

351. The water blowing machine consists of a reservoir of water AB, into the bottom of which the bent leaden pipe BCH is inserted; of a condensing vessel DE, into whose top the lower extremity H of the pipe is fixed, and of a pedestal P resting on the bottom of this vessel. When the water from the reservoir AB is descending through the part CH of the pipe, it is in contact with the external air by means of the orifices or tubes *m*, *n*, *o*, *p*; and by the principle of the lateral communication of motion in fluids (art. 160.), the air is dragged along with the water. This combination of air and water issuing from the aperture H, and impinging upon the surface of the stone pedestal P, is dispersed in various directions. The air being thus separated from the water, ascends into the upper part of the vessel, and rushes through the opening F, whence it is conveyed by the pipe FG to the fire at G, while the water falls to the lower part of the vessel, and is discharged by the openings M, N.—That the greatest quantity of air may be driven into the vessel DE, the water should begin to fall at C with the least possible velocity; and the height of the lowest tubes above the extremity H of the pipe should be three-elevenths of the length of the vertical tube CH, in order that the air may move in the pipe FG with sufficient velocity.

Way in which the wind is generated.

352. Fabri and Dietrich imagined that the wind is produced by the decomposition of the water, or its transformation into gas, in consequence of the agitation and percussion of its parts. But M. Venturi, to whom we owe the first philosophical account of this machine, has shewn that this opinion is erroneous, and that the wind is supplied from the atmosphere, for no wind was generated when the lateral openings *m*, *n*, *o*, *p* were shut. The principal object, therefore, in the construction of water blowing machines, is to combine as much air as possible with the descending current. For this purpose the water is often made to pass through a kind of cullender placed in the open air, and perforated with a number of small triangular orifices. Through these apertures the water descends in many small streams; and by exposing a greater surface to the atmosphere, it carries along with it an immense quantity of air. The water is then conveyed to the pedestal P by a pipe CH opened and enlarged at C, so as to be considerably wider than the end of the tube which holds the cullender.

353. It has been generally supposed that the waterfall should be very high; but Dr Lewis has shewn, by a variety of experiments, that a fall of four or five feet is sufficient, and that when the height is greater than this, two or more blowing machines may be erected, by conducting the water from which the air is extricated, into another reservoir, from which it again descends, and generates

generates air as formerly. In order that the air which is necessarily loaded with moisture, may arrive at the furnace in as dry a state as possible, the condensing vessel DE should be made as high as circumstances will permit; and in order to determine the strength of the blast, it should be furnished with a gage *a b* filled with water.

Cause of the rain wind.

354. The rain wind is produced in the same way as the blast of air in water blowing machines. When the drops of rain impinge upon the surface of the sea, the air which they drag along with them often produces a heavy squall, which is sufficiently strong to carry away the mast of a ship. The same phenomenon happens at land, when the clouds empty themselves in alternate showers. In this case, the wind proceeds from that quarter of the horizon where the shower is falling. The common method of accounting for the origin of the winds by local rarefaction of the air appears pregnant with insuperable difficulties; and there is reason to think that these agitations in our atmosphere ought rather to be referred to the principle which we have now been considering. For farther information on this subject, the reader is referred to Lewis's Commerce of Arts, Wolfii *Opera Mathematica*, tom. i. p. 830. *Journal des Mines*, N° xci. or Nicholson's Journal, vol. xii. p. 48.

Sect. II. *Bramah's Hydrostatic Press.*

Description of Bramah's machine.

Plate CCLXXV. fig. 6.

355. The machine invented by Mr Bramah of Piccadilly, depends upon the principle, that any pressure exerted upon a fluid mass is propagated equally in every direction, (art. 111.). It is represented in fig. 6. where A is a strong metallic cylinder, furnished with a piston B perfectly water-tight. Into the bottom of this cylinder is inserted the end of the bent tube C, the interior orifice of which is closed by the valve D. The other extremity of the tube communicates with the forcing pump E, by which water or other fluids may be driven into the cylinder A. Then, if any pressure is exerted on the surface of the water in the cylinder E by means of the lever H, this pressure will be propagated to the cylinder A, and exert a certain force upon the piston B, varying with the respective areas of the sections of each cylinder. If the diameter of the cylinder E is equal to the diameter of the cylinder A, and if a force of 10 pounds is exerted at the handle H, then the piston B will be elevated with a force of 10 pounds; if the diameter of E be one-half that of A, the piston B will be raised with a force of 40 pounds, because the area of the one piston is four times the area of the other. Or, in general, if D be the diameter of the cylinder A, *d* that of the cylinder E, and F the force exerted at the lever H, we shall have $d^2 : D^2 = F : \frac{F \times D^2}{d^2}$, which is the force exerted upon the piston B. Thus, if $d = 2$ inches, $D = 24$ inches, and $F = 10$ pounds, then $\frac{F \times D^2}{d^2} = \frac{10 \times 24 \times 24}{2 \times 2} = 1440$ pounds, the force with which the piston B is elevated. Now, as this force increases as d^2 diminishes, or as F and D^2 increase, there is no limit to the power of the engine; for the diameter of the cylinder A may be made of any size, and that of the cylinder E exceedingly small, while the power may be still farther augmented by lengthening the lever H. The same effects may be produced by injecting air into the pipe C by means of a large globe fixed at its extremity. Upon the same principles the power and motion of one machine may be communicated to another; for we have only to connect the two machines by means of a pipe filled with water, inserted at each extremity into a cylinder furnished with a piston. By this means the power which depresses one of the pistons will be transferred along the connecting pipe, and will elevate the other piston. In the same way water may be raised out of wells of any depth, and at any distance from the place where the power is applied; but we must refer the reader, for a detailed account of these applications, to the specification of the patent obtained by Mr Bramah, or to Gregory's Mechanics, vol. ii. p. 120.

Sect. III. *On Clepsydræ or Water-Clocks.*

History of clepsydræ.

356. A clepsydra or water-clock, derived from κλέπτω, "to steal," and ὕδωρ, "water," is a machine which measures time by the motion of water (art. 159.) The invention of this machine has been ascribed to Scipio Nasica, the cousin of Scipio Africanus, who flourished about 200 years before the Christian era. It was well known, however, at an earlier period, among the Egyptians, who employed it to measure the course of the sun. It is highly probable that Scipio Nasica had only the merit of introducing it into his native country. These machines were in use for a very long period, and continued to be employed as measurers of time till the invention of the pendulum clock enriched the arts and sciences.

The clepsydra of Ctesibius.

357. The clepsydra, invented by Ctesibius of Alexandria, was an interesting machine. The water which indicated the progress of time by the gradual descent of its surface, flowed in the form of tears from the eyes of a human figure. Its head was bent down with age: Its look was dejected, while it seemed to pay the last tribute of regret to the fleeting moments as they passed. —The water which was thus discharged was collected in a vertical reservoir, where it raised another figure holding in its hand a rod, which, by its gradual ascent, pointed out the hours upon a vertical column. The same fluid was afterwards employed in the interior of the pedestal, as the impelling power of a piece of machinery which made this column revolve round its axis in a year, so that the months and the days were always shewn by this index, whose extremity described a vertical line divided according to the relative lengths of the hours of day and night. Among the ancients the length of the hours varied every day, and even the hours of the day differed in length from those of the night: for the length of the day, or the interval between sunrise and sunset, was always divided into *twelve* equal parts, while the length of the night, or the interval between sunset and sunrise, was divided into the same number of parts, for hours. A farther description of this beautiful machine, and others of the same nature, may be seen in Perrault's *Vitruvius*.

358. The method of constructing clepsydræ, when the vessel from which the fluid issues is cylindrical or of any other form, has been shewn in Prop. VII. Part II. Instead of dividing the sides of the vessel, for a scale to ascertain the descent of the fluid surface, the following

Clepsydræ. Fig. 3. following method may be adopted. In the bottom of the cylindrical vessel ABCD, which is about 12 inches high, and four inches in diameter, is inserted a small glass adjutage E, which discharges the water in the vessel by successive drops. A hole F, about half an inch in diameter, is perforated in the cover AB, so as to allow the glass tube GI, about 16 inches long, and half an inch in diameter, to move up and down without experiencing any resistance. To the extremity of this tube is attached the ball I, which floats on the surface of the water in the vessel, and is kept steady, either by introducing a quantity of mercury into its cavity, if it be hollow, or by suspending a weight if it is a solid which does not sink in water. When the vessel is filled with water, the ball I will be at the top AB; then, in order to graduate the tube C, let the water flow out at E, and by means of a watch mark the points on the tube which descend to F after the lapse of every hour, every half hour, and every quarter, and the instrument will be finished. In order to use this hydroscope or water-clock, pour water into the vessel ABCD till the hour of the day is about to descend below F; and when this is done, it will point out any succeeding hour till the vessel is emptied.

Hamilton's clepsydra. Fig. 7. 359. The clepsydra, invented by the honourable Mr Charles Hamilton, is represented in fig. 7. An open canal *e e*, supplied with a constant and equal stream by the syphon *d*, has at each end *f f*, open pipes *f* 1, *f* 2 of exactly equal bores, which deliver the water that runs along the canal *e*, alternately into the vessels *g* 1, *g* 2, in such a quantity as to raise the water from the mouth of the tantalus *t*, exactly in an hour. The canal *e e* is equally poised by the two pipes *f* 1, *f* 2, upon a centre *r*; the ends of the canal *e* are raised alternately, as the cups *z z* are depressed, to which they are connected by lines running over the pulleys *l l*. The cups *z z* are fixed at each end of the balance *m m*, which moves up and down upon its centre *v*. *n* 1, *n* 2, are the edges of two wheels or pulleys, moving different ways alternately, and fitted to the cylinder *o* by oblique teeth both in the cavity of the wheel and upon the cylinder, which, when the wheel *n* moves one way, that is, in the direction of the minute-hand, meet the teeth of the cylinder and carry the cylinder along with it, and slip over those of the cylinder when *n* moves the contrary way, the teeth not meeting, but receding from each other. One or other of these wheels *n n* continually moves *o* in the same direction, with an equable and uninterrupted motion. A fine chain goes twice round each wheel, having at one end a weight X, always out of the water, which equiponderates with *y* at the other end, when kept floating on the surface of the fluid in the vessel *g*, which *y* must always be; the two cups *z*, *z*, one at each end of the balance, keep it in equilibrio, till one of them is forced down by the weight and impulse of the water, which it receives from the tantalus *t t i*. Each of these cups *z*, *z*, has likewise a tantalus of its own *h*, *h*, which empties it after the water has run from *g*, and leaves the two cups again in equilibrio: *q* is a drain to carry off the water. The dial-plate, &c. needs no description. The motion of the clepsydra is effected thus: As the end of the canal *e e*, fixed to the pipe *f* 1, is the lowest in the figure, all the water supplied by the syphon runs through the pipe *f* 1, into the vessel *g* 1, till it runs over the top of the tantalus *t*; when it immediately runs out at *i* into the cup Z, at the end of the balance *m*, and forces it down; the balance moving on its centre *v*. When one side of *m* is brought down, the string which connects it to *f* 1, running over the pulley *l*, raises the end *f* 1, of the canal *e*, which turns upon its centre *r*, higher than *f* 2; consequently, all the water which runs through the syphon *d* passes through *f* 2 into *g* 2, till the same operation is performed in that vessel, and so on alternately. As the height to which the water rises in *g* in an hour, viz. from S to *t*, is equal to the circumference of *n*, the float *y* rising through that height along with the water, allows the weight X to act upon the pulley *n*, which carries with it the cylinder *o*; and this, making a revolution, causes the index *k* to describe an hour on the dial-plate. This revolution is performed by the pulley *n* 1; the next is performed by *n* 2, whilst *n* 1 goes back, as the water in *g* 1 runs out through the tantalus; for *y* must follow the water, as its weight increases, out of it. The axis *o* always keeps moving the same way; the index *p* describes the minutes; each tantalus must be wider than the syphon, that the vessels *g g* may be emptied as low as *s*, before the water returns to them.

360. For farther information respecting subjects connected with hydrodynamics, see the articles *FLOATING Bodies*, MECHANICS, MILL, PUMP, *RESISTANCE of Fluids*, *RIVER*, *SPECIFIC Gravity*, *SHIP-Building*, and *WATER-Works*.
