[4207.]—THE subjoined sketch of an ornamental table pillar will show by what means one portion of the work can be ornamented, although the pillar on the whole would be unwieldy. The top portion has a pin at each end, tapped or screwed with the ordinary wood screw-box, as heretofore described. The usual size for this class of work is 1¼in. tap and box. To those who have no tap or box a plain pin can be turned, and when ready to be fixed, glued. The bottom pin is turned about 3½in. in length, for the purpose of passing through the bale A into the block B, a hole is bored previously and tapped. The advantage of a screwed pin is that the table and pillar can be packed into a small compass. C the mitre cut in the block for fixing the claw. A great quantity of the London furniture is manufactured in this manner for the purpose of shipment. Some manufacturers use iron screws, in some respects same as the common bed screw, with the exception of the ends, which are jagged and driven into the end of the wood, a small hole having previously been bored. A nut is fixed in the other part of the wood, a hole a trifle larger than the screw bored, and both parts screwed together, and afterwards turned in the lathe. The general term applied to such is portable furniture. In all operations with a screw box, care should be used, as an inexperienced person can very easily spoil a box or a tap in a moment. Hard wood, such as ebony or rosewood, or even boxwood, should not be used; but if an article of the above woods are required, a hole should be bored in the article, and a beech pin inserted. Care should be also taken that the pin to be tapped should fit the lid of the box. The amateur will find a circle marked upon the box the size of the centre-bit required to bore a hole for the purpose of tapping a female thread. The tap should be entered carefully, at the same time pressing somewhat hard upon the handle, and turning the tap gently round to the right. When entered about one-third, unscrew, and re-enter the tap again until the head of the tap enters the hole. The prices of taps and boxes will be about the following:—⅝in., 3s. 6d.; 1in., 4s. 6d.; 1¼in., 5s. 6d.; and larger sizes in proportion. It is a tool no amateur turner should be without. SAMUEL SMITHER.

[4208.]—A CORRESPONDENT (let. 4099, p. 198), signing himself "Smithereens," pens a sentence that almost takes away my breath—"No one can cut soft wood with a tool set in a radial line." I do not remember ever stating that it could. Had he taken the trouble to look carefully at the sketch, he would have perceived a thumb-screw for the double purpose of tightening the cutter, and fixing at what angle was required. It is a well-known fact that according to the nature of the wood to be turned so the angle of the iron. It is not a fact (*i.e.*, practical) that the iron must be set at a tangent to the circumference of the wood to be operated upon, or to the circumference of the rod. If very soft wood, the iron may be fixed at an angle of 30°, or even 35°; if very hard wood, such as ebony, box, or *lignum vitæ*, the rod may be cut, and cut cleaner with the iron perfectly vertical. The circumference has nothing at all to do with it, it is the nature of the wood to be operated upon. Regarding the assertion that one cutter will only cut a certain sized rod, our friend is in error again. Several sizes can be made with the same tool. The only alteration is the insertion of a loose collar with a slot for the cutter. I made several collars of cast iron, turned smooth, and fixed in with two screws in the face. If a quantity is required, of course a superior iron chuck is preferable; but as the question was asked how to make the rod, I deemed it was not required for a permanent affair. SAMUEL SMITHER.

GOLAIL OR INDIAN PELLET-BOW.

[4209.]—THIS bow is in very common use among residents in East India, many of whom attain to great dexterity in its use. It forms a capital weapon against squirrels and such small game, and perhaps some readers of the ENGLISH MECHANIC would like to know something of its construction. It is generally formed of a good piece of split bamboo, but can, of course, be made as any English bow; it is stringed with two strings instead of one. At a short distance from the top fastenings the strings are separated by a short stick about two inches long, notched at the ends, placed between them as in the drawing, and in the middle, between the two strings, is fastened a piece of cloth or soft leather, in which to place the pellet. The bow is held in the left hand, the pellet, or marble of hard burnt clay, between two fingers of the right hand. The bow is then fired, a peculiar twist of the left hand being given at the same time to prevent the pellet striking the thumb of the left hand—which is very often the case until "practice makes perfect." The peculiar twist is hard to explain in writing, but after a few attempts to avoid hitting one's fingers will soon be apparent to the tryer. The bow is generally about 5ft. high. A A, the two strings; B, piece of wood separating strings; C, cloth holder for pellets. G. W. C. H.

CLAVICLE, HUMERUS, AND NEW CRANIUM.

[4210.]—THE fossil figured No. 1 has long been somewhat enigmatical among our coal-measure specimens, and it is only recently that the balance of evidence seems to point in favour of its being a clavicle of a tolerably abundant coal-measure fish, the generic name of which is *Ctenodus*. Of the Ctenodi there are several species, and the fishes vary in length from a few inches to four or five feet, some of the bones, resembling that figured, are upwards of four inches long, and that now represented, which is of natural size, is considerably below the average dimensions of those found.

Fig. 2 represents a humerus or femur of natural dimensions; it differs considerably from those that were illustrated in your issue No. 296, Nov. 25, 1870, p. 224, letter 816, and probably belongs to one of the ambulatory reptilia or labyrinthodontia, the remains of which are so comparatively abundant in our northern coal shales. The specimen was found isolated, and it is impossible, therefore, to identify it as belonging to any special reptilian form with which we are at present acquainted.

Fig. 3 is an outline sketch of an inner or lower aspect of a cranium of what appears to be a new batrachoid form of coal-measure vertebrate. The coal-measure Batrachian it most nearly resembles is that known as *Batrachiderpeton lineatum*, but it differs from that Batrachian in so many particulars that it cannot for an instant be referred to it.

According to the illustration of the inner aspect of the cranium of Batrachiderpeton, given in the Transactions of the Tyneside Naturalists' Field Club, Vol. IV., part 1, plate iv., Fig. 1, the head of Batrachiderpeton resembles that of the new reptile head in outline; that is to say, its length and breadth are about equal, but in that respect only does it resemble our new fossil cranium. The premaxilla of Batrachiderpeton is crowded with small conical teeth, while the premaxilla of the new specimen has not any small conical teeth, but their position is occupied by a small ridged pecten-like plate, which differs from any dental apparatus I have yet discovered or examined. The vomer of Batrachiderpeton is covered with small rounded elevations or teeth, and each side of the vomer is flanked with a row of eight teeth nearly as large as are those on the premaxilla. The vomer of the new Bratachian is toothless, and with the exception of the maxilla there are no indications of conical teeth on the under surface of the cranium. The maxilla of Batrachiderpeton, so far as the figure of it gives any information, is adontoid, and in that respect it differs from that of

FIG. 1

FIG. 2

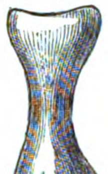

FIG. 3

our new Batrachian, inasmuch as between the points marked *a* and *a*, a distance of 1¾in., there are distinctly visible 34 maxillary teeth. The teeth are arranged at nearly equidistant intervals; they are small, glistening, and slightly striated. Those that are broken transversely show in their transverse sections large pulp cavities which are filled with the white lime-like material which is found in the teeth and bone cavities of larger reptiles and fishes. The cranium is fractured diagonally, as represented by the figure, and the posterior portion of the specimen is entirely removed. A small portion of the outer surface of the cranium is exposed, and it presents the reticulated appearance which usually characterises the surfaces of the bones of the labyrinthodonts and reptiles of the coal period. I am indebted to Messrs. Simm and Taylor for the opportunity of examining and describing these interesting specimens.

Newcastle-on-Tyne. T. P. BARKAS, F.G.S.

ONE PROOF OF THE DELUGE.

[4211.]—IT is a trite remark that the amusements of men of great mental power are generally, whether by contrast or otherwise, childish. I am, therefore, not surprised to find that our instructive and parenthetical correspondent "E. L. G." should be found amusing himself with endeavouring to get the birds and beasties, not to mention the insect millions, into his Noah's Ark. I am afraid, however, that he has not in all his long defence of that tide which led to so much misfortune enabled us to answer these questions: Granting the water, whither did it go to when no longer required to correct mankind? in what manner did it, being universal, rush along so as to "round" our hills, and also our ancient earthworks, our barrows and railway cuttings? and, lastly, supposing the water from the comet to be distilled, or at least fresh, how is it that we still enjoy oysters, and that sharks enjoy us? For, as to the last question, I would remind "E. L. G.," who knows all things, that the monsoon rains in India destroy millions of sea-fish at the river mouths. We might also ask how it was that the force capable of rounding the hills left vegetation unharmed, unless

"E. L. G." believes our coal-fields to be "Diluvii Testes," which belief he seems perfectly capable of holding. It is soothing in this scientific age to find one man not uneducated who clings to the romantic tales of our young days. M. Paris.

THE DELUGE.

[4212.]—"E. L. G." is, no doubt, one of our cleverest contributors, and one from whom we have all, at some time or other, derived considerable benefit; but what on earth has possessed him lately to become such a regular Don Quixote, at one time breaking a lance against decimals, at another, accounting for a mythic deluge by a mythic comet? It strikes me that "E. L. G." is one of those people who first desire a theory, and then look for facts to support it, and to such, "trifles light as air are confirmation strong as proof from Holy Writ." I had intended to ask "E. L. G." a few questions, but I see "Sigma" (letter 4086) has in some degree anticipated me. Like "Sigma," I want to know what has become of the water, and am desirous also to learn what proof is there that comets are composed of water at all, or that they contain any considerable quantity of that fluid? Loose reasoning is a waste of the editor's time; it is also a waste of the reader's, and of valuable space, and I believe it is principally owing to a habit of so, to say, not "taking the bull by the horns," that all three are often wasted. In order that I may not so offend, I shall not attempt to answer "E. L. G.'s" *flooring* proof of the deluge, but content myself by asking him to prove to me that a comet could cause the deluge.

Un Irlandais.

ELECTRIC SPARKS.

[4213.]—Letters 4168 and 4169 furnish some reasonable grounds for believing that the phenomena under debate do occur in some places and conditions of air; they also show how information is drawn out by discussions, and even by erroneous statements. But they do not at all affect the commencement of the discussion itself, because the generation of these sparks was a mere incidental portion of the subject, which was in some way developed into the main point. The real question was not whether quarter-inch sparks could be generated of tension enough to light gas (it being, of course, well known that friction of the feet on carpets will always produce some electric tension), but whether electric sparks were generated having a tension of some miles, whether such sparks were transmitted through the air, so causing the spread of extensive fires, rather than that such spread was due to mere fiery sparks mechanically carried by the air.

Sigma.

[4214.]—"Sigma" has been perfectly right in not accepting a scientific fact without its being duly authenticated, but he is wrong in sneering at the testimony of Americans. He says "We electricians of the English Mechanic have not yet forgotten Paine's electro-motor engine." To this I can only reply that I hope "Sigma" does not entirely ignore all American scientific authorities, nor that as an electrician he does not forget that at present Professor Morse's telegraph instrument is almost universally used in England.

The question of electrical sparks being easily produced in the United States is now too old and too well authenticated to bear a fresh discussion. I inclose a page from the "Year-Book of Facts" (1859) which if you will kindly publish will convince many of your readers, and perhaps, even "Sigma" of the truth of "Philo's" assertion:—

ELECTRICAL PHENOMENA IN NEW YORK AND OHIO.

There has been read to the American Association at Baltimore, a paper "On some Electrical Phenomena witnessed in houses in the cities of New York and Cleveland, Ohio," by Professor St. John. (See also the paper read to the British Association in 1857, by Prof. Loomis, "Year-Book of Facts," 1859, p. 147.)

By the invitation of Professor Loomis, of the New York University (says Professor St. John), I accompanied him on the evening of the 12th of February, 1858, to witness some experiments on electricity, exhibited in a house in Fourteenth-street, in the city of New York. The rooms in which the experiments were performed had upon the floors thick velvet carpets, and the usual furniture of elegant houses; they are warmed by furnaces, and are kept at a nearly uniform temperature of 70° Fahr. The experiments were performed by the gentleman and lady of the house, and Professor Loomis, who had put on dry slippers. After walking rapidly through the parlours with a shuffling motion, very bright electrical sparks were exhibited when the hand was presented to the chandeliers or other good conductors communicating with the ground. Gas was ignited at one of the burners by a spark from a key in the hand of the lady, and sulphuric ether inflamed by the spark passing from her finger to the liquid which I held in a metallic cup in electrical connection with the earth. The spark was made to pass between two small insulated brass balls, with a view to measure its length. The greatest length attained was ¼in. The spark exhibited a beautiful appearance in a darkened room when the fingers were brought near to the wall-paper, dispersing itself through the space of a foot or more over the gilded ornaments of the paper. On the evening of the 5th of March, the coldest day of the season, the experiments were repeated in the same rooms, when a sensible increase of electrical intensity was discerned. The gas and ether were inflamed by Professor Loomis holding a brass ball in his hand, and the length of the spark attained was a little more than ¼in.

These phenomena were similar to such as I often witnessed during the winters of 1854-5 at the Cleveland Female Seminary, located in the south-east quarter of the city of Cleveland, Ohio. The building is three stories high, of brick, with a sandstone basement, and is warmed by three furnaces supplied with the ordinary bituminous coal of south-eastern Ohio, the fires declining, but not becoming extinct during the night. The temperature of the rooms varied considerably, sometimes rising above 80°, but rarely falling below 60° even during the night. The rooms in which the electrical manifestations were conspicuous were the parlours on the first floor above the basement. The floors of these rooms were covered with substantial Brussels carpets. The seasons when they attracted especial attention were periods of severely cold weather—the thermometer on one occasion indicating 23° below zero; the electrical excitement diminished in mild weather, and ceased entirely when it rained. The carpets on the halls and other rooms were thinner fabrics than Brussels carpeting, or composed partly of cotton or linen, and upon these the electrical phenomena were barely discernible. In the parlours, electricity was manifested during dry cold weather at all hours of the day, but much more strikingly in the evening, after the young ladies had spent an hour in recreation and dancing. On such occasions the intensity of the spark was such as readily inflamed ether and pulverised resin, and measured repeatedly one-half inch, passing between insulated balls to the furnace register, which was in good electrical communication with the earth. All persons remaining in the rooms were enabled to communicate sparks to conductors, but the longest sparks were given by two boys of the ages of nine and eleven years, after running and sliding upon the carpets; this we attributed to the friction evolved by their unconstrained freedom of motion. These boys wore dry slippers, were clad in woollen, one of them wearing flannel next to his person, and the other cotton; the latter, who was of more vigorous constitution and active habits, giving the more vivid spark. A difference of electrical accumulation was also discernible among the young ladies, which we were inclined to ascribe to diversities in their dress, silk, woollen, cotton—the silk and woollen appearing more favourable to success. In one instance the different degrees of moisture upon the skin seemed to affect the amount of electricity communicated. These phenomena attracted the attention of all the inmates and visitors of the seminary; many persons expressing surprise, and some consternation, on receiving a shock, as they entered the room and took the hand presented to welcome them, preceded by a vivid spark. The passage of the spark over glass by bits of tinfoil disposed in letters, and in the "spiral tube," together with the usual experiments on electric light, were repeatedly exhibited as a source of amusement. Traveller.

COMPETITIVE EXAMINATIONS.

[4215.]—To raise the discussion (see letters 4110, 4163, and 4164) out of localism altogether and place it upon a broad footing, I will, with permission, cull one or two facts from the report of a deputation to Mr. Forster on this "Science Question":—

"There has," said Mr. Busbridge, "been a marked decrease in the number of students in practical, plane, and solid geometry, and in building construction. In subject I. in—

1869	1870	1871
1,308 passed	680 passed	763 passed
1,217 failed	2,679 failed	1,010 failed
2,525 total	3,359 total	1,773 total
Above 50 per cent. passed	Above 20 per cent. passed	Decrease of about 50 per cent.

In Building Construction—

974 passed	395 passed	516 passed
1,025 failed	2,235 failed	393 failed
2,000 total	2,630 total	909 total
About 50 percent. passed	About 15 per cent. passed	Decreased to about ⅓ of number."

Has the above nought to do with us mechanics? Who were these science classes and examinations established for if not for us who have not had the advantage of a good school education? Is this an incentive for us to push onwards? I know the answer. Reward should not be your aim, but the gaining of knowledge. Just so, but how about our teachers—poor, hard-working men—men who do their duty well—who not only give us a minimum of twenty-five lessons, but fifty, or sixty, or more, and then we fail. Our teacher's fault. How is it that he is so successful with another class of scholars? Further, Mr. Russell said, "The one point he wished to direct Mr. Forster's attention to was the standard of examinations, its capricious changes, and singular uncertainty. . . . Teachers made no complaint of a high standard, but they considered themselves unfairly treated when questions of too difficult a character were set, and when the answers were judged by a much higher standard than that which the official syllabus indicated as essential for a pass."

I have before me certain examination papers set this year, and I know that in the majority of cases a student cannot pass the elementary stage with twenty-five or thirty lessons, unless he comes with some previous knowledge. Take as an example—Stage 1: Mathematics. Given twenty pupils who know the first four arithmetical rules and no more; drum fractions, decimals, practice, proportion, interest, stocks, square and cube root, the metric system, &c., algebra up to quadratics, and "Euclid," Book I., into their heads in thirty lessons, and I'll honour you. Similarly, take a class in "Theoretical Mechanics," assuming again they know little or nothing of mathematics, and after twenty-five lessons what do they know? I fancy "Steam" is easier. Again, take the "Practical Plane and Solid Geometry," and how do the students fare? I might go on, but the above is sufficient. Little is said about the above statistics. I leave your readers to ponder well over them, and judge whether the examinations are as easy as Mr. Harrison would have us believe.—For the last time,

A Desperate Character.

THE ALCOHOL QUESTION.

[4216.]—"Saul Rymea" (let. 4098, p. 198) accuses me of a "leap in the dark" in differing from Dr. Richardson. I did not intend to differ from him so much as to adduce another reason. As for assuming that alcohol too suddenly carbonises and hydrogenises the blood, I did not expect any scientific person could doubt it. C_2H_6O is ethyl alcohol (spirits of wine), boiling point 78·4° C.; and what else, I ask, can cause any action so sudden on the nerves and brain and heart as the rapid carbonising and hydrogenising of the blood? Has "Saul Rymea" read Odling's "Lectures on Animal Chemistry"? I suppose the precise formula of muscle and brain remains unknown; but Dr. Odling gives the ratio of carbon atoms to nitrogen atoms as very near 4 to 1. "In the most minute fragment of muscle, then, for every single atomic proportion of nitrogen there are four atomic proportions of carbon" (4 carbon to 1 nitrogen). Say there are 8 carbon to 2 nitrogen. All muscular exertion depends on muscular metamorphosis by oxidation. "A free supply of thoroughly oxygenated arterial blood is essential for complete well-developed muscular action. . . . . The volume of oxygen which has circulated through a contracting muscle is less than one-fourth of that contained in blood which has traversed the same muscle at rest; while there is a corresponding (not equal) increase in the volume of its carbonic acid. . . . . The irritability of muscular fibre out of the body is arrested by its removal from oxygen, and again manifested on its re-exposure thereto;" and, other things being equal, "the amount of urea, $CN_2H_3(HO)$, excreted by the kidneys, and of carbonic acid, $(CO)''H_2O_2$, excreted by the lungs, is proportionate to the muscular activity of the individual." Thus muscular action depends on muscular oxidation. "If we take the two proportions of nitrogen existing in muscle, and add to them the one proportion of carbon necessary to form urea, we shall have seven proportions of carbon left for conversion into carbonic acid, thus:—

$$7 \text{ carbon to } \begin{cases} 1 \text{ carbon,} \\ 2 \text{ nitrogen."} \end{cases}$$

Thus the complete oxidation of muscle results in the appearance of one-eighth of its carbon as urea, and of seven-eighths of its carbon as carbonic acid.

Now we find in alcohol no nitrogen to replace the nitrogen oxidised into urea (CN_2H_4O); but we have carbon and hydrogen which pass off by oxidation at the lungs, demanding the pulsation of the heart. I think the rapid effect—quickened circulation, &c.—produced by alcohol is sufficient proof of rapid absorption of it into the system, and as it lacks nitrogen it is inadequate to replace muscular tissue or any other part of the human frame but fat: it may contribute to fat and to the development of heat or rapid vibration of atoms and molecules. At the blood vessels in the lungs, oxygen at the outsides draws through them carbon and hydrogen to which it unites, whilst more oxygen fills up the place in the blood vacated by the carbon and hydrogen, and what is it that causes this interchange but near-enough presence of the interchangeable and adequate heat (the hammering by atoms) to vibrate the atoms to re-coalescence? Solar heat vapourises the water of the Atlantic, and transmits it in cloud and rain to all parts of the earth; so does heat effect transfer of atoms from molecule to molecule to maintain the equilibrium of aptitude, and accomplish the purposes of creation. And, I ask, may not the action of the heart be hastened by a more rapid absorption of carbon and hydrogen in the blood, at once producing greater heat and being more abundantly presented for oxidation? The heart may be the pump, but heat is the power that works it. Is not, then, alcohol a stimulant of the heart's action? Oxidation thins or refines the blood and causes it to flow more briskly.

The forces that maintain the circulation are (1), the propulsive action (*vis a tergo*); (2) the contraction and elastic reaction of the coats and arteries; (3) the activity of the nutritive and secretory processes attracting blood to the capillaries (*vis a fronte*); and (4) in the case of the returning or venous current—general muscular contraction (combined with the valves in the veins which prevent reflux), and the tendency to vacuum in the chest formed by its expansion during inspiration. Now the heart *does* receive monition; it has a force in front and a force in rear. On an average, we may suppose the whole quantity of a person's blood is 28lb., and that in the ventricles 2oz., and the pulsations are 75 per minute; thus, 150oz. of blood passes through the heart every minute, and the whole 28lb. passes through in less than 3 minutes. I quote these averages from Gutch's "Register," 1859. Now respiration requires pulsation to present more carbon to oxidise, and in 24 hours one person produces 10·666 cubic feet of CH_2O_3 by respiration (removing a like bulk of oxygen from the atmosphere), contributing about 125lb. of carbon annually towards increase of vegetation by absorption through foliage when oxygen is again set free for respiration. As for the heart having no sense, is it not sufficienfly connected by nerves with the brain and other centres? I deem blood is carbonised and hydrogenised too rapidly or suddenly when it is too largely swallowed in a liquid state without any admixture of nitrogen which is needful to replace the tissues decomposed and carried off during all muscular if not other action; the temperature and proximity of carbon and oxygen in the lungs, must, I think, before all the displaced carbon has its vacated place re-occupied by another element oxygen, pump the blood forward by rarefaction from two causes, the one the departure of carbon, the other the wave motion forward propelled by the newly entered oxygen, whilst valves admit of no retrograde motion. Does "Saul Rymea" suppose that alcohol runs through a person without change, or that it all passes off through the lungs as aqueous vapour? Does he wish proof that alcohol in the stomach, or blood, is split into carbon, hydrogen, and oxygen? All heat, from whatever burning source, is but solar heat, stored up, it may have been for ages, in the coaled timber of a pre-historic age; but solar combustion arranged the atoms where they are. The plant absorbs solar energy in pulling apart carbon, hydrogen, and oxygen; the animal disperses solar energy by recombining the oxygen and carbo-hydrate, in the pulling apart of which that energy had been absorbed or rendered latent; the sun's force is hoarded by the plant; it is dissipated by the animal, though in a more penetrative sense force, like matter, is indestructible. Nature may employ every practicable outlet to throw off a smothering over supply of alcohol, but all the energy from it is derived by the conversion of it into some portion of tissue, and, at least ultimately, into CH_2O_3 in the lungs.

But the force derived from hydrogen is greater than that from carbon, and there is three times the volumer quantity of it in alcohol, but the weights are C_{12}, H_3, C_8. Assuming muscle-formula is $C_{12}H_{10}N_2O_4$, and subtracting all the oxygen and nitrogen with the necessary hydrogen, in forms of water and ammonia, so as leave a residue of $C_{12}H_2 \times O$, then 269 grammes of muscle would leave 144 grammes of carbon and 2 grammes of hydrogen for oxidation, which should furnish 517,280 kilogrammetres of motion, thus:—

	Grammes.		Kilogrammetres.		Kilogrammetres.
Carbon	144	×	3,392	=	488,448
Hydrogen	2	×	14,416	=	28,832
					517,280

Hence, 1 gramme of muscle should furnish $517{,}280 \div 269 = 1923$ kilogrammetres of motion, force sufficient to lift 1923 kilogrammetres to the height of 1 metre, but imperfect data renders this but approximative. Have we not in alcohol, then, an adequate spur to circulation without the paralysation of any check-nerve to the heart? Deficient nitrogen must arrest molecular change in a very short time, so as to much lower the temperature of the frame, unless extra oxidation at the lungs suffice to maintain it. As to "Saul Rymea's" heart beating on seeing a mad bull rush at him, I am not prepared to prove, and have not attempted it, that that proves no nervous paralysis of resisting muscles. I merely suggest what, to my state of information, seems an adequate and likelier cause, and that is a spasmodic effort of nature demanding swift oxidation to do the greatest possible amount of work in the shortest possible period, and to be more a spur than any paralysis; nevertheless, may they not go together and maximumise resultant energy?

It is easy to say the brain regulates the heart's action, but what regulates the action of the brain? As a physical agent it requires more than carbon and hydrogen to long maintain its operation; and like every other part of the frame would soon collapse into cold rigidity did not the vibratory impulse of combustion, of atomic clashing or interchange, promote or maintain its elasticity. I ask, may not, cannot, or are not, obstructive molecules formed, when no nitrogen is presented when required, that may in capillary vessels obstruct the true vital order of atomic recombinations, which combinations I have faintly shown in the muscle-transformation attending on all vital activity? Some one well versed in physiology may explain. J. BARWICK.

TIDAL POWER.

[4217.]—I THINK that tidal power might be employed for dredging, a vessel being moored at the bows, and fitted with an undershot-wheel, preferably of Poncelet's pattern, with curved floats. The advantage of having the vessel moored at one end is that reversing-gear would not be needed. Some suppose that the undershot-wheel does the most work when moving at very nearly one-third the velocity of the stream; others think that a velocity of about one-half that of the stream gives the greatest efficiency. Chambers, in his "Natural Philosophy," takes the former view of the case. Suppose the tide flows with a velocity of 6ft. per second, and that the velocity of the wheels is 2ft. per second, therefore the relative velocity of the tide compared to the wheels is 4ft. per second. From the formula $V^2 = g\,h$, or $h = \frac{V^2}{2g} = \frac{V^2}{64} = \frac{(4)^2}{64} = \frac{1}{4}$, since a cubic foot of water weighs 62½lb., we get a pressure of about 16lb. on each square foot of the immersed float; but the wheels, moving at 2ft. per second, or 120ft. per minute, gives $16 \times 120 = 1920$ units of work done per minute for each square foot of the immersed float. If each float measured 10ft. broad by 4ft. deep, the work done on the two wheels $= 10 \times 4 \times 2 \times 1920 = 80 \times 1920 = 153200$ units per minute, or nearly five horse-power. Allowing for the modulus of Poncelet's wheels, we get about three horse-power effective. The practical difficulty, however, in dealing with tidal and wave power is first to get hold of the power, which, in the latter case, is not easy; and, secondly, to utilise it. It should be remembered that steam-power is (say) fifty times cheaper than manual labour, and electro-magnetic power rather cheaper, in most instances, than manual power. Thus it will be readily seen that in endeavouring to utilise tidal power for any particular purpose we must not forget the class of power it is intended to supersede. We seem to want a good method of accumulating power. I should like some practical calculations as to the units of work accumulated by compressing air. Would some of your correspondents kindly oblige me in this? Stretching indiarubber, as tidal power, &c., might be rendered useful in accumulating force. Probably more work can be done in employing it to turn wheels than in simply raising a floating body, as in the former case a great quantity of water successively moves the wheel; in the latter case a mass of several hundreds of tons is raised ten feet or more every high tide, or twice in 24¾ hours (say). And, since a horse-power is $33{,}000 \times 60$, nearly 2,000,000 units of work in an hour, or about 900 tons raised a foot high in an hour, the power obtained by lifting vessels is not so much as might at first sight be supposed; besides, in utilising slow motion, the machinery requires to be very strong. Six feet per second is a very strong tide, being upwards of four miles per hour. The power to be obtained by the tides varies as the cube of their velocities.

PHILANTHROPIST.

TO THE BANJOISTS.

[4218.]—I SEND a sketch of a banjo, with an accompaniment of my own invention, which I have had in use for some time, and it accords very nicely with the voice, or with a "nigger" troupe. Fig. 6 is banjo, with bottom upwards; 1, spiral spring with knocker joined to the stem of banjo that goes through the hoop; 2, a loop that the catgut goes through for pulling the

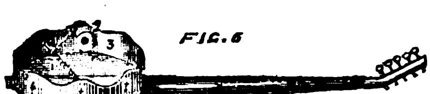

FIG. 6

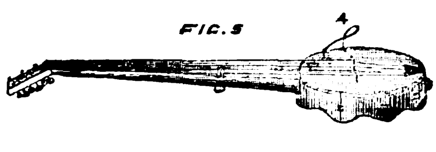

FIG. 5

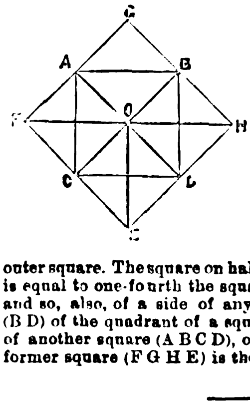
striker; 3, a bell fastened in inside of hoop to strike on (a clock bell will do). Remember, the bell must be fastened freely to make it sound well. Fig. 5, banjo with face upwards, showing the end of the catgut with loop for putting on the finger 4. Remember, the loop of catgut must go on the third finger, and the catgut must be slack to use it and stop it at will.

A MUSIC PLAYER.

PYTHAGORAS' THEOREM.

[4219.]—REFERRING to C. J. Recordon's Fig. (4125, p. 203), as a new proof of Theor. Euclid I., 47, being in a square, while Pythagoras' is on a right-angled triangle of three unequal sides, I send a diagram illustrative of the ratios of squares on diagonals, and of the semi-square and quarter-square triangles on the same line, half the line, and quarter of the line: it may not be familiar to all your young readers. I have not met with it in any class book, and I therefore suppose it may instruct some, and, simple as it is, submit it for your insertion if thought worthy.



E F G H is the square of diagonal of the square A B C D, and is divided for showing triangular proportions of diagonals and squares. The inner square is half the square in the diagonal—the four triangles in the inner square equal half the eight triangles in the outer square. The square on half of a diagonal of a square is equal to one-fourth the square on the whole diagonal, and so, also, of a side of any square. The diagonal (B D) of the quadrant of a square (C B H D), is the side of another square (A B C D), of which the side of the former square (F G H E) is the diagonal, and so on.

J. BARWICK.

MUSICAL INSTRUMENTS.

[4220.]—I AM sorry that I cannot inform my friend "The Harmonious Blacksmith" of more than one of the eleven curiously-named instruments he has kindly placed before our attention. Perhaps I am selfish, but I wish we had more musical correspondents like him; there must be some, as evidenced by the interest shown at the sale of the Gillott's collection lately. I extract the following out of an old book:—"Basset-Horn, the richest of all wind instruments (called also cornet, by reason of its curvature), is believed to have been invented at Passau, in 1770. It was afterwards perfected by Theodore Lotz, in Presburg. It is, properly considered, an enlarged clarionet; and notwithstanding the difference of its form, it resembles that, not only in its qualities and tone, but also as regards its intonation, the mode of holding it, and fingering it, so that every clarionet-player can perform on it without practice. Besides the mouth piece, by which the intonation is given, it is formed of five pieces —the head-piece, called the barrel, two middle pieces, the trunk, and the bell, which is usually of brass. It has fifteen ventages, of which four are provided with open, four with closed keys. Its compass is three-and-a-half octaves, from lower F in the bass to double C of the treble. It is seldom used in the orchestra; however, it is found in Mozart's Requiem, and some other pieces. The Basset-horn may be also used as a bass instrument." FIDDLER.

NOVEL TELESCOPE.

[4221.]—SOME years ago I found that a chink in the slates of an unceiled schoolroom admitted an image of the sun. This was found to be inverted, and estimating the apparent size of the sun as less than a silver sixpence, the image was magnified five or six times. What most attracted my attention, was the passage across the disc of small cirrous clouds, whose transit I endeavoured to time by the beats of a chronometer watch. In the outside heaven, no cloud was visible, yet there, on the solar image, the hairlike wisps were seen passing rapidly. It is evident that if we could ascertain the height of these *cirri*, we might regard it as the perpendicular of an inverted triangle, whose base is the sun's diameter, and apex the pupil of the eye. Hence, by an easy proportion, the actual length of the base in miles, and the velocity of the wind which carried the *cirrus* across the sun. I cannot now recover the data and conjectural computation, but I remember that the result, 800 miles per hour, seemed incredible, and I halved it; still, 400 miles seemed to philosophical quidnuncs an impossible absurdity, and I was well laughed at. Meteorological investigations in the United States, 1¼ miles high, conducted on Mount Washington, have proved the velocity of the wind at an elevation far short of that reached by *cirri*, to be 150 miles per hour. Now, Gay-Lussac, having ascended in a balloon to a height of four miles and three-tenths, saw the *cirri* above his head, apparently as high as when he looked at them from the ground. Assuming them to have been eight miles and six-tenths high, this is more than six times the height of Mount Washington; and the measured velocity of the wind there, multiplied by six, would give 900 miles for the proportional, or probable, velocity at the height at which the *cirri* floated. The objection that aqueous vapour could not ascend so high is nugatory, since the *cirri* are certainly of electrical origin. THOMAS BUCHANAN.

SPECULUM WORKING, &c.

[4222.]—I SHALL be glad if you will insert in an early number of the ENGLISH MECHANIC the following account of the performance of a home-made speculum, as I think it will be encouraging to those readers who are desirous of constructing their own telescopes:—The mirror is 5⅞in. aperture, 51¾in. focal length, worked from a piece of rough plate-glass solely by hand, no machine whatever being employed in its production. It has been silvered by a modification of the Rochelle salt process, which gives good results, and which I will describe when I have perfected it in some details. I have mounted it in the Newtonian form with a "perfect plane" by Browning, and Huyghenian eyepieces with powers varying from 36 to about 270 diameters. The highest power is the one I generally use. It shows the stars as perfectly round discs, with one or two diffraction rings, but very few and short rays even with first-magnitude stars such as Vega, none at all with smaller ones. I can readily see two faint comites to Vega and the Debilissima pair between ϵ^1 and ϵ^2 Lyræ. The following stars are well divided with round discs, γ Leonis, ι Leonis, ϵ Boötis, ϵ^1 and ϵ^2 Lyræ, λ Ophiuchi, and ζ Aquilæ. η Coronæ is just divided, and ζ Boötis is seen as two discs in contact.

I shall feel obliged to any of your correspondents who will give me the most recent measures of the last two pairs, as they seem about my limit at present.

I shall also feel obliged to the Rev. H. Cooper Key if he will tell us what he finds to be the best proportion of diameter to focal length. My speculum is almost precisely 9 diameters. His large speculum, 18in. diameter, is, I believe, about 10ft. focal length, or about 7 diameters, but I understand he finds that this is too short a focus for the best results.

A. WOOLSEY BLACKLOCK, M.D.

High-street, Godalming, Surrey, May 20.

P.S.—With reference to silvered glass sun-screens, has anybody tried silvering the first surface of the ordinary rectangular prism? I should think this would be the best plan of all.

ERRATUM.—In my letter (4109) "On Communicating Rotary Motion to Ball Fired from Smooth-bored Gun," ninth line from top, for "150 turns a minute" please read 150 turns a second," the rifling of the Enfield being at the rate of about a complete turn in 6½ft.—PHILANTHROPIST.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[10185.]—**Wallaroo Copper (U.Q.).**—In reply to "C. W.," I beg to state that this copper comes to England either refined or in bars, similar to what is received from Chili. It is used for the same purposes as English copper; the reason of its commanding a higher price than English or Chili copper is on account of its being generally of a superior quality.—J. ROSKELL.

[10844.]—**Chemical (U.Q.).**—In reply to "Cuprum," Muspratt, in his article on "Copper" (p. 528), and Mitchell, in his "Practical Assaying" (p. 365), give the equation as follows: — $2CuO + 2Cu = 2Cu_2O$.—J. ROSKELL.

[11196.] — **Turning Perpendicular Shaft.**—"Tubal-Kain" states that the sketch I sent on turning perpendicular shaft would not drive if carried out as per sketch. I beg to differ. I have tried the same upon an ordinary drill shaft, and I found that, unless the centre of the pulley on the perpendicular shaft was in a correct line with the vertical shaft, the band came off. Theory and practice oftentimes differ. Regarding my stating spur wheels for bevel, I stand corrected; it was an oversight on my part. I am well aware that the greater the distance betwixt vertical and perpendicular shaft the better for driving; in fact, if very close, they would not drive at all. I certainly in my sketch described them very close.—S. SMITHER.

[11228.]—**Stereotyping.**—No practical man would think of using any other than that which is known as the "paper" process, a description of which is given in a letter on "Stereotyping," page 231, Vol. XIII., of this publication. The process, however, is really much simpler than would appear from the description there given. Should "A Country Printer" require a cheap casting-box, I would call his attention to a letter on the subject on page 337, Vol. V. A complete apparatus for small sizes can be purchased for about £5; the one I have is of this description, and works well. In reply to "A Country Printer's" inquiries, (1) it is not sufficient to pour metal upon the mould, as the metal will cool before it can take a sufficiently clear impression. (2) Have nothing to do with plaster. (3) Old type metal is the best and cheapest material.—A CAMBRIDGE GRADUATE.

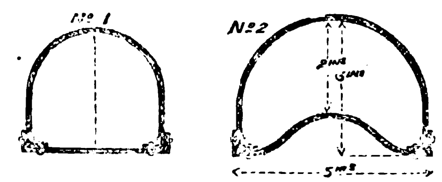
[11268.]—**Tempering Knives and Trowels.**—Would "Homer" kindly try a little water from the wash-basin, or soap-suds, say about a teacupful to a gallon of clear cold water, in which to immerse his hot steel blades; afterwards blaze off with oil to what hardness he requires, and let us know what progress he makes? Any buckle can easily be taken out by hammering on the anvil while still in a hot state with the burning oil, when once he has practised it a little.—LINUM.

[11324.]—**Salt Damp in Walls.**—Salt is very hygrometric. I think that it will be difficult to give a reliable remedy, but I would try the following:—Take off the paper, and after a few days of very dry weather apply hot irons to the affected spots to take out the damp to a certain depth in the plaster, and whilst the wall is still hot, give it a quick and liberal coat of some light-coloured oil paint; when dry, apply another coat, without heating it previously, and paper in due time.—BARBAROS.

[11338.]—**Motive Power for Amateurs.**—If "A Barrister" (p. 206) thinks I had any idea of producing perpetual motion he is mistaken. I took the idea from an illustration which appeared in the MECHANIC some years since. "A Barrister" proposes to have a fly-wheel fixed to the saw spindle, driven with a crank at one end. Where does he mean to get his power from—by treadle or hand? I think he forgets the speed a circular saw requires to run.—ZOO ANDRA.

[11349.]—**Heating Bar Iron (U.Q.).**—An ordinary smith's forge, blown by a fan, instead of the ordinary bellows.—W. H. HEY.

[11355.]—**Model Steam Boat (U.Q.).**—Not long since I constructed a boiler similar to what "N. G. H."



wants. It was made as No. 1 of copper, the thickness of a new sixpence; rivets ¼in. apart. I think you would get more steam out of No. 2, but I do not think the pressure you would obtain would be anything near 30lb.—T. W. M. J.

[11393.]—**Metallic Harmonicon.**—I am afraid that neither "Zoo Andra" not Samuel Kempling know the meaning of "inverted," for if they did they would not try to maintain that "inverted aquarium" (No. 11393, page 103) is correct; if this aquarium is to be "inverted," where is the "solution of alum" to go? On the ground certainly. I think "Zoo Andra" has made another great mistake in his "excellent description of the musical glasses in his possession;" he says that the great expense of making these harmonicons is getting the glasses all blown to the right notes; if the glasses are to have water in them that would materially alter the pitch, so all the bother of getting the glasses the right pitch would be useless, as they would (as it appears to me) have to be tuned by the quantity of water put into them.—TUBA MIRABILIS.

[11395.]—**Foreign Wood (U.Q.).**—In answer to "C. C.," I believe the fibre comes from India in bales, weighing 2½cwt., and of different colours, each being worth about £7; it is also delivered in another form, termed a "dole," which consists of a coil of the yarn closely tied up and bound with pieces of palm wood from ⅜in. to 3in. square. I might send a description of the manufacture and many interesting details concerning cocoa-nut fibre if approved by the Editor.—H. B. E.—[Please send.—ED.]

[11397.]—**Sting-proof Gloves (U.Q.).**—Try a pair of Hawesling gloves with long gauntlets.—H. B. E.

[11420.]—**Sewing Machine Extras (U.Q.).**—The sewing-machine extras in which there are no moving parts, are made of white metal, others of iron.—T. W. M. J.

[11458.]—**Carmine Staining (U.Q.).**—I cannot, unfortunately, lay my hands upon the number containing this query; but, so far as I remember, the querist wishes to know the proper time to commence the staining process. The answer is:—Immediately the section is cut, and whilst the specimen is living, or as near it as possible. In using magenta for staining wood sections it is immaterial when the section is stained, perhaps the older the better.—H. P. H.

[11519.]—**Horse-power of Compound Marine Steam Engine.**—This is "calculated" in the ordinary way, but taking into account the expansion of the steam. See the method of Mr. Gray on p. 188. G. Lamb says calculated, but does he mean for an engine actually at work? if so, that is done from the indicator diagram.—M. E.

[11528.]—**Silicate of Soda.** — For cementing object-glasses I should not recommend the above. You cannot be sure that the silicate will remain perfectly transparent; dry with two pieces of common flat glass and you will see the effect.—THE WELSH SHEPHERD.

[11531.]—**Water Wheel.**—I have not the number by me in which my answer appeared, but the assertion that "D. S." has made is partly true. I made the reply mentioned under a misunderstanding, because the term rotary engine is generally understood to mean a steam-engine, and it was in that sense I understood it. A rotary water engine is usually called a turbine, distinguished by the name of the inventor. I commend to the notice of "D. S." the following extract, from the *Engineer* of 1871. In a criticism upon a trial of water motors that had just taken place in Massachusetts, the editor says, "Massachusetts is blessed with a great deal of water power; as a result it is a very paradise for makers of turbines of all kinds. The turbine gentlemen are strong in the matter of circulars. For a long time past there has been a rivalry, not only as to who is the best maker of turbines, but as to who can write the best circular. Under the pressure thus brought to bear, the duty of the turbine has been gradually augmenting in Massachusetts, it has risen steadily from 75 to 98 per cent.; it stuck there for some time, until a new manufacturer came upon the field. He looked with scorn on a duty of 92 per cent., and boldly produced a turbine which gave out 135 per cent. of the gross power produced by the fall." This may be the case of our friend exaggerated. At the trial referred to, there was not one (and there was almost every variety of turbine tested) that produced 90 per cent. of the power of the water, and very few produced the power promised. This was at a trial, and every one knows that in general every-day work falls below the trial percentage. In conclusion, I would ask "D. S." how he knows what percentage he obtains from the wheel shaft, if he employs a dynamometer, and what construction is it? as I think that there must be some mistake in the enormous percentage named. If correct, if this invention were patented, the inventor would obtain a fortune as startling as the percentage.—P. W. H. J.

[11597.]—**Mean Longitude of the Sun, &c.**—Much obliged to "A Fellow of the Royal Astronomical Society" for his notice (p. 171) of my query. What I want is really a resumé of the motions of the sun and moon such as is given by Francis Baily in his "Astronomical Formula" (1827), only as adapted to the latest modern tables, which will be Leverrier for the sun, and Hansen for the moon. Delambre adopted for 1801:—

	Deg.	Min.	Sec.
Mean longitude of the sun...............	280	39	10·2
Longitude perihelion	279	30	5
Sec. motion for 100 years	0	45	45
Similar Burg. for the moon:—			
Mean longitude	118	16	56·1
Anomaly	212	6	56
Motion of mean longitude in 100 years	307	52	43

—W. H.

[11572.]—**Compressing Water.**—J. Westwood seems to ignore the explanation which I gave him on page 157—viz., that there is a known compressibility in water which is due to the air contained in it, which may be proved by placing water under the receiver of an air-pump, and, upon exhausting, the water will appear to be in a state or ebullition, similar to boiling, consequent upon the air leaving it.—A., Liverpool.

[11589.]—**Dry Steam.**—I trust that I am as willing to be corrected if I state anything which is contrary to known facts, as to give others the benefit of what little knowledge and experience I may be possessed of. It appears to me that it is "Caloric" who is in a fog, and not myself. I reassert that there is no necessity to go to the chemist's to answer this query, as the reply on page 157 is, in my opinion, correct, and I will take his own experiment to prove my position. Does he wish me to understand that if steam at 3lb. per inch be passed through pipes in a furnace that it will remain at that pressure? If so, I will believe that when I see it, but not before. It appears patent to me, irrespective of what the pressure might be in the boiler, that the steam exposed to a higher heat in the furnace will become, to all intents and purposes, high pressure; and, therefore, my answer that there will be plenty of heat, with but little of water in a given volume of it, is correct.—A., Liverpool.

[11594.]—**Foreign Calculation of Engine Power.**—A French horse-power is equal to 4,500 kilogrammetres per minute, equal to 32,549 foot-pounds. Do you want the formulæ for calculating? The English rules are generally used in the United States.—M. E.

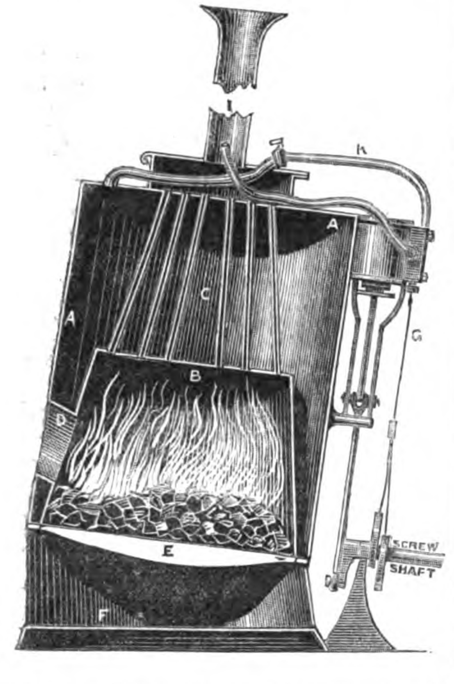
[11632.]—**Debility.**—I did not say (p. 182) that homœopathists had no cure for constipation, but that the patient under treatment for tumour was obliged to seek relief under another system for it, as the medicine given for tumour had no effect on the bowels. I may further add that the homœopathist on being pressed for opening medicine refused, stating the tumour must be cured first, recommending that fruit should be eaten instead. Thus the natural channel for removal of effete and noxious matter would have been closed had his directions been followed. Many common articles of food and drink of every-day use are forbidden to homœopathists, as they counteract the medicines. Now, can the votaries of this system say—not merely assert—but say with scientific certainty that they have discovered all the substances which produce this effect? Again, even perfumes will destroy the effects of the medicines; how, then, about the garden flowers, the hawthorn, the hay fields, and the sea breeze, which the happy dwellers in the country cannot avoid if they would? And should there be in any article of common use some undiscovered substance, some unknown quantity, that vitiates their prescriptions, then the followers of homœopathy are, despite all their precautions, "Walking in a vain shadow, and disquieting themselves in vain." As to whether the "Altera-Tonic" system is true or not I only ask investigation. For myself I am satisfied of benefits not only in my own case and that of my friends, but also with domestic pets. The mission of the ENGLISH MECHANIC, as I take it, is to answer the question of one of old—"What is truth?" but not like him to leave the Judgment Hall before the answer is given.—AMATEUR.

[11632.]—**Debility.**—I wonder if "Amateur" (page 182) was joking when he wrote of the above. I cannot imagine any one speaking seriously in that manner against one of the "learned professions." If "Amateur" has obtained a benefit from the use of the elixir, &c., let him still believe in it, and also in the fallacious idea that *all* disease originates in nervous debility. Others, on the contrary, will keep their own opinions without running down any one. I don't say that the elixir is useless, because it has never been my luck to try it. Of the antagonists of the *Anti-Lancet* I cannot so speak; still, it would be out of the way for me to try to prove their worth, for they are numerous enough to do it themselves in deeds, which are far stronger than any words.—OLD CHEESEMAN.

[11654.]—**Cleaning Violoncello.**—I bought a violoncello so completely encrusted with dirt that few would have taken the trouble to attempt to clean it. In the first place, I dusted it well, took down the bridge (there was only one string to hold it up), and removed the tailpiece, and then I washed it thoroughly with soap, water, and flannel, using turpentine to remove the rosin. After drying I rubbed the instrument all over with the naked hand slightly moistened with olive oil. The results were most satisfactory, and it has now a brilliant polish.—R. E.

[11655.]—**Making Gold and Silver Leaf Adhere to Fabric.**—Dissolve gum arabic rather thick, and add about one-third of brown sugar, lay it on the fabric with a camel's-hair brush, and let dry; now breathe upon it, and apply your gold or silver leaf, let dry again before you rub off the edges; or a still cheaper material is dissolved glue and about one-third treacle, applied warm to the fabric, and in about half an hour it will be ready for gilding. If your substance is too thick, thin it with water, if too sticky take less sugar or treacle.—THE WELSH SHEPHERD.

[11656.]—**Boiler for Small Steamboat.**—"L. M. F." has not stated how he intends to fit his boat up. I do not know whether he intends to fit up as paddle or screw. It is almost a general practice now to make small boats, screws. If that is his intention, he should have a short vertical boiler with one cylinder down the side, coupling direct upon the screw shaft; this is, I am confident, the best arrangement for a boat of that size. I send a drawing of the kind of boiler. I have seen a good illustration of that class of boiler in Shand and Mason's steam fire-engine. This boiler ought not to weigh more than four or five hundred-weight with fittings, the shell to be of mild steel, three-eighths or five-sixteenths of an inch thick; the tube plate ½in. best Lowmoor wrought iron, the tubes of hard soldered brass ⅛in. thick, and 1in. internal diameter; number of tubes, 8; length, 16in.; diameter of boiler, 2ft., height, 30in.; diameter of firegrate, 9in.; height of firebox, 1ft.; fire-door, oval, 6in. by 3in.; chimney, 6in. internal diameter, and ⅛in. thick sheet iron; height of chimney, 6ft. from stalk, with or without a hinge joint at the bottom, according to the height of the bridges. For such a small engine I would not recommend a Giffard's injector, being what Mr. J. Bourne would call a battle trap. With muddy water they are failures.



The engine to be 7in. by 3½in. stroke, connected with a clutch to the screw shaft to throw out of gear when pumping water; this secures the advantages of a donkey pump. Space occupied by engine and boilers, 2½ cubic feet. The space around the engine and boiler could be filled up by coal bunkers. This is a design for a river steamer. I would not recommend a small steamer for the sea; better make it a sailing vessel at once. There will be constant trouble on account of the tubes being encrusted with salt. If he intends the steamer for the sea, at the bottom of the boiler might be placed a cast-iron tank, to contain fresh water for the boiler. It will be of no earthly use trying to make so small an engine into a condensor. This engine will be 2 horse-power nominal. If "L. M. F." intends to make it a paddle steamer I will send a different design. References:—A, shell of boiler; B, fire-box; C, tubes; D, opening for fire door; E, fire-bars; F, ashpit; G, engine; H, smoke-box; I, chimney which lifts up with the hinge shown on the left hand; J, exhaust pipe; K, steam supply pipe.—P. W. H. J.

[11663.]—**Steam Power.**—I thank "P. W. H. J." for his answer (p. 207), but I find it is not quite what I want. Will he kindly say, if I make the flue of tubes, what size they should be, how many, and what distance they must be carried above the fire-box before emerging into the chimney? The steam pressure I could not state, not knowing what I could obtain in so small a boiler. The resistance would not be very great, as I intended my model to represent a steam crane. Could he tell me how to ascertain the pressure in model boilers? I want a small pressure gauge, but cannot afford to get one. Could I construct one simple and small? If so, how?—T. W. J.

[11664.]—**Polishing Bullock's Horns.**—Polish with oil and whiting, or willow charcoal powder.—W. H. HEY.

[11677.]—**Rendering Wood Incombustible.**—Deal boards become almost incombustible when painted over with a diluted solution of waterglass (silicate of soda). The waterglass is usually sold as a thick fluid, like honey. This may be thinned out with water, about six or seven times its own bulk. The water must be soft water; boiled water will do. Use a clean brush, and apply the solution warm. In about twenty-four hours a second coat, and perhaps a third, will render the wood almost incombustible. Use a new brush. Wash it in clean water after using it, or it will get too soft. Avoid grease or fat on the boards before you paint them. The felt recommended to you is most likely roofing felt, which I would not recommend in your case, as it soon becomes brittle, and is only preserved with pitch and tar—a very combustible material. It seems to me that slates are the only material for your roof.—THE WELSH SHEPHERD.

[11681.]—**Waterglass.**—Waterglass will not do for the bottoms of boots used in salt water, nor for boots used on land. Waterglass will do to preserve wood, mortar, cement, and stone, but not for leather.—THE WELSH SHEPHERD.

[11694.]—**Green Fly.**—It is clear "H. S. C." has never tried cigar ends. These rank bits of "'bacco" are regular settlers for all insect life, and beat shag tobacco and negrohead and tobacco paper hollow. *Modus operandi*: Place a small flower-pot, bottom up, on three bits of broken pot. Stand another pot upon it, keeping the holes one over the other. Put in a handful or two (according to size of greenhouse) of the cigar ends, together with a live coal, in the centre, and the tobacco will burn out steadily and thoroughly. These cigar ends are not easy to get; but at some of the large cigar divans can be bought of the careful attendant at 2s. per lb.—JANNIFRED.

[11706.]—**Optician's Lacquer.**—See p. 515 of last volume (query 10466).—W. H. HEY.

[11710.]—**Cleaning Oil Painting.**—The cleaning of oil paintings is in many cases a very difficult operation, which ought not to be undertaken by an amateur if the painting is a valuable one. There are many paintings spoiled by cleaning, because almost every painting requires a different treatment. Most of the early paintings upon wood are not oil paintings at all, but entirely prepared and painted with distemper or size colours, and only varnished over with sandarac or mastic varnish. Afterwards the artists used a distemper ground, and painted their pictures partly in size and oil colours. Then canvas pictures were painted entirely in oil, yet even many of those oil paintings have in some places touches of body or water-colours; in fact, almost every artist has a method of his own, and any one undertaking to clean a painting ought to see at once by what technical means the painting was produced, because what might be used with perfect safety to clean one picture would be harmful to another. The above general remarks on paintings will show to E. Parker that it requires more space to meet every case. However, I will give him one method which is safe in every case, but it may not always have the desired effect:—First, dust your painting with a dry brush or rag, then take some water which has been boiled for some time; when quite cold dip a soft sponge or a wash-leather in the water, and squeeze the sponge or leather so that it only remains damp. Now go over your painting, and wash your sponge out again until the water comes clean out of the sponge. When all the dirt is removed from the painting, a dry wash-leather or a very soft cotton rag will entirely dry the surface of the painting. The water should be used very sparingly, because water is a great enemy to oil paintings. Now, put your painting in a bright light (but not in the sun) and leave it there for a day. If the colours have become generally brighter, perhaps exposure to bright light for a few days will be sufficient; if not, take a piece of cotton wool and dip it in clean spirit of turpentine (not too full). Commence on the top of your painting, going lightly over it and so downwards; touch every place, but do not touch the same place a second time. When your cotton wool is empty, fill again until your picture is all gone over; in about half an hour you may go over your picture a second time. If not perfectly clean and fresh after the second operation it wants another treatment.—THE WELSH SHEPHERD.

[11711.]—**Time at Our Antipodes.**—I fear the diagrams in reply to this query on p. 234 will not be sufficiently intelligible to "T. S.," partly on account of my having omitted to give the corresponding astronomical and civil times at 270° and 90° respectively, and partly from "T. S." concluding that a message telegraphed from London at noon on Tuesday, May 7, would be dropped at New Orleans at 6 a.m. on the *same* day. Now, as Wednesday succeeds Tuesday, it must have an *absolute* commencement somewhere on the earth's surface. That Wednesday, reckoned civilly, commences at any place at the moment when it is noon at the Antipodes there can be no doubt; diagram No. 4 shows that the civil Wednesday commences at London when the sun passes the meridian on the same day at the Antipodes—*i.e.*, Tuesday 12 at night at London is synchronous with Wednesday 12 at noon at the Antipodes. Applying this to Calcutta and New Orleans the times for diagram No. 3 will stand thus:—

0° astronomical time,	Tuesday, May 7, 6 hours.		
civil	,,	Tuesday, May 7, 6 p.m.	
90° astronomical	,,	Tuesday, May 7, 12 hours.	
civil	,,	Tuesday, May 7, 12 night.	
180° astronomical	,,	Tuesday, May 7, 18 hours.	
	Wednesday commencing.		
civil	time, Wed.	May 8, 6 a.m.	
270° astronomical	,, Wed.	May 8, 0 hours.	
civil	,, Wed.	May 8, 12 noon.	

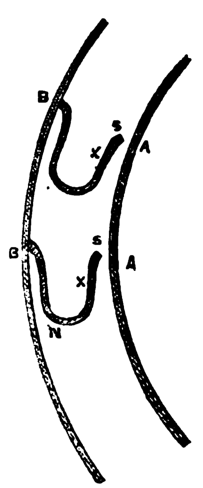
From these we find that when it is 12 at night at Calcutta, Wednesday commencing, the sun is passing the meridian at New Orleans 12 hours later. If now we take the times for diagram No. 2 we have—

90° astronomical time,	Tuesday, May 7, 6 p.m.	
civil	,,	Tuesday, May 7, 6 p.m.
0° astronomical	,,	Tuesday, May 7, 0 hours.
civil	,,	Tuesday, May 7, 12 noon.
270° astronomical	,,	Tuesday, May 7, 18 hours.
civil	,,	Wed. May 8, 6 a.m.

As, therefore, the difference of time between 12 at night and 12 at noon is twelve hours between any place and its antipodes, so in the case of London and New Orleans, the difference of time, reckoned according to the earth's rotation, is 18 hours, and the message is dropped at New Orleans 18 hours in time later than its despatch, or at 6 a.m. on *Wednesday* morning, not on Tuesday morning. I beg to apologise for having given this extra trouble to "T. S." and your readers.—W. R. BIRT.

[11721.]—**Assayer's Duties.**—I have been waiting for "Un Irlandais" to answer this query, as it was addressed to him. I am sorry to have to discourage "G. T. H.," but the knowledge which he seeks is considered a trade secret by all Cornish assayers acquainted with the subject, a great number of whom do not understand it themselves; if this had not been the case, I would have been happy to have given him all the information that lay in my power. To satisfy a person that this was kept a secret, I once wrote to a recognised assayer in Cornwall, and offered to pay him for instructing me in the method. His reply was in the following words:—"The information for which you ask is, if I may call it such, so much professional capital I should not like the idea of making a charge for instructions. The example given by "G. T. H." would, if worked out by the method given by "Un Irlandais," give the price to be paid for such ore almost £1 16s. per ton, whereas it is really worth about 16s. 8d. per ton, according to the right method of calculating. I trust "G. T. H." will not think me discourteous in thus replying to his query.—J. ROSKELL.

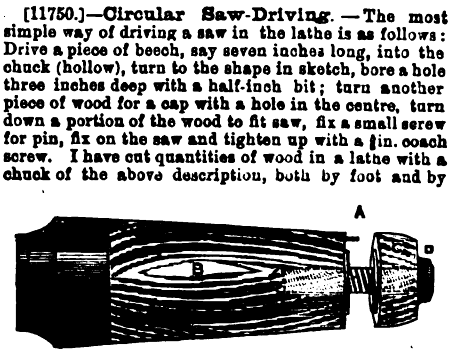
[11731.]—**Hairwash.**—If "Excelsior" will try a mixture of pure glycerine 1 part, and rosewater 4 parts, he will, I think, find that it keeps the skin of the head clean and soft, and prevents the formation of scurf. If he finds the wash too sticky he can add more rosewater. The above are the proportions used constantly by myself and many friends with perfect satisfaction.—SEPOR, St. Petersburg.



[11737.] — **Fairbairn's Ventilating Bucket.** — The peculiarity about these buckets is that they are made with one uniform curve, so as not to receive the water with such a shock; but they allow the water to transmit its force uniformly, and as a natural consequence it has more effect. I inclose drawing. A B are the buckets, and the ventilating spaces are A S. These spaces allow the buckets to empty themselves, but their greatest use is to permit the air in the buckets to escape easily. These buckets also empty themselves sooner than any other sort.—P. W. H. J.

[11749.] — **Cementing Iron in Wood.** — Take equal parts of powdered resin and dust of Bath brick. Mix, fill partially the hole in the wood, heat the screw well, and it will bed firmly.—JANNIFRED.

[11750.]—**Circular Saw-Driving.**—The most simple way of driving a saw in the lathe is as follows: Drive a piece of beech, say seven inches long, into the chuck (hollow), turn to the shape in sketch, bore a hole three inches deep with a half-inch bit; turn another piece of wood for a cap with a hole in the centre, turn down a portion of the wood to fit saw, fix a small screw for pin, fix on the saw and tighten up with a ⅝in. coach screw. I have cut quantities of wood in a lathe with a chuck of the above description, both by foot and by



steam power. Description of sketch: A, groove for the saw; B, the wood for the chuck; C, the cap; D, the coach screw partly screwed up. Do not use a 12in. saw if a 9in. or even 6in. will do the work. Make a table same as an ordinary stool, fastened to the lathe with a screw-bolt, or a table fixed in the socket of the rest.—SAMUEL SMITHER.

[11756.]—**Power of Water Wheel.**—I commence answering this query in ignorance whether the wheel is overshot, undershot, or breast. I also am not supplied with one of the dimensions of the buckets; these dimensions I shall have to suppose. If I am wrong, let "Water-Wheel" substitute the dimensions that he has omitted for mine, and if unable to work it out write again. I shall suppose the wheel to be a high-breast one. The water takes 90 seconds to traverse (100 × 3) feet, ∴ it runs $\frac{100 \times 3}{90}$ feet, or 20ft. in one second. The contents of the reservoir are 15,120ft. (cubic). The probable number of buckets on the wheel is 30, and the contents of each is (say) ½ c. ft. By tables in Molesworth's "Pocket-Book," I find that for that diameter of wheel the velocity of circumference to be 12·2ft. per second; and from that I deduce the number of revolutions to be about 15 per minute. Let T be the time that it would take to entirely empty the reservoir, then 15 × 30 × ½ c. ft. × T = 15120,

$\therefore T = \frac{15120}{15 \times 30 \times \frac{1}{2}} = 2\frac{7}{30}$, or 2¼ hours nearly.

There is a formula also given in Molesworth that, to be understood, I must give *in extenso*. Let Q be the quantity of water discharged in cubic feet per minute, h = head of water in feet, P = effective horse-power. Then $Q = \frac{881\ P}{h}$ for high-breast wheels. Then, applying it, ∴ Q = 30, P unknown, h = 6; ∴ $\frac{30 \times 15}{4} = \frac{881\ P}{6}$; ∴ $P = \frac{675}{881}$; but would practically be about 1 horse-power. Then 1 horse-power acts continuously for 2 hours, and it would be equal to ½ horse-power acting for 4 hours, or ⅓ horse-power for 6 hours, or ¼ horse-power for 8 hours. I don't exactly see the meaning of the latter portion of your query. There are three things that it may mean—viz., a sluice to let the water on the wheel, a tap or sluice to let the waste water out, or there may be a leak in the bottom, and you may want to stop it up. If you require a sluice, the best plan universally adopted is a sliding-door or shutter. The same remedy is best for the second supposition, and for the third part a leak can always be puddled up with clay.—P. W. H. J.

[11770.]—**Magnetic.**—Place the marked end (the north pole) of your magnet on the centre of compass needle, and draw it along to the end marked S on the needle. Repeat this operation about twenty times. Now place the other pole of magnet on centre of needle, and draw along to the end of needle marked N. This should be done the same number of times.—Glatton.

[11777.]—**Postage Stamps.**—Paper a room! The blue and variegated stamps arranged to form diamonds or other patterns, with the penny stamps as grounding, have a good effect. Paste on to what paperhangers sell as lining paper. The best structure to adorn will be, perhaps, that which George Colman, the younger, so neatly introduces

> And in the garden's deep recess
> He 'spied a house so little, it seem'd raised
> More for man's visits than his fix'd abode.

—Jannifred.

[11781.]—**Lathe Query.**—1. I send sketch of a tool called in the trade V screver; can be purchased at many tool shops; if far away from such procure an old file, soften the same, grind it to the shape, and cut a V groove with a small file on one side only; when dull sharpen or grind the reverse side. 2. A treading tool must be ground upon a sharp edge of the stone, moving it about so as not to flatten the same, then use a piece of Turkey stone, filed up to fit the groove, do not grind the flat side on the stone, but when sharpening the same

just touch it gently, the flat side on the stone; or a bead tool can be sharpened with a round file, but that is a makeshift way. I cut a groove ⅛in. deep in a small stone ⅛in. from the edge, the rounded projection to fit the tool; this is the best way that I know of. 3. When I wanted any ferrules I bought a piece of brass tube and cut them off with a small circular saw; the saw I used was only 3½in. in diameter. Iron ferrules I used to cut with a file, but the time occupied in so doing was so long that I found it pay better to use brass.—Samuel Smither.

[11785.]—**London Blackbeetles.**—A certain remedy is to procure some bracken, *Pteris aquilina*, or common fern, plentiful on commons, and put it down about the house at night. The blackbeetles will eat it ravenously and soon die, and their relatives will pick their bones. It is commonly used in the North of England.—Watts.

[11785.]—**London Blackbeetles.**—I know that a house terribly infested with this insect, a veritable pest wherever found, or under whatever name known, blackbeetles, cockroaches, or (Hibernicé) slocks—was clearedin a couple of weeks by a free use of chloride of lime. They were "upstairs and downstairs, and in my lady's chamber;" the chloride of lime was dusted and sprinkled plentifully, evening after evening, in the basement rooms, and on the cracks of the plaster of the walls, and corners of ceilings, turns of the staircases, &c., and in about a fortnight the whole colony had politely "skedaddled," and did not return. When once away they must be kept away by starvation—that is, not the least crumb of anything eatable is to be scattered about and allowed to remain on the floors, tables or shelves where the pests can reach them. In using chloride of lime be careful to secure everything in steel or polished iron from its fumes. The knives, door-keys, fire-irons, grates, &c., should be well oiled, and kept so while not in actual use, so long as the pungent chlorine prevails in the house; else rust will completely spoil them. Before I heard of the chloride, I once cleared an infested house by a daily and nightly crusade against the beetles, 50 to 100 being the number of our victims every twenty-four hours during one whole season; we managed to inveigle them into all sorts of traps—unwashed jamcrocks, with a little cold water in the bottom, paper bags which had held sugar, dust-pans and shovels with cucumber parings on them—set about the kitchen floor, a large pan of water left in the centre, the gas down, and all left quiet for fifteen to twenty minutes, when by a little quiet dexterity, one person going to each trap while one turned on the gas, we often destroyed twenty at a time, and could repeat this five or six times of a night.—H. O'B.

[11788.]—**Bunions.**—"Der Mond" must paint the bunion with Veratrum viride, which generally gives rapid and perfect relief. The lotion may be obtained of any homœopathic chemist.—Old Cheeseman.

[11791.]—**Colonel Stuart Wortley's Emulsion Process.**—*Collodion.*—Plain collodion 1oz., dried bromide of cadmium 7gr., nitrate of uranium 30gr., nitrate of silver 18gr. *Preservative.*—Gum arabic 60gr., sugar 60gr., pyrogallic acid 3gr., water 6oz. (this is the latest published, but the Colonel says he has discovered a better one). *Developer.*—A, carb. ammonia 64gr., water 1oz.; B, bromide of potash 24gr., water 1oz.; P, pyrogallic acid 96gr., alcohol 1oz.; M, methylated spirit; W, water. The solutions are mixed in the following proportions, and used in the following way:—Mix together 5dr. of W and 2dr. of M, and pour the mixture carefully on the exposed plate; pour it back into a developing glass, and add twenty drops of P, and pour on and off for about a minute; then add from twenty to thirty drops of A and five drops of B, and pour on again. The image should appear in about thirty seconds, and gradually acquire sufficient intensity to give good prints. If it comes too slowly, add more A; if there is any tendency to fog, add more B; fix with weak hypo. The exposure should be a little longer than for wet collodion. If "R. M. H." is inexperienced in dry plate work, he should let Colonel Wortley's process alone, and practice with tannin, collodio-albumen, beer, or coffee, by either of which first-class negatives may be obtained. If, however, he is thoroughly up to it, he may give it a trial; he must stick closely to the formulæ, see that his chemicals are perfectly pure, and be prepared to give ungrudgingly both time and patience; and, after all, if his success is no better than mine, he will lay it aside as unworkable, as no ordinary amount of development will give more than a faint image, utterly useless as a printing negative.—Auld Reekie.

[11792.]—**Compound Engine.**—There is not a fixed proportion, because it depends in some measure upon the pressure at which the steam enters and leaves the high-pressure cylinder. In an engine of 80 horse-power at the Royal Arsenal Gun Factory, at Woolwich, the diameter of the large or low-pressure cylinder is 31in., by 6ft. stroke; diameter of small or high-pressure cylinder is 15⅞in., by 4ft. 6in. stroke. Then, again, the dimensions of a 30 horse-power engine, the length of stroke of high-pressure cylinder 2ft. 9in., diameter 14½in. The length of stroke of low-pressure cylinder is 5ft., diameter 28½in. I believe that it is a general rule to have the steam-receiver of about the same capacity as the high-pressure cylinder.—P. W. H. J.

[11793.]—**Area of Chimney.**—The area will depend upon the height, because a tall narrow chimney will do the work of a broad-based one, within certain limits, not so tall. There appears, however, to be more advantage in increasing the height than the width, for a given quantity of bricks. The diameter at the base should not be less than $\frac{1}{10}$ height, as if so there would be danger of a strong wind giving it a "turn." There is a rule for steam-engine furnaces that might be applicable. Let F be the quantity of coal consumed per hour in pounds, h = height of chimney in feet, H P = indicated horse-power of engine; A = area of chimney at top in square inches. Then $A = \frac{15\ F}{\sqrt{h}} = \frac{150\ H\ P}{\sqrt{h}}$. As a general rule applicable to almost any sort of furnace, the chimney area should be from $\frac{1}{16}$ to $\frac{1}{20}$ of the firegrate surface. It might probably be $\frac{1}{25}$ with advantage in the puddling furnaces.—P. W. H. J.

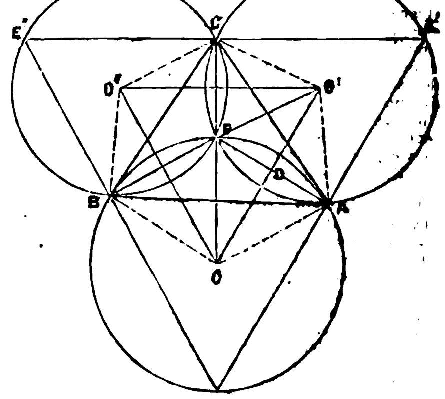
[11793.]—**Area of Chimney.**—There is no fixed area proper for a chimney in proportion to its fire-grate, for it depends upon, not the size of the grate, but the quantity of air that must pass up the flue, and the rate of the draught, both of which vary greatly, even for furnaces used for the same purpose. Some steam-engine furnaces, for example, burn coal at the rate of about four pounds a square foot of grate per hour; many burn four or five times as much, and some more than ten times as much, requiring, of course, far more air than the first. Again, some furnaces burn nearly all the oxygen of the air that passes through them; most do not burn half of it; and in many a still larger proportion of the air escapes unburnt and worse than useless, for the unburnt air carries away heat produced by that which is burnt. Far less attention has been paid than its great importance deserves to deciding what is the best proportion of air to burning fuel. If there be too little air, fuel is wasted by its imperfect combustion, especially of its carbonic oxide and other gases, and the formation of soot; if too much, heat is carried away uselessly, while if it be not sufficiently divided, and so chills the fire or flame, both forms of waste are caused. I believe "Falstaff's" safest plan will be to make his chimney flue a good deal larger than is strictly necessary (how large I cannot guess without more data), and to have some ready means (by damper or otherwise) of diminishing the width of the opening for smoke into the flue, which he can regulate by trial. As a general rule, a large rather slow burning, but not dull fire, gives more useful heat in proportion to the fuel it burns, than one burning fiercely.—Philo.

[11796.]—**Coloured Printing Inks.**—"An Amateur Printer" must first obtain the following articles: Three cans of varnish, strong, middle, and thin (it will keep any length of time); a marble slab, about 24in. by 18in.; a muller, and a palette-knife. Before beginning to mix any colour be sure that the slab, knife, and muller are perfectly clean. Suppose a nice red ink is required to print some fine work: Take a quantity of the best pale vermilion and spread it on the slab. Break it up with the muller, then add some of the middle strength varnish, and with the knife mix it up, adding very little varnish during the mixing; then give it a few minutes' rough grinding, after which scrape it all to one corner of the slab; then take a small portion at a time and grind until perfectly smooth. This is the whole process of grinding, varying slightly with coloured bill inks. A great deal depends upon the roller used in working with coloured inks, which, if possible, should never have been used for black. A roller cast hard, and quite dry on the face, will work the above red ink perfectly clean and regular; a soft roller would not take the ink at all. A little alteration is required in mixing the above ink where it is required to print with a forme containing large display lines. Use equal quantities of vermilion and orange lead, using more varnish so as to make it thinner, and therefore not so hard a roller will be required. Rose lake, crimson lake, and Indian red are used to produce the various tints of red. For a dark green, mix a bright blue, then add yellow in small quantities, prepared and mixed before from bright chrome yellow. For a light green, the yellow is first mixed and the blue added afterwards. Indigo and Prussian blue are very dark. Autwerp blue is a light and soft smooth colour, often used to lighten the above darker blues. Chinese blue makes a remarkably rich colour. In mixing these blues it is best first to grind them in water before adding the varnish, placing the slab before the fire to evaporate the water, adding the varnish in small quantities, and grinding as usual. Different shades of brown can be made by mixing red and black. For bill ink, mix first with a quantity of water, grinding with the muller; after this, take the thin varnish and keep adding a little as the grinding goes on until the ink is of the proper consistence. This process applies to all colours. For red the principal ingredient is orange lead, adding a small quantity of common vermilion. Any of the above colours and varnish can be obtained from the printing-ink manufacturers.—Zoo Andra.

[11797.]—**Preserving Moths and Butterflies.**—Merely touch the bodies of either moths or butterflies with a weak solution of chloride of mercury in alcohol by means of a soft camel's-hair brush. The spirit will dry off without injury to them.—W. J. May.

[11798.] — **Uncoiling New Wire Rope.**—"Boiler-Minder" should place the coil of wire rope on a revolving table, which can be made by a cart wheel, the axle made fast by wedging it in the ground; then put your coil on the table, loose the outside end; after you have taken the bands off the coil, then walk away with the end of the rope as the table turns round, having some one to instantly stop the table when you stop pulling the rope down.—An Old Rope Maker.

[11801.]—**Question in Trigonometry.**—Construct the triangle A B C, upon each side describe an equilateral triangle, from the centres of each equilateral triangle describe circles intersecting each other in P, which will make an angle of 120° as required. To find A P, first find the angle B A C, which will be found = 52° 2′ 37″; also the angles B A O and C A O′, each equal to 30′, which, added to BAC, make the angle O A O′ = 112° 2′ 37″; also A O′ = ½ A C × sec. 30° = 520 × sec. 30° = 600·444, and similar A O = 650·674, with A O = 650·674, A O′ = 600·444, and angle O A O′ = 112° 2′ 37″. Find the angles O O′ A and A O O′, which



will be found = 85° 31′ 41″, and 32° 25′ 42″ respectively. Then O A· × sin. O O′ A = 32° 25′ 42″ = A D = 348·919 = ½ A P, whence A P = 697·838, similar B O P = 497·462 = and B P = 602·342 are found; or with angle A P B = 120, A B = 1127, A P = 697·838. A B P = 32° 25′ 41″ is found, and B A P = 60° − 32° 25′ 41″ = 27° 34′ 19″ = sin. A P B : sin. B A P : : A B : P B = 602·342. Also C A P = B A C − B A P = 52° 2′ 37″ − 27° 34′ 19″ = 24° 28′ 18″ Then sin. 120° : sin. 24° 28′ 18″ : : 1040 : B P = 497·842. A demonstration and detail might be given, but it would take too much of your valuable space.—H. H.

[11801.]—**Question in Trigonometry.**—I presume "Numa" is quite as competent to answer as to ask this question; but as there may be, among the numerous readers of the English Mechanic, some who are not so, but who may nevertheless be interested in it, I will state for their information that they may learn how to solve it from Kerigan's "Mathematical and General Navigation Tables," Vol. I., page 623, and from various books upon trigonometry, but from none better, that I know of, than Kerigan. It is one of six cases or varieties of a general problem said to have been originally proposed by Richard Townley, Esq., and solved by Mr. John Collins, in the "Philosophical Transactions," No. 69, A.D. 1671. See pages 78 and 79 of "Elements of Plane and Spherical Trigonometry," by Dr. Gregory. The general problem is a very useful one in trigonometrical surveying, particularly in coast and harbour work. In the case put by "Numa," I believe A P = 700, B P = 600, and C P = 500.—THEODOLITE.

[11808.]—**Photographing the Sun.**—I cannot claim to be one of "our" astronomical correspondents, but I think I can give "Passyunk" a reason for his want of success in photographing the sun. I believe he has used too long exposure. We have until recently photographed the sun at this Observatory on every available occasion, and have found a much smaller slit necessary than the one named by your inquirer as employed by him. Our slit is adjustable, and the degree of aperture varied with the state of the baths, &c., between (say) 0·3in. to 0·10in.; only on very rare occasions do we open it to a greater extent. It is, of course, necessary to have a pretty strong spring to pull the frame containing the slit down very rapidly. In some of the instruments more recently constructed than the Kew heliograph, variation in the time of exposure is obtained by interchanging a series of diaphragms, having slits from one-fortieth of an inch to one-tenth of an inch, and by altering the strength of the spring, but I think such a complication is unnecessary.—G. MATHUS WHIPPLE, Kew Observatory.

[11809.]—**Cool Air in Hot Climates.**—I fear "C. H. B." will not find the machine for producing cold by first compressing air and then allowing it to expand, available as a cheap mode of cooling a house, though it is the cheapest plan I know for producing cold artificially on the large scale. This machine is used for condensing Young's paraffin, and is found cheaper than the one worked with ether. I believe the patent is for the particular form of machine in use, and do not suppose that it attempts to secure a monopoly of the employment of condensed and expanding air for obtaining cold. It is very possible that the manufacture of ice by such methods would be a paying business at such a place as Malta—*i. e.*, that it might be cheaper to import fuel to work an ice-making machine than to import ice from Etna or elsewhere; but it must, I think, be cheaper for "C. H. B." to buy ice to cool air than to work a machine to cool it. Mr. Julius Jefferies, F.R.S., the very ingenious inventor of the respirator (which has saved multitudes from death and suffering), once proposed to obtain cool air for the hospitals and barracks in parts of India by drawing from or driving through a number of dry wells the air needed for their supply. As the earth a little below the surface is at about the mean temperature of the locality, the air from wells dug in it is cooler in summer and warmer in winter than the outer air. There are several evident objections to the plan, and it has not, I believe, been tried, though it seems worth trial in places where the soil is dry and pure. Mr. Jefferies maintained that the interest of the cost for making the wells would be far less than the annual cost of other modes of obtaining coolness. The plan is described in detail at p. 177-8 of Vol. I. "Royal Commissioners' Report on the Sanitary State of the Army in India. 1863."—PHILO.

[11810.]—**Colds in the Head, &c.**—"X. Y." may cure a cold in the head, &c., by putting his feet into hot water until perspiration is caused on the forehead; drink a tumbler of cold water when in bed, and well cover himself with bedclothes.—OLD CHEESEMAN.

[11811.] — **Lime-juice and Glycerine.**— "Country Barber" should pay no attention to "Mayland," who evidently does not know anything about the subject. If carbonate of potass be added to lime-water, the lime will be thrown out of solution, and the resulting mixture will be a mess. The following formula is that of one of the largest wholesale houses in the trade:—Olive oil (bleached, if the cream be wanted white), 20oz.; lime-water, 20oz.; glycerine, 2oz.; essence of lemon, 100 drops. Of course, this is simply a lubricating preparation. If "Country Barber" wants something that will entitle him to print on his label, "One of the best preparations ever introduced for preventing the hair falling off, or becoming prematurely gray," he should add to the oil a quarter of an ounce of cantharides, shake it well occasionally, and after it has stood for 24 hours, filter through paper before adding it to the lime-water.—AULD REEKIE.

[11812.]—**Aerated Waters.**—If "Country Barber" wants aerated water in very small quantities, his simplest plan would be to get one or more of the ordinary gasogenes, perhaps the five-pint size would be the best. If they are required on a larger scale, but not large enough to keep a machine working, a coppersmith could easily construct a large enough apparatus on the gasogene principle. If the water is to be added to syrups, it does not need to be highly charged, as the sugar causes much frothing up.—AULD REEKIE.

[11818.] — **House Heating.** — "Relwot" might adapt to his purpose the plan to be carried out for heating the hall and passages of my house, where flues cannot be constructed for stoves. The fireplaces in the library, dining, and drawing rooms are supplied with sheet-iron (cast) backs: a hot-air chamber is built behind; pipes communicate with the outer air on one side, and with the hall on the other; the air enters the hot-air chamber, becomes heated, and passes into the hall. At the back of the kitchen range is a similar arrangement, though there a second iron plate is used, which is open to the scullery at the back, giving a hot surface for drying washed clothes in wet weather; the hot-air chamber between communicates with the room above, which is heated by this means. The name of the architect, who is an eminent man in his profession, would be a sufficient guarantee for the plan answering. —A CAMBRIDGE GRADUATE.

[11821.]—**Holly.**—I think "X. X." must have barked it before allowing it to season. That used by me retains its whiteness by keeping bark on till in condition to work up.—W. K.

[11824.]—**Punching Machines.**—Use cast steel, avoid upsetting the point of punch, temper down to a dark straw colour by heating thick end of punch.— KYRLE.

[11825.]—**Testing Bleaching Powder.** — The chlorine in bleaching powder (chlorinated lime: calcium chloro-hypochlorite) is easily estimated volumetrically by means of a standard solution of sodium hyposulphite. The hyposulphite solution is prepared of such a strength that a litre of it will exactly decolourise one-tenth of the atomic weight of iodine, taken in grms. To prepare it, dissolve 28 grms. of the crystallised hyposulphite in a litre of distilled water, fill at 100 c. c. burette with this solution, and drop it into an aqueous solution of 1·27 grms. of pure iodine (dissolved with the aid of about a couple of grms. of potassium iodide) until the colour of the iodine disappears. The exact point at which the reaction is complete is more readily determined if a little mucilage of starch is previously added to the iodine solution; the dark blue colour produced is not discharged as long as a trace of free iodine remains. Note the number (n) of c. c. of hyposulphite solution used, put 800 c. c. of the solution into a graduated jar, and add distilled water until it measures $\frac{800 \times 100}{n}$ cubic centimetres.

If, for example, 92 c. c. were used in the experiment, then (92 : 100 = 800 : 869 5) add water to the 800 c. c. until it measures 869·5 c. c. This forms the standard solution. To test the bleaching powder, weigh a grm. of it accurately, mix it with about a fifth of a litre of water containing excess of potassium iodide (say 8 grms.), and acidulate with hydrochloric acid; the liquid now assumes a reddish colour, or an intense blue colour if a little mucilage of starch be added. Into this carefully drop the standard solution from a burette until the colour is discharged. Probably about 85 c. c. will be required if the sample is of an average good quality. If the quantity is exactly 85 c. c. it represents 30·175 per cent. of available chlorine in the sample of bleaching powder. The theory of the process is as follows: On adding the bleaching powder to acidulated water, chlorine is liberated

$$Ca(ClO)Cl + 2HCl = CaCl_2 + H_2O + Cl_2,$$

which immediately displaces iodine from the potassium iodide

$$2KI + Cl_2 = 2KCl + I_2,$$

and when the sodium hyposulphite reacts on the solution containing free iodine, a colourless solution is formed containing sodium iodide and sodium tetrathionate

$$I_2 + 2Na_2S_2O_3 = 2NaI + Na_2S_4O_6.$$

As the two atoms of chlorine in the first equation liberate two atoms of iodine in the second, which require two molecules of hyposulphite for discoloration, it follows that two grm. atoms of chlorine—*i.e.*, (35·5 ×2=) 71 grms.—require two molecules of the hyposulphite, which are contained in 20 litres (=20,000c.c.) of the standard solution; therefore

				grm. chlorine in 1 grm.
c. c. = $2Na_2S_2O_3$	c. c. used	Cl_2		of bleaching powder
20,000	: 85	= 71	:	·30175

or 30·175 per cent.—NIL SINE LABORE.

[11825.]—**Testing Bleaching Powder.**—Obtain an alkalimeter tube, graduated to 100 parts, from the operative chemist. Take 50 grains of the sample to be tested, pound up in a mortar with a little cold water, let it settle, and pour the clear liquid into the alkalimeter. Add more water to the bleach grouts, and proceed in the same manner again until the alkalimeter is full to the graduation No. 0. If the operation is properly conducted all the chlorine in the sample will then be in solution, and transferred to the graduated tube. Next take 78 grains of protosulphate of iron reduced to a fine powder, and dried between blotting-paper, and dissolve in about 2oz. of warm water acidulated with a drop of vitriol. Then add the chlorine solution to the iron solution, until a drop of the latter ceases to produce Prussian blue when brought in contact with a drop of a strong solution of red prussiate of potass. The most convenient plan is to drop the potass solution on a white porcelain plate with a glass stirrer before commencing, in (say) 20 places. If a delicate test is required, the chlorine water should be added to the iron, drop by drop, as you approach the supposed degree of strength, and a drop of the mixture tested after each addition of chlorine. When the potass solution ceases to produce Prussian blue on contact with the iron solution, read off the number of degrees of your chlorine solution used, and divide 2,000 by the number. Add 1 for loss, and you have the answer. Thus, *e. g.*, if you have used 66-hundredths of the solution in the alkalimeter (2000 ÷ 66) + 1 = 31¼, which is the strength of the sample or the percentage of chlorine it contains.—F. C. S.

[11826.]—**Tinning and Soldering.**—Is not "A., Liverpool," doing wrong in recommending resin as a flux for soldering tin, &c. I think muriatic acid is generally used. The acid, or chloride of zinc either, may be removed from the hands by washing them in clear water before applying the soap.—W. T. M. D.

[11826.]—**Tinning and Soldering.**—The chloride of zinc causes the solder to adhere to the iron. The resin or tallow merely acts as a flux for the solder, and leaves a bright and clean surface on it. It is possible to tin the surface of iron with the aid of resin alone, but is both troublesome and difficult.—H. RULE.

[11827.]—**Sight.**—Yours is a case of myopia, which may be corrected by the use of suitable spectacles. From what you say, I do not think any other remedy is needed. The "invisible spectacles" are those whose metallic frames are so fine as to be invisible at a short distance—at least, mine were sold me under that name. The number of focus of the glasses may be ascertained from an optician or oculist.—OLD CHEESEMAN.

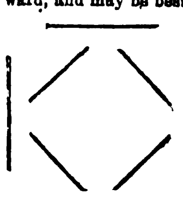
[11827.]—**Sight.**—I have in my eyes a disease called "conical cornea;" the right eye is worse than the left. It is the cornea or pupil of the eye grown too prominent or cone-shaped, causing my eyelashes to be in the way of vision. The right eye being more conical than the other, causes me to see things double. The shape of the cornea being so, it admits too much light. I wear concave spectacles, with brass plates blacked next to my eyes, the brass plates having vertical slots in them which limit the amount of light let into the eyes, but this improved the right eye but very little, the cornea in that eye being extreme conical. My right eye has been operated upon; it has had the point of the cornea taken off. As the eye is not yet recovered from the operation, I cannot tell you the result, but from present appearances I think it will be better. You ask if yours is a case of myopia, or weak sight. I should think, from what you state, it is the former, if it is not the same case as my own, as what you say about looking through a pin-hole resembles my looking through vertical slots. No doubt you find a person's face is confused unless nearly close to you, and the same with the letters across the street. Have you tried your eyes to see if they are both alike? as that is very likely the cause of your seeing things double, &c. By looking in a glass you may tell whether your eye or eyes are conical. If you live in or near London, I should advise you to go to some respectable optician, or to Guy's Hospital, and see Dr. Bader, who treated me. Should you like any further information, I shall be most happy to give you any, if you will send your private address through the MECHANIC.—T. BROWN, Shoreham, Kent.

[11831.]—**Thermometer.**—The division of the mercurial column in the stem of a thermometer is generally caused by the presence of a small quantity of air in the tube which has been insufficiently boiled before sealing off, and the thermometer having been shaken the mercury and air have become mixed. If "A. G's." instrument has a tolerably wide bore he may succeed in getting his column whole again by repeatedly knocking the bulb on a table, so as to jerk the air up to the top again; if, however, it is a fine tube he must immerse the bulb in a freezing mixture until all the mercury has contracted into it; on removing it vertically the air will ascend to the top of the tube, and his thermometer will be all right.—G. MATHUS WHIPPLE, Kew Observatory.

[11832.] — **Paper-hanging, Sizing, &c.** — Better let the walls get dry; after rub down with coarse glass-paper, on cork or small block of wood; use no umber, but well size the walls (dilute with hot water) when dry proceed to paper. Do not size the stone jambs, which is the cause of the paint chipping off. I should give two coats all turps paint. Regular mixing quantity. Extra boiled oil, which will give the required gloss.—W. K.

[11833.]—**Smoky Chimney.**—Try a galvanised sheet-iron pipe 2ft. higher than ridge.—W. T. M. D.

[11833.] — **Smoky Chimney.** — The smoke of "F. R.'s" chimney appears to be beaten down by a wave of wind passing over the higher roof ridge to the windward, and may be best guarded against by one of what used to be called Day's wind guards, the patent for which must have expired long ago. It consists of four sheets of iron set upright in a square, but not meeting at the corners, with four other sheets set also in a square, each opposite to a corner of the inner square, the opening at top being closed with an octagonal plate to stop any downward current. Whichever way the wind blows it is stopped from blowing into the chimney, while that which blows between the plates tends to rarefy the air in the chimney and help its draught.—PHILO.



[11834.]—**Springs.**—I have been a gun-lock filer all my life. If your steel is of a sharp nature do not heat it too hot; if of a soft nature, to a good heat. Cool it in water. Warm your spring over the fire just to dry the water, and then rub a candle over it. Put it over the fire, the strong part first, and the blaze will gradually run off. Allow it to cool of itself. You will find this all you will require.—HALIFAX.

[11835.]—**Arsenic in Wall Papers.**—Metallic zinc and dilute sulphuric acid are mixed in a bottle fitted with a glass tube drawn to a fine point at one end so as to form a jet, and fixed tightly into a bottle with a cork. Hydrogen will escape from the mixture, and after this has continued for a minute or so, the substance suspected to contain arsenic is to be added, and the cork and tube fitted tightly into the bottle. The gas is allowed to escape again for a minute or two and then lighted (it is necessary to allow the gas to escape, as, if there is any air mixed with it, an explosion would occur on lighting it), and a piece of white china held close over the flame, when, if arsenic is present, a bright black spot will condense on the china, like smoke. This is metallic arsenic. This test is based on the fact that nascent hydrogen in the presence of arsenic is converted into arseniuretted hydrogen, the burning of which consumes only the hydrogen, thereby setting the arsenic free. The ordinary commercial zinc and sulphuric acid both contain arsenic, so "G. C. C." had better procure them from some chemist.—F. GREENWAY.

[11835.] — **Arsenic in Wall Papers.** — The presence of arsenic in green wall paper can easily be detected by either of the following methods:—Take a test tube furnished with a cork, into which a glass tube is inserted. Scrape from the wall a little of the green powder, and place this with some clean granulated zinc in the test tube, add a solution of one part sulphuric acid to eight of water, when, if arsenic be present, arseniuretted hydrogen will be given off. On burning the gas arsenic is deposited in the metallic state upon a piece of cold porcelain held in the flame. Many compounds of arsenic heated on charcoal in the inner blowpipe flame give a garlic odour of arsenic.—E. B. H.

[11836.]—**Voicing Organ Pipes.**—It is impossible to give a clear explanation of voicing. It is the most intricate department of organ building. There are a few rules to be followed out, but the observance of these goes but a little way to producing fine quality of tone. To be a good voicer, one must have genius, coupled with experience. Zinc is the wrong metal for pipes; a fine quality of tone cannot be got out of pipes made of it, although some builders use this metal for large pipes, as it is cheaper than organ metal. If "Aleph" wishes to have a nice toned organ, he must have his pipes made of organ metal, block tin and lead. If "Aleph" can afford it, he should buy some metal pipes ready voiced from an organ builder. It would be better to have one good stop than three with a bad tone. If "Aleph" will publish his address I shall be pleased to send him more particulars.—PNEUMATIC LEVER.

[11839.]—**Plates Chemically Clean.**—In solar photography freedom from photographic defects in the negatives is a *sine qua non*, spotting by hand and touching up being, of course, out of the question. We have, therefore, had considerable experience in various plate cleaning processes, and I can speak as to the efficacy of potassic cyanide as a cleansing agent. We have always employed it as a solution made into a thin paste with Tripoli, and having well washed the plates after rubbing with it, have not found our bath deteriorated by its use. There is one drawback to this process—the time required for cleaning a plate is about eight to ten minutes, and so it would hardly do for quick work.—G. MATHUS WHIPPLE, Kew Observatory.

[11840]—**Whooping Cough, &c.**—This complaint is classed amongst the zymotic order of diseases by the Registrar-General, and, like its congeners, small-pox, typhoid fever, &c., must run its course, for there is no known successful method of cure adopted by medical practitioners. On this subject "T. C. H." may possibly with some advantage consult a few remarks in Vol. XIII., p. 413, letter 2259. The treatment there prescribed is based upon what are believed to be rational views; has never failed, within my experience, in zymotic complaints in general in preventing them, and has even cured a few cases of whooping cough; although this latter part is beyond my province as a sanitarian, and encroaches upon the duties of the physician.—W. R.

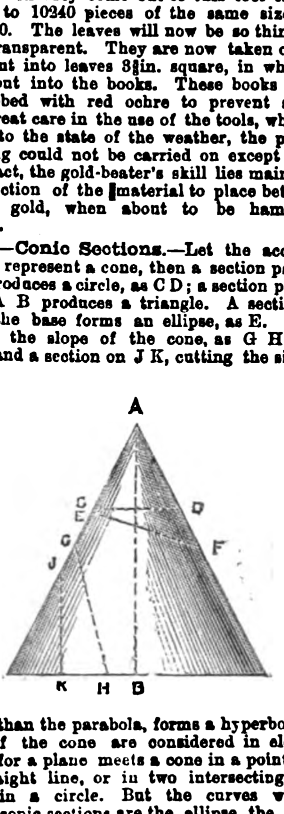
[11840.]—**Whooping Cough, &c.**—There is no ascertained specific that will cure whooping cough, and the medical profession is divided as to what causes it. Cochineal in one drop doses in water three times a day will give great relief. Proved.—WATTS.

[11840.]—**Whooping Cough, &c.**—If "T. C. H." lives in a town where there are some gas-works, and will take the person who is suffering from whooping cough into the purifying room connected with the gas-works during the time the men are employed taking out the lime, with which the gas has been purified, the person will derive an immense amount of benefit from doing so even for once. The time generally taken to effect a cure is about three times, though some have to go four times. In its pure state, the lime is slaked, and spread in layers about 2in. or 3in. thick on iron grates, and the gas allowed to force its passage through them for a certain time. When the covers of the purifiers are taken off, the lime is found to be caked; the impurities which are contained in the gas turn it to a green cast; it also gives off a very peculiar, and to those who are not used to it, a very sickening smell, which appears to have a very beneficial effect upon those who are suffering from whooping cough. At the first it irritates the patients very much, but after a time it seems to soothe them instead. If a child, its head must be held over the lime, so as to inhale some of the gas, as long as it can bear it. If "T. C. H." takes something with him to hold some lime, he can take some home for the patient to smell at occasionally during the day; he will find it will repay all his trouble.—THORP.

[11846.]—**Gold Beating.**—The gold is prepared by melting in a plumbago crucible, and then cast into ingots, forged, and passed between rollers until it assumes the shape of a long ribbon, and as thin as ordinary writing paper; each of these ribbons is cut into a number of small pieces, and forged upon the anvil. These small square pieces weigh about six grains and three-tenths each, and are about the 760th part of an inch thick; they are next annealed, and interleaved with vellum about 4in. square; about twenty vellum leaves are placed on the outside; the whole is then placed in a case of parchment, over which is drawn another similar case, so as to keep the packet tight and close on all sides. It is next laid on a smooth block of marble or metal, and the workman begins beating with a round-faced hammer weighing 16lb.; the packet is turned over occasionally, and the beating continued until the gold is extended to nearly the size of the vellum leaves. The packet is then taken to pieces, and each piece of gold is divided into four, with a steel knife having a smooth but not very acute edge. These pieces are next interlaid with pieces of animal membrane, from the intestines of the ox, of the same dimensions and in the same manner as the vellum. The beating is continued, but with a hammer weighing only 12lb., till the gold is brought to the dimensions of the interleaved membrane. It is now again divided into four, by means of a piece of cane brought to a fine edge, the leaves being by this time so thin that any accidental moisture condensing on an iron blade would cause them to adhere to it. The leaves are next divided into three equal portions, and interleaved with membrane as before, and beaten with the finishing hammer, weighing only 10lb. The packets are now taken to pieces with the aid of a cane instrument and the breath, are laid flat on a leather cushion, and cut into squares one by one, by a small square frame of cane made the exact size; and are lastly laid in books of twenty-five leaves each, the paper of which is first smoothed and rubbed with red chalk to prevent the leaves adhering. By the weight and measure of the best leaf gold it is found that one grain can be made to cover 56¾ square inches, and from the specific gravity of the metal, together with this admeasurement, it follows that the leaf itself is 282,000th part of an inch thick. This, however, is not the extensibility of the metal, for by computing the surface covered in silver gilt wire, and the quality of gold used, it is found to be only one-twelfth that of gold leaf, or 3,384,000th part of an inch in thickness; nevertheless, it is so perfect as to exhibit no cracks when viewed under the microscope. See Luke Hebert's "Mechanical Encyclopædia."—W. H. HEY.

[11846.]—**Gold Beating.**—The gold-beater first obtains a quantity of gold from the refiners, then mixes it with the requisite quantity of alloy; too much alloy will, however, completely spoil the colour. He then proceeds to melt it up in a small crucible by subjecting it to a very intense heat. When melted it is poured into a mould, and produces an ingot of 1½in. by ¾in. broad by ¾in. long. It is now rolled through rollers, gradually decreasing in size until it is a ribbon of more than six yards long, and three quarters of a yard wide. Next it is placed in the annealing furnace, and heated to a low red heat to soften it. It is then cut into 1½in. squares, weighing between six and seven grains. Each square is now placed between sheets of vellum, and the whole put into a sort of leather bag. They are not handled by the hands, but with tongs tipped with ivory. This bag is next beaten with a hammer weighing about 16lb. It is hammered until the little gold-leaves of 1½in. square become 4in. square. These leaves are again cut up. At this stage of the process the gold is what is called dentist's gold. The 640 pieces into which the 160 had been beaten are now in another bag placed between leaves of gold-beater's skin, and again beaten. When they come out of this tool the leaves are equal to 10240 pieces of the same size as the original 160. The leaves will now be so thin as to be perfectly transparent. They are now taken out of the tool and cut into leaves 3⅝in. square, in which state they are put into the books. These books have the leaves rubbed with red ochre to prevent adhesion. Without great care in the use of the tools, which vary according to the state of the weather, the process of gold-beating could not be carried on except at great loss. In fact, the gold-beater's skill lies mainly in the proper selection of the material to place between the sheets of gold, when about to be hammered.—P. W. H. J.

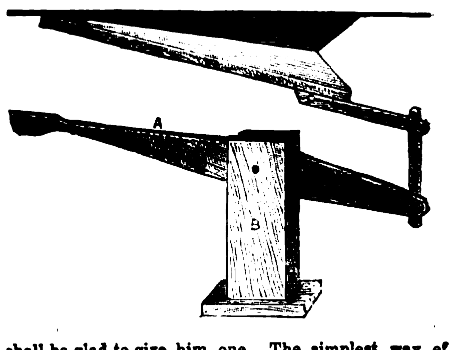
[11848.]—**Conic Sections.**—Let the accompanying figure represent a cone, then a section parallel to the base produces a circle, as C D; a section parallel to the axis A B produces a triangle. A section at an angle to the base forms an ellipse, as E. A section parallel to the slope of the cone, as G H, forms a parabola, and a section on J K, cutting the side at an



angle less than the parabola, forms a hyperbola. Some sections of the cone are considered in elementary geometry, for a plane meets a cone in a point, or in a single straight line, or in two intersecting straight lines, or in a circle. But the curves which are peculiarly conic sections are the ellipse, the parabola, and the hyperbola.—P. W. H. J.

[11850.]—**Pitches of Screws.**—The pitch of a screw should be about its diameter; 28ft. is a very coarse pitch for an 18ft. screw; however, the practical results obtained from fine-pitched screws running at a high velocity as compared with rather coarsely-pitched screws running at a lower velocity have not been very different. I think 20ft. quite too much for a 10ft. screw; where two small screws are used instead of a large one their combined area should not be so great, as they work at a greater depth in the water, and the water in escaping in the line of least resistance to the surface has a greater weight of superincumbent water to disturb. Bourne thinks well of twin-screws (his work on the screw-propeller is rather expensive—3 guineas, but if a reading of it can be obtained it gives a great deal of information). You do not say how much water the first ship draws. I think 10ft. too shallow a draught for the second. The resistance of well-built vessels, according to Bourne, depends mainly on fluid friction, principally the rubbing of the bottom against the water, and vessels of very shallow draught for their tonnage having so large a surface do not do well; also, if your first vessel has 18ft. draught of water, and (say) 9ft. over the screw shaft, your second would have only 5ft. of water over the shafts, and the water would be more likely to be churned. I am not a practical shipbuilder, however, but I should not recommend the plan. I give my opinion for what it is worth.—PHILANTHROPIST.

[11853.] — **Pedal Harmonium.** — What does "G. J. C." mean by putting reeds on to pipes? Is he thinking of the free reeds with tubes used in some organs? If so, the tubes are quite unnecessary in a harmonium. The ordinary harmonium reed of 16ft. pitch will do very well for a pedal stop. If "G. J. C." wants a plan of the pedals, action, and soundboard, I



shall be glad to give him one. The simplest way of applying a foot blower to the feeder is as under. This action should be made of hard wood for strength. The lever marked A must be placed to come to the proper position for the foot. It must also be centred so as to get the desired length of stroke. The fulcrum marked B should be screwed down to the floor, or be fixed firmly to the case.—PNEUMATIC LEVER.

[11856.]—**Military Examination.**—Both pure and applied mathematics are required, but the paper is not a very stiff one, except for the Royal Engineers and Artillery. In modern languages either French or German; I believe it is not imperative to pass in both, but certainly in one of them. It is necessary to serve as a sub-lieutenant for at least twelve months with one of the Queen's regiments, and then to pass a military examination, before being eligible for a subaltern's commission.—ARTILLERY CAPTAIN.

[11860].—**Magnetic Machine.**—I really cannot take on myself the construction or device of such an apparatus. For generation of oxygen on a large scale, the manganite of soda process would probably be much cheaper, and for a small scale even the chlorate of potass. A magnetic machine for the purpose would require steam power to drive, and be costly.—SIGMA.

[11875.]—**Spectrum Colours.**—There are no pure pigments. It is impossible to obtain a pure white by the use of the colour top.—H. P. H.

[11898.]—**Tempering Cast Steel Chisels.**—Bring them down to a blue, then immerse in cold water.—W. T. M. D.

[11898.]—**Tempering Cast Steel Chisels.**—A word of advice as respects making tools out of files. Unless all the teeth marks be well ground off before hammering the file, any chisel made will be worthless as when the teeth are hammered in they form cracks. Once more, as to tempering, do not heat during any part of the manipulation above blood red. Dip in water with the chill off, brighten on stone, and dip again when blue appears.—A., Liverpool.

[11900.]—**Electro Plating.**—One or two Smee cells will suit best, and all further apparatus would be a jar or two of the required sizes. I think Watts' "Electro-Metallurgy," published in Weale's series, about the best small manual. I hope shortly to be able to commence my own papers on the subject.—SIGMA.

[11918.]—**Fumes from Gasworks.**—These are mainly impure gas itself escaping and let off in opening purifiers, retorts, &c., also from the oxide of iron purifying material. They contain, therefore, excess of sulphur compounds, and also many hydrocarbons, much of which will be washed out in rainy weather while traversing a quarter of a mile of air. It would be a puzzler to give names to all the ingredients of these "perfumes," but it is the sulphur and ammonia compounds which give them their principal pungency.—SIGMA.

[11919.]—**Trigonometrical.**—The following is the solution "Thetamu" requires:—

$$\text{Sec. } 2A = \frac{1}{\cos. 2A} = \frac{\cos.^2 A + \sin.^2 A}{\cos.^2 A - \sin.^2 A},$$

$$= \frac{1 + \tan^2 A}{1 - \tan.^2 A},$$

$$= \frac{2 \tan. A + 1 - 2 \tan. A + \tan.^2 A}{1 - \tan.^2 A},$$

$$= \frac{2 \tan. A}{1 - \tan.^2 A} + \frac{(1 - \tan. A)^2}{1 - \tan.^2 A},$$

$$= \frac{2 \tan. A}{1 - \tan.^2 A} + \frac{1 - \tan. A}{1 + \tan. A},$$

$$= \tan. 2A + \tan. (45^\circ - A).$$

For A substitute $\frac{A}{2}$. Then sec. A = tan. A + tan. $\frac{90 - A}{2}$. *Q. E. D.*—F. B.

[11919.]—**Trigonometrical.**—Required to prove that sec. A = tan. A + tan. $\frac{90^\circ - A}{2}$.

$$\text{2nd side} = \frac{\sin. A}{\cos. A} + \frac{1 - \tan. \frac{A}{2}}{1 + \sin. \frac{A}{2}},$$

$$= \frac{\sin. A}{\cos. A} + \frac{\cos. \frac{A}{2} - \sin. \frac{A}{2}}{\cos. \frac{A}{2} + \sin. \frac{A}{2}},$$

$$= \frac{\sin. A}{\cos. A} + \frac{\cos.^2 \frac{A}{2} + \sin.^2 \frac{A}{2} - 2 \sin. \frac{A}{2}. \cos. \frac{A}{2}}{\cos.^2 \frac{A}{2} - \sin.^2 \frac{A}{2}},$$

$$= \frac{\sin. A}{\cos. A} + \frac{1 - \sin. A}{\cos. A},$$

$$= \frac{1}{\cos. A} = \text{sec. } A. \quad \textit{Q. E. D.}\text{—R. G. G.}$$

[11919.]—**Trigonometrical.**—W. R. B., W. Busk, Coriolanus, W. P. Wedgewood, and J. H. T. have also answered this query.

[11920.]—**To "Jack of All Trades."**—I apologise for answering this question, but have a fellow-feeling with our suffering friend, and sincerely hope he will get better. It is a case of over-taxed brain, and nothing but time will cure it, and a proper attention to the state of the blood. Plenty of cold water applied to the head, and rubbing with coarse towels. Drink a glass of cold water the first thing on rising; it is often better than an aperient taken the night before. Always walk four miles a day in pleasant places, or in pleasant company. Either find some new thing to occupy the mind, or rout up some old game of youthful experience, such as draughts, &c., with a chatty friend; in short try and be young again, and let the troubles alone, it's the best way, for they are very wilful, and don't care a button for us. Please return their compliment; get out of the doctor's hands as soon as possible. Never give way to extremes, and you will gradually get better. I had four years of it, and found the spring and autumn the worst times.—FIDDLER.

[11928.]—**Microscope.**—The later volumes of the ENGLISH MECHANIC contain several articles on the choice and use of the microscope, but as "A Canadian Subscriber" may not be able to procure these volumes except at great cost, I may, perhaps, be allowed to repeat in brief what I have elsewhere said at considerable length. The essentials of a microscope in its mechanical arrangements are steadiness, freedom from complexity, perfection of workmanship, and consequent smoothness of action of the moving portions. The optical requirements are clearness of definition, and freedom from colour. The powers will vary from 10 or 20 diameters up to 10,000 diameters with the objective used. The 2in., 1in., ½in., ¼in., and ⅛in., form a very good working series with oculars A B D. The price will vary from £5 5s. to £40. With the objectives named, a good monocular stand and various accessories should be obtained for the latter sum. The price of a really good and useful monocular stand only would be £10 or £12; the stage having concentric rotation, but not mechanical arrangements for moving the object. I should not myself advise the purchase of a larger stand than this, which, with a series of good working objectives (first-class quality), polariscope, &c., would cost from £20 to £25, and serve the purchaser for the rest of his life. What is known as the Jackson Lister stand is the best. It is not an easy task to give maker's names; to give all would occupy too much space; to give a few is invidious. Every worker has his own fancy and leaning towards a particular class of instrument, and is favourably disposed towards the optician from whom he has purchased it, or from whom he has received assistance in carrying out his crotchets. Messrs. Beck, Powell and Lealand, Ross, are of world-wide fame; Messrs. Swift, Crouch, Wheeler, Ladd, are well-known firms; but these by no means represent the quarter of our good and trustworthy opticians. My old, but very ugly, friend, Beck's "Universal," is the one I have chiefly used. My "first-class" one is by J. E. Winspear, of Hull, an optician whom it is my pleasurable duty to mention, on account of his great courtesy and assistance in various optical matters. "Canada" might safely trust himself to Mr. Winspear, or any other of our leading opticians. Prices and descriptions of particular instruments could only appear as an advertisement.—H. P. H.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last J. Roskell has answered 10185, 10344; W. H. Hey, 11349; "T. W. M. J.," 11355, 11420; "H. B. E.," 11395, 11397; "H. P. H.," 11458.

QUERIES.

[11930.]—**Shape of Pitch Polisher, Figure of Speculum, &c.**—Will Mr. Purkiss kindly say if, when the pitch polisher is used for spherical polishing, he uses it with the marginal facets circular, or does he cut off the circular portion in order that each facet may be square? Likewise, in grinding, does he allow the glass disc slightly to exceed the size of the iron tool? I ask these questions because I experience some difficulty in figuring the marginal inch of my mirrors, consequently, I have re-read his instructions in Vol. X., and find that he there recommends, first, to prepare the glass disc, then the wooden model of the iron tool, and this model is to be exactly the same size as the glass disc. Now, an iron disc cast from this model, would be, when cold, somewhat smaller than the model. What I wish to know is, does Mr. Purkiss use it so? Again, will Mr. Purkiss, "F. R. A. S.," or any other of "our" readers well versed in such matters as the following, say what figure must a mirror be that shows an artificial star with a round disc, surrounded with two or three rings in their proper order, and then outside of this again, with a ring consisting of something like a score of wings of light? Is it marginal flatness?—OPTICAL BRICKLAYER.

[11931.]—**Hydraulic Indicator.**—Will some correspondent give me information respecting this instrument, how attached to a press, and what the action?—SEPOR (St. Petersburg).

[11932.]—**Organ Bellows.**—I have a small organ of seven stops, with two manuals and pedal. Each of the manuals has a separate bellows and reservoir, the two parts of the organ having been got at different times. Will some of our organ building friends tell me if it would be advisable to join the two reservoirs by a wind trunk, and so do away with one of the blowing handles? One bellows is considerably larger than the other, and would, I think, easily supply both reservoirs.—W. M. S.

[11933.]—**Botanical Query.**—Will any one tell me of a book by which I could study botany in the Bengal Presidency?—LINDSAY.

[11934.]—**Case for Violoncello.**—Will some kind reader give me some wrinkles for making a case for a violoncello—one strong for travelling, and to contain, besides the instrument, all that a player would want, at a distance from home? I know how nicely and completely violin cases are made now, but those for violoncellos are different. I do not know how to make or arrange the pockets, and to make the most of the space. Give some hints as to this, the thickness of the wood, the best material for lining, how padded, the proper place for bows, and such other information as will be useful. If a woodcut of the interior could be furnished it would be of much value. A paper by a competent hand, on cases for musical instruments, wind and string, now that amateur musicians are so numerous, would be of service to many.—R. E.

[11935.]—**Lacquer for Brasswork of Electrical Machines.**—With all the letters on electricity, and on the manufacture of plate and other machines, I do not think there is any mention of a lacquer or varnish for the brasswork, such as conductors. I have been making one, a large plate machine, but after finishing up the brasswork it soon gets dull and unsightly. Would it be as good a conductor if covered with a thin coat of lacquer?—G. H.

[11936.]—**Bachhoffner's Lamp.**—Can any of our numerous correspondents give particulars respecting Bachhoffner's "Domestic Safety Paraffin Lamp," its peculiarities and construction?—ULTRAMARINE.

[11937.]—**Filtering Water.**—Having the water supply of a mansion derived from the surface drainage from a clay soil it is much coloured. Can I by any filtering process discharge or precipitate the yellow colouring matter? The water comes from pond in earthenware pipe to cemented tank 10ft. square; thence by 1in. lead pipe to house, where a small charcoal filter in connection with cistern has hardly produced any effect on colour.—JANNIFRED.

[11938.]—**Carpenter's Bench and Tool Chest.**—Will some reader tell me what are the proper adjuncts and fittings of a carpenter's bench? Also the best way of fitting up a carpenter's or cabinet-maker's chest, so as to contain all the tools required for general work and so as to economise space as much as possible? I believe these questions were asked two or three years ago, but no replies were forthcoming.—R. E.

[11939.]—**Pantograph.—Wood Engraving.**—Will any reader be good enough to tell me how to make a pantograph for copying and reducing drawings? Also what books are best and most useful to learn drawing as applied to wood engraving? Any hints upon wood engraving, both as a pastime and profession, would oblige—ZOO ANDRA.

[11940.]—**Waterglass as a Preservative of Natural History Subjects.**—Will some one kindly tell me if waterglass can be used as a preservative for natural history subjects, and if they have tried it? I saw an account in the *Art Journal* two years ago, I think, of a method of applying the waterglass in a spray to moths and butterflies. Would there not be great waste of the glass by this means? Also, where can I get the waterglass, as I know nothing whatever about it? An answer will greatly oblige—G. W. C. H.

[11941.]—**Chemical Experiments.**—Would any of your chemical students who have successfully performed the following experiments, give me the necessary details including weights of materials employed. (1) Preparation of hydrogen by the action of zinc on caustic potash. (2) Preparation of ozone by acting on potassic permanganate by strong sulphuric acid. (3) Preparation of a solution of ammonic molybdate (for testing the presence of phosphoric acid). I have tried various methods proposed by various authors, but have been unsuccessful.—NIL DESPERANDUM.

[11942.]—**Steam Velocipede.**—Having a wish to construct a steam velocipede to carry two persons, would "Jack of All Trades" or some kind subscriber give me the following information?—The length of stroke and diameter of a pair of oscillating cylinders, with size of boiler; also the simplest mode of admitting and exhausting the steam, whether three or four wheels is best, and, if on three wheels, can it be steered with the third wheel behind? A sketch would greatly oblige—A SUBSCRIBER.

[11943.]—**Worms for Fishing.**—I remember that once there was given in the ENGLISH MECHANIC a way to prepare worms for baiting, but I cannot find it, in spite of hours of careful searching. Would any kind reader repeat it, or tell me where to find it?—BARBAROS.

[11944.]—**Fishing Rod.**—Would some one kindly tell me how to make a fishing-rod that can be turned into a walking-stick, what material to be used, and how to manage the joints? Length about 10ft. to 12ft.—BARBAROS.

[11945.]—**Leaky Tap.**—Is there any method of stopping a large brass water tap from leaking, beside grinding? This process has been tried twice, and cured for a while, but the too frequent repetition of it will lower the plug until it becomes useless. What is the best stuff to use for grinding taps?—W. T. M. D.

[11946.]—**Imitation Bronze.**—Will any of "our" readers inform me how to make an imitation bronze, the same as used by gas-fitting manufacturers? I have heard they coat the brasswork with corrosive sublimate dissolved in hydrochloric acid. If this is the case, is it put on with a brush, or how?—A. R. F.

[11947.]—**Power of Water Wheel.**—Required, the horse-power of an overshot water-wheel, 3ft. 6in. in diameter, and 6ft. wide. The weir to be close to the buckets, and its stream to be 1in. deep and 6ft. wide. Also, what must be the diameter of two pipes to supply the weir with that quantity of water?—N. K. R.

[11948.]—**A Bad Sleeper.**—After sleeping two or three hours at night I am woke up by an excessively dry mouth and tongue, and an exceedingly bitter taste. I eat but very light suppers. Age 56. Can any one tell me of a remedy?—N. K. R.

[11949.]—**Doctors' Commons.**—Will any subscriber kindly inform me the cheapest and best plan of obtaining a copy of my father's aunt's will without the expense of a journey from Scotland to London, or can any other than legal gentlemen obtain a copy by a visit to Doctors' Commons? Any advice on this subject will greatly oblige—AUSPICIOUS.

[11950.]—**Sewing Machine Difficulty.**—A few days ago I took to pieces a "Defiance" sewing-machine by Judkins, and, unfortunately, failed to notice the relative position of the shuttle to the needle-bar. Will "Jack of All Trades," or any one able, kindly tell me where the shuttle should be when the eye of the needle is on a level with the cloth plate? Needle bar and shuttle are actuated by separate spindles, and each spindle has a small toothed wheel at one end, both being worked by a larger wheel placed between them. It is the removal of this large wheel that has occasioned my difficulty.—LOVATT.

[11951.] — **Photography.** — Will some practical photographer kindly inform an amateur as to the best and most efficient way of washing prints, say a dozen or more at a time, size 6½in. × 4¼in.? I have no water laid on in the house, but have a pump handy. State length of time necessary to complete the operation.—CAMERA.

[11952.]—**Nettle and Ivy Leaves.**—Can any of "our" chemical contributors of the ENGLISH MECHANIC inform me what are the chemical and medicinal properties of the common nettle—also of ivy leaves—and what percentage of tannin and potash they contain?—INQUIRER.

[11953.]—**Chemistry.**—Among your correspondents are many able chemists, and among your readers there must be many who, like myself, acquired a few years ago, a more or less fair acquaintance with chemistry and the old system of notation. Will any one of the former do us the favour to give a short explanation of the changes that have taken place, so that in reading a chemical paper, all our previous knowledge may not be lost? At present I find it very difficult to recognise even old familiar friends.—PATERFAMILIAS.

[11954.]—**Harmonium Stops.**—I am a new subscriber to your magazine, and beg to put myself among the list of inquirers. I have a small harmonium without any stops, and only one row of vibrators, and knowing that the expression stop in larger harmoniums is merely a mechanical affair, I would like, if any of your numerous readers could inform me, how to apply it to my small instrument, or any means whereby I can make some variation in the tone, louder or softer at will, or if such a thing has been explained in any former number, please state which. Also if tremolo stop could be attached to such an instrument.—B SHARP.

[11955.]—**Traverse Gear for Engines.**—Would any kind reader of the MECHANIC be kind enough to give me an idea of the newest and most improved style of traverse gear for beetling engines?—AN INQUIRER.

[11956.]—**Pill Making for the Million.**—Will any of your talented readers suggest a way by which pills could be made in large quantities, the usual methods being anything but satisfactory, considering the high price of the machines? The confectioners, I understand, are able to produce small globular sweets, in form resembling pills, in considerable quantities; therefore, I think a modification of their process might be what I require. Perhaps some of your readers can assist me. —ACETUM.

[11957.]—**Straightening Band Saws.**—Can any of "our" practical friends inform me of a good method of straightening band saws? In my business, using as many as thirty saws in a week, or at least having them in use, I find sometimes several twisted, and, therefore, useless, unless broken and rebrazed, or sometimes hammered. Regarding the setting of band saws, would the following be a practical system of setting saws? First using an ordinary saw set, and afterwards drawing a piece of steel, with a groove cut the width of the set required, drawing the same completely round the saw. The usual mode of setting saws with the hammer oftentimes cracks the saw, thereby causing a breakage.—SAMUEL SMITHER.

[11958.]—**Level of Railway Curve.**—A locomotive engine weighing 10 tons, passes round a curve 560 yards radius, at the rate of 40 miles per hour. What should be the difference of level between the inner and outer rail to prevent accident? Space between rails, 4ft. 9in.—PUPIL.

[11959.]—**Vandyke Brown.**—Of what is this pigment made, and what is the method of preparation?—RECIPROCITY.

[11960.]—**A Brewer's Query.**—Will some of your chemical friends kindly answer me the following question? I am a maltster and brewer, and have my brewing copper very clean and bright. I find that in boiling with some hops it turns the copper very black at the top, and with other hops it does not. I should like to know the reason why?—BREWER.

[11961.]—**The Leclanche Cell.**—I wish to ask a question with regard to this much talked of cell. I have had them in use for ringing bells, &c., for many months, and like them better than any other form of cell I have tried for this purpose; when, however, there has been a continuous use of the current for (say) two months, I often find the zincs and porous pots covered with an almost insoluble white substance, and shall be greatly obliged if "Sigma," or some other brother reader who has had considerable experience, will kindly enlighten me and others as to the cause of this phenomenon, and the nature of the incrusting substance. According to my experience, the Lelanché cell is the least subject to local action or waste of material during the incompletion of the circuit of any other form. Will "Sigma" say if he knows of any other equal to the Leclanché in this important respect, also whether the zincs are amalgamated or not?—HERCULES.

[11962.]—**Telegraphy in the United States.**—Will you, or one of your numerous correspondents, favour me with the names of the principal telegraph companies of the United States, and their respective head-quarters? Information as to their relative commercial success will also be esteemed.—MANIPULATOR.

[11963.]—**Brass Springs.**—I am constructing a commutator for a telegraph, in which I require brass springs; I find the brass bends without springing back, how am I to get over this difficulty? Can the brass be tempered like steel?—GLATTON.

[11964.]—**To Prevent Paper Sticking to Silk after being Printed with Metal Leaf.**—Would some kind reader tell me what will prevent paper from sticking to silk after being printed or stamped with metal leaf? In printing or stamping silk for felt hats, we are obliged to put pieces of paper under every one, and the silk being so fine, the mixture of powdered resin and shellac runs through and makes the paper stick fast to the silk, and causes the work to look very bad; and if we use stiff paper, when we pull it off it breaks the stamp. We have rubbed the paper with French chalk, but without any effect. The mixture would not do to be made any weaker. The above is done with a hot brass block.—J. B. SHARPLEY.

[11965.]—**To Blacken Brass.**—Could any of your correspondents tell me how to blacken brass like the tubes of French opera-glasses?—INVICTUS.

[11966.]—**Dandelion Roots.**—Will some of "our" friends kindly inform me when the dandelion root has its best properties, and the proper time to get them up, so has to make wine of them? also, which has the advantage in its virtues, the flower or root?—LEICESTER.

[11967.]—**Emigration to San Francisco.**—If any brother reader can answer the following I should be most grateful. (1) Can a mechanic do better as regards saving money at San Francisco than he can in England? (2) I am aware that the wages are high, but I suppose the necessaries of life are so too. (3) Would it be advisable to take a good stock of clothing? (4) What is its distance from New York by rail, and how long does it take to travel it? (5) How do passengers manage, as regards provisions, &c.? (6) Where can I obtain a map and book giving information of towns, population, &c., of California? (7) Is San Francisco considered healthy? (8) Is there any other town preferable to it in the above State? (9) I noticed in a steamship company's circular this item: "Dogs not taken on any terms." Is this the case with all companies? (10) What is the rate of income-tax in the United States?—LIBRA.

[11968.]—**Dog with Weak Sight.**—I have a young dog near-sighted; I am afraid he will turn blind. Can any one tell me a remedy?—LIBRA.

[11969.]—**Cochineal.**—Can the cochineal be reared in this country?—WM. HAMILTON HEY.

[11970.]—**Water Regulator.**—Will some one give me a hint about making the above? My coil is too strong at present for taking shocks, giving 0·2 of an inch spark in air. How long should the glass tube be to give a moderate shock? Any information will oblige—GLATTON.

[11971.]—**Calcined Ironstone.**—Will any of "our" kind readers give a description of the calcining of ironstone in kilns, and if it is more profitable to calcine in kilns than in the open air?—LOVE.

[11972.]—**Hot Soldering Iron.**—I want a small soldering iron for soldering small articles about the size of match-boxes; I have no gas. Can I keep it hot by using benzoline oil in any way?—A COUNTRY TINKER.

[11973.]—**Magnetic Engine.**—Will any one give me information (with sketch) for making a simple electro-magnetic machine?—GLATTON.

[11974.]—**Arsenic in Sulphuric Acid.**—Will some of our readers inform me in what form arsenic exists in sulphuric acid made from pyrites, and what per cent.? Is it not as an arseniate?—IN DIFFICULTY.

[11975.]—**Silver Plating.**—I saw the other day a large plaster cast covered with a fine silver surface, which I was told was laid on with a brush, as the article was too large to operate on in a bath with safety. No doubt "Jack of All Trades" or some other of "our" contributors will be able to describe the process for me, and confer a favour upon—UN IRLANDAIS.

[11976.]—**Curve of Tensions.**—It is well known that if the base of a right-angled triangle be taken to represent the resistance of a telegraph line through which a current is passing, the altitude to represent the tension of the battery end of the wire, then the hypothenuse will represent the tensions at the different points of the wire—that is, supposing the insulation resistance to be infinite. Now, it is evident that when the insulation resistance is small, then the line of tensions will no longer be a straight line, but will dip. I want to know the exact nature of this curve, supposing the insulation resistance to be perfectly the same throughout the whole length of the line. Perhaps some of your talented electrical contributors can enlighten me.—O.

[11977.]—**Whistles.**—I have turned several ivory and other whistles, but find those of smaller bore are often louder and a better note than larger. What is the proper proportion of depth to size of bore, and what should be the relative sizes of the blow-hole and the escape-hole in proportion to the depth and diameter of the bore? There must be some rule. Is there any limit to size and power of a common whistle beyond that of the strength of a man's lungs?—JANNIFRED.

[11978.]—**Dyeing Mohair Dress.**—Will some one more learned than myself inform me if I can dye a mohair dress brown colour, the present colour being blue, with black stripes?—BLACKING.

[11979.]—**Tinning Iron.**—Can any reader tell me the process by which iron is tinned by dipping in a solution of tin in acid? I can tin iron in the usual way by preparing the iron by immersing in dilute sulphuric acid and dipping in molten tin, but if the other could be accomplished without heat it would answer much better. As it is for manufacturing purposes, none but a practical recipe would answer—such, plainly put, would be of great help to one who has often helped other readers. —H. RULE.

[11980.]—**Coal in Worcestershire.**—A relative of mine, owning a large estate in Worcestershire, knowing that coal is found in the county, wishes to know whether it is likely that coal exists on his estate, and as I have been much interested lately in an article on "Coal-Measures and Coal-Supply" in your paper, I venture to ask for further information on the subject, especially as to what strata usually overlie coal-measures, and whether the presence of coal on the estate could be ascertained by boring without much expense. The soil on part of the estate is very red in colour, but it varies considerably. The estate lies about four miles west of the city of Worcester.—AN OLD SUBSCRIBER.

[11981.]—**Science Examination.**—Will some of "our" science teachers tell me when will the result of the chemistry examination be known? How long is it, generally, after the examination takes place?—J. R.

[11982.]—**Thrush.**—Can any one tell me the proper food for a tame thrush, also the way to rear young ones?—A. C. L.

[11983.]—**To Gloss Ribbon.**—Will some one kindly inform me how to gloss and stiffen old silk ribbon that has been re-dyed when being ironed, in the same way which ribbon dyers do it?—GLARE.

Z.—Schoolboy.—Artilleryman.—J. K. W.—Philanthropist.—A Dead Shot.—A Subscriber.—Geo. Beal.—G. E. N.—Inquiring Mind.—Leon Jourd'hui.—E. C.—Woodman.—Elijah E. Dunn.—J. M. Rodwell.—A.W.D.—S. H. Cash.—Zeta.—J. K. P.—John Hopkins.—A. K. L.—C. Glasgow.—Cobbler.—Artillery Captain.—Ignoramus.—A Glasgow Highlander.—J. C. J.—R. B.—Pulse.—E. W. D.—Geo. Fox.—J. B. Gill.—Waverley.—J. P. R.—A Paper Maker.—Saul Rymea.—Civil Engineer.—The Harmonious Blacksmith.—J. B. Smith.—A Gunsmith.

SNATCHBLOCK says "It will be a great boon to myself and others to see the ENGLISH MECHANIC printed in larger type."

INQUIRER.—First query inserted. A Cornish bushel is 8 gallons.

J. J. ALLINGHAM.—Please send us the results of your experiments. We can get bushels of illustrated patented inventions at the Patent Office, but, alas! how few of them are worth anything.

LINUM.—Your letter on the "Creation of Man," and Adam's duties and behaviour in the Garden of Eden, would take us a little beyond our depth as indicated in our pages.

Communications which can only appear as advertisements to hand from J. J. P., Charlie Brown, Speculator.

T. BORNY.—Consult indices for information on gilding.

R. BROWN.—What do you mean by colouring eggs in the sun?

J. B., G. F. B., R. B., H. A. K., H. J. H., A. C. L., Hard as Stone, Ashtonian, Economy, W. B. N., J. Renworthy, G. R. S., are referred to indices to back vols.

A YOUNG WOULD-BE BEGINNER.—You can easily get the information you want by writing the publishers.

AN OLD SUBSCRIBER.—The scanty particulars afforded render it impossible to tell whom your picture represents. Consult a dealer. We doubt its being by Sir Joshua Reynolds.

W. H.—Use a little violet powder.

A SUFFERER.—Consult a physician.

ONE IN A FIX.—You must have looked through your indices and prayed that you might not find it. See p. 546, Vol. XIL, for soldering without fire or cold brazing.

PNEUMATIC LEVER must leave the question of space to our discretion.

J. MORRAY.—You must search for yourself at the Patent Office. You can hardly expect us to find space for the descriptions of prior inventions bearing on a certain industry, that you may see whether yours is like them.

S. W. B.—We do not know what you mean; you cannot *magnetise* indiarubber.

Y. Z.—He can only enter the merchant service, unless you wait till he reaches the prescribed standard.

FLEXIBLE MARBLE.—With reference to our Useful Note on the subject, in No. 372, Mr. W. J. Hay writes that it may interest some of our readers to know that specimens of flexible marble can be seen in the Hartley Museum, at Southampton, which is open to the public daily.

J. GILBERT.—We do not remember your communications. We do not insert all replies that reach us—sometimes because we think a query has already received sufficient attention.

M. R. C. S.—The discussion is closed.

'OBBY 'OSS.—Please look up our back volumes, and you will find you are rather behind time in endeavouring to initiate a discussion on the respective merits of the Phantom and Tension bicycles.

ROLAND.—We fear none of our readers will be able to tell you "what induced Sir Walter Scott" to write the passage you quote.

SPEIGHT.—See description of Indian pellet bow in this number.

TEACHABLE.—You must repeat your query, and give more distinctly the dimensions of the gear. We cannot understand them.

APPRENTICE.—Order through Trübner and Co., Paternoster row; the other queries are advertisements.

ANXIOUS STUDENT.—Write to the Secretary of the Science and Art Department, South Kensington.

ERITO.—Acceptable.

NOBILITY.—The covers can be had. You may bind the advertisements up with other pages if you like.

S. SPIERS.—We cannot publish your address so that "Anglo-America" can write privately. Send what information you have for the benefit of all.

WEATHER.—Buy the back number, if you want the information.

SILVESTER FIRTH.—See reply 11656 in this number.

ONE IN A FIX.—In the case of a person dying intestate, leaving a wife and children, one-third of his personal property goes to his wife and the rest to his child or children. A mother-in-law takes nothing. We wish correspondents would adopt less common signatures. Another writes giving the same *nom de plume* as yourself, and neither of you add any place of address or anything else whereby we may distinguish you.

A SUBSCRIBER.—We do not charge for the insertion of queries, and have devoted your stamps to the Lifeboat Fund. For information about lumbago, see pp. 304.

AND

WORLD OF SCIENCE AND ART.

FRIDAY, MAY 31, 1872.

ARTICLES.

ASTRONOMICAL NOTES FOR JUNE.

By a Fellow of the Royal Astronomical Society.

THE right ascension of the Sun at Greenwich mean noon on June 1 is 4h. 38m. 40·85s., and his declination 22° 8′ 25·4″ north. He will consequently be found a little to the south-east of the well-known wide double star τ Tauri. He rises in London on the 1st at 3h. 50m. a.m., and sets at 8h. 5m. p.m., while on the 30th his rising takes place at 3h. 49m. a.m., and his setting at 8h. 18m. p.m. in the same locality. At 3h. 32m. a.m. on the 21st his longitude is 90°, or he is technically said to enter Cancer, and summer commences. As at this instant he attains his greatest northern declination the 21st will be the longest day, the sun rising at 3h. 45m. a.m., and setting at 8h. 19m. p.m., thus remaining above the horizon for 16 hours and 35 minutes. The absence of real night is now quite noticeable, twilight being perceptible from sunset to sunrise. The equation of time is subtractive up to the 13th, after which it becomes additive. On the 1st, 2m. 25·29s. must be taken from the instant of apparent Greenwich noon to give the time which a clock ought to show, and this diminishes to 11·62s. on the 13th. At noon on the 14th 0·95s. must be added to the time shown by a sundial or other meridian instrument to obtain true mean time, a quantity which increases to 3m. 22·96s. by the 30th. While on this subject, we may call attention to the fact that the 20th and 21st of June are excellent days for obtaining a meridian line by the method of equal altitudes, for setting a sundial, or for any analogous purpose; inasmuch as the Sun's change in declination at that time is practically imperceptible. The semi-diameter of the Sun at his transit at Greenwich on June 1 is 15′ 48·0″, and this occupies 1m. 8·43s. of sidereal time (convertible into mean time by the subtraction of 0·19) in passing the meridian. On the 30th the Sun's semi-diameter will have diminished to 15′ 46·0″, but this will take 1m. 8·79s. of sidereal time (or 1m. 8·60s. of mean time) for its transit. The Sun is now fast approaching his apogee. The sidereal time at mean noon on June 1 is 4h. 41m. 6·13s., and on the 30th 6h. 35m. 26·31s., the mean time at sidereal noon, or mean time of transit of the final point of Aries, being 19h. 15m. 44·02s. and 17h. 21m. 42·56s. on those days respectively. There will be an annular eclipse of the Sun on June 5, after our midnight, but it will be wholly invisible in this part of the world. Spots, faculæ, and other indications of solar activity continue to be manifest, though, as we have recently intimated, in diminished numbers.

The Moon will be New at 3h. 23·4m. a.m. on the 6th; will enter her first quarter at 7h. 19·2m. a.m. on the 14th; be Full at 6h. 57·7m. in the morning of the 21st; and enter her last quarter at 9h. 27·4m. at night on the 27th. She is 24·9 days old at Greenwich mean noon on the 1st, and, pretty evidently, 28·9 days old at the same hour on the 5th. Then on the 6th, at that instant, her age will be 0·4 day, and so on until the 30th when it will obviously be 24·4 days. At 6 a.m. on the 16th, Libration will bring additional surface in her south-east quadrant into view, while at 1 in the afternoon of the 28th more of her south-west surface will be visible from the same cause. The Moon will, however, in each case be, of course, below our horizon. She will be in conjunction with Mercury at 7h. 21m. a.m. on the 4th; with Venus at 3h. 16m. a.m. on the 5th; with Mars at 4h. 46m. in the afternoon of the same day; with Uranus at 5h. 18m. on that of the 9th; and with Jupiter a little later at 6h. 24m. Lastly, she will be in conjunction with Saturn 29 minutes after noon on the 22nd.

The Moon will occult only three fixed stars this month (two of them at very inconvenient hours), and approach very close to a fourth. The last-mentioned phenomenon will occur first in point of time, as at 51 minutes after midnight on June 17 she will be almost in contact with μ Libræ. Then on the night of the 21st at 10h. 46m. σ Sagittarii will disappear at her bright limb, reappearing at her dark one at 11h. 57m. During the early morning of the 27th, at 3h. 29m., 30 Piscium will be occulted by the bright limb, and reappear from behind the dark one at 3h. 52m. Lastly, at 3h. 9m. a.m. on the 30th, BAC 755 will disappear at the Moon's bright limb, and emerge from behind her dark limb at 3h. 52m. also.

The remarks which we made last month (p. 136) with reference to the unfavourable position of the planets for observation, apply with even increased force to the condition of things obtaining during June. Mercury is a morning star, and rises at the beginning of the month, about three-quarters of an hour before the sun (of course, in strong twilight), southing and setting in full sunshine. Every day, however, finds him closer and closer to the Sun, with which he will be in superior conjunction at 9h. 46m. on the night of the 24th. Mercury will be in conjunction with Mars at 4h. 14m. during the early morning of the 18th, and with Venus at 5h. 38m. in the afternoon of the same day. His conjunction with the Moon at 7h. 21m. a.m. on the 4th has been mentioned above.

Venus is also a morning star, and equally badly placed for the observer. Her diameter is only about 10″, and she is very nearly round; so that, even if she be caught in the field of the telescope, she is about as uninteresting an object as can well be imagined. She rises, souths, and sets in full daylight during the whole of June, and is rapidly approaching the Sun. We have referred previously to her conjunction with the Moon at 3h. 16m. a.m. on the 5th; and to that with Mercury at 5h. 38m. p.m. on the 18th. We may add that she will be in conjunction with Mars at 5h. 49m. in the early morning of the 17th.

Mars is much too close to the Sun to be visible; moreover, his apparent diameter only subtends an angle of some 4″. His conjunction with the Moon at 4h. 46m. in the afternoon of the 5th; with Venus at 5h. 49m. a.m. on the 17th; and with Mercury at 4h. 14m. a.m. on the 18th have been before spoken of.

Jupiter now, owing to the protracted daylight, and his steady approach to the west, is visible only during a comparatively short period of the early night. He rises, of course, in bright sunlight during the whole of June, is on the meridian on the 1st at 3h. 19·4m. in the afternoon, and sets about 20 minutes past 11 at night. On the 30th he will south at 1h. 49·2m. p.m., and set about 9h. 42m. He is travelling slowly through Cancer this month; and starting on the 1st from a point south of μ^2 in that constellation, will, by the 30th, be found forming an obtuse-angled triangle with η and θ. At 6h. 11m. in the afternoon of the 5th, he will be in conjunction with Uranus. It will, of course, be far too light for the smaller planet of the two to be discerned at the instant of conjunction with the amount of optical power at the command of those for whom these Notes are chiefly written; but, as Jupiter and Uranus will approach each other within a single minute of arc, they may be seen later on in the evening in the same field of view, even with a high power. At 6h. 24m. p.m. on the 9th, as indicated in a previous paragraph, the thin crescent Moon will be some 3° (and a few minutes) north of Jupiter.

The visible phenomena of Jupiter's satellites this month are few indeed. Satellite 1 will be occulted at 9h. 31m. on the evening of the 1st. If it be not too light on that of the 2nd, the egress of satellite 2 at 8h. 40m., and the egress of satellite 1 at 9h. 6m., may possibly be perceived. The shadow of satellite 1 will pass off at 10h. 2m.; as will that of satellite 2 at 10h. 30m., but Jupiter will be very low down at the time of the occurrence of the latter phenomenon. It is barely possible that satellite 4 may be seen to reappear from occultation at 8h. 12m. in the evening of the 6th; and further that the ingress of satellite 2 at 8h. 32m., and that of satellite 1 at 8h. 46m. p.m. on the 9th, may be detected. The shadow of satellite 1 will enter on to Jupiter's limb at 9h. 36m. on the same evening (the 9th), as will the shadow of satellite 2 (Jupiter being close to the horizon) at 10h. 11m. afterwards. On the evening of the 10th satellite 1 will reappear from eclipse (under unfavourable circumstances for detection) at 9h. 9m. 28s. On the next night, the 11th, it is just possible that the egress of the shadow of satellite 3 may be perceptible at 10h. 5m.; while the same may be said of the egress of the shadow of satellite 1 at 8h. 19m.; and the reappearance of satellite 2 from eclipse at 10h. 14m. 9s. on the 18th; of the occultation of the same satellite (2) at 8h. 43m.; and the egress of satellite 1 from Jupiter's disc at 9h. 37m. on the evening of the 25th.

Saturn is now above the horizon at a rather more convenient time for observation, but is so extremely low down that telescopic scrutiny of him is almost futile labour. He rises on the 1st about 20 minutes to 11 at night, and is on the meridian at a quarter to 3 o'clock the next morning. On the night of the 30th he rises at 8h. 42m., and souths 43 minutes after midnight. He travels during June from east to west, through a perfectly barren region in Sagittarius. We have already adverted to his conjunction with the Moon 29 minutes after noon on the 22nd.

Uranus continues to occupy a position somewhat to the south and east of μ^2 Cancri, and travels in an easterly direction through a small arc during the present month. As we remarked in our May notes, his proximity to Jupiter renders all our observations with reference to the visibility of that planet equally applicable to him. Their conjunction at 6h. 11m. in the evening of the 5th; and that of Uranus with the Moon at 5h. 18m. p.m. on the 9th have been spoken of under their proper headings.

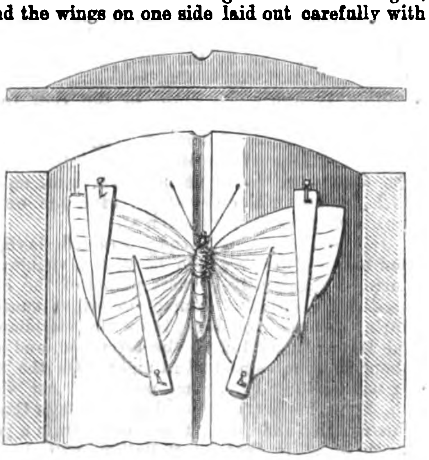
Neptune rising in twilight, and southing and setting in bright sunlight, is still, for all practical purposes, invisible.

June, from some cause unknown, is a month conspicuous for the absence of shooting stars from its night skies.

THE ARRANGEMENT AND PRESERVATION OF INSECTS.

WE promised in a recent article (p. 187) to give some hints on the arrangement and preservation of specimens of the Lepidoptera, and presuming that some few of our readers are anxious to have everything in readiness for the captures they hope to make, if they have not already made a goodly number, we proceed to give a few instructions which may serve to guide the entomological tyro in obtaining a practical knowledge, and preserve him from disappointment at the outset of his career. Probably the first thing which will trouble the would-be collector will be the cabinet or case in which he can preserve and exhibit his trophies, and it is a difficulty not easily overcome where funds are limited. There are numerous designs for cases and cabinets, all of which are excellent in their way, and serviceable articles for the purpose intended, but they are, unfortunately, also rather too costly for the means of many of our readers, while many others would not feel justified in spending so much money on "mere butterflies," as they are sometimes contemptuously termed. Nevertheless, it is quite possible to make cases at a moderate outlay, which, while answering all the purposes of the more finished receptacles, with their contents will still be not unornamental when seen in a parlour or drawing-room. It would be well for the embryo entomologist to settle at starting to what extent he is likely to be successful in his efforts at collecting, which will largely depend, of course, on the time at his disposal and the enthusiasm which he throws into the work. Where a complete collection of the Lepidoptera or Coleoptera of the British Islands is aimed at, a cabinet is certainly to be desired, as it admits of a more systematic arrangement of the specimens, and while keeping them all together facilitates reference. Where, however, the collector is contented with the more beautiful individuals of the family, or merely seeks to obtain specimens found in his immediate neighbourhood, a few of the ordinary glass-topped cases will answer his purpose, and these may stand on sideboards, tables, or shelves, or in any position where they can be shaded from the fiercer light of the sun. When we state that a good collection of the British Lepidoptera would require about 40 drawers, and that the price charged by the best makers for their cabinets (the cheapest, too, in the long run) is something like £1 a drawer we have furnished a few data to guide our readers as to how far towards a complete collection they are prepared to go. There is another plan, however, which is preferred by many of our best entomologists, who aver that it is superior to a cabinet, and that is a series of store-boxes made to imitate books, kept like them in a book-case, and lettered or labelled for easy reference. Under this system of arrangement there is, of course, no limit to the extent of the collection, save its completeness and the amount of shelf-room obtainable. We would not advise any of our readers, except those who are very skilful with tools, to attempt the construction of a cabinet, which is a difficult piece of work to turn out in a satisfactory manner; we may mention, however, for the benefit of those who may be determined to try, that a very suitable size can be easily found from the following dimensions. The number of drawers should be not less than 40, 18in. square (*i.e.*, the same width and length), and 2in. deep externally. They should be made to fit accurately and be interchangeable; and when arranged in two columns in a handsome case, with labels at the sides or on the front of the drawers, will be found all that can be required. The ordinary glass case, however, is not beyond the skill of the average amateur joiner or cabinet-maker, and besides being the least expensive, will be found to answer the purposes contemplated in these articles. The best wood of which to make these or any other receptacles for preserving specimens of insects is undoubtedly mahogany, either Spanish or Honduras. If this is procured from the yard care should be taken to ascertain that it is well-seasoned; but the cheapest and best way of obtaining suitable material is to purchase some second-hand fragments, such as the broken flap of a table, often to be picked up at the broker's shop or old-material dealer's. The size of the cases will depend on the taste of the maker and the positions they are intended to occupy, but like the drawers they should not be less than 2in. in external depth, and would be better 2½in., as there should be rather more than an inch left between the cork and the glass. They may be made of the same depth back and front, or constructed so that the glass may slope, at the taste of the collector, but if made only 2in. in depth the glasses must almost necessarily be fitted into frames to lift on and off. The easier way, however, is to construct the upper edge all round with a rabbet lined at bottom and side with chenille or velvet, into which the glass is dropped. The glass should be perfectly colourless, the kind used for pictures. "flatted sheet," as it is called, and should have a piece of ribbon fixed at one end or edge, by which to lift it up, an operation that must always be performed slowly and with care. The bottom of the case is to be entirely covered with a piece of cork of the best quality, about a quarter of an inch thick; but as it is rather difficult to obtain cork of the requisite quality and suitable dimensions, two thinner pieces are often glued together, or the lining may be filled in in sections of the size of the good material obtainable. Generally speaking, for cases of ordinary dimensions, a sound bottom can be secured by glueing two pieces, each nearly an eighth of an inch thick, together, for if there is a hole in one it will most likely be covered with sound cork in the other. The cork bottom being prepared and finished by smoothing it with glass paper, is firmly and evenly glued into the case, and kept in position by a piece of wood and a weight, till the glue is set and dry. The next operation is papering, *i.e.*, covering the bottom, and the sides if desired, with "tea" paper—the technical term for the sort used, but any paper possessing an even surface, perfect whiteness, and sponginess of nature, will answer the purpose. This should be carefully pasted in with thin paste, to which a few drops of carbolic acid or a small quantity of corrosive sublimate has been added to prevent mildew, as well as alum to insure hardness in drying. The case is now complete, with the exception of marking off the bottom into spaces, and before this is proceeded with, it will be well to obtain the dimensions of the principal specimens from a friend's collection or wait till the specimens themselves are caught. In the arrangement of a collection of Lepidoptera, those of the same family should be placed together, being divided into genera. A label with capital letters should run across the space so occupied above the first row, and above the first insect in the row should be placed a label with capital letters the initial of which is the largest; and under each species its distinguishing name in small letters, *e.g.*, VANESSIDÆ, the name of the family; VANESSA, that of one of the genera; and *Antiopa*, that of a species. Lists of the names are, however, sold at the naturalists' shops, which can be cut up and pasted in, and of course look neater as a rule than when the pen is used.

Having thus prepared the case, and presumably obtained some of the insects whose beauties we wish to retain as "joys for ever," the next [illegible] will be setting, and here we have a [illegible] methods—the saddle or rounded, the high, the low, and the flat. Neither of these plans represent the insect as found in nature, and as saddle-setting is the system generally pursued in this country, we shall content ourselves with giving a description of its principal points, leaving the refinements of manipulation adopted by some lepidopterists to be discovered by each collector for himself. For saddle-setting, then, cork saddles will be required, of the shape shown in plan and section in the figure; these are fixed to thin pieces of wood, and vary in size from ½in. to 5in. in breadth, and about a foot in length, depending as regards the latter measurement on the dimensions of the setting-house, where that useful adjunct is employed. These pieces of cork are best obtained from the cork-cutter, who can make the groove much cleaner and better than an unpractised hand, but if it is impossible to obtain his assistance the saddles may be made in two pieces, and glued side by side to the boards, leaving sufficient width between them to accommodate the body of the insect, or a V-shaped groove may be cut out with a penknife, but the cork must be finished off by smoothing with glass-paper all over. A setting needle and a setting bristle will also be required, which are fixed into corks or small pieces of wood as handles. The braces employed to keep the wings in position are wedge-shaped pieces of stout writing-paper, or card for large specimens, and are placed as shown in the engraving. The saddles being ready, one of the captures is pinned to a saddle of a suitable size —that is, rather wider than the insect with fully-expanded wings—the pin being inserted at the part marked by a dot, with its head slanting forwards a little. The legs are then arranged, and the wings on one side laid out carefully with



the bristle and the setting needle—the former being employed to press the wing down to the cork, the latter to lift and guide it into position from the under side. This accomplished, the fore wing is braced down as shown, and a similar course pursued with the hind wing. The other side is then treated in a like manner, the antennæ arranged, and the body raised by placing small pieces of wood in the groove when that is too deep, or by a brace under the whole length of the body. It will be obvious that the minutest directions will be of little avail where skill and lightness of hand are wanting, and what we have said will be sufficient to guide the uninitiated in doing good work where practice can alone give proficiency.

The setting carried out satisfactorily, the specimens must be allowed to remain on the saddles till perfectly dry, the time thus occupied varying with the seasons and the weather. For this reason, and from the danger of damage specimens run while lying about for weeks, many lepidopterists make use of a setting-house, which is easily made out of an old box (free from mites, though), by putting ventilators of perforated zinc or wire gauze in the bottom and the lid, and then turning the box on its side, and nailing strips of wood on the ends inside to act as ledges on which to rest the saddle-boards. These should be at least 2in. apart, so as to allow of a free current of dry air.

When the insects are thoroughly dry, which will generally be known by the stiffness of the abdomen, they may be removed to their permanent resting-places; and then will begin a whole host of troubles—grease, mould, and mites being the worst. Grease may be removed by sinking the insects on loaded corks in benzole or turpentine, and drying them in powdered French chalk. Mould should be prevented by keeping the case away from the damp and allowing a free access of dry air around it; but all the specimens should have the underside of the abdomen anointed with a dilute spirituous solution of phenol, carbolic acid, or corrosive sublimate. The strength of the solutions may be tested by trying them on black paper, on which they should become speedily invisible. Care should be taken that the glass of the case fits air-tight, and fresh specimens should be kept in a separate and smaller case till evidence is afforded that they are free from parasites. Various essential oils, camphor, mercury, and numerous insecticides are recommended to be placed in the case, but phenol properly used will be found as satisfactory as anything.

There is one other little point worth mentioning, and that is when it is found desirable to reset an insect, it may be relaxed either in a jar containing damp sand or in an ordinary flower-pot sunk a few inches in the ground and covered with a tile or a piece of slate, and the earth drawn over. When sufficiently limp the insect should be reset as soon as possible, and when dry, as far as Lepidoptera are concerned, the parts of the wings where they join the body should be slightly touched with a solution of pale lac. We have now, however, so far exceeded our limits that we have only space to wish all intending collectors the success they may merit.

THE SCIENCE DEPARTMENT AND SCIENTIFIC EDUCATION.

By C. H. W. BIGGS.

It is unfortunate, perhaps, that our daily and weekly press is mainly employed in criticising what is to be, instead of devoting some part of its labours to the discussion of what is. No doubt it is desirable to educate the public mind in regard to every important Bill before Parliament. The public mind educated, the public voice approving, the measure sooner or later becomes law, and then to a great extent passes out of men's minds. Witness the Irish Church question, how much paper and time was wasted before the Bill became law, yet how little has it been discussed since. Witness, again, the New Army Regulations; or, better still, the Reform Bill. Differing from any of these, and, perhaps, from every other topic of public discussion, the Education Bill is not relegated to obscurity; but there is a good reason for this, inasmuch as we have not yet settled our system of education. At present we are trying an experiment, a costly one it is true, and that is a very good reason why we should hope for the best. Still, I am sorry to say, it seems to me to be a failure. I am not thinking of the politico-religious part of the question, simply because I don't believe in it. There is a political question, but no religious one. So long as our primary schools are unconnected with the secondary and higher schools, so long shall we have to bewail an incomplete system of education; so long as compulsion is left to the liberty of the school boards so long shall we complain; so long as the schoolmaster himself occupies his present position in the social scale so long will there be strife and bickering. Who on earth would think of examining lawyers, or doctors, or architects, as to the attainments of their assistants, by means of men who know nothing of law, or physic, or building, except just so much as they had picked up during a university career? Yet, forsooth, schools are examined by men who know literally nothing of school work—men who have obtained their appointment because of a distinguished career at their Alma Mater, or from interest. Lawyers have the woolsack before them; doctors are honoured by knighthood; architects, literary men, civil engineers, and other professional men (if they are at all distinguished) make money, become landowners, get into Parliament, ay, and even into the House of Lords; but whoever heard of a schoolmaster, no matter how talented, how distinguished among his fellows, obtaining anything more than a school? Further, our existing primary schools are literally starved for want of funds. Ten times the teaching power is required for the schools to be brought up to any degree of excellence, and this teaching power can only be had by increasing the funds at the disposal of school managers. Again, what teaching power we have is to a great extent lost, because so widely diffused. In many towns there are a dozen little fiddling schools, where two good large ones would amply suffice, and then all the first divisions, thrown into two divisions, would require but two masters instead of twelve; the other masters could take the other divisions. In other words, by amalgamation, a class of about forty boys would be obtained of about the said attainments, and these a master could easily manage, instead of there being a little school of forty boys of different attainments, and, therefore, in different standards, and thus out of one man's power. But what has all this to do with the Science Department? More, much more, than my readers may at first imagine. However, these allusions have been thrown out more as hints than as consecutive, hardly-connected, I might say, arguments, in order that many more minds may give attention to the subject. Were I to attempt to argue the question fully, I should require not a column or two but several numbers of the ENGLISH MECHANIC.

Now, the ranks of the working classes, whether mechanics or farm labourers, are, for the most part, recruited from the boys of our day-schools. The Science Department was instituted for the benefit of these working men: for our engineers, our builders, our carpenters, our wheelwrights, our smiths, our ship-builders, and so on. Whether *these* people are benefited or not is another question. I know that many people who can and who ought to pay for their sons' education in various branches of science, send their boys to the science school, where for from 2s. 6d. to 4s. they receive certain instruction; these pupils are presented for examination, pass, and the country pays the master £1 or £2 per head, as the case may be. These students are sons of "foremen," "master-men," and so on; people who know—who realise the value of a technical education, who by means of their own technical knowledge have raised themselves above the majority of their shopmates. They are determined their children shall further improve upon their position, and thus constrain them to take advantage of the opportunities offered. They know that as a rule the lessons given, the lectures delivered, are the best that can be obtained; the men who give them know their business too well to do their work in an unworkmanlike manner. Why do the children of the rank and file of our workmen neglect to embrace these advantages? Is it because they know not the value of them? Is it because they are stubborn, clumsy, thickheaded clodhoppers? Oh! no. But there must be a reason. What is that reason? Is it not because the knowledge imparted to them in our primary schools is insufficient to allow them to understand, or, at least, is such that they cannot during the short course of lessons in the science class understand sufficiently well to be able to pass the required examination of the department? Surely, "To him that hath is given, and to him that hath not nothing is offered." Take the majority of cases: the boy leaves school at eleven or twelve years of age, he can read and write tolerably, knows the first four simple and compound rules, and probably a little of fractions. What can the science master do in one course of lessons? What does he do? Just enough for some 70 per cent. of his pupils to fail. Now if, on the contrary, there was a sufficient number of masters in our elementary schools the rudiments of science could easily be taught in these schools, and the pupils having received an elementary knowledge would when in the workshop see the necessity of extending that knowledge; thus our science schools would be filled by the very people for whom they were intended. Instead of being the mere cadres of classes the classes would have their full complements. With improved knowledge we get improved workmen, in every sense of the word, less publichouseism, more attention to home and home comforts, and, above all, an increased desire to see their children better educated. The Science Department must recast its system of examination. The papers now set are similar to those given to some of the higher forms in our large schools. Where the pupils have the best masters, the best apparatus, and a great deal of time for the study of the subject, it may suit some people to say these examinations are easy, so they are, in one sense, but they are very difficult for the people for whom they are intended; in fact, just difficult enough to keep the money necessary for the extension of the classes in the Government coffers, instead of being utilised by paying teachers, or rather, I should say, the money voted by Parliament is most unaccountably swallowed up by the department. If a statement in the *Schoolmaster* of May 18 is to be believed, no less than £90,000 was required to pay a staff of clerks, &c., to carry on the business of the department, whilst £20,000 found its way into the hands of the teachers. I wonder how many manufacturers spend £5 10s. on clerks to £1 on workmen; for this is about the proportion required by the science department. Further, although not agreeing with all the *Saturday Review* says, I can heartily acquiesce in its statements every now and then relating to this particular department. Over and over again has this paper required some alteration in the work given or undertaken by the head of the department. It argues, and with some reason, that a man cannot well do two things at once—cannot look after the science and art of the United Kingdom, and also devote attention to the annual international bazaars, not to mention other things. A deputation of science masters recently had an interview with Mr. Forster, and one ground of complaint was that they did not agree with the system of payment by results. Now, it would be well that all science masters—and, indeed, all masters—should understand that public opinion will not allow public money to be paid away without in some measure knowing what it goes for. If £90 goes to clerks, and £20 to masters, the country knows that the masters have passed a certain number of pupils, and that the clerks have written a certain number of letters, the examiners looked over a certain number of papers, and so forth. If, on the contrary, £50 is paid to masters because a certain number of lessons are given, then any one may give the worst lessons, do the least work, but get real pay. It can't be. Let us have fair examinations, and be paid fairly for our work. Local subscription fees, &c., one moiety, Government grant the other moiety. It is not about the payment by results that I find fault, it is that the examinations are not adapted for the working classes; the examinations are not conducted properly. The minimum number of lessons should consist of at least forty instead of twenty-five—that is, they should be given through the ordinary school terms—not during the winter months only, but throughout the year. It should be compulsory upon our elementary schools to teach the elementary branches of science. That this is not impossible I know, but the one great requisite "teaching power" must be obtained. A boy at ten years of age ought to—ay, and under able tuition would—be able to read well enough to dispense with "reading lessons," write well enough to dispense with writing lessons. The time previously devoted to these subjects might be given to others, more particularly to science. Boys read with avidity the penny-dreadful literature, give them something to interest them, and I'll warrant they will read. Their exercises will give them sufficient writing. By twelve years of age a boy should be able to manipulate fractions and proportion pretty thoroughly, and then his scientific education would advance a step. By fourteen years of age, or the time I would have fixed as the earliest for leaving school, he would be an interesting subject to be moulded and formed, licked into his true shape by the science master. Now all ye English mechanics who read this, give a small portion of your time to the thought of what is, and what ought to be; don't be led away by the counsels of anybody; if you are educated enough, that will suffice—if not, it is your duty to look around you for better means wherewith to accomplish the ends you have in view.

VEGETABLE PALÆONTOLOGY.

[FROM OUR OWN REPORTER.]

DURING his present course of Swiney Lectures, delivered at the Geological Museum, Dr. Cobbold gave a brief sketch of the science of fossil botany, of which we give the following abstract:—

This science has not had that time and attention bestowed upon it which it ought to have had, the truth being that other departments of palæontological science were not attractive. The geological record, too, is very fragmentary, as compared with that of zoology. A few eminent men, however, have worked at the subject and given it its present standing. Looking back, there are three names which stand out pre-eminently in this respect, Lindley, Brongniart, and Unger. In later times a number of workers have been engaged on this subject, and progress is daily being made. Hooker has described the subject as one of extreme difficulty, and the conflicting opinions held about various objects confirm this statement.

We may take as a starting point the following general proposition:—Throughout the entire series of fossiliferous strata which happen to contain fossil plants, there is no evidence of the existence of any type of plant life which cannot be referred to one or other of existing orders of plants upon the globe. In other words, there is no fossil plant known which is so distinct as to deserve being placed in a group of ordinal value by itself. Exception might be taken as follows: Some botanists place the Calamites in a separate family, and call it Calamitæ, or Calamitaceæ; but do they present characters of such extreme markedness or distinction as entitles them to be separated into an ordinal group by themselves? He (Dr. Cobbold) had looked very carefully into the matter, and he thought that although they present some features which distinguish them from all existing species of Equisetaceæ, they merge so imperceptibly into that group that they could not fairly be separated from them.

In this respect there is a great contrast between the palæontology of plants and animals, for of the latter 8 or 9—or some say 10—groups of ordinal value have flourished and become extinct.

The vegetable kingdom may be divided (according to Lindley) into seven great classes, as follows:—

1. *Thallogens*, as algæ, fungi, lichens, &c.; they are the lowest form of stemless plants, and are little better than mere masses of cellular tissue. The oldest representative of this class is Oldhamia in Cambrian times. It is one of those fossils about which there has been a great deal of discussion and a great variety of opinion, some placing it in the animal and some in the vegetable series.

2. *Acrogens*, a low class of plants with stems of a peculiar structure, flowerless—as ferns, mosses, &c. The earliest representative is Psilophyton, a gigantic lycopodiaceous plant, described by Dr. Dawson. This class was well represented in Devonian and Carboniferous times by ferns, calamites, lycopods, &c.

3. *Rhizogens*, or rhizanths, a small order, comprising the peculiar plants Rafflesia and Balanophous.

4. *Endogens*, comprising two divisions: (*a*) those with complete flowers, as palms, orchids, lilies, &c.; (*b*) those with incomplete flowers, as grasses, sedges, screw pines, &c. According to Professor Tournell, of Sweden, the earliest record of this class is Eophyton in Cambrian times, which he, at the Norwich meeting of the British Association, put forward as a monocotyledonous plant. The members of that Association, however, were divided in opinion as to its vegetable character, and the same uncertainty still exists. Mr. Carruthers, of the British Museum, believes in it. Mr. Etheridge does not. The lecturer said he himself had looked carefully into it, and as far as he was able to judge, he concluded that the evidence as to its vegetable character is entirely unsatisfactory.

5. *Dictyogens*. A small class, containing only four orders, and not represented as fossils. As examples may be mentioned yams and sarsaparillas.

6. *Gymnogens*, as pines, firs, yews, and cycads. As the name implies, they are naked seeded plants, and as a group have played a not inconspicuous part in the history of organic life on the globe. Their first appearance is in Devonian times, as Conifera, and they flourished in enormous numbers in the Carboniferous period.

7. *Esogens*, flowering plants having two or more seed lobes. This is the highest class of vegetable life, and is divided by Lindley into three divisions: (*a*) apetalous (willows); (*b*) monopetalous (laviates); (*c*) polypetalous (cruciferæ, rosaceæ, &c.). The earliest form is Esogeria in Jurassic rocks: the first trace of arborescent Esogens is derived from the Cretaceous beds.

In one respect there is a parallelism between the record of animal and of vegetable life, viz., that in ascending the geologic series, higher and higher forms successively appear, and the highest development of each kingdom was the last to appear. Certain of the older rocks give us a more or less fair and adequate notion of the extraordinary prevalence of plant life, and of the forms of that life in ancient periods of the earth's history. They show clearly that these forms were of a lower type than those which existed in more recent periods, and all discoveries tend to confirm the great truth above stated. With respect to the group which has played the most important part in ancient times we must say the ferns and their allies—acrogens—were most prominent.

A sketch of a portion of a Brazilian forest of the present day will serve to give some idea of the extremely luxuriant growth of vegetation in ancient times. The large tree ferns which exist in such numbers in that country were more num-

Carboniferous times, and nearly so in Devonian times. Nine-tenths of the flora of the Carboniferous period consisted of ferns, equisetums, and lycopods. The record which we have is only an imperfect record, and when we consider the whole mass of coal formed from these ancient forests, and containing myriads and myriads of these forms, we may, in some measure, realise the extraordinary state of things which obtained in that period. These productions, which imply a warm and moist climate, were not confined to tropical regions of the earth. At the present time as you go from the tropics towards the poles, the ferns dwindle in size from stately trees to mere shrub-like plants. There is one exception to this —viz., in New Zealand, which is an extra tropical country, and there we get tree ferns, but in no other part of the world in such a high latitude. But the most striking fact in this connection is this, that travellers who have investigated Arctic and Antarctic regions have found remains of ferns and dicotyledonous trees in latitudes as high as Bear Island and Melville Island. This implies that there was a time when the condition of our planet was such that a tropical, or, at all events, a sub-tropical climate, existed as far as 75° N. They found ferns and calamites in abundance in Carboniferous rocks. Dr. Hooker says the views of astronomers on this subject are merely technical, they cannot at present explain how it could have been that so high a degree of temperature should have occurred at such latitudes.

With regard to the first indication of vegetable life it is not positively ascertained. The earliest recognised form occurs in Silurian beds, but certain geologists carry the series farther back. Dr. Dawson and others have found in Laurentian rocks, in America, masses of graphite 25ft. in thickness. It is believed by every one who has chemically examined graphite that it results from the disintegration and decomposition of vegetable masses. All traces of structure have been lost, but the chemical constitution is such as to indicate that there must have been in those early times vegetable life of some kind or other—most likely of lowly organised stemless thallogens. If so we have a still further parallelism between the animal and vegetable series.

In Cambrian rocks occurs the disputed Eophyton, the vegetable character of which is not yet established.

The Silurian rocks chiefly contain fucoids, and these are the first undoubted vegetable remains. The following may be taken as type forms; one in the Llandovery beds, discovered by Mr. Lees, named by the lecturer on that account Leesia. In the next set of beds—Wenlock Limestone—occur Chondrites, and in the following Ludlow beds Actinophyllum; in the same set of beds and the succeeding passage beds are found Spongarium and Pachytheca. All the above are fucoids.

Devonian beds show an advance in structure from thallogens to acrogens and gymnogens. As type forms we may take Psilophyton, allied to Lycopodium; Dadoxylon, allied to the Araucarias of Australia and adjacent parts; Lepidodendrons, allied to ferns; Calamites, allied to Equisetums; Sigillaria, allied to ferns; and two fruits, possibly of flowering plants, *Cardiocarpon cornutum* (palm-like, monocotyledonous), and *Antholites Devonicus* (perhaps phenogamous, and allied to Liliaceæ).

The Araucarias, found in the Devonian and Carboniferous rocks in great numbers, are now confined to the southern hemisphere. They occur in Australia and the adjacent islands (Norfolk Island pine), and are large trees, 200ft. high and 20ft. in circumference. They existed in our country and in Scotland in Carboniferous times. The lecturer had seen the trunk of one of them, 30ft. long, dug out of a quarry in Scotland. The lepidodendrons form a group which some botanists think ought to rank as a separate family. They have very marked affinities with lycopods, ferns, and coniferæ, and may be regarded as an osculant, or rather, multiple type branching out in these directions.

In the Carboniferous period nearly all the Devonian types were repeated in far greater abundance. Besides those were *Megaphyton magnificum* (a tree fern), and Palmacites (monocotyledons), &c.

Permian beds contain no sigillaria, but ferns and calamites are abundant. Other type forms are Walchia (a conifer), and Podocarpon (palm-like trees).

In Triassic rocks ferns and equisetums are still abundant. Perhaps the most typical form is *Pecopteris Whitbyensis*, a fern. Pecopteris is also found in Carboniferous rocks.

Jurassic rocks have as type Podocarya (in the inferior Oölite), comparable to the screw pines (Pandanaceæ) found in Australia at the present day.

In the Cretaceous period diatoms are found, but it is not intended to say that this is the first time of their appearing; they also occur in great numbers subsequently in Tertiary times. Also Myrtaceæ and Proteaceæ (Banksia and Gryphyllia), and dicotyledonous trees, representing oaks, figs, and walnuts.

In Eocene beds the types may be taken as Chara, Comptonia, *Nipadites ellipticus*, and palms. The most interesting are the fossil fruits found in Sheppy (Nipadites, palms, &c.). Dr. Hooker says some of the palm fruits from Sheppy, which must have flourished on the banks of a river in Eocene times, cannot really be distinguished from palms which are living on the borders of the Ganges at the present day.

The Miocene floras are but feebly represented in Britain by the lignites of Mull and Bovey Tracey; the Pliocene floras still more feebly; while, as examples of vegetation in the Quaternary period, we have peat bogs and forest beds, with dicotyledonous trees in great numbers.

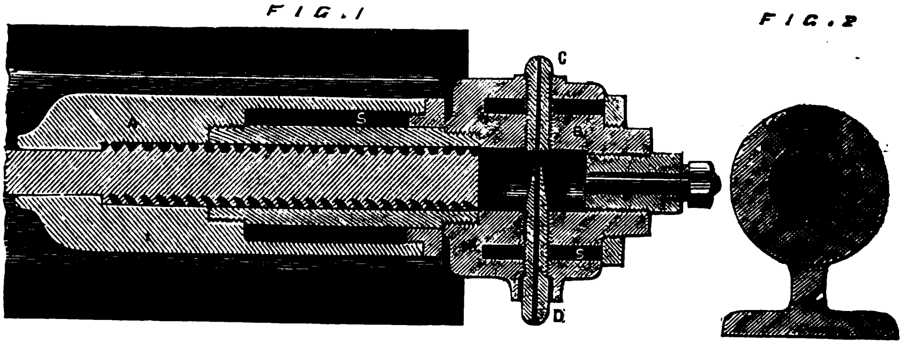
The above type forms must not be understood to be a complete catalogue of the flora of each distinct epoch, nor in all cases the most important parts of it, but are merely features selected from the various epochs which will serve as starting points for further research.

W. H.

WIRE-COVERING MACHINE.

A MACHINE for covering wire with rubber or guttapercha, or other insulating material for telegraphic and other purposes, has been patented in this country by Mr. A. G. De Wolfe, of Connecticut, U.S., the principle of which will be understood from our illustration, which represents the most important part of the apparatus. The principle of the invention consists in forcing the insulating material by means of a screw into a chamber through which the wire to be covered is made to pass at right angles to the axis of the screw. In Fig. 1, which is a horizontal section through the centre of the portion containing the essential features of the machine A is a cylinder, containing a screw of nearly the same diameter as the bore of the cylinder. This screw is constructed upon a shaft carried in suitable bearings, and receives motion from a pinion gearing into a toothed wheel fixed on the shaft, the end of which works against a thrust-pin in order to sustain it against the back-pressure produced by the action of the screw on the contents of the cylinder. B is a short extension piece screwed on to the end of the cylinder, and stopped by a screw plug, as shown, thus leaving an internal space of about 2in. between the end of the screw shaft and the stopper, which space, when in work, will be filled with the insulating material. In this extension piece on one side is screwed the die C at right angles to the axis of the screw shaft, and on the other side a guide piece D is inserted in a similar manner so as to be in line with the die. Around the extension-piece B, and part of the cylinder A, steam is circulated in the annular chambers S for the purpose of keeping the rubber or guttapercha at the required consistency. The cylinder A is, of course, fixed and mounted on a suitable frame, and the shaft being rotated any plastic material will be forced by the action of the screw into the space left in the extension piece B, and the wire being passed through the guide-piece D and die C is coated with the insulating material, the thickness of the coat being regulated by the bore of the die. The rubber, guttapercha, or compound used for covering the wire, is placed in the cylinder through an aperture near the back end of the screw, and is, of course, carried forward by the action of the thread of the screw; a section of the cylinder at this point is shown in Fig. 2. Tubing can also, it is said, be made by means of this apparatus, when the guide-piece D is removed and a suitable die substituted for the wire-covering die shown at C.

FIG. 1 FIG. 2



FRESH VEGETABLES AND SWEET SALADS.

THOSE who value fresh vegetables and sweet salads will have none washed in the garden. Neither the one nor the other should be washed, says the *Gardeners' Chronicle*, until they are just about to be cooked or eaten. Even potatoes lose flavour quickly after being washed, so do carrots and turnips; while water will speedily become tainted in summer in contact with cauliflowers and cabbages, and thus destroy their freshness and flavour. The case is still worse with salads. If washed at all, it should be only just before they are dressed, and they should be dried and dressed immediately. Nothing ruins the flavour of vegetables, and renders good saladine uneatable, sooner than water hanging about them. If lettuces are quite clean, they make the best salad unwashed; but if washed the operation should be done quickly, and the water instantly shaken out, and the leaves dried with a clean cloth. But, alas! how often are they cut and washed in the garden in the morning, and pitched into water in the scullery sink until wanted. Then we are gravely assured that our gardeners cannot grow salading like the French! But what French "artiste" would be mad enough to rinse out his salad juice, and then recharge his lettuces and his endives with semi-putrid water?

The best practice is simply to remove all superfluous earth by scraping or rubbing, and all rough tops or leaves by cutting. Enough tender leaves may still be left on cauliflowers and brocoli to overlap the flowers. Salad should be sent in from the garden with most of the outside leaves and main root on. The tender leaves are easily tainted and injured by exposure, and if the chief root is cut off sharp much of the juice oozes out at the wound. Where vegetables and salading have to be bought from a town greengrocer the conditions are altogether different. Not only washing, but soaking often becomes requisite to restore something like pristine crispness.

THE PREVENTION OF FIREDAMP.

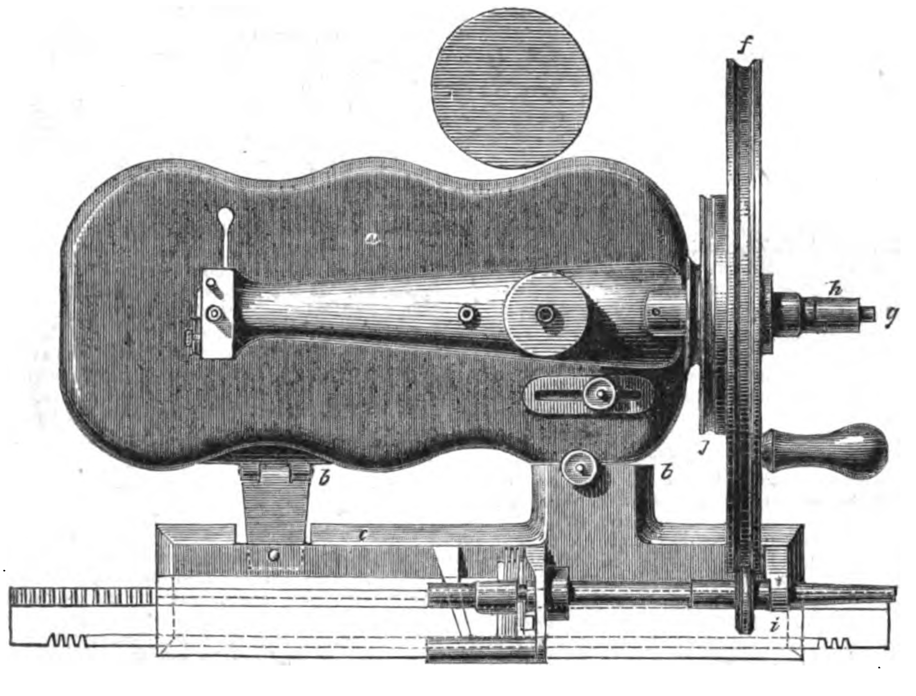
A FEW years since a very ingenious apparatus was invented for detecting the presence of firedamp in mines. It is known, says the Paris correspondent of *Engineering*, that when two different gases are inclosed and separated from each other by a light membrane, an exchange of the gases takes place through the diaphragm, and the pressure increases in the space into which the lightest gas flows. The inventor, founding his invention on this natural principle, known as endosmose, devised a box, the sides of which were formed of membrane; the air in the box was in communication with a mercurial gauge. When a rush of firedamp took place in a mine gallery where this apparatus was placed, the gas penetrated the sides of the box, and the pressure rose, sending up the mercury, which acted on a bell, or other indicator, and gave warning of the imminent danger. This invention is worthy of notice, but the many practical difficulties that attended its introduction into mines prevented its successful application, and now another apparatus having the same object has been introduced by M. Tarquan. This apparatus consists of a bell actuated by clockwork, the striking motion being checked by an unevenly balanced arm, the lighter end of which is held by a cotton thread impregnated with saltpetre. The apparatus is placed in a wire gauze cage.

The firedamp, when it occurs, penetrates with the air into this cage, and quickly ignites from contact with a lamp that burns therein, and as a necessary consequence burns the thread, and sets free the balanced rod that checks the bell, which then gives the alarm.

COMBINED KNITTING AND SEWING MACHINE.

THE sewing-machine has now become almost a sine-quâ-non in all well-appointed households, and a steadily-increasing number of machines are manufactured yearly, for the saving in the labour of the needlework necessary where there is a large family has made a very successful appeal to the thrifty housewife, who appreciates at its full value the advantages offered by the machine over the hand-driven needle. Another kind of useful domestic machine is also finding its way into public favour—viz., the knitting-machine, several descriptions of which we have illustrated from time to time. We have now to bring before the notice of our readers a method of combining a knitting and sewing machine in one piece of furniture, so that both can be worked simultaneously or either separately. In order to accomplish this Mr. A. Pilbeam, who has recently patented the combination, takes a knitting-machine of that class which has a single needle and a reciprocating comb, such as that described in the Specification of an Invention, No. 2639, 1869, which is commonly known as the "Hinckley" knitting-machine. In this machine the reciprocating comb is arranged to slide to and fro in front of the machine, and is operated through a rack by a peculiarly constructed switch wheel. This wheel carries on its shaft a frictional pinion, and thereby receives motion from a grooved driving-wheel. The machine is provided with an eye-pointed needle, operating with a reciprocating motion across the comb. The frame or bed of the knitting mechanism is attached by hinges or other suitable connections to the base or bed of the sewing-machine, in such a manner that the said knitting mechanism can be swung down in front of the machine away from the driving-wheel. The latter is preferably placed on the shaft of the sewing mechanism. There is also a counting or indicating wheel which may be removed from its usual position, and placed at one end of the machine, so that it shall not interfere with the desired adjustment of the parts. In some cases, instead of making the entire knitting mechanism adjustable, the driving-wheel may be supported in eccentric bearings, which may be turned on their axes to move the said wheel into or out of gear with the pinion. The sewing mechanism employed may be that of any ordinary sewing-machine which has a horizontal shaft for operating the needle bar. On the driving-wheel there is a smaller wheel to receive a belt or cord for operating the machine by a treadle. The driving-wheel is fitted to turn loosely on its shaft, but is provided with a clutch or other contrivance, whereby it may be connected to the shaft or released therefrom, so that the driving wheel may be made to drive the sewing mechanism, or may be turned without driving the same as desired. Sometimes an adjustable wheel is fitted to slide on a key or feather on the shaft, and arranged to enter within the rim of a small wheel fixed on the driving-wheel, thereby locking the two wheels together, so that the required motion is imparted to the sewing mechanism, the same being stopped by simply sliding the adjustable wheel out of the other wheel.

In the figure, which is a plan of the machine, showing the knitter turned up and in gear with the driving-wheel, A is the bed or base of the sewing mechanism, the table on which it is generally mounted being removed; B B are the joints or hinges which connect it to the bed C of the knitting mechanism. When the knitting mechanism is turned up it is supported on a board or slab placed over the recess which receives it when turned down. F is the driving-wheel, fitted loosely on the shaft G of sewing machine; H is the clutch whereby the wheel is connected to the shaft; when it is desired to release the wheel, one part of the clutch is withdrawn from the other part; I is the frictional pinion on the shaft of the knitting mechanism, which is made to gear with the wheel F when it is desired to operate the knitter; J is the belt wheel or pulley, whereby the machine is operated from a suitably-arranged treadle. When the sewing mechanism is arranged like that of the machine known as the "Willcox and Gibbs," and others of the same class having an under shaft extending below the cloth plate, the patentee prefers to provide for throwing the sewing mechanism into and out of gear by making the pinion which drives the under shaft slide into and out of gear with the wheel on the driving shaft.



DRYING BY CHEMICAL ACTION.

THAT wonderful property, says the *Scientific American*, called by chemists affinity, which exists between different substances, exerts a force so much greater than any which is practicable to the resources of mechanics that it may be made one of the most effective means known whereby the desiccation of substances can be accomplished. Sometimes it may be employed singly. In other instances, it may be used in connection with heat or mechanical action, or all three may be used together. There are few substances that have no affinity for water, but there are some which seize upon it and hold it with such intense force as almost to defy separation. The strongest chemical reagents, such as sulphuric acid and the other strong acids, the alkaline bases, potassa, soda, lime, &c., owe much of their usefulness in the arts to their affinity for water. There are few substances that have so strong an attraction for water that some one of the alkaline bases will not seize upon it and hold the whole of it.

Of course, when water is an essential ingredient of a compound, and not an extraneous substance, its removal effects decomposition; and in all such cases, the use of chemicals for drying—as it not only removes the superfluous water, but injures what remains—is, of course, inapplicable. One of the most important processes in which chemical drying is employed, and one of the best illustrations of the principles upon which it is based, is that of *separation*, as it is called, in the soap manufacture. The fats or oils used for soda soaps are first saponified by an excess of the solution of caustic soda, technically called "ley." The soap thus formed contains glycerine, excess of water, and soda, which it is desired to remove. Now, although the soap has a strong affinity for water, it could be dried sufficiently by the slow and careful application of heat, but to do this would require a long time, and, besides being very tedious, would be a very expensive process. Soda, or chloride of sodium (common salt), has a much stronger attraction for water than soap. If either of these substances in strong solution should be added to the soap in sufficient quantity, and heat be applied, the following actions are set up:—The soap floats upon a strong solution, "ley," of soda or salt (sometimes both are used). The heat applied to the bottom of the kettle drives off a portion of the water in the solution, which is replaced by water attracted to the salt or soda from the soap; this is in turn converted into steam by the heat, and so on, the soda or salt taking water constantly from the soap, which the heat expels until the soap has been sufficiently freed from water. Meanwhile the soda ley has dissolved out all of the glycerine, and the water in departing from the soap has carried with it the excess of alkali, adding it to the solution at the bottom of the kettle, and so the purified soap floats in hard grains or lumps upon the ley. The soap being then drained is ready for the subsequent operations, which fit it for sale and use.

This is a fine example of chemical action combined with heat to eliminate water. Another illustration is the production of absolute alcohol by distilling it in contact with quicklime, the latter seizing and holding all the water contained in the alcohol, which then passes over and is condensed in the receiver.

Chemists pass gases through quicklime, chloride of calcium, calcined potash, or soda, to rid them of watery vapour. Polished metallic articles, liable to tarnish through the action of watery vapour, may be protected by placing them in a case in which is also placed a little quicklime. Whenever the lime falls into fine powder, it is an indication that it has absorbed all the water it can hold, and that a new supply of quicklime is required.

Very rapid drying without heat can be accomplished by the use of quicklime and a fan blower, using the same air over and over, first passing over or through the substance to be dried, and then over quicklime in lumps. The process can be accelerated greatly by heating the air on its passage from the lime to the substance to be dried (the heating greatly increasing the absorbing power of the air) and keeping the lime cold by means of tubes through which cold water passes. By regulating the heat properly, very delicate substances may be thoroughly desiccated without injury. The writer has applied this process in certain operations with great success. Where an operation of this kind is conducted on a large scale, the lime can be renewed over and over again by calcination, which drives off the moisture (and, perhaps, carbonic acid) it has absorbed.

The hints thus thrown out may serve as a guide to inventors who are devising means for the desiccation of fruits, vegetables, meats, &c., and for the concentration of milk, &c. Processes of this kind are being extended rapidly at the present time, and the preparation of articles of food, in a palatable form, and in a condition to keep a long time, is daily becoming of greater industrial and commercial importance.

TEA DRUNKARDS.

DR. ARLIDGE, one of the Pottery Inspectors in Staffordshire, has put forth a very sensible protest, says the *Lancet*, against a very pernicious custom which rarely receives sufficient attention, either from the medical profession or the public. He says that the women of the working classes make tea a principal article of diet instead of an occasional beverage; they drink it several times a day, and the result is a lamentable amount of sickness. This is no doubt the case, and, as Dr. Arlidge remarks, a portion of the reforming zeal which keeps up such a fierce and bitter agitation against intoxicating drinks might advantageously be diverted to the repression of this very serious evil of tea-tippling among the poorer classes. Tea, in anything beyond moderate quantities, is as distinctly a narcotic poison as is opium or alcohol. It is capable of ruining the digestion, of enfeebling and disordering the heart's action, and of generally shattering the nerves. And it must be remembered that not merely is it a question of narcotic excess, but the enormous quantity of hot water which tea-bibbers necessarily take is exceedingly prejudicial both to digestion and nutrition. In short, without pretending to place this kind of evil on a level, as to general effect, with those caused by alcoholic drinks, one may well insist that our teetotal reformers have overlooked, and even to no small extent encouraged, a form of animal indulgence which is as distinctly sensual, extravagant, and pernicious, as any beer-swilling or gin-drinking in the world.

REVIEWS.

Natural Philosophy for General Readers and Young Persons. By E. ATKINSON, Ph.D., F.C.S. London: Longmans.

THIS is an elementary and popular Natural Philosophy, translated and edited by Dr. Atkinson from Ganot's elementary work. It has its origin in a suggestion frequently made to its Editor, that he should compile an abridgment from his larger work, well-known by the title of Ganot's "Physics," which should be suited for elementary instruction, and in which mathematical formulæ could be dispensed with. Finding that to produce an abridgment of the larger book would be a work of difficulty, and, if it was to be anything more than a mere collection of extracts, would involve the re-writing of the greater part of the matter, Dr. Atkinson resolved to translate the book which Ganot had written with a similar object, and which, we need scarcely say, is as well suited to its purpose as the larger work. The present volume is not a mere copy of the more elaborate one, although, as a matter of course, the facts, and in many places the phraseology, may be the same. Neither is it a strict reproduction of the French original, nor a mere rudimentary exposition of the subjects with which it deals; for Dr. Atkinson has made such alterations and additions as fit the work for use as a text-book for the middle and upper classes of schools, while sufficient information is given to enable the recipient to pass the matriculation examination at the London University. The book is abundantly illustrated with explanatory and pictorial cuts, and is really the best work of the kind for junior students and drawing-room readers. There is a slight error in one of the illustrations, which it might be well to correct in a second edition. In Fig. 260 the letters *v* and *j* will hardly convey the idea that they are meant to indicate the positions of the green and yellow in the spectrum to those unacquainted with French, though a mistake could hardly be perpetuated when reference is made to the well-executed coloured frontispiece which represents the solar spectrum with Fauenhofer's lines, and the spectra of potassium, sodium, cæsium, and rubidium.

The Sun: Ruler, Fire, Light, and Life of the Planetary System. By R. A. PROCTOR, B.A., Hon. Sec. R.A.S. London: Longmans.

WE have already spoken in a favourable manner of this book, and need not now occupy much space in noticing the second edition, the appearance of which we hail with great satisfaction, not alone because it affords some evidence that its author is in a pecuniary sense reaping the reward of his indefatigable and painstaking labours, but because it is also a proof that the public are inclined to pay more attention than was formerly their wont to scientific subjects. This edition has been thoroughly revised, and contains much new matter, such as an account and an analysis of the observations made during the eclipse of December, 1870. Although Mr. Proctor did not wait for the observations made during the recent eclipse, his chapters on the circumsolar region are none the less complete, though the facts on which they are based are less striking than the overwhelming evidence obtained in December, 1871. Several new illustrations supplied by Mr. Brothers, Professor Young, and others, serve to make the volume the completest as well as the most popular treatise on the nature and phenomena of the sun hitherto published.

Geometrical Conic Sections. By J. STUART JACKSON, M.A. *Solid Geometry and Conic Sections.* By J. M. WILSON, M.A. London: Macmillan & Co.

THESE are two little books which will be found useful and suggestive by students of the subjects on which they treat. The first has been written with the object of giving the student the benefit of the method of projections as applied to the Ellipse and Hyperbola, a method calculated to produce a simplification in the treatment of those curves, and to make their properties more easily understood and remembered. Mr. Jackson points out in his preface that by this method it is a consideration of importance that we can see at once from the form of the cone the general form of the curves cut from it by a plane in different positions; and by turning the plane about a certain line we see how the curves pass from one form into another.—The little work by Mr. Wilson is written with the view of introducing into schools some portions of Solid Geometry now very little studied in this country. Short appendices on Transversals and on Harmonic division are added, and the chapters on Conic sections are condensed to suit the wants of schoolboys by defining these curves as sections of a cone, and immediately deducing their fundamental properties, and by taking the ellipse and hyperbola together where possible.

A Treatise on the Metallurgy of Iron. By H. BAUERMAN, F.G.S. London: Lockwood & Co.

THIS is the third edition, revised and enlarged, of an account of the production of iron, which is tolerably well known, and is generally favourably received. It is a concise treatise on the manufacture of iron, giving a short but ample history of iron working, the methods of assay, with analyses of iron ores, and the various processes employed in the production of iron and steel. The author has availed himself of the numerous and valuable works published on the subject in Germany and France, as well as the elaborate and expensive volumes issued in this country. The additions to the present edition have been introduced in their proper positions, and include a notice of the Siemens-Martin steel process and the methods proposed by Heaton, Ellerhausen, and others; but we miss a description of the Danks' mechanical puddler, although previous attempts in this direction are recorded. This will be considered a fault in a work which is otherwise well suited to convey accurate knowledge on the most important metal industry of this country. The book appears to have been in the press in the autumn of last year, which would probably account for the omission—an omission to be regretted, but which by no means invalidates the book from being one of the best treatises on the subject in a small compass extant.

Electrical Tables and Formulæ. By LATIMER CLARK and ROBERT SABINE. London: E. and F. N. Spon.

MESSRS. CLARK AND SABINE have here brought together a mass of information of great value to telegraph inspectors and operators, which is, moreover, we believe, perfectly reliable. It would be impossible within the limits of a short notice to enumerate the various subjects on which information is given, suffice it to say that everything necessary for designing, working, and laying out telegraph lines, whether land or submarine, together with many useful tables founded upon actual practice, find a place in this book, and although the authors say that in bringing together so heterogeneous a mass of materials it was found difficult, if not impossible, to follow consistently any systematic plan of arrangement, the volume is none the less valuable on that account, while a copious index supplies an efficient remedy for a defect which was unavoidable. Many of the first electricians have furnished contributions, and the writings of others have been utilised in making the book a perfect vade-mecum for the constructors and manipulators of the telegraph.

Elements of Chemistry: Theoretical and Practical. By W. A. MILLER, M.D., &c. Revised by HERBERT MCLEOD, F.C.S. Part I. *Chemical Physics.* London: Longmans.

THIS is the fifth edition of Dr. Miller's well-known "Elements of Chemistry," which has been revised throughout, but without being altered unnecessarily. The rapid progress made by recent research in some branches of physical science, however, necessitated additions to the text as left by Dr. Miller in the fourth edition—the most important of these being, of course, those relating to solar chemistry and the theory of atomicity. Noting these facts is all that is necessary in recommending to students this new edition of a work of established reputation.

Geological Survey of Ohio. Report of Progress in 1870. By J. S. NEWBERRY. Columbus, Ohio: Nevins and Myers.

THIS is one of the yearly reports of those exhaustive surveys carried out in the different States of the great Republic of America, forming a volume of nearly 600 pages, with several maps and geological charts, showing the formation of the surface and the positions of the various strata as found in the State of Ohio. These geological surveys are prosecuted in America under State patronage, and by means of State funds, and result, as a rule, in the collection of information of importance, directly or indirectly, to every citizen of the State; thus the object of the survey is, first, a general view of the relations of agriculture to geology; a classification of soils according to their chemical and physical characters; an inquiry into their sources of fertility, their adaptability to different systems of agriculture, their deterioration, renovation, &c.; second, a description of the natural soils of the State classified by districts and properties; an inquiry into the sources whence they are derived, their adaptations, their changes under cultivation, methods and materials for the restoration and maintenance of their fertility, with an investigation into the properties and distribution of such fertilisers as are found within the district. Besides all this, chemical analyses of the minerals found are made; their uses and the best methods of working them are pointed out; in fact, this geological survey, of which these yearly volumes are but portions, embraces the physical features of the country, its climatology, and an account of its productions; the natural history of the principal animals inhabiting it, and elaborate treatises and catalogues of the botany, zoology, and palæontology of the region. It must be acknowledged that this is good work, work which will not fail to make a handsome return in the future for the money and time expended on it.

Pocket-book of Mechanics and Engineering. By JOHN W. NYSTROM, C.E. Philadelphia: Lippincott and Co.; London: Trübner.

THIS is a really valuable pocket-book for the mechanic and engineer, containing as it does the first principles of every science with which they have to deal, and of others with which they have no concern in their occupation. Thus, it includes the prominent facts of mathematics, with the integral and differential calculus, geometry, land surveying, "railway mechanics," astronomy, acoustics, dynamics, chemistry, hydrostatics, optics, &c. It is replete with useful and reliable tables, and bristles with formulæ. The calculations have all been made with Nystrom's Calculator, which received the first premium at the Franklin Institute Exhibition. There is an ample supply of explanatory woodcuts and plates, and altogether this is one of the best "pocket-books" we have ever seen.

Catalogue of Model Steam-Engines and Castings. London: John Bateman.

WE have received from Mr. Bateman a copy of his catalogue of model engines and castings, and the useful tools which he also supplies. Those of our readers who are intent on making model engines, steam-hammers, pumps, and sundry other machines, will do well to procure a copy. The idea of supplying the rough castings of the various parts, on which the amateur could exercise his ingenuity as fitter and finisher, originated, we believe, with Mr. Bateman, and a very good idea it is. There are hundreds of amateur mechanics who would occupy their spare time in a useful and instructive manner, if suitable materials for them to work upon were provided. The difficulty and cost of obtaining the requisite castings, which it is almost impossible the amateur should make for himself, has hitherto stood in the way of the more universal development of latent ingenuity and skill; but this state of things has been put an end to by Mr. Bateman, from whom the castings of parts of locomotives, engines for model boats, and various other mechanical contrivances, are now to be obtained at certainly a moderate expense, and with a very little expenditure of time and trouble. Those of our juvenile readers, too, who have a little spare time on their hands, cannot occupy it in a more pleasing or profitable manner than in constructing a model engine, and a perusal of Mr. Bateman's catalogue will show them how to set about it.

We have received numerous books which we cannot spare space to notice at present, and many others to which we can only briefly refer. Among these is a pamphlet *On the Curability of Cancer*, by Dr. G. von Schmitt (Wyman and Sons), in which the author asserts that cancer is curable by medical treatment without surgical operation. Dr. Schmitt employs plaisters and ointments as remedies for cancerous tumours, and says he has had fair success. He gives an account of the medicaments he employs and prints some of the "testimonials" he has received. Of his system we can only say that as condurango has been thought worthy of trial at several public institutions, the same plan should be adopted with Dr. von Schmitt's method—that is, if he is willing. — *Science Lectures* (John Heywood, Manchester) is a book of 140 pages, containing the discourses delivered in the Hulme Town Hall, last year, by such men as Professors Huxley, Roscoe, Odling, and Wilkins, and Dr. Carpenter. The lectures appear to have been well reported, and the book is simply "dirt cheap."—*The French Student's Pocket Vade-Mecum*, by B. E. le Bret (John Heywood), is a concise list of verbs, &c., for handy reference.—*A Bird's-eye View of the Metric System*, by George Hogg (J. Heywood), is a sheet containing the metric measures, weights, and money, with the British equivalents, but omitting the metric equivalents for the various English weights and measures. — Messrs. Griffin send an excellent series of *School Board Readers*, adapted to the requirements of the new code. The series comprises two parts of the elementary reading book, and books for the six standards, "containing no distinctive denominational teaching." The series has been edited by a former "Her Majesty's Inspector of Schools;" but we should think he would hardly award a prize for grammar to the boy who said "The sow is bad for the boy did hit *him*" (Lesson 15).—*The Year-book of Facts for* 1872 (Lockwood and Co.), is similar to the volumes issued in previous years. Independently of the fact that the "cuttings" are not always taken from the best sources, a few editorial notes would be of great assistance to uninitiated readers, numbers of whom may retain the impression, for instance, that Mr. Payne's magnetic engine is the wonderful discovery which the account given on page 143 makes it.

THUNDERBOLTS AND LIGHTNING.

WE are indebted to an American correspondent for a copy of the Philadelphia *Public Record* containing an account of a lecture delivered by Professor John Wise, at the Wagner Institute, on "Thunderbolts and lightning." The lecturer commenced by saying that he had no speculative theories to subserve, but would simply relate the facts as observed in his investigations of the phenomena of lightning, and would then show by these facts that the lightning rod too often played the part of an incendiary. After reviewing twenty-nine cases of lightning stroke that occurred in Philadelphia last summer, and showing that the greatest loss of property took place under the supposed protection of the lightning rod, he noted a large number of cases that occurred in other places. The destruction of the extensive pattern shop of Morris and Co., and the Pekin woollen mills of Manayunk, caused a loss of over 100,000 dollars, and both those establishments were defended by lightning rods. He stated that small bodies of iron when struck by a thunderbolt, will scintillate vivid sparks, and thus ignite any adjacent inflammable matter. He also reviewed three cases of lightning stroke as they occurred in Iowa City, Terra Haute and Indianapolis, where the lightning was communicated from the rod to the gaspipes in the buildings, set fire to the gas, and then passed out to the gas mains in the street, where, in one case, it burst the lead packed joints here and there for a distance of 1,000ft. and in the other two it totally burned out the lead packing, leaving nothing but a little dross in its place.

The lecturer arrived at the following conclusions derived from an examination of many cases during the last three years:—That lightning is an accumulation of force in the cloud. That when the cloud becomes surcharged it explodes with a discharge always toward the earth. That it generally comes from the west and south-west. That its main force is in its axial line of projection. That it strikes buildings indiscriminately as to lightning rod or no lightning rod, and that in either case its dynamic force appears to be the same. That when it strikes a bar of iron, as a spike or clamp, or even a shingle nail, it burns the surface and scintillates bright sparks, which are capable of igniting adjacent inflammable material. That a thunderbolt is neutralised the instant it meets its correlative equivalent of metal surface. That when it strikes the lightning rod, that being only a fractional quantity of its neutralising equivalent, and the earth or water at the rod's terminal point being but a poor conductor (four hundred millions of times slower than iron), it meets a cul de sac, recoils and heats the rod sufficiently to melt its point and to scintillate sparks from its surface which set fire to the building. That in a house with a metal roof there is no danger of harm from a thunderbolt, either to persons or property. That whenever the lightning rod is struck by a thunderbolt it proves its own inefficiency, since Franklin's theory was that it would prevent thunderbolts, not catch them. That there is no reliable evidence of upward strokes of lightning and that the recoil of a thunderbolt upon the rod is what leads to that notion.

VOLCANOES AND EARTHQUAKES.

THE following paper, by Mr. W. H. Corfield, which bears upon a subject of interest at the present time, and also upon the discussion which has been carried on for the last month in our pages, is extracted from *Nature*:—

The remarkable series of volcanic phenomena which have lately been exhibited at various parts of the earth's surface within so short a period of time, gives much matter for consideration, and must in due time afford us a rich harvest of facts with which to test the numerous theories which have been started to account for the occurrence of volcanic eruptions and of earthquakes. Even from our at present scanty information we have, I think, something to learn.

First in the series, so far as I am aware, was the very severe earthquake at Independence, Inyo County, California, which took place on Tuesday, March 26, commencing at 2 a.m., and lasting till 7 a.m., during which time "the earth was never for a moment perfectly quiet, and every few minutes heavy shocks, of a few seconds' duration, were occurring; in all there were more than fifty very heavy shocks." This place is only fourteen miles from the Black Rock, a volcano in the Sierra Nevada mountains, "the sides of which are covered with lava, and which is supposed to be an extinct volcano." It is stated that "during the time the shocks were most severe, flashes of light were seen to issue from the top of this mountain, and streams of fire ran down its sides."

The result of this earthquake is summed up in a few words as "the whole country turned topsy-turvy" (*Virginia City* (Nevada) *Enterprise*).

Then a few days afterwards came the terrific earthquake in Antioch, which commenced on April 3, and continued with greater or less severity, "in Aleppo, and as far east as Orfa, beyond the Euphrates," for more than a week, becoming very severe on April 10; here there appears to have been no actual volcanic phenomenon; but it appears from the letters of the Rev. W. Brown in the *Times*, that there exists in the immediate neighbourhood a mountain, "the peculiar conical form of which is very suggestive of an ancient volcano."

The latest African news tells us that "several violent shocks of earthquake had occurred at Accra, on the Gold Coast, on April 14 and 15, causing considerable damage to the place." And as unwonted atmospheric disturbances have often been connected with volcanic phenomena, it may not be out of place to mention here the fearful hurricane which wrecked every vessel but one in the Harbour of Zanzibar on April 15.

And then on April 24 began the recent eruption of Vesuvius, which will be for ever memorable, not only on account of its magnitude and grandeur, but also, and still most so, by reason of the amazing intrepidity of the man, who, from a pure love of science, remained at his post, like the gatekeeper of Pompeii, throughout the whole of that terrible time, but happily was not, like that heroic soldier, buried in a shower of ashes; the world was spared the loss.

Now, is there any connection between these phenomena exhibited in so distant parts of the earth's surface? One thing is certain—namely, that within the short space of a month all this has occurred, and one can hardly help thinking that somehow or other these volcanic countries must be connected underground; it has long been thought that Etna and Vesuvius are points on a volcanic area which passes north-west to the Eifel, Auvergne, and Iceland; has the neighbourhood of Antioch, with its unenviable notoriety for earthquakes, or the West African coast, anything to do with this area? But if so, what shall we say of the Sierra Nevada? Why should its volcanoes be active at the same time? Why should the country there be "turned topsy-turvy" by earthquakes?

While pointing out these coincidences, we must not jump too hastily to conclusions from them; for on the one hand we are told that although the Antioch earthquake extended so far east, yet, to the north and south, even at a few miles' distance, nothing whatever was observed; and, on the other hand, that the Californian earthquake was of so superficial a character that "at Hot Springs, while severe shocks were felt on the surface, the men in the mines, 200ft. deep, felt nothing of them." Now, the evidence goes to show that the latter earthquake was directly connected with the eruption of a volcano in the neighbourhood, so that, although the origin of the disturbance may be underground, possibly at a very considerable depth, the shocks are at a certain distance quite superficial, and, moreover, are transmitted in certain definite directions.

Taking all these facts together, they would rather seem to favour the conclusions that at any rate a great many, if not all, of the volcanic regions of the world are connected, and that they are not merely parts of the earth's surface which happen to be over isolated subterranean furnaces, but places where access to the exterior is more easy for the molten matter which lies underneath a great part, perhaps all, of the earth's crust. I must not be understood to be upholding the (shall I say exploded?) theory of the internal fluidity of the earth; I merely mean to point out that such coincidences in point of time ought to make one hesitate before rushing to the other extreme, and looking upon volcanoes as mere local eccentricities.

But it will be said, if there is any general commotion under even the volcanic area of Europe, why do not the extinct volcanoes of Auvergne break out again? Here is a difficulty which is not at all solved by the suggestion that at first occurs to one, that as the raising of the country has drained the enormous lakes, on the borders of which these volcanoes stood, there is no longer a supply of water to rouse them into action, for are there not lakes still in the Eifel, nay, are not those lovely lakes actually in the craters of extinct volcanoes?

Again, who has seen the wonderful natural harbour of Messina from the high ground above the town without believing it to be an extinct submerged crater? If there be still liquid rock below these craters, it may be that they are no longer the points of least resistance. And this is the probable explanation of their inactivity; for it must not be imagined that an eruption of Etna or of Vesuvius, or of any other volcano, necessarily means an ejection of ashes, lava, &c., from the crater, or from any crater; not at all, the weakest point in the vicinity gives way, and thus we have the numerous cones formed which surround every considerable volcano for some distance.

The mention of Auvergne leads me to make a few remarks on the disputed point, as to whether or not the volcanoes in that country have been in eruption within historic times, especially as I see that a correspondent (see also let. 4203, p. 254, from the Rev. H. C. Key) has come to the conclusion originally drawn by "an eminent historian and antiquary, Sir Francis Palgrave," as long ago as 1844, and adopted by theological writers ever since, that because a Bishop of Vienne established Rogation days on account of some alarming terrestrial phenomena which happened in his diocese, therefore the volcanoes of Auvergne were in action at the time. We have two documents which refer to this matter—a letter written by Sidonius Apollinaris (who lived in the very centre of the Chaine des Puys, and on the border of a lake which was actually formed by the damming up of a stream by one of the most recent of the lava-currents) to Mamertus, Bishop of Vienne, in which he speaks of the earthquakes that had occurred in the neighbourhood of Vienne; of fire issuing from the earth and wild beasts taking refuge in cities; and the Rogation Homily of Alcimus Avitus, the successor to Mamertus, which mentions the same catastrophes.

Now, in the first place, Vienne is more than seventy miles in a direct line from the more recent Auvergne volcanoes; in the next, Sidonius himself makes no mention in his writings of any eruptions having taken place in his neighbourhood, although he wrote poems describing the beauty of the scenery; and even Auvergne is not mentioned by any ancient writer, except by Cæsar, who encamped there and laid siege to a city situated on a table-land, with craters close at hand in almost every direction; nor by Pliny, who gives a list of all the then known volcanic countries, including some very out-of-the-way ones; nor by Strabo, nor by any of the poets, as a country where volcanoes were ever known to have been in action.

For these reasons, and because no volcano could have burst out near Vienne without leaving some traces of its existence, Dr. Daubeny concluded that the Bishops of Gaul alluded to earthquakes; especially as "the underground thunder, the opening of fissures in the ground, the bursting out of flames and gases, the projection of water and of stones, the smell of sulphur, the alarm evinced by the animals of the spot and neighbourhood, the elevation or depression of the land, noticed by Sidonius and by Avitus in the passages referred to by Sir Francis Palgrave, are all reported as concomitants of the great earthquakes which have occurred in more recent times." Geologists have since accepted this conclusion as the correct one, in opposition to what I may call the theological position.

There was, however, a volcanic region which had not been visited by any English geologist, and which had not been described—viz., the basin of Montbrison, through which the Loire flows. Of this Mr. Scrope says in his work (2nd Ed., p. 28), "a further examination of this basin seems very desirable;" now, as this district lies about half way in a direct line between the "Puys," about Clermont Ferrand and Vienne, it occurred to Dr. Daubeny that the disturbances spoken of as in the neighbourhood of Vienne, might have taken place around Montbrison, and accordingly, in the autumn of 1866, he visited that locality, and I had the honour of accompanying him on the occasion. We examined carefully the volcanic hills of the neighbourhood, and could find no trace of recent volcanic eruptions: in his own description of this expedition published in the *Quarterly Journal of Science* for January, 1867, and republished in his "Miscellanies" (Vol. I., p. 74), just before his death, he says:—

"I am now prepared to say that, without pretending to have surveyed the entire district, I saw enough to convince me that no volcanic disturbance which had occurred within this area at so late a period as that alluded to could have escaped our notice, and that every indication of igneous action which presents itself throughout the country bears marks of a much greater antiquity.

"Thus much, at least, I can venture to affirm—namely, that neither craters, streams of lava, scoriæ, nor even cellular trap, are to be met with anywhere within the limits of this district. On the contrary, the only igneous rocks which came under our observation consisted of a compact basalt, containing nests of olivine, a material which could only have been elaborated by the aid of great pressure, and under a different configuration of the surface from that now existing."

The Doctor therefore reiterated his statement that "the lively picture drawn by Sidonius" should not "be regarded in any other light than as the offspring of a lively imagination, dwelling upon reports which had reached the author with respect to some fearful earthquake which may have occurred in the neighbourhood of Vienne."

I will conclude by advising those who wish to study volcanic phenomena to go to Auvergne: they can do so at almost any time of the year, mid-winter, when it is far too cold for comfort, being the exception; they will there see results of volcanic action far more varied and instructive than at Vesuvius or even at Etna, and they will also be able to study the effects of denudation on a gigantic scale. Few geologists seem to appreciate the fact that within 24 hours of London is one of the largest, richest, and most beautiful of the volcanic countries in Europe.

HINTS ON COLOURING PHOTOGRAPHS.

THE increasing demand for coloured photographs, either as cartes-de-visite, stereoscopic enlargements, or slides for the magic lantern, opens a suitable field of labour, says Mr. J. Martin, in the *Photographic News*, for the educated of either sex; in fact, they are the only fit persons to undertake it, as it requires a lightness of touch not generally possessed by those accustomed to labour. But none can hope to succeed without some degree of talent, and who have had a sufficient practice in the use of colours to enable them to paint a tolerable picture without a copy, not a vile travestie of some chromo-lithograph, which is often the only practice afforded to school pupils. No particular box of colours, however prepared, will bridge over the want of experience.

The greasiness of the surface of albumenised paper offers some obstacle to the uninitiated, but this is easily overcome by adding a little prepared ox-gall to the colours used, or even by passing the tongue over the surface. The greatest drawback I have found has been the difficulty of obtaining purity of tints in the half-shades and reflections of the flesh, owing to the muddy-brown colour to which the print has been toned, a sort of smudge which no transparent colour can remedy. This, and the tendency of silver prints to become yellow by age, has often caused me to consider whether it might not be better, when they are especially prepared for colouring, to use some other process, which would give a more favourable tint for working upon. As I believe any variety of tint can be given in carbon printing, this, with its permanence, would point it out as the most preferable, but would, probably, greatly increase the expense of a single copy only.

When oil colours are to be used, two or three coatings of weak size, made of gelatine, should be given to the print beforehand, and allowed to dry. As in water, transparent colours can be used, and the effect much improved by touching the high lights with opaque ones.

In portraiture, should the painter be sufficiently master of his art to paint a good picture in the usual way, he will find it much better to use the photograph as a copy than as a substratum.

Transparencies on glass must always receive a weak coat of varnish before colouring, otherwise dabbing in the skies will do injury to the impression.

It should be understood that there is a great difference between colouring—that is, tinting—a photographic print and painting upon one; the former requires little more than tasty manipulation, the latter the skill of a well-trained artist.

Retouching negatives also offers suitable employment, especially for female artists, as it requires light and delicate handling. I should think that an artist capable of retouching from the life—that is, taking sittings from customers—would be considered a desideratum in many photographic establishments, and be liberally remunerated.

ACTION OF A MAGNET ON THE ELECTRIC LIGHT.

THE following account of the action of a magnet on the electric light is contributed by Professor E. J. Houston to the *Journal of the Franklin Institute*:—

Having occasion recently to set up a large battery for experimental illustration of the properties of the light of the voltaic arch, I noticed a fact which I believe has hitherto escaped observation. The battery consisted of about eighty half-gallon cells; fifty-five were Browning's modification of the nitric acid battery of Grove. The negative element consists of sawed strips of very dense coke, the positive element of zinc, so arranged as to use both surfaces of the coke. The remaining cells were of the iron battery. When first set up, the arch between the carbon electrodes measured fully 2in., while the flame frequently reached an equal distance above the upper carbon. The quantity of the current was very good, much better, in fact, than the size of the plates would have led me to expect.

The phenomenon to which I would call attention is as follows:—Wishing to show the well-known experiment of the rotation of the light by a magnet, I approached a compound bar magnet to the light, holding it with one end pointing directly to the arch, in a horizontal plane equidistant between the carbon electrodes. When the nearest end of the magnet was 4in. from the electrodes, the light was instantly extinguished. The regulator of the light which was employed is a form recently patented by Browning of London. The carbon points are kept at a constant distance from each other by the action of a small magnet worked by the battery current. Though inapplicable to small batteries, for the current I employed it gave a light admirable for its steadiness. Thinking that the extinguishing of the light was produced by some cause other than the approach of the magnet, the experiment was repeatedly tried in a number of ways, until it was clearly shown that the cause could not be attributed to accident, but to the approach of the magnet. Though I have failed to find any published notice of this phenomenon, it seems probable that it may already have been observed, as the conditions of the experiment would be almost exactly reproduced whenever the rotation of the light of the voltaic arch by the magnet was tried. Still, it may be conceived that though the necessary conditions for success in this experiment have often been *nearly* reproduced, they have seldom, if ever, been exactly reproduced; for it was noticed that in no case was the light extinguished, unless the length of the arch was nearly as great as the tension of the electricity admitted; that is, unless the electrodes were separated by nearly their maximum distance, consistent with the passage of the current. Were this condition not observed in all cases, the approach of the magnet produced no other effect than the rotation of the light, until it assumed a position in a vertical plane 90° from a similar plane passing through the magnetic axis of the bar. Then, again, another necessary condition is that both the tension and the quantity of the current be of a strength greater than that of the current on which the experiment of rotation is generally tried. I have experimented with flames when these latter conditions were absent, and although the rotation was observed, the extinguishing of the light was in no instance produced. The compound bar magnet employed is formed of three bars, held together by brass screws. It is 1ft. long, 1in. broad, and ¾in. thick, and is not at all remarkable for the strength of its magnetism.

As to the cause of the phenomenon, I think it may be attributed to the tendency of the flame to rotate on the approach of the magnet. This might cause the extinguishing of the light in two ways; either by the irregularities on the surfaces of the carbon electrodes offering greater resistance to the passage of the current from some points than from others, or by the current being unable to pass through the greater distance of the arched path, which is always assumed by the light on the approach of a magnet. Another assumption, which, though perhaps not as simple as those already mentioned, is at least as probable, is that on the approach of the magnet, there is a slight increase in the non-conducting power of the medium between the electrodes, produced by their polarisation, and which, though always acting, can only manifest itself in a striking manner when the distance between the electrodes is near a maximum, and the tension of the current is exerted to its utmost in passing through the non-conducting medium. This assumption of the polarisation of the medium between the electrodes, and its consequently diminished power of conducting the current, seems to be somewhat sustained by the fact, that a powerful electro-magnet, in the form of a horse shoe, when approached, did not extinguish the light, although it produced rotation of the current, for we may conceive that the two poles, acting simultaneously on the medium, would neutralise each other's effects.

I noticed, on several occasions, that the south pole of the magnet would not extinguish the light until it was approached 1in. nearer than the north pole, namely, to within 3in. of the electrodes. This, however, may have been accidental.

THE RECENT ERUPTION OF VESUVIUS.

THE following is the substance of a lecture delivered at the University, Naples, by Professor Palmieri, on May the 9th, as reported by the *Times* correspondent:—

Great interest was excited by it. Several thousands assembled, and on Professor Palmieri entering the hall he was received with a round of applause. The terrible conflagration of the 26th of April, said the Professor, may be regarded as the finale of the eruption which began on the 1st of January, 1871, and has lasted, with alternations, up to the present time. It generally happens that the eruptions, which are small and gentle at their commencement, terminate with great violence, carrying destruction to human dwellings and devastation to the country. Among the most fearful eruptions which history records was that of 1631. It is related that on that occasion 4,000 human beings were killed, and 6,000 animals, cattle and sheep. Three centuries had elapsed since the mountain had given signs of activity; grass grew in the very crater, and shepherds took their flocks there to pasture. Thus it happened that taken unexpectedly many were swallowed up in the abyss which was opened; many were drowned or buried in the fiery flood, and others were destroyed by the pumice and burning stones which were vomited out of the summit and from other mouths. In strong centrical eruptions—by which is to be understood those which come from the upper cone of Vesuvius—great fissures are usually produced, which eject matter from as many different mouths, the lowest of which are the most dangerous. Such was the case with the recent eruption; for on the night of the 26th of April a mouth was opened in the Atrio del Cavallo, in the long fissure which had been made previously. The opening of this mouth formed, as it were, a hill in the Atrio del Cavallo resembling a chain of small mountains, and from underneath the lava issued calmly and rapidly, like a river of fire, while from the principal cone was ejected a continuous and violent shower of lava, smoke, ashes, and other fiery projectiles, which rose to the height of 1,500 metres (between 5,000ft. and 6,000ft.), while the mountain thundered terribly. Many had gone on that day and evening to see the lava, several of whom the Professor had endeavoured to dissuade from entering the Atrio del Cavallo. Those who arrived later and remained until after midnight became the victims of their curiosity. Between 2 and 3 o'clock in the morning the Atrio opened with a fearful roar, and from the new mouth issued the lava with great impetuosity, wrapped in a cloud of "boiling" smoke, ashes, and red-hot stones. Those wretched persons who were there were scalded by the smoke and wounded by the projectiles; some of them died immediately, others later. Of the others who remained on the farther side no traces remained, they having been swallowed up and buried by the burning stream. Those tremendous disasters may be foreseen and prevented, but a good service of guides is necessary; moreover, the Observatory should be well arranged, well organised, and good *employés* appointed to remain on the mountain during the eruption to give the alarm. On the night of the 26th of April the lava precipitated itself into the Fosso della Vetrana, and, descending on the incline of the mountain over former beds of lava, invaded S. Sebastiano, Massa di Somma, and Coreola in the Cupa Giorvano, so called because, as it is said, that famous painter had a villa there. From 1852 to the present time the lava has filled up the Fosso della Vetrana to the height of 200 metres; if further additions be made hereafter, the Observatory must be destroyed, as the last lava is only a few metres under its level. The lava here has the breadth of a kilometre, and on the banks of this river of fire—a remarkable and novel phenomenon—small craters have been formed by the lava, which thundered like the principal crater, and ejected smoke, ashes, and stones to the height of 70 or 80 metres. These observations are of great assistance to science, as they show the course of operations in the interior of Vesuvius. I trust, said the Professor, that the lava will not make me pay dear for this good service by invading the Observatory. The velocity of the lava varies from 180 metres a minute to a few millimetres, depending much on the condition of the land, being quicker on the incline, less so on the plain and where there are obstacles. Issuing in a liquid form from the mouths, it runs with great velocity, but slackens its pace as it advances, cooling gradually, and forming, as it were, a skin on the surface. This increases in solidity, and so the progress of the stream is diminished. When the lava ceased, Vesuvius continued to eject ashes and pumice, and still thundered; then the roaring ceased, and the rain of ashes decreased in quantity. Afterwards came heavy storms, which are commonly dangerous, as they are the occasion of great floods which, carrying down the ashes and pumice which cover the mountain, complete the ruin of the lands which have been spared by the lava. After the eruption of 1631, the floods were so strong that the damage done by them was not less than that occasioned by the lava, and the lands of those who suffered were exempted from taxes for ten years, like those which were damaged by fire.

There are some who think—and the opinion is general among the agriculturists of the Vesuvian district—that the ashes are beneficial to the land as manure, but that they injure and sterilize it if water be added. The analysis of these ashes shows that a portion is soluble in water, another part not. This has the same properties as the contemporaneous lava, and is a species of silicate which may be useful to the land. After the eruption of 1812 there was an extraordinarily abundant harvest in the Puglias, and it was attributed to the ashes of Vesuvius, which had been carried there by the wind. The ashes soluble in water, however, containing chloric acid, sulphuric acid, salmarina, burn land and wither vegetation. The beautiful country near Vesuvius which had been exposed to the recent conflagration is now a scene of squalid desolation. The harvest of this year is absolutely lost, and of that of next year we cannot indulge any cheerful hope. During the late eruption a report was spread in the city, giving rise to great alarm, that the crater of Vesuvius had become an electric pile, and that at a certain hour a strong earthquake would shake Naples to its foundations. That report was exaggerated, but the currents of electricity developed in the volcano were very strong. These phenomena do not accompany all eruptions. In this, the latest, the Professor observed a large quantity of lightning which flashed in the great pile of smoke and ashes which rose from the crater. The noise which accompanied this lightning varied according to the length of its duration. When short, the noise was full and round, so to speak; when it was longer it produced a sound which was dry and hissing like that of tearing paper. The lightning is generated by the violent ejection of smoke and ashes, by means of which the electric current is established. The lava is now firm; is spent and yet smokes—not to be wondered at after so recent an eruption. We have seen the lava of 1858 still smoking in several places. These jets of smoke are called "fumaroli." These smoke-holes are communications between the upper crust of the lava which has hardened and the internal mass still incandescent. Around these holes are formed sublimates of oxide of copper, of chloric acid, of sal ammonia, of sulphur, &c., which invest the lava with forms and colours at times the most beautiful. The Professor said he had analysed the smoke which rose from the lava, and had discovered that it dissolves in salt water. From this he inferred that the waters of the sea are disturbed by those terrible convulsions, and are mingled with the fire. At the conclusion of his lecture, Palmieri said that on the evening of the eruption Vesuvius appeared to sweat fire through every pore, which by night appeared like so many specks of flame attached to the back of the dark cone; by day those flames were changed into smoke. Palmieri thanked the authorities and all others who had manifested so lively a sympathy for him, which had well repaid him for the labour and anxiety he had undergone for the benefit of science. What I now send is, says the correspondent, of course, only the digest of a lecture which will, no doubt, be published. It is, however, a faithful report, as I have been permitted to translate some notes which were taken on the occasion. Many addresses from public bodies have been forwarded to Palmieri expressive of admiration, and his Majesty has sent him a distinguished decoration—the Grand Cross of St. Maurice and Lazarus.

THE ANTI-MILDEW GRAIN PROTECTOR.

A MECHANICAL method of preventing corn and seed in bulk becoming affected with mildew has recently been shown in London by Messrs. Adutt and Co., of Mark-lane. It is an invention by Mr. Joannides, and consists of an arrangement of perforated and solid tubes, on the principle of the siphon, whereby the air is passed through the mass of the corn as stored in the hold of a ship, in granaries, or in warehouses. It is well known that the commercial value of cargoes is frequently reduced by a portion becoming damaged, and then as the samples taken from each hold are mixed by the brokers for disposal in the markets with a view to insure a fair average, the whole cargo thus really becomes reduced in price. This and many other illustrations which might be given would show that the prevention of mildew is not only of high importance intrinsically, but considerable expense might be well incurred to avoid the deterioration of large quantities on the voyage. For hay ricks, too, a good system of internal ventilation would go a long way towards preventing heating or in facilitating drying. The apparatus consists mainly of a system of double tubes, one external and perforated all over, the other internal and only perforated at the end of each branch. The arrangement is as follows:—There is first a vertical perforated cylinder, from which fore and aft and port and starboard perforated arms extend in single or in two or more tiers. The cold air taken in at the bell mouth of the vertical tube descends, and finds escape partly through its own perforations and partly through those of the branches, and thus intermingles with the grain through every interspace. When heated or under pressure in the closed hold, a portion of this air escapes by the internal tubes, and thus a constant circulation is maintained, as may be shown in the models by means of smoke. A full-sized machine ordered for Wallachia may be now seen at Messrs. Rotherall and Bastin's, Blackfriars. In length its tubes are 32ft., across the ship 19ft., the vertical tube being 13ft., or, in other words, the tubes extend nearly across the hold in both directions; above the hatches the tubing to the bell-mouth will rise some 7ft. For granaries and other magazines, where a strong current cannot be insured as on board ship, an Archimedian screw arrangement has been made for forcing down the air into the store amongst the corn. Experience will no doubt show other advantages and applications. The plan has the merit of simplicity and of working without need of any continuous attention.

CHEMICAL NOTES.

Potash from Maize.—The American *Journal of Pharmacy* gives the results of some researches into the chemical constituents of the cobs of Indian corn. In a series of analyses it was found that the cobs contain on an average, in 1,000 parts, 7·62 parts of carbonate of potash, or nearly twice as much as the best specimens of wood. Statistical data are given showing that, taking the average production of corn in the United States alone, there might be extracted from the ash of the cobs, quantities of which are used as fuel for steam-boilers, no fewer than 51,612 tons of pure carbonate of potash, while, moreover, a quantity of chloride of potassium may be simultaneously obtained: 100 parts of the cobs, dried at 100°C., contain on an average 1·171 ash, consisting of 0·899 KCl, 0·836 K_2CO_3, 0·230 silica, lime, iron, and charcoal, and 0·105 loss.

The Formation of Glycogen in the Liver.—Some years ago Dähnhardt removed the glycogen from numerous livers, and then found that, by the action of gently oxidising substances, glycogen could be obtained, which, by the action of saliva, was again convertible into sugar. In other words, he maintained that there was or might be a post-mortem formation of glycogen. Dr. Luchsinger has lately repeated these experiments in Kühne's Laboratory, with a different result. He thinks that Dähnhardt did not entirely remove the glycogen originally present, and that if this were thoroughly and completely extracted by rapid division of the organ after death, and boiling the pulp in successive quantities of water till all opalescence had ceased to appear, no further formation of that substance would occur.

Detection of Vitriol in Vinegar.—The following process will, says the American *Journal of Pharmacy*, detect the 500th part of free sulphuric acid, and is accurate for all practical purposes. An ounce of the vinegar to be examined is reduced by evaporation on a water-bath to about half a drachm, or the consistency of a thin extract; when quite cold, half a fluid ounce of strong alcohol is added, and thoroughly incorporated; the free sulphuric acid will be taken up by the alcohol, to the exclusion of any sulphates; the alcoholic solution should stand for several hours, and then be filtered; add to the filtrate 1 fluid ounce of pure distilled water, and evaporate the alcohol off by the application of a gentle heat; the remaining liquid is then left for several hours, and again filtered; to the filtrate, previously acidulated with a few drops of pure hydrochloric acid, a solution of chloride of barium is added, which, if sulphuric acid be present, will yield a white precipitate.

A New Method of Obtaining Potassium.—Professor Dolbear gives the following as a new method by which he obtained potassium:—White stick caustic potash of commerce was dissolved in water and then treated with sulphuretted hydrogen in the way commonly described for making potassium sulphide, K_2S. The solution was evaporated until it was solid when cool, when the yellowish mass was mixed with more than its bulk of iron filings and chips, and the whole put into an alembic for distillation. The heat of a furnace was applied till the alembic was of a bright red heat, and the products of distillation were received in common coal oil. The product was rather small, as some of the potassium vapour decomposed the heated vessel; nevertheless, the potassium showed itself, when the oil was poured off and the residuum turned upon water, by its characteristic ignition and flame. The reaction is simple, and may be thus represented: $KS + Fe = FeS + K_2$. He says that he has not conveniences for experimenting upon this on a scale large enough to test its comparative value; it needs some special arrangement of protected vessels, as it violently attacks common crucibles, porcelain, and glass. The materials used for thus obtaining it are of the required cheapness, and the iron sulphide product can again be used to furnish sulphuretted hydrogen for another quantity. It is probable that sodium can be obtained by an analogous process.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

*** *In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

GLASS SUN-SCREENS—THEORY OF VISION—PAINTING THE SPECTRUM—PURCHASE OF A SPECTROSCOPE—AND SECONDARY REFLECTIONS.

[4223.]—DID Mr. E. L. Berthon (let. 4148, p. 224) ever try *smoking* the field-lens of an eyepiece for solar observation? It is only a rather rough way of doing what he advocates, absorbing light and heat by minute solid particles. In the one case they are of carbon, in the other of silver; but the principle is the same. It is no novelty.

I begin to see that "E. J. D." (let. 4161, p. 227), is writing, not for his ostensible purpose of obtaining information, but in reality for the sake of arguing. Commencing on p. 510 of Vol. XIV. (let. 3493) with an account of an experiment which, I sincerely believe, he had never tried, he requested to know how certain alleged effects were produced? Since then he has kept up a desultory fire of questions, every one of which he might have answered for himself by reference to any decent work on optics; and now, in his last communication, he makes a variety of vague shots and random assertions, and demands an explanation *not of what really occurs*, but of his own imperfect and confused ideas of it. What, I should like to know, does he imagine to be (so to speak) the dimensions of a ray of light? because he talks of one as though it were a cylinder of the size of an average walking-stick. Has he no means of access to any work dealing with the amplitude of the vibrations of the differently coloured rays? And can he not thence form some notion of the uncountable millions of rays which would be thrown off his hypothetical statue? As for what he says about mirrors and their action, I confess that his argument might be enunciated in provincial Japanese for all that I can make of it. How on earth can "direct parallel rays" proceed from any part of a man's body to a mirror? Rays *diverge* from a point, though, of course, the more distant such point is the nearer they approach to parallelism. Surely, "E. J. D." does not wish me to reproduce the time-honoured diagram of the gentleman of easy manners in knee breeches and a bag wig, admiring himself in a looking-glass; which has done duty in books of optics as an illustration of reflection since a period long anterior to that at which any reader of these lines entered this world? I really should be ashamed, sir, to ask you to engrave it. Besides, "E. J. D." can easily make a simple sketch for himself. For example, if he will draw his own profile facing a mirror, surmount his head with a tall conical cap, and from the apex of this cap draw lines to represent rays radiating in every possible direction, he will find that a certain portion of such rays only will reach the mirror. If now, at every point of contact of these rays, he will erect a perpendicular, and make the angle of reflection of each ray equal to its angle of incidence, he will see immediately what rays will reach his eye, and will hence be able to determine at once in what direction the reflected image will appear. Again, his notion—or rather Sir David Brewster's—of "three primary colours," has been long since exploded, Helmholtz, Sir John Herschel, and Maxwell, all having shown that prismatic yellow and blue can, under no circumstances whatever, be made to produce green, while a mixture of prismatic green and red *does* produce yellow. Moreover, the spectroscope demonstrates irrefragably the definite character of the refrangibility of the various colours of the spectrum. Who, too, if it be not a rude question, has been cramming poor "E. J. D." about Encke's Comet, "and the settlement of "the ridiculous theory of ether existing in space"? and, supposing that it were proved to-morrow that Encke's Comet was retarded by (say) Mercury, how could, or would, that affect the theory of the luminiferous ether? The real fact, however, is that "E. J. D." has all this time (while apparently sitting in *statu pupillari*), been engaged in instructing me, and I, ungrateful wretch that I am, even now don't see it.

"Utile Dulci" (query 11875, p. 236) may paint the spectral colours upon his disc by employing the following pigments—he should use the ordinary cake (not moist) water-colour paints, and rub them up with water to the consistence of cream—carmine, Mars orange, cadmium, lemon yellow, emerald green, ultramarine, Prussian blue, and rose madder. I may add, as possibly being of some use to your correspondent, that if he divides the circumference of his cardboard circle into 360°, violet will fill a sector of 109°, indigo one of 47°, blue one of 48°, green one of 46°, yellow one of 27°, orange one of 27°, and red one of 56°.

"W. H. H." (query 11906, p. 237) will scarcely get a spectroscope of any use to him under five guineas, at which price what is called the student's spectroscope is sold. By the aid of such an instrument, and a Bunsen's burner, he will soon learn to identify the spectra of many of the metals and metalloids, and to map them; as also to compare them with the dark absorption lines in the spectrum of sunlight. I do not think that a micro-spectroscope is a good thing to begin with. It shows the absorption bands in various vegetable infusions, in blood and other fluids, &c., beautifully; but although all this is curious and interesting enough, it is of very limited and special use, and teaches the student very much less as to the great fundamental principles which underlie spectrum analysis than does the form of instrument which I have advised "W. H. H." to procure. Having mastered this, he may have a spectroscope fitted either to his microscope or telescope, and will be in a condition to employ it to advantage. I have mentioned five guineas as the smallest price at which an efficient instrument is procurable, but if my querist can afford ten guineas he will get a very superior one. Beyond this price, however, I would certainly counsel him, as a beginner, on no account to go. I would, in conclusion, recommend "W. H. H." by all means to go to the leading maker. A "cheap and nasty" spectroscope is an uncommonly poor investment.

Is Mr. Buchanan (let. 4188, p. 251) perfectly certain that the appearance which he attributes to double *refraction* has not its origin in double reflection instead? I mean to a second reflection from the inner surface of the window pane. This is a phenomenon of the very commonest occurrence.

A Fellow of the Royal Astronomical Society.

LONGITUDE — JUPITER'S TEMPERATURE — PRONUNCIATION—THE PLANET VULCAN—AND DOUBLE STARS.

[4224.]—In its existing form the letter (4143) of "L. T. Y." on p. 224 admits of no answer. All that your correspondent says, in effect, is that, by observing the transit of a star, or stars, he found his clock to be 49sec. wrong. But then he goes on to add the wholly inexplicable assertion that he "found the average correction to be 49·23 sec.," and that he has "since ascertained, from official survey map, the exact correction to be 49·87 sec." The exact correction with reference to what?—the difference of longitude between his observatory and his office—the Philadelphia Observatory, or where? because not a solitary scrap of information does he give with regard to this, the very gist of his question. The whole communication is a puzzle: because Philadelphia (the High School Observatory) is 7m. 34s. east, or fast, of Washington, the American initial Meridian. Nor does the introduction of the English *Nautical Almanac* mend matters, inasmuch as Philadelphia is 5 hours and 38 seconds west, or slow, of the Meridian of Greenwich, for which our British Ephemeris is computed. Besides, it is of no earthly use for a man to determine his local time (even with the most refined accuracy), for the purpose of ascertaining his longitude from some other station, unless he knows the precise time at such station at the exact instant of his own observation. How any possible means can exist of "determining correction for longitude without the aid of other observers" is a profound and awful mystery to me.

The question (11883, p. 237) of Mr. Whitaker directed my attention to the article in the *Cornhill Magazine*, "A Giant Planet," which I have since read through with a great deal of interest. After my own expression of opinion, repeated more than once in these columns, as to the enormous extent of Jupiter's atmosphere, my querist will readily imagine that I have somewhat carefully considered everything that has been advanced to account for the marked changes which even moderate telescopic power enables us to detect in it. I do not think, then, that I am exaggerating when I say that the author of the paper referred to seems to me to have propounded the only theory that gives even a plausible explanation of the appearances which we witness. If we assume, as we have every right to do, that the members of our own Solar system had a common origin, and have cooled down from a state of incandescent gas, then, obviously, the largest bodies, and notably those surrounded by the densest atmospheres, would retain their heat the longest. I find then no difficulty in the conception that Jupiter may, even yet, retain a temperature such as that postulated by the author of the essay in the *Cornhill*. I do not say that this theory will account for *all* the phenomena recorded, because other causes have probably operated in producing them. If, for example, there be any truth in the recently advanced idea that the colouring of Jupiter's equatorial region undergoes a *periodical* change, this certainly would seem to demand something more than the mere constant effects of an invariable high subjacent temperature, and of the planet's rapid rotation, to explain it; but this would scarcely invalidate the theory advanced by the *Cornhill* essayist, if we view it as an explanation of the leading phenomena exhibited by the "Giant Planet." "The name of the writer is not given," as Mr. Whitaker remarks, but I really should trouble myself exceedingly little as to the authorship of such a paper as the one we have been discussing. Personally, I should endeavour to ascertain, in the first place, whether the writer's assertions were made concerning facts; and in the next, whether his inferences from such facts were legitimate ones. Once satisfied on these points, it would matter nothing to me whether such an essay proceeded from the pen of the Astronomer Royal or from that of Orton "the Claimant."

In answer to the second part of Mr. Whitaker's query, I may tell him that Sirius is pronounced with the first *i* as in sit; and with reference to the third, express my belief that the planet Vulcan has no existence. I by no means intend to assert that a planet, or planets, may, and do, not exist between Mercury and the Sun; but as to Lescarbault's planet, to which the name of Vulcan was given and an orbit assigned, it seems morally certain that it *must* have been picked up long before this had it been an objective entity.

I cannot find any very recent measures of ζ Boötis (asked for in let. 4222, p. 257), although I have a strong impression that some were made and published not long since. The latest that I am cognisant of, of η Coronæ, are those by Mr. Knott, who gives position angle 45·85°, distance 1·003", epoch 1871·54. Why does not Dr. Blacklock try ξ Ursæ Majoris, of which the components are now, as nearly as may be, 1·05" apart? This is a good deal within the theoretical separating power of his aperture, but is a very good test notwithstanding.

A Fellow of the Royal Astronomical Society.

MR. GOSSE'S "OMPHALOS."

[4225.]—Mr. Gosse (let. 4204, p. 255) invites me to *answer* his "Omphalos." I most distinctly decline to do anything of the sort. There is simply nothing in it to answer. At the risk of being again accused of "gratuitous ungentlemanliness," I say, quite deliberately, that I never read such a mass of utter rubbish in my life as the book in question; and I assert with the utmost confidence that this opinion will be found to be justified by every single review of the work which appeared in the scientific journals at the time of its publication. I feel, however, that an apology is due to Mr. Gosse for my assumption that his performance had passed into the butterman's hands; as it would seem to be still cumbering the shelves of Mr. Van Voorst. Requiescat in pace.

I protest against the implied notion that an anonymous writer is bound to say smooth things. If there is one thing that I hate utterly, it is quackery, be it religious, scientific, literary, or political; and if any man, even my nearest and dearest friend, puts forth a mischievous or (as in this case), merely a hopelessly foolish book, neither fear nor favour shall prevent me from giving an honest opinion of it in the very plainest English at my command.

"Accepting my postulates," says Mr. Gosse. Exactly: Accept the postulate that 5 — 3 = 19, and see whether I will not deduce results before which "The Glorious Metric System" shall pale and dwarf into utter insignificance.

And now, lest, as is probable, a very large proportion of your readers should wonder what this precious book is all about, and imagine that there may really be something in it: let us hear its pervading idea, as tersely expressed by the great American essayist, Oliver Wendell Holmes:—"Mr. Gosse can believe that a fossil skeleton, with the remains of food in its interior, was never part of a living creature, but was made just as we find it—a kind of stage-property, a clever cheat, got up by the great Manager of the original Globe Theatre." This is "reconciliation"—with a vengeance!

A Fellow of the Royal Astronomical Society.

A NEW FORM OF COMBINED VIOLIN, &c.

[4226.]—I have before tried to deprecate any appeal to me by "The Harmonious Blacksmith" (let. 4201, p. 254) on subjects of which he is a most thorough master, but of which I am even as a little child learning its alphabet. If I wanted an opinion, or information, recondite or elementary, with regard to any form of musical instrument, he is (merely as a matter of course) the first man whose aid I should invoke; and here he is claiming *mine!* Such an inversion of the proprieties has scarcely occurred since Mr. Tapley was moved to exclaim (anent Martin Chuzzlewit's apology to him in Eden), "The head partner a asking forgiveness of Co., eh? There must be something wrong in the firm when that happens. I must have the books inspected and the accounts gone over immediate."

But, having guarded myself from any possible imputation of a claim on my part to speak *ex cathedrâ*, I may say that the ingenious instrument devised by "The Harmonious Blacksmith" seems to possess considerable capabilities for the performance on it of *simple melody*. It seems to me, though, that the bridge (or whatever answers to it, for this is not indicated in his sketch) would have to be very much arched, and this would necessitate a peculiar style of bowing. Fingering, too, would, I fancy, be a bit of a puzzle. These, however, are matters of detail, and in no sense affect the principle of the instrument. I should not anticipate the difficulty alleged as a probable one by "The Harmonious Blacksmith's" friend—viz., the want of synchronism in the vibration of the soundboards, tied together as they would be; but it is almost impossible to reason *à priori* with reference to so perfectly novel an arrangement, and "an ounce of practice" would most peculiarly in this case be "worth a pound of theory."

Should "The Harmonious Blacksmith" go to the cost of having his curious invention constructed, it will be interesting to learn the result of his first fiddle.

A Fellow of the Royal Astronomical Society.

OBSERVATIONS ON "THE HARMONIOUS BLACKSMITH'S" NEW FIDDLE.

[4227.]—Since reading the interesting letter of our musical friend, I feel several inches taller, and in return, hope "The Harmonious Blacksmith's" shadow will never grow less. But I must again draw "our" readers' attention to the great difference in producing tones by percussion and bowing. I may beat a drum more and more, and till it bursts it will sound louder and louder; this applies to all percussion instruments, but I cannot bow a string, increasing the pressure every time, and produce music; instead of that I should have a series of terrible noises or shrieks. Therefore, it seems to me impossible for one string (bowed) to move more than one soundboard, made of the same wood. Our new fiddle would do if we had a string to each soundboard, and I would ask could one string be connected with each breast without the admission of a soundpost? I do not mean to go through the middle of the series, but attached by some arrangement of bridges, bringing them under one bow. It may be remembered that I noticed lately the curious fact, that if a violin string is bowed directly on its side, half the power is gone (to be bowed near the nut), but still more curious, the tone when played in this mode is revived when the soundpost is removed. I think from this that the soundposts in the new fiddle would act as dampers to the tone, because the strings would be played on their sides. I say on their sides, for having no bridge there would be no distinction between one side or other of the strings. I wish all instrumentalists, especially violoncello players, to notice the hint I gave about sound reflectors for the back of fiddles. I tried the tone of a violoncello with a piece of mahogany placed against its back, and it was increased not a little, but very much. Of course, this is treating the fiddle as a musical box; it sounds better on a table than when held in the air. However, don't run away with the idea that a box made of hard thick wood would be better; it would act the contrary, so would a box of soft wood. Yet I am inclined to think that the reflector should not be of uniform thickness, but I am ignorant on this point. Two pieces of half-inch stuff, however closely placed together, make a bad reflector, but in the whole condition of 1in. is very good. Does not this seem to point to the idea of so many atoms or centres being required to each tone, these grains together forming columns of resonant matter? If the said columns were not required, metal soundboards or reflectors would do better than wood. The grain of the wood, I need hardly say, forms the columns I allude to. We may now understand the reason why the breast of a violin is made in two pieces or halves. The bridge has two feet, one on each piece, and they act and react on each other. Now, if we had more pieces, we should have more centres, atoms, and columns for the sound, but the bridge would have more feet to connect them, if that were possible to manage. I want to enlist the sympathies of Mr. Schucht in this matter of violin breasts and reflectors (both distinct things), especially after reading his observations on soundboard construction, on p. 71, let. 2734, Vol. XIV. There is a law hinted at and a promise to describe it. May I respectfully ask him to favour us with the description, as I think it might apply to the present subject? He states, I think, that in a soundboard constructed of narrow lengths of hard and soft wood alternately joined together, friction was caused between the two opposites. How about making the breast of two pieces, one thick, the other thin, hard or soft? If this would answer, then we might do without the back, and making another breast, so as to bring the different kinds of wood under each other, connected by soundposts alternating on each side of the bridge (it will never do to have them directly under each other), we should be able to bow the top side of the strings, and thus get the full benefit of this combination.

Fiddler.

STRANGE AND RARE MUSICAL INSTRUMENTS.

[4228.] — "The Harmonious Blacksmith" (let. 4137) will find a good description of the corno di bassetto or krumm-horn, in Albrechtsberger's "Thorough-Bass and Harmony," three volumes in one, p. 250. Extract therefrom:—"It is distinguished from the clarionet by being curved, and reaching a third lower, and has the largest compass of all wind instruments; contains four whole octaves in regular order. The clarionet is to the corno di bassetto what the hautboy is to the English horn, and both may be termed branches of the same stem. The scale is the same as clarionet, but it contains four lower notes.

Aleph.

[4229.]—Corno di Bassetto (not de), Basset Horn, a species of clarionet, sounding a fifth lower than its notation. Its tube, which is longer than the clarionet, is bent about the middle, forming an obtuse angle, and has at the lower end a small metal bell. By the aid of special keys it produces two notes which are wanting in the clarionet—viz., small C and D (really large F and G). Its scale is written in the G clef, extending from small E to three-lined D (really large F to two-lined G). Mozart uses it in his opera "Il Clemenza di Tito;" and in the Requiem wherein the whole chorus of wood instruments is represented by two basset horns and two bassoons. Its tone is soft, elegiac, and rather lugubrious; it is very rarely used, having given place to the more powerful clarionet. The Germans call it "krumm-horn"—*i.e.*, crooked horn, a corruption of which term, "Cremona" is still used by organ-builders, as the name for the stop which closely imitates its tone.

Strathburys, Glasgow. W. B. Marshall.

PRIMITIVE PIANOFORTES, *ALIAS* DULCIMERS, WITH AND WITHOUT STRINGS.

[4230.]—IT may be held to be evidence of an uncultivated musical taste, but I can't quite get over my affection for one of my early loves, to wit, the dulcimer. Doubtless, this is a very primitive sort of pianoforte compared with our modern repetition concert grands, but, like most old things, which have not become quite extinct, and also some which have, it has some elements of goodness, for it is capable of yielding sounds whose loudness and timbre may be varied at the will of a skilled player to a much greater extent than those of any pianoforte with manual keys I have had the good fortune yet to hear.

About forty years ago a man, then considerably past middle age, used to obtain his rather precarious livelihood by singing in the streets and in public-houses, especially at old Bagnigge Wells tavern, then one of the few existing predecessors of the modern music-hall. This not very refined vocalist, who, like Mr. Sims Reeves, was troubled with a chronic hoarseness, accompanied his not remarkably sweet voice on a large dulcimer, possibly ancient French "Pantaleone," "converted," as my religious friends term it, and having wire substituted for its original catgut strings. His instrument was far longer than any other dulcimer I have seen, being about 7ft. long by, perhaps, 2ft. 6in. wide in the middle. In form it was a truncated triangle, about half a yard wide, or, perhaps, less at each end, and its compass was, if I remember correctly, four and a half octaves from F F to C in alt. It was a trichord (although it had not what the piano advertisers term a "trichord action," whatever that may mean), for about two octaves, bichord to about C C, and below that note unichord. It had no covered strings, but F F, which was about 6ft. long, was strung with copper wire, nearly, if not quite, one-tenth of an inch in diameter. This instrument was tuned in the scale of F major, without any semitones not in that key, so but very little modulation was possible on it.

The certainly clever, if not very refined, performer on this primitive pianoforte, held in his hands two triple-headed hammers, whose three heads, each about 1¼in. long, were covered with leather, differing much in thickness and hardness, one pair being extremely hard, and used—excepting for the higher treble notes—almost exclusively for fortissimo passages; another pair, which were of medium hardness, were those he generally employed. The third pair of hammers being, like the writer, extremely "soft," made the instrument do what he has been doing for a long time—viz., "sing small"—*i.e.*, pianissimo. As these hammers were disposed radially at 120°, and their sticks had three flats—I don't mean E flat major, but three flat surfaces, whose positions corresponded with theirs—the performer could change his hammers instantaneously by causing their sticks to perform one-third of a revolution between his fingers and thumbs, by which he held them; in a word he was able very easily to "get down to the flats," which was more than the Claimant said was possible on or with the French horn. I fear he, however familiar with "flats," was not quite up to the Attorney-General or Mr. Hawkins, probably because they are "sharps," certainly not B or other flats.

This three-headed cerberus—I mean hammer—enabled the performer to vary the loudness and timbre of the sounds to a greater extent than any pianist can do (for few pianofortes are provided with two sets of hammers), even if his instrument be provided with that excellent thing the celeste; consequently, the powers of expression of the dulcimer player exceeded those of any young lady who has learned (or whose trusting parents fondly suppose to have learned) the "Pihanner." From the proportions of its strings I need hardly add this was a very powerful instrument, indeed this is a necessity when you have to perform in the public streets, and are *assisted* (?) by a continuous cart-wheel accompaniment. It was far louder than any grand piano then made; both its bridges were fixed on its sounding board, which must, I think, have caused it to produce louder sounds, at least in the bass; besides which, as the performer held his rather long-handled hammers in his hands, he was enabled to strike its strings with far greater force than any player can do who has to perform on an instrument provided with a mechanical action, be that action "Der Englisch Mechanick," the German action, invented by Stein, or even Erard's French mechanisck (said to be the most powerful of all, which I greatly doubt), Mata's, *alias* Hopkinson's, action, which I know to be more powerful than any other now in use, or even my own horizontal grand action, which far surpasses them all in the force with which its hammers strike the strings. This very primitive pianoforte, *alias* dulcimer, was, indeed, a very effective instrument for accompanying the voice, and was, in my opinion, far superior to small bells for instrumental performance.

Some quarter of a century later, when the performer on the above instrument must, in the ordinary course of Nature, have "gone over to the majority," as the French people express the termination of mundane life, I became acquainted with an old journeyman pianoforte-maker, who was often seen (and heard) in the City performing on a very powerful dulcimer, which he constructed something like one of the modern fashionable six-feet grands. It was a trichord instrument throughout its compass, six octaves from C to C, with the semitones complete, seventy-three notes, excepting about an octave and a half of bichord-covered strings in the bass. Although, perhaps, two feet shorter, it was considerably wider than its predecessor above described, and its sounds yet more powerful, excepting, perhaps, in the lower part of its bass; at this we need not be very much surprised, when I relate its trichord C's were strung with No. 16, 17, 18, and 22 wires. Power, in the sense of loudness, was, indeed, almost a necessity for accompanying the remarkably loud bass voice of its constructor, who, if surpassing Stentor had been the chief qualification for that office, might, like E. J. Reed, have been "Chief Constructor to the Navy," for his voice rivalled Lablache's in power if not in purity and sweetness—sooth to say, there was but little "sweetness or lightness" in it, and the very smallest conceivable "melos" in his melody. Genealogies are sometimes rather difficult to trace, but I think my "horsey" friends would, had they but heard him, have had not the least difficulty in determining its parentage, and that, in sporting phraseology, it had certainly been "got by Mr. Black Smyth's Big Rubber out of Mr. Ffrench Roll Baker's Rough Rasp." The "Harmonious Blacksmith" is extremely sorry to add that that regard for truth which distinguishes him compels him to testify that he often hears many voices, both masculine and feminine, which sound to him very much as if they were descended from the same dam and sire.

We owe something to the dulcimer, doubtless it was the father of the pianoforte, and is a very old friend indeed, not to mention that it formed part of the collection of musical instruments which belonged to our amative and harmonious sovereign, Harry the Eighth, who, poor man, must needs have required all the musical instruments he could purchase to preserve him in harmony with his many wives. It has not yet quite gone out of use even "until this very day," in those conservative—Mr. John Stuart Mill would have written "benighted"—localities yclept country places. Well can I remember, when a young man (alas! like the days when we went gipsying, "a long time ago") the dulcimer was in frequent use, not only for accompanying the voice, but even as a solo instrument, of some pretensions. It has long been known to the Wise Men—also to certaynge and sundrie other not wise—men of the East, under its oriental names, Santir and Sar Mudal. In Poland and Hungary it is known by the names Cymbaly and Cimbalon, but the old clavicembalo, or keyed cembalo, seems almost certainly to have been a virginal, spinett, or harpsichord, whose strings were plucked, not struck by hammers. Specimens of the Oriental santir, also of English and Italian dulcimers, are in South Kensington Museum, some of which have four, or even five, unisonous strings to each note, enough to frighten, if not to horrify, a modern pianoforte-maker, who fears to employ more than two or three strings at most for one note.

Although I see by an editorial announcement that "the pianoforte alliance" is likely to be carried out without any assistance of mine in what a fellow correspondent termed "organising a plan" (most cordially do I wish the said alliance every success, and that it may prove to its members "La Belle Alliance"). I fear it has been my misfortune (by incidentally mentioning the opinion of the late W. F. on the possible cost of producing good, plain, cheap, pianos) to excite hopes which seem far from realisation; for in our present not very far advanced state of civilisation, in which property is held by individuals and not in common, if a piano costs £10 to make its maker must possess an amount of self-abnegation—or imprudence—not very often to be met with in ye British manufacturer of pianofortes, or other commodities, if he were habitually to sell it for prime cost. "Needs must when the thingummy drives," and, there is no "thingummy" like poverty, so he may occasionally be compelled even to do this, which enables his Christian brother to take advantage of his misfortune, and practically illustrate the wise precept "do as you are done by," by buying a bargain; but such bargains, although advertised daily, are not always to be purchased, and, I fear—or rather hope—the members of the piano alliance will have to pay for their instruments prices which afford the maker sufficient profit to live on until all they, at least, have their turns served—after which, of course, the maker may go to the "thingummy" if he cannot do better. So much for the bargain hunters, with whom I have but small sympathy, but as many fellow readers resemble the writer in thinking they could spend considerably more money to advantage if they had it, and, possessing more brains than money—in which respect, by the way, they do not resemble the writer at all, for he possesses very little brains indeed—would be quite willing to purchase a piano if they could (but cannot) afford to do so, I would suggest that a very tolerable substitute for one—especially if only required for accompanying the voice—is a really good dulcimer, say such an one as that last described. It might be an improvement to extend its compass to F in the treble, and, where room is not important, to make it about 2½ft. longer, so that its C C C string might be about 6ft. long between its bridges. I should also recommend making all its covered strings the same length as the longest uncovered ones, which would be about those of C C, a bichord note of (say) No. 30 steel wire, the first four bichord notes below it being covered on No. 28, the eight notes below them, unichord, covered on No. 30. Such a primitive piano as this would not cost more than about a fourth what a plain piano stands its maker in, for like the unsuccessful litigant, it has "no case." I hope, Mr. Editor, none of my fellow readers will not consider it their duty to "abuse its solicitor."

Before I conclude—which by this time the reader will probably be quite willing I should do—I may remark that strings with a soundboard are not the only instruments of "mysick" which can be struck by hammers held in the hands, or impelled by some kind of "mechanick." Bars of wood, glass or metal, plates of either of the latter materials, whether flat or rendered concave (when they become gongs or bells, in proportion to the degree of concavity imparted to them), or, indeed, almost any sonorous and elastic substance, may be substituted for strings, often to great advantage; but the generic name of all these instruments is harmonicon, or harmonica, not dulcimer. According to the various materials employed for producing sounds, they "suffer a change," not invariably into "something rich and strange," for often they have assumed the various forms of the old familiar nigger wooden harmonicon which a fellow correspondent lately asserted was invented (?) by a German organ builder. So I suppose it logically follows that Lord Lytton's doubts as to the origin of the Teutonic race are now quite solved, and the Germans now proved to be veritable niggers, which must needs be a very great consolation to the French. The modern zylophone is another example.

(Query: Is this anything else than the claquebois, or straw fiddle, of the French?) the Greek name of which, evidently, was not selected by one whose head was also ligneous, for it is notorious that a good Greek word goes a long way in the musical as well as in the commercial world. Allied to these are the rock harmonicon and other harmonicons of glass and metal, of which the Javanese Gender is one of the very best, because its sounds are augmented by the resonance of air chambers. For this instrument the designation of dulcimer, in the sense of producer of dulcet sounds, would be very appropriate.

THE HARMONIOUS BLACKSMITH.

BELL PIANETTE.

[4231.]—I HAVE not at present the name of the patentee, but I will search and send it as soon as I can. In the meanwhile, "Ye Harmonious Blacksmith," may find, if he has not done so already, some very interesting descriptions of similar instruments in Dr. Brewster's "Natural Magic" (Family Library).

S. BOTTONE.

PIANO QUATOR, ALIAS TETRACHORDION.

[4232.]—ALTHOUGH not directed to me, I take the liberty of answering the query put in letter 4155, p. 225, as my relations with the inventor, M. Baudet, of Paris, and my business transactions with Messrs. H. Stead and Co., the purchasers of the patent, enable me to speak with confidence. The tetrachordion was first exhibited under the name of "Piano Quator" at the Paris Exhibition, 1867. The English patent was bought last year by Messrs. H. Stead during the course of the London International Exhibition of 1871. Messrs. Stead thinking, doubtless, that a Greek name would be more palatable to the English public than the French one, changed its title to tetrachordion, with what propriety I shall not attempt to determine.

S. BOTTONE.

HIMMER'S GALVANIC BATTERY.

[4233.]—THIS arrangement of cell, described by you in No. 369, p. 113, has had a careful testing at my hands. You express a desire that any of your readers who might experiment upon it should communicate the result. The following is my experience:—Two cells were constructed, the details precisely as you gave them, and then left undisturbed. In the course of a few hours the inner vessel C (in your diagram) became two-thirds full of the copper solution—in fact, it rose, as expected, to a level with the cork inserted in the flask. The current of these two cells, although feeble, was sufficient to work my electric clock, which it continued to do for a few days, but with gradually diminishing energy. I now found that although the copper solution formed a distinct line in the vessel, a slight diffusion took place throughout the whole of the saline solution in the outer vessel, giving it a faint blue tinge, and, of course, precipitating on the zinc, thus wasting that element and diminishing the energy of the combination. I am confident that no arrangement could be adopted where an entire separation of the fluids could be obtained for any length of time—we know that not even porous cells will effect it. The battery, therefore, in my hands is a failure. I trust, however, that the experience of other experimenters will be given in your pages, and that it may prove more satisfactory.

GEO. FOX.

SAFETY LAMP FOR MINERS.

[4234.]—IN your issue of May 17th, you have given a prominent place to an account of Mr. Plimsoll's Safety Lamp for Miners, as if it were a novelty. Lest he or your readers should suppose that the idea of making a lamp to go out when firedamp enters it is new in itself, or its application, I beg to draw your attention to the fact that the first lamps made by Sir Humphry Davy had the same objection (!) and were abandoned by him on account of the inconvenience which the extinction of the light causes. Others have made lamps on the same principle. I have in my possession one of Eloin's lamps, which is almost identical with Mr. Plimsoll's, and which inevitably goes out in an explosive mixture, and for that reason is not used or approved of. If the viewer of a mine, in searching for firedamp, had to grope his way in the dark back to a safe place every time he encountered a small collection of gas, in order to re-light his lamp in safety, his operations would be slow and laborious. The fact that an explosion of gas takes place, in any degree, within a lamp whose openings are so limited in number and extent, raises a doubt as to its safety. See Sir H. Davy's remarks and experiments on this point.

A. K. J.

ENTOMOLOGICAL.—ON EGGS.

[4235.]—EGG hunting is difficult from the smallness of the objects; however, many eggs may be found if diligently sought for. Both sides of the leaves, and also the stems of the food plants of the larvæ should be looked upon; the bark of trees, when rough, is often a favourite place to find eggs on. A few kinds lay their eggs on aquatic plants. One great secret in egg hunting is to know the appearance of the different kinds of eggs, of which, I fear, only a very few are even tolerably well known; and an examination of the anal segment of the female often will show likely positions for the eggs, according as the ovipositor is long or short. Of course, any unusual protuberance on plants should be well looked at. Another, perhaps easier, method of procuring eggs is that of inducing females to lay in captivity. Some kinds lay very easily, whilst others, on the contrary, lay with great difficulty, and sometimes need the food plant.

Most of the butterflies require space and the presence of the food plant, though I have found some (such as *A. Galatea*, *C. Pamphilus*, and others) lay without these incentives. Some of the moths require to be fed on sugar and water from a small piece of sponge, and many of them require suitable surfaces, whilst other moths cannot be induced to lay at all. I do not think that it is a good plan to put eggs on the food plant while being hatched, but they should be placed in the sun for a short time daily about the time of hatching. Finally, eggs should never be handled more than is absolutely necessary, and I recommend all collectors to make notes on all eggs they have anything to do with.

ENTO.

COLLIERY EXPLOSIONS AND THE WEATHER.

[4236.]—AN ingenious plan for diminishing the risk of explosion from increase of fire-damp with diminution of atmospheric pressure was suggested many years ago, but has never, so far as I know, been fairly tried; some of your readers may, however, be better informed. The proposal was to diminish the atmospheric pressure artificially in the mine when the men and their lights are away, so much as to make it unlikely that it would be as much diminished naturally when they are present. If this were done at short intervals (say once a day), it would most frequently prevent unexpected evolutions of gas from goafs, or other cavities, in excess of the ordinary ventilating power, and thereby diminish one of the great risks of mining. The mode proposed for diminishing the pressure of air in the mine was by stopping the downcast shaft, while the air is pumped out of the upcast by a ventilating engine or fan. It was expected that rarefaction, equal to a fall of an inch or two of the barometer, might be got, and as much of the gas of goafs, &c., forced out harmlessly as would be forced out by an equal fall of the barometer. I am sorry I cannot call to mind the name of the ingenious proposer of this plan.

P. H. HOLLAND.

AMERICAN SCIENCE.

[4237.]—"TRAVELLER" (let. 4214, p. 256) may be assured I do not "ignore all American Scientific Authorities," nor does he quite truly characterise my remarks (p. 228) as "sneering at the testimony of Americans." Science is of no nationality, except that, as far as America is concerned, the conditions of life, and the turn of the national mind, are unfavourable to that devotion to abstract research which constitutes science as distinguished from the practical application of the teachings of science. Therefore, of course, I should accept the teachings or evidence of an American scientific man as on a par with those of English, German, or French authorities. But it is very different with the mere loose gossipry which commonly passes for science, and very different when we are considering mere extracts from newspapers, or statements made in "popular" lectures.

The fact is, that there are constantly put forth in America statements which are utterly fallacious, often mere jokes, which pass from paper to paper till they assume the form of received truths. One instance is that to which I referred—viz., Paine's electro-motor, which was supported by the most determined assertions, and published as an established fact, despite of the ridicule and opposition of the really scientific men of America itself.

Another instance I will give, which touches also upon the authority of the "Year-Book of Facts," which, useful as it is, being a mere compilation, is not necessarily to be taken as an authority to be relied on. Some years ago (I do not now remember the time, but I think over twenty) there was a great American scientific discovery which was to supersede the "Morse's telegraph." One of those gentlemen who study Nature (?) discovered (or said so) that snails possess a power of sympathy closely allied to that claimed by human clairvoyants; two snails thus in sympathy would answer to each other's motions, though the whole body of the earth was interposed. The discoverer made up sets of nests corresponding to the letters and other signs needed, and in the corresponding nests placed snails thus "en rapport;" when the snail in (say) B nest, at New York, was touched, the sympathetic snail in B box, at London, moved its horns, and thus it was easy to transmit messages across the world. N.B.—I read the account of this in the "Year-Book of Facts," given with perfect calmness as one of the discoveries of the year, made in America, and quoted from American papers. No doubt it originated in a joke, one of those peculiarly American jokes. But such jokes are the ground of my remark that I should require anything rather out of the way, and given on American authority, to be well supported.

SIGMA.

ON MANCE'S METHOD OF MEASURING THE INTERNAL RESISTANCE OF A VOLTAIC CELL.

[4238.]—"SIGMA," in his excellent papers on electricity in the ENGLISH MECHANIC (which, it is to be hoped, will be published separately, and, if the suggestion may be pardoned, will include the method about to be described), did not allude to the mode of measuring the internal resistance of a cell, which Mr. Mance laid before the Royal Society in January of last year; and, as I have seen no notice of it in your columns, I am disposed to think it is not so widely known as it deserves to be: since, for simplicity, rapidity, accuracy, and elegance it has not, I believe, been surpassed.

Let X (Fig. 1) represent the cell whose internal resistance is to be ascertained, G a galvanometer, A and B two resistances, whose ratio is known, R a set of resistance coils, and K a key. The connections are shown in the figure. The current starting from X will suffer a bifurcation: one portion will pass through G (deflecting the needle) and R round to X, and the other part will go through A, B, and R to X. When the key K is depressed, a portion of the current which has passed through A will proceed at once to the cell X, without going through B or R. With the arrangement as here described, G will be always deflected; and, generally, if we depress the key K, the deflection will be altered—with a small or no resistance in R in one direction, and with a large resistance in R in the opposite direction. There is, therefore, a resistance which can be used in R, such that on depressing the key K the deflection of the galvanometer is unaffected. When this is the case, the following condition holds good:—Where X, A, B, and R represent the several resistances of the parts of the apparatus so lettered respectively—

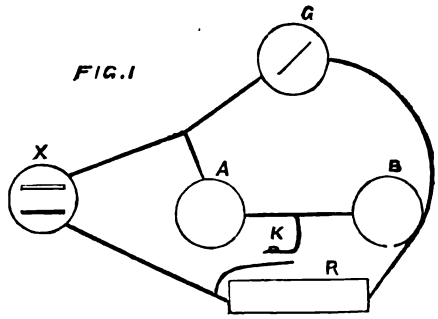


FIG. 1

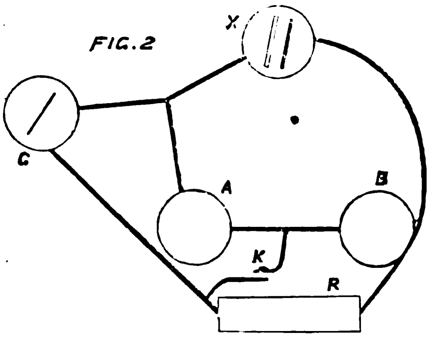

FIG. 2

$$X : R = A : B \quad (1)$$

$$\text{or } X = \frac{A}{B} \cdot R.$$

And, as we know the ratio $\frac{A}{B}$, we shall get at once the value of X. For example, suppose $B = 100$ A, or $\frac{A}{B} = \frac{1}{100}$, and that we wish to ascertain the internal resistance of (say) a Léclanché cell, and we find that on putting in R 654 Ohms, the deflection of G is unaffected when we depress the key K. Then $X = \frac{1}{100} \cdot 654 = 6{\cdot}54$ Ohms, the amount required.

We see that in this process we are quite independent of the resistance of the galvanometer (which, by the employment of a shunt, may possess any degree of sensibility we please), and of the electro-motive force of the cell, and it can be performed in a very few minutes. There is a corollary from this process, which was brought before the Royal Society by Sir William Thomson, at the same time that Mr. Mance's paper was read, and which, I think, may likewise be interesting to many of your readers. Transpose X and G in the arrangement before described (everything else remaining the same), which will then become that shown in Fig. 2. It is evident that as a portion of the current must pass through G, it will be always deflected. Add such a resistance at R that on depressing the key K, the deflection of G remains unaltered; and let G be the internal resistance of the galvanometer. Then—

$$G : R = A : B$$

$$G = \frac{A}{B} \cdot R.$$

In other words, we can ascertain the resistance of a galvanometer from the deflection of its own needle.

PI.

"UN IRLANDAIS" AND THE DELUGE.

[4239.]—IF it were not that three several querists, "F.R.A.S." (let 4184, p. 228), M. Paris (let. 4211, p. 255), and "Un Irlandais" (let. 4212), all independently, it would seem, and, besides, the original jocular propounder (let. 4086, p. 196, let. 4193, p. 252), repeat, in apparently sober earnest, his amusing question of "Where is the water gone to?" I should not think of answering it seriously. In the whole of this Deluge matter, observe, I am fighting alone (unless Mr. Gosse or some other physicist likes to help me), on behalf, not of any ancient document, but solely of *Natural Law* versus *Miracles*; the constancy or continuity of the known parts of the *course of nature*, against Lyell and other *miracle-mongers—i.e.*, resorters every moment to the unknown, to purely hypothetical interruptions or reversals of what is known. Accordingly, I thought it enough to tell the first questioner that the water of the Deluge, whether little or much, "obeyed all the same laws as yesterday's shower" (p. 226, bottom). It is impossible to do more with a man who replies that "this is absurd" (p. 252, bottom), and according, at the top of the same column, invents some unknown law whereby water that fell on land would not remain thereon long enough to *press* it? One who can thus catch gravity asleep (a problem to which I have been taught that even catching the weasel so was a trifle) is as much above physics as the emperor that declared himself "super grammaticam," and is truly consistent when, having thus got his water off the hills in such double-quick time as never even to exert pressure, he gets it back again in time, two paragraphs later, to repeat the "great question," where is it gone to? Whoever means to answer him (for I shall not) must at least be told first how he gets it back again from the sea, to which, just above, he has sent it all!

Now for the sober querists. Their question is, being on a globe, with a certain quantity of water, equivalent to a layer of fixed but unknown depth, so little known from soundings hitherto that probably no man can say whether (in a universal layer) it would be nearer 2 miles than 4, or nearer 4 than 2, but seemingly between these limits, they ask what is become of a still *less* known addition believed to have been made of this same substance; for I have observed (p. 226, col. 1) that while the cometary fall is certain (as I am bound to show by many more evidences yet unmentioned) its amount may, for aught I can see, have been either several furlongs, or not a quarter of a furlong. If the present stock is only equivalent to 2 miles, and the diluvial fall was 5 furlongs, then the antediluvian stock was but 11 furlongs. If the present is as much as 4 miles, and the addition was but half a furlong, then the previous stock was 31½. But whatever the ratio of the antediluvian stock and the addition, whether 2 to 1, or 50 to 1, the addition is simply gone *wherever there is water*—part into the querist's inkstand, and part into his veins, and some into the 8 or 10 inches that the atmosphere holds in circulation (as it did previously), and some more, in their several proportions, to the Caspian, and Lake Tchad, and the ocean.

Some may need to be reminded, by the way, that for long after our fathers' descent from Ararat, that mountain must have been on a coast, the coast of the great Central Asian sea, then covering most of Tartary, which took centuries to evaporate down to the low level of its now shrunken remains, the Caspian Sea and Lake Aral, and during all those ages must have made the Asiatic climates far moister than now. If much of the Sahara be below sea level, of course that also took a long time (but less) to evaporate.

As my last questioner, "Un Irlandais" (p. 256), couples this with two other questions, in seemingly a more decent temper than most, I may here reply to him. His second is, "What proof is there that comets are composed of water at all, or that they contain any?" Answer: No proof whatever; and, though none can tell what to-morrow may prove, I do not the least anticipate any such proof, because I think it most probable there is *no* water in most of them, or even in any. This, at least, has been my belief hitherto. But the question has no more connection with the Deluge, or my theory thereof, that I can see, than the question whether floods kill sea fish (let. 4211), or whether land animals have last spread from one hundred centres or one thousand. Their spreading from "*a single*" one (lets. 4049, p. 171, 4184, p. 228) is simply an absurdity, and I never heard of another person than "F. R. A. S." or of *any book* or serious writing, that assumed such a thing. If he has rightly quoted Professor Owen, it would seem such an absurdity has somewhere been broached, and it might be interesting to be told where; but I have nothing to do with it till "F. R. A. S." or some one explains what bearing it has on any deluge. As for Noah's, according to the professedly contemporary journal, the oracles predicting it (Gen. vi.) declared that every living substance was to be destroyed *from off* (v. 18, marg.) the earth, land, or ground; and survivors accordingly held (for nobody could have *seen*) that whatever was "on the dry land" died (vii., 22). In other words, every living substance, animal or plant, was either drowned or *off the ground*. Whatever was not afloat was to die, and whatever did not die, to be afloat; and doubtless plenty of organisms would be both one and the other; but before "F. R. A. S.," or any one, can add that *whatever* died *also* floated, or *whatever* floated *also* died, he must write a new Bible of his own, with which I have no more to do than with any of those quoted by Colenso; with that reverend divine, for instance, who (according to him) writes that the door of Noah's Ark was in its bottom story!—or any other miracle-mongerer. Old documents, as well as new, of any soberness, always presupposed in the reader, whether in relating divine or human words, not only thorough inquiry into their language, but also some little common sense.

For the third question, "Un Irlandais" will content himself by asking me to prove *to him* "that a comet could cause the Deluge." Well, to any one who may show that he knows the chief points yet discovered (and by "discovered," observe, I mean *ascertained*) respecting comets, the earth, and the properties of fluids —at least water and elastic fluids, and their relations to heat—if any one decently acquainted with these things asks for such proof I will give it. But as no one so acquainted *would*, I conceive, *ask* for proof of anything so obvious, the most natural inference is that "Un Irlandais" has never cared to learn more of them than his letter shows, or than "Santalinus," M. Paris, or even our joker of p. 252 (against whose diffuse chaff I must protest, as covering too much paper), who ignores (p. 196, col. 1) any difference between undulating strata and undulating ground!—evidently assumes the chalk downs, as the last review ground at Lewes, to be plutonically crumpled up, strata and all, into their knolls and coombs!—imagines "mathematicians can show" the earth to have a "crust some 800 miles thick," (whereoff earthquakes are continually shaking bits without being felt 50 miles off!—a building shaken down the other day in Furness peninsular without Manchester knowing of the shock,—and dislocating cracks confined to a few miles long, not only ancient ones by countless thousands, but five modern, cracked in colonised countries within living memory, none 100 miles long; and the two in Cutch not 10 miles apart, thrusting up a wedge of all the strata but 10 miles wide, and, "mathematicians" are to show, 800 deep! "Un Irlandais," for aught that yet appears, may be of the calibre of this chemical joker, who, when challenged to prove a comet weighing less than a trillion tons, quotes triumphantly one (p. 252, col. 3) whose mass is declared to be, "astronomically speaking, inappreciable." His wisdom takes for granted that, in the said comet's place, a trillion tons would be a mass astronomically *appreciable!* "Un Irlandais" may be as profoundly ignorant of all the sciences he is meddling with as even this joker, and in that case I entirely deny any such right as he would seem to claim to tell me I show *nothing* till I have taught *him* the facts of astronomy, geology, general mechanics, and pneumatics, that he has not cared to study, and newspapers do not happen to thrust on him. I will teach them, if any fairly inquisitive readers desire it, but this has not yet appeared. Fairly inquisitive ones would know the evidences that all comets are globes of aëriform fluid, much rarer even at their centres than our air; in short, atmospheres without a planet (as our moon seems a planet without atmosphere), and simply what our fluids, one or more, would be if isolated in space. Our sea, or a tenth part of our sea, detached and left alone to revolve about the sun, would be merely a comet *of steam*, and a very large one, but as rare even at the centre, and of a mass as "astronomically speaking, *inappreciable*," as any of the 300, large or small, on record. If Roscoe or Huggins, or any F.R.A.S., ever wrote or said (which I do not believe yet), that "we do not know whether there is *as much* matter in this comet (whatever one be meant) as would fill this room," that is logically a fact, perhaps. Possibly we are *not* certain there is more, but if Roscoe or Huggins ever said so he was merely playing the buffoon, as much as his quoter (p. 252). He must have known it was just as unproved, whether in "this comet" or any other, there was "*as little* matter as a trillion tons," and it is equally unproveable, as yet, whether a tenth of a trillion, or a twentieth, or a hundredth of that mass, of any aëriform fluid (therefore, of any comet) would be little enough to fall on the earth without deluging her. Any weight approaching the first-named would infallibly do so, whether it were of steam or any dry uncondensable gas, because, in either case alike, the vast equal addition of pressure on highlands and seas would so tend toward equalisation of their loads, *at first*, as to level them. But with dry air only added, this levelling (and therefore inundation) would be far more permanent than with steam precipitated as rain, the latter making only a short temporary levelling, followed by upheavals into still *more* inequality than before, as well described by our joker at end of his paragraph (top of col. 3, p. 252), and there is abundant evidence of such effects, and all others of a *steam* comet-fall 50 centuries ago, but not of one of *gas* for at least many thousands. I can but conclude by challenging, as before, any scientifically informed reader to dispute soberly any single position in any line I have yet written on the subject (pp. 91, 146, 175, 200, 226, 229).

E. L. G.

"E. L. G." AND HIS PET DELUGE.

[4240.]—"E. L. G." (in let. 4176) has given about the most delightful piece of romance I have seen for a long time; it is a fine specimen of Dr. Tyndall's scientific use of the imagination. It puts me in mind of a pamphlet I had the pleasure of reading some time ago, written by (I think) Dean Cockburn, who, on the strength of having walked through the Box Tunnel, thought himself competent to annihilate and utterly smash up the geologists. Does "E. L. G." really expect us to swallow all his poetical descriptions with the all-digesting faith he ascribes to the Lyellists? Unfortunately, facts are dead against his theory, which has only a comet specially manufactured for the occasion from the recesses of his inner consciousness, like the German's camel, to support it. I will cull a few facts which are, to all unprejudiced minds, utterly subversive of "E. L. G.'s" fancies. For instance, the high Alps have a flora very much resembling (and identical in some species with) that of the Arctic regions. If the Alps only arose four or five thousand years ago, how did this flora get there? On the other hand, if the Alps existed before that time, the hot water and steam would have destroyed all these Arctic plants. Again, Mr. Wallace has shown that in passing from one island to another in the East Indian Archipelago over a deep strait of only fifteen miles in width, he leaves one fauna, and arrives at another perfectly distinct. If animals were floating about on islands of matted timber would they not have become mixed? How does "E. L. G." account for that phenomenon? Then there are the reef-building corals, which "E. L. G." so carefully avoids mentioning; these animals, as Mr. Gosse can tell him, cannot live in fresh water, nor at a greater depth than thirty fathoms, yet Prof. Agassiz, no Lyellist, mind you, but a cataclysmist of the deepest die, reports, from personal knowledge, that they must have been growing without a break for at least thirty thousand years. Yet "E. L. G." would have us believe that these animals existed comfortably under the pressure of a mile more or less of fresh water, to say nothing of the temperature. After all, where is the necessity to do all this violence to nature? Noah's flood might easily have been partial, if one must have it. How could Shem, when he left his untouched journal for the perusal of that accurate Hebrew scribe, Samuel, the first of his race, how could he, I repeat, know that the whole earth was under water?

P. SANTALINUS.

SELENOGRAPHICAL.—GASSENDI.

[4241.]—I SEND a sketch of Gassendi to show the features *a* and *b* as they appeared to me on May 18, at 9h. 30m., Dublin mean time, omitting several minor objects which I saw on the same occasion. Striking differences will be observed between M. Gaudibert's sketches (lets. 3462 and 4076) and mine in the way they represent the above formations—differences that doubtless show the effect of different states of illumination when the several observations were made.

J. BIRMINGHAM.

CONCRETE.

[4242.]—SHORT hours of labour—high wages—trade-unions, and the suicidal policy of putting the best workman on a level with the worst, are putting the ordinary mode of building with stone, brick, or timber quite out of the power of those who cannot command the enormous rents paid in large towns, and who may wish either to construct cottages for the labouring classes at a fair return of profit, or who are compelled to erect farm buildings to keep pace with the modern improvements in farming. There is one solace, however, to those who, like myself, are afflicted with a building mania. The complaint brings about its own cure either in diminished work or the application of scientific processes almost entirely independent of what is called, or rather miscalled, skilled labour. High prices and inferior work in the building trade have set the brain of the mechanician to work to design apparatus, and that of the chemist to discover compounds by which the material may be made, and the house constructed at one and the same time by labour that does not arrogate to itself the term skilled, but which is content to earn a fair wage in exchange for a fair amount of labour. As far as the mechanic is concerned, there is luckily not much scope for ingenuity. The alleged inventors of framing, notwithstanding their claims to protection under the magic word "patent," with the exception of a larger use of iron in the place of wood, have advanced but little beyond the appliances used by the Moors in Spain 700 years ago, or the Lombards in Italy longer. For my part, had I not laid out a heavy sum in frames, bolts, and ironwork, I should, at all events in walls of a thickness of 1ft. and upwards, use the old plan of wooden putlogs, mortised to receive the ends of the uprights kept together at the top by a rope, twisted in the same manner as a frame-saw is kept tight. The task for the chemist, however, is one of infinite difficulty and perpetual experiment, the successful result of which often depends upon a difference so slight as to escape the eye or head of any one, save that of the never-wearied chemist. Latterly, the attention of the chemist has been drawn to the feasibility of doing artificially what has been done by nature on a large scale in the formation of stone, by means of heat and pressure and a due admixture of silex, alumina, lime, and the oxides of iron. Until very lately the expense of the cementing medium has been a great bar to the substitution of artificial material as a substitute for the brick or the stone taken from the earth and worked by man for the required purpose. The prejudices of architects and builders, and a fear of disturbing vested interests, have also had their effects in preventing the more general application of artificial stone. The engineering necessities of the present day have necessitated the uses of artificial stone in submarine constructions and other works, where there was either a difficulty in procuring stone of sufficient size, or a difficulty of placing stones of a large size in proper position. These necessities created a demand for cement, and this demand in its turn has caused a supply of a good article formed from lime, clay, and silex, at a cost which puts it within the reach of those who feel inclined to construct. To bring cement, however, into general consumption, it must be produced at a still lower rate than at present. The chemical discoveries of late years, however, seem to indicate that, valuable as the Roman cement invented by Barker, and the Portland cement invented in 1824 by Aspdin, of Wakefield, are, there are other materials that afford a strong, nay, a stronger cement than the carbonate of lime burnt with silex and alumina alone. Mr. Ransome, by his ingenious process, has formed a stone by means of silicate of soda (made by heating flints and soda under a pressure of several atmospheres), mixed in certain proportions with clean sand, in which he can cast the most exquisite mouldings with an arriss as sharp and clear as the most skilled of masons can form on Bath or Portland stone, and then by a still more ingenious process he converts his silicate of soda stone into a hard and durable silicate of lime by a bath of chloride of lime: the chlorine leaving the lime to go to the soda and form common salt, and the silex and lime combining and forming a very hard stone. Whether this stone is lasting or not time alone can prove; but I believe the stone has been exposed to extremes of heat and cold with impunity. Curiosity led me about two years ago to send out some of the Ransome's grindstones to India to some works with which I am connected, and also to buy three or four for home use. One of the latter has been in use incessantly since then, and if it has worn a little, at all events it has worn evenly, and completely put to the blush the old Newcastle grindstone. It is a great favourite with my carpenters, who one and all agree that it is the best they ever saw. Again, General Scott, R.E. the constructor of the Albert Hall, has invented a cement which I see advertised in your columns as selenitic mortar, in which, as far as I can make out, by the application of sulphate of lime with the decarbonised carbonate of lime, he produces a cement at a very moderate cost; and if the advertised results are borne out in actual work, a cement of wonderful powers has been made. Curiosity, and your notice of the selenitic mortar in a late number of the ENGLISH MECHANIC, led me to call at the wharf in the Belvedere-road, Lambeth, where I was shown samples of concrete of different sorts, all apparently good. Among the rest a piece of concrete was shown to me said to be formed of selenitic mortar 1 part, selenitic clay from the neighbourhood of Leicester 5 parts, sand and gravel 40 parts. As far as I could judge, the concrete seemed sufficiently good for any thickness of wall. Its value will depend upon its power to resist compression; if good in that respect, the uses of this lime at 25s., and of the selenitic clay at 16s. per ton, will reduce the cost of concrete made with the selenitic mortar as compared with Portland cement very materially. It appears now that General Scott is converting the sediment of town sewage into selenitic mortar. I have ordered a truck-load of five tons of selenitic lime; the result shall in due course be communicated to you.

Another most important discovery has been made of late years in the production of an artificial stone of surpassing hardness, and capable of a beautiful polish by the mixture of caustic magnesia slacked with chloride of magnesium. This is an invention of M. Sorell, which he communicated to the French Academy as far back as 1867. So great are its agglutinative powers said to be that one part of the chloride of magnesia is sufficient for twenty of agglomerates in the shape of sand, gravel, stone, &c. I am afraid, however, the cost of the magnesia would make it too expensive a cement. The experiments of M. St. Clair Deville, however, seem to point out a mode by which the magnesia may be availed of at a less cost, and by an apparently easy process, by the burning the dolomite or magnesian limestone to an extent sufficient to decarbonise the carbonate of magnesia entirely, and the carbonate of lime only partially. This result was commented on in a late number of this journal.

If Deville's process can be carried out on a large scale in the factory successfully, we have the means within our reach of forming a cement of agglutinative powers, vastly superior to the Portland cements, by a comparatively easy process, avoiding the construction of the expensive drying vats and furnaces necessary for the due admixture and subsequent calcination of the clay and lime of the Portland cement. For Deville's process all that seems necessary is the proper calcination of the magnesian limestone. This can be done effectively at a moderate cost, nature having placed the limestone and the coal close together, as the coal-fields of England, from Durham down to Nottingham, seem to be skirted on their eastern side by the dolomitic formation. General Pasley, in his experiments thirty years ago, tried magnesia and lime for an hydraulic cement, and he seems very nearly to have hit on Deville's discovery, but he did not go far enough.

I am not a chemist (would that I were); it strikes me, however, that the result of M. Deville's experiments in the calcination of the dolomite is another example of the necessity in chemical experiments of examining closely the state of things, not only after entire disintegration has taken place, but also during the intermediary process. After all that has been said by Vicat, Pasley, Austin, Totton, and a host of other writers, on cements and mortar, on the necessity of thoroughly decarbonising the lime, one would scarcely have expected to find that in the mixture of carbonate of lime and carbonate of magnesia, the cementing powers depended entirely on a partial decarbonisation of the lime. The magnesian limestone, which supplies the lime for the greater part of the West Riding of Yorkshire, burnt as it is in the neighbourhood of Pontefract, forms but an indifferent mortar; burnt, however, under the eye of the far-seeing chemist, it appears to make a superlatively good cement. If this Dolomitic cement can be made at a cost exceeding but a little the cost of ordinary lime, its use will result in concrete monolithic erections throughout the kingdom, and then for ever farewell to bricks, brickmakers, bricklayers, and stonemasons, and all their wicked devices of needles in clay, soda-water bottles filled with explosives, picketing, rattening, and intimidation, which are rapidly converting good mechanics into worthless workmen, and driving capital away from the kingdom. The applicability of concrete in a monolith to large and high buildings, in the shape of warehouses, has been shown by the erection of the warehouses in Great Guildford-street, Borough, where Mr. Tall converted all the old brickbats, broken bottles, and oyster shells that he could get together into as strong a set of buildings as could be contrived. My belief is, provided a cement can be formed of strong agglutinative powers, like that of M. Sorell or St. Clair Deville, at a less cost than the present cost of good Portland cement, that in twenty years monolithic concrete buildings will supersede bricks and mortar, just as much as iron has superseded wood in the construction of ships. It is for the chemist, however, to discover the means of making a good cheap cement, and it is my belief that brains and money together would, in following out the track pointed out by Deville, find an ample reward in the manufacture of dolomitic cement. I trust that this letter will elicit some remarks from some of your able correspondents on questions of chemistry.

KHODA BUX.

HOW WE SEE A DISTANT OBJECT.

[4243.]—"E. J. D." (letter 4170) says that I forget "that if the black statue were placed in a room hung with black, and the sunlight admitted, that the statue would be quite distinct in all its details;" but "E. J. D." forgets to state what the texture of the hangings is to be, whether black calico, or black silk, or black cloth. Let us suppose it to be cloth. No doubt the statue would be distinctly visible, for the simple reason that the so-called black cloth is not black. "E. J. D." is an amateur artist; let him paint a portrait of a friend in a black cloth coat, if he has not done so before, and he will be surprised to find how great a quantity of white he has to mix with his black pigment in order to get the correct hue of the cloth, and the reason is not far to seek. If we examine the cloth under a microscope, we find its surface to consist of innumerable little black filaments, each with its own appropriate glittering high light, dispersing small glints of light in all directions. No wonder, then, that the statue should appear distinct against such a background. The true test would be to place the statue in a room the walls of which were equally as black and polished as the statue. "E. J. D." then proceeds to say: "In fact, a light background would render the statue more indistinct." Surely, "E. J. D." does not contend that a black statue against a white wall is not more visible than if against a black one. These are very simple matters, but it is absolutely necessary that we should reduce such questions to axioms before we can arrive at a clear solution of the question "How we see a distant object." It is much more necessary to settle a little question such as this than to speculate on the physical constitution of light; deeply interesting as those speculations are, they should be eliminated from the present discussion; rays, vibrations, undulations, pulsations of ether, &c., are no doubt good working hypotheses, but at the same time they are only so many ways of saying that we don't exactly know what light is; but we do know some of the invariable laws of its action—*e.g.*, the equality of the angles of incidence and reflection, and we know that any theory that contravenes or ignores that law must be wrong. "E. J. D." seems to think that the well-known laws of the action of light do not adequately account for the fact that an object is distinctly visible to numerous spectators in various positions; but if we consider that in ordinary daylight light pours down upon an object from all directions, the infinite reduplication of reflection in the air itself, which is a reflecting medium, and from surrounding objects, and then consider that almost every object we see is either fibrous, or granular, or striated, it is not wonderful that reflections of that light (according to the law of incidence and reflection) should be found to suit the requirements of any number of spectators. The polished statue is granular in its texture, but, generally speaking, the more polished an object is the less visible are its details at a distance. The ancients were aware of this, and in statues destined to be placed at great heights were in the habit of granulating the surface artificially by pitting it over with a small punch, so as to give more angles of reflection. Glass, though a good reflector of light, is not very visible; but if we grind the glass, so as to comminute the reflection, it becomes more visible.

What does J. Barwick mean by the remark that reflected light will not penetrate paper or porcelain? This is surely contrary to our every-day experience. I write this in a room with a north aspect; no light enters the window but reflected light from the clouds and the houses opposite but that light shines bright enough through paper or a china saucer. BOBO.

[4244.]—IN let. 4160, p. 227, occurred the gross error, "Brings light to us from the sun in 192,500 seconds of time;" of course, it should be, brings it at the speed of 192 500 miles per second (*i.e.*, according to Herschel); the wave of light is but 474⁶/₇ seconds in transit from the sun at that rate, or, roundly, eight minutes. And in the next sentence occurs, "If, however, different notes of the spectrum travel like distant notes of sound;" "notes of the spectrum" should be colours, or tints, or waves of the spectrum, for light has waves within waves more than any intricate machinery has wheels within wheels. Thus set right myself, I go on to "E. J. D.;" he must place his meaning of "but if a mirror be placed where the eye was, the rays to it causing reflection proceed from the object to the mirror in right lines parallel to each other" in more lucid language if he wants satisfactory elucidation of fact. He must look, too, at light as radiating by a fluid whose pulsations of condensation in front, and rarefaction behind, extend (with varying force, it may be) all around, except where intervening objects intercept. Angles of incidence and reflection are not those by which objects are directly seen, but as seen by reflection, as from a surface of mercury; so that it is wrong to speak of light as passing from objects only in one angle. As to the rays which reach the eyes of the spectator of his own reflection on the mirror when he looks at the feet, he sees those rays (or receives those pulsations) which, shaped and tinted by his shoes and stockings, strike the mercury; and his eyes receive corresponding rays from thousands of so arranged atoms (say) of the cosmic fluid, as well as do the eyes, and every portion of all the objects intercepting (but themselves unintercepted) all around.

The telescope renders distant objects more distinct by concentrating rays to a focus; parallel, if not divergent rays striking the lens are all converged by it to enter the eye, and are adjusted to a more suited focus than the unaided eye could adjust for. The man's eyes whose crystalline lenses are smaller than his neighbour's sees less of surrounding objects than his neighbour does, because fewer of the illuming ether atoms can impinge thereon. Not long ago, I used to write more strongly than "E. J. D." about the "ridiculous theory of ether existing in space"; and before he writes more thus presumptively, he certainly, as I have done, should closely study Tyndall's two works on Heat and Sound, and then have a sparring match with Tyndall's exposition of the theory, instead of with the phantoms of not over-imaginative brains. If "E. J. D." finds the study of the position and the size of the orb in combustion, whose agitation of the cosmic fluid or ether forms the sight-giving waves, too deep, he may as well drop the sight subject altogether.

J. BARWICK.

BRIDGE CONNECTING ENGLAND AND FRANCE

[4245.]—I THANK "A Friend of Progress" (p. 201) for the interest he has taken in experimenting on the practicability of my plan of building the bottom piers or abutments required in the construction of bridges, where the depth of water has hitherto proved an insurmountable barrier to their accomplishment, that barrier being now removed. I have no doubt but that he has been fully able to convince himself that my plan of building is not only suitable for deep sea water but also for rivers of moderate depth, such as the Severn, Thames, Humber, Tay, and others, where the trade and commerce of the country renders it desirable to have bridges constructed much nearer the sea coast than formerly, as in all such rivers where the bottom is found to be free from naked rocks, my plan of building on the surface of the water will be found decidedly preferable and inexpensive compared with any other plan that has as yet been adopted.

I was scarcely prepared to admit that a vacuum could be formed with any shroud sunk only to a depth of 4ft. 7in., however compact the beds may have been, as it is evident that many particles of the bed would be displaced and forced aside by the shroud in the act of sinking, which, I should imagine, may explain the reason why the pump had to be kept in motion three minutes before any indication of a vacuum could be perceived, as it would require some time before the action of the water could arrange or carry down sufficient deposit to fill up the displacements, and until this was accomplished no vacuum would be formed, as otherwise the water would enter the shroud. I observe by "A.'s" letter (p. 230), that he considers compressed air as the reason, but except some obstruction were placed to cut off the communication with the pump, compressed air could not occur, as I have shown in my former letter (p. 63), where I say "and when they (the shrouds) are correctly set (or sunk) the pumps should be put in motion, not sooner, as the inclosed water under the timbers B and C escapes through the pump valves, keeping them open so long as any sinking takes place." I am very well pleased with the experiments made by "A Friend of Progress," and if my plans are as eagerly entered into by railway companies and others, we may soon expect to see our rivers spanned with what may be termed our treble combined railway bridges.

SHOLTO DOUGLAS.

THE ALCOHOL QUESTION.

[4246.]—WHAT I complain of in Mr. Barwick's treatment of this subject (see lets. 4052, 4216) is not so much that *he* should take a "leap in the dark" as that he should bring forward his crude hypotheses and pit them against the well thought-out theories of scientific men. Since writing my previous communication (let. 4098) I have read Dr. Richardson's paper, and I send an extract bearing on the point in dispute in order that Mr. Barwick may see the doctor's estimate of the theory, against which, but without offering a single particle of evidence tending to prove its incorrectness, he has brought forward *his* idea of "too suddenly" carbonised and hydrogenised blood producing an acceleration of heart-beats. Dr. Richardson says: "Recently some new physiological inquiries have served to explain the reason why, under alcohol, the heart at *first* beats so quickly and why the pulses rise. At one time it was imagined that the alcohol acted immediately upon the heart, stimulating it to increased action, and from this idea—false idea, I should say—of the primary action of alcohol many erroneous conclusions have been drawn. We have now learned that there exist many chemical bodies which act directly by producing a paralysis of the organic nervous supply of the vessels which constitute the minute vascular circuit. These minute vessels, when paralysed, offer inefficient resistance to the stroke of the heart," &c. It will be seen from this that Mr. Barwick has taken up with a portion of an old theory which was "at one time supposed" to be correct, and he has spoilt even that fragment. It will also be seen that I have italicised the word *first*, to draw Mr. Barwick's attention to a point I mentioned before, that granting his assumption of "rapid oxidation," how are we to account for the diminution of temperature as the stages of alcoholism progress, for the blood on his hypothesis must be more and more carbonised and hydrogenised the more alcohol one drinks, and must necessarily require more "rapid oxidation" still? Mr. Barwick now writes, with all gravity I presume: "As for assuming that alcohol too suddenly carbonises and hydrogenises the blood, I did not expect any scientific person could doubt it." I do not know that I am a scientific person, but I beg to inquire of Mr. Barwick, first, how he imagines the blood becomes carbonised and hydrogenised; second, how that effect is accomplished suddenly; and, third, how "*too*" suddenly? I wish to know, also, what "scientific person" ever asserted that the blood *was* carbonised and hydrogenised by the imbibition of alcohol. It appears to me that Mr. Barwick should not throw aside so readily the oxygen contained in alcohol, for it would at all events go a little way towards preventing the necessity for "rapid oxidation." Is it possible, however, for alcohol to carbonise and hydrogenise the blood without being split up into its constituents? If Mr. Barwick says yes, will he kindly say, also, whether it acts upon the red corpuscles or upon the serum, or on both, for at least one "scientific person" has some little doubt upon the point. I think Mr. Barwick will acknowledge that Dr. Richardson has just one or two claims to be considered a "scientific person," and I find him saying, "When I sat down to write this essay, I noted many points of peculiar scientific interest as deserving my attention, and amongst these one specially important—the question how alcohol, after it has been taken into the organism, is disposed of, whether by conversion into a new product, by which it *ceases to be alcohol*, or whether by leaving the body as it entered it, an unbroken chemical compound." This question he does not answer, because he is merely giving an account of the effect of alcohol on the body, but I will venture to predict that when he does answer it, his theory (if not something more conclusive) will be that alcohol leaves the body as C_2H_6O, an unbroken chemical compound. Mr. Barwick seems especially fond of quoting symbols and formulæ, but may I ask him why he speaks of alcohol as boiling at 78·4° C., and as composed of C_2H_6O? Why, that is alcohol, it is true, but such alcohol as no one ever drank and lived to tell the tale! Surely, Mr. Barwick knows that the alcohol spoken of by Dr. Richardson is the ordinary spirit supplied by the wine merchant and the publican (and the grocer), which, when of a strength known as proof, fortunately rarely sold and still less rarely consumed, contains 50 per cent. of water. I don't think I shall be far wrong, indeed, if I assume that every 100 gallons of commercial "spirits" dispensed for drinking purposes contains 70 gallons of water; and this proportion is often still further increased by the consumer who is a trifle wiser than the confirmed dram-drinker. Mr. Barwick will see that the proportion of carbon (supposing the alcohol is really split up and assists in forming blood) is very different from what he puts it, being considerably reduced by the hydrogen and oxygen of the water.

Why Mr. Barwick should have written such a rigmarole as that on p. 256 passes my comprehension. What "muscular metamorphosis by oxidation" has to do with this question directly I do not see; for a man may get drunk almost without moving a muscle. Neither can I accept the phrase from the scientific schoolboy's copy-book—"All heat, from whatever burning source, is but solar heat"—as an answer to the question, What becomes of alcohol in the system? because it appears to me to be a trifle too vague, and because also I can conceive that there may be and are other suns possessing their own "potential fires." Mr. Barwick, however, assures me that "all the energy from it (alcohol) is derived by the conversion of it into some portion of tissue." This is, unfortunately, a statement with a double meaning. *All* the energy may mean *none*, even as the words are written; but it also means none, because in the opinion of more than one "scientific person" alcohol is never converted into tissue.

I would also caution Mr. Barwick against his favourite Gatch (no doubt a remarkably "scientific person"), because if Mr. Barwick really believes that the whole 28lb. of blood in his body passes through his heart every three minutes he is a most remarkable example of a "scientific person." Why, at what rate does he think the blood travels in the capillaries, where the "atomic clashing or interchange" is prevented by "obstructive molecules," which upset the "true vital order of atomic recombinations"? Would it surprise him to learn that it crawls along very slowly, in order that those very "atomic recombinations" of which he so glibly speaks may be effected. What manner of "scientific person" is he who asserts that the quantity of blood in an average man's body weighs 28lb., and that it *all* passes through the heart in three minutes? (Don't tell me Gatch, if you please.) What I mean by the heart having no sense is simply this: It cannot possibly know that the blood is carbonised, for it has no nervous *system*: it is utterly devoid of sense and feeling, is incapable of experiencing pain; and, when we consider the work it performs, on which, too, our very existence depends, we must acknowledge the wisdom which so made it. It is a wonderful piece of mechanism, but physiologically it may be likened to a bag of muscle with telegraph wires to the battery governing its motions. Therefore, I still hold it true that alcohol is not food: it is eliminated or excreted as it came in, unaltered save that it may be robbed of its flavouring essence. Even so small a quantity as a spoonful in a pail of water would not be split up by the digestive organs. But alcohol is probably vaporised in the stomach and partially dispersed over the system. We know that it gives off vapour or a subtle ether—witness the powerful odour of rum, which has often been detected in the brain cavities of those dying of alcohol-apoplexy when the head has been opened—no slight proof that Mr. Barwick's hypothesis is utterly untenable; for if spirits were digested and split up, their peculiar odours would be in doubt whether to accompany the carbon or the hydrogen, or the oxygen which Mr. Barwick has unaccountably lost, although he acknowledges that its proportion by weight is 8 ($C_{12}H_8O_8$). Mr. Barwick also seems to be unaware that although the action of the heart is accelerated, the quantity of blood propelled into the arteries is not thereby *necessarily* increased.

SAUL RYMEA.

[4247.]—"BUSY BEE" (let. 4156) wants to know if I can furnish any reason for my remark as to alcohol, tea, and lemonade. I can. H_2O, water, is common to them all; C_2H_6O is ethyl alcohol; theine or caffeine, $C_8H_{10}N_4O_2$, is the active principle of tea and coffee; and $C_6H_8O_7$ is citric acid, which, along with a little malic acid, gum, &c., characterises lemon-juice. The grand distinction is the very small quantity of O in alcohol, the large quantity in lemonade, the large quantity of N in theine or tea, and its total absence in alcohol and citric acid. Pure tea has a most soothing and invigorating effect on the nerves and brain, is a most wholesome stimulant (with sugar and cream), aiding the latter processes of digestion, and arousing the faculties to renewed activity. Theine contains all the organic elements; but if "Busy Bee" is hard-worked, tired, and hungry, bread and butter and eggs will supply elements needed by the brains, and which neither theine, cream, nor butter contains.

As regards alcohol, a little experience in the trade and bustle of the world shows that its imbibers carry around them the most offensive atmosphere, which might accelerate the growth of timber in the direct rays of the sun, but is certainly very damaging to the air of rooms, offices, or shops; alcohol much promotes heat, but fires and closeness of houses promote it better.

The large proportion of O in citric acid, and still larger in tartaric acid ($C_4H_6O_6$), in which by weight we have C_{48}, H_6, and O_{96}, whilst citric acid is C_{72}, H_8, and O_{112}, renders those acids, I presume, sources of oxygen beyond the air at the lungs, which their enlivening properties indicate, whilst alcohol after a short period of stimulation torpifies and stupefies.

I agree with "Busy Bee" that we need a better knowledge of the constituents of all our food substances, and I smile at the alacrity displayed about the weights of bread and the measures of barley being tested by accredited inspectors, whilst a callous indifference is manifested on all sides about the testing or ascertaining the precise composition, in its chemical formula, of every article offered in our markets for food. Society is surely in its infancy; and chemistry in its relation to the laws of life and health lamentably too little recognised. If the people, instead of but striking for wages, would combine to support accredited testors in every town and village through the land, they would impress ultimately on society a respect and admiration which they certainly cannot by agitation about wages, which they do not know how to spend most economically. As for distinguishing foods from stimulants I cannot, unless we say *mere* stimulants, as certainly a few good cupfuls of tea with nice etceteras is at once highly stimulating, strengthening, and nutritive.

J. BARWICK.

SPECULUM WORKING.

[4248.]—IN reply to Dr. Blacklock's question (let. 4223), I beg to say that I consider 12 diameters of the speculum to be the best for the focal length. Beyond that there is no advantage, either in ease of vision or facility in figuring. A focus of 9 or 10 diameters gives admirable results with care; but he who attempts 8 or 7, even though he be a perfect master of the process, must be prepared to bestow a considerable amount of patience and time on the work. I do not believe it is possible to produce as good a speculum of 8 diameters as of 12.

The focal length of my own 18in. speculum is 7 diameters, and it is not a bad one. I am inclined to think that the great facility in using so large an instrument which this short focus gives me, counterbalances the slight disadvantages. Still, were I to do the work again, I would have worked to 13ft. focus. I heartily congratulate Dr. Blacklock upon his success.

H. C. KEY.

[4249.]—IN answer to "Optical Bricklayer" (query 11930, p. 263) the edge of pitch tool should be circular, and its polishing surface precisely the same diameter as speculum, but to insure the edge facets giving the same pressure as the rest, I find it better to have the iron tool a little larger (as Mr. Key recommends), say not less than ½in. larger than the mirror, so as to allow the pitch the same slope at the edge as in the gutters, as it is of great importance that the edge facets should exert as much pressure as the central ones. As far as my own practice goes, I have worked several good mirrors on an iron tool no larger, and in one case even smaller than the mirror, but the figuring was very troublesome, and led me to prefer a larger tool, which admits of greater accuracy with much less trouble. It must not be forgotten, however, that whatever may be the size of the tool the polishing surface should exactly correspond to the size of mirror.

I could not give "Optical Bricklayer" much idea of the figure of his mirror unless he states the appearance of the enlarged star disc, either within or without the focal point, as the focal point itself is of no use whatever as a test. I should imagine the appearance he describes indicates hollowness at the edge of mirror; to prove it let him push in the eyepiece, and if the wings which surround the star disc contract the edge of mirror is too hollow, but if the wings expand the edge is too flat.

W. PURKISS.

ATMOSPHERIC ELASTIC FORCE.—SUPPORT OF SPINNING-TOP.—UPWARD DEFLECTION OF BULLET.

[4250.]—THANKS to "Philo," to "A.," and to M. Paris for their obliging replies. The attempt to balance a top (without rotation) in that position which it assumes in spinning being quite futile, we become aware that the upsetting force of gravitation has to be encountered from first to last in order to its support while spinning. This upsetting force is thus understood to be constant in its action, and is clearly defined in direction. If certain forces, therefore, are named by the replicants as nullifying or overcoming that of gravitation, it becomes them (especially if their argument is advanced in the form of positive statement) to show that the forces to which they attribute the support of the top do act in a direction opposite to that of gravitation, or that out of the conflict of them a resultant force is produced opposite in direction to that of gravitation, and in power equal or superior to it.

Now, supposing that the word "tendencies," which "A." and M. Paris oppose to gravitation, can be admitted in mathematical demonstration when a defined and active force is required, yet the very language in which they describe the action of such tendencies or forces forbids the conclusion at which they arrive—viz., that they nullify or overcome gravitation. For if (let. 4130) under their action "the body has an equal tendency to fly away in all directions," this equality of forces or tendencies can only operate to the nullification of each other, and the independent force, gravity, is left as free to act as though the others had no existence. And if (let. 4131) "the attraction of cohesion" fully explains why a body should rotate rather than scatter its component particles in tangential lines, it offers no explanation why the axis of such a rotating body should assume and maintain a certain direction when free to take any other. But supposing that these "rectilinear tendencies" become rectilinear forces, pulling the top from various points as by multitudinous lines, so as to hold it in a certain position, they must be all equal, or the preponderating force of some of them would drag the body out of that position of repose which a top assumes and maintains while spinning with full power. But if they are all equal and opposite, and all in one plane or system of parallel planes of revolution, then they neutralise each other, and leave no resultant to oppose to the upsetting action of gravity.

But let us suppose a top to be set on its point, and from three points in the circumference of any plane of rotation equidistant from each other three lines pass over three pulleys with equal weights to act on them, then the supporting effect of these rectilinear tendencies will be fairly represented. Then, in what position of the axis will the top be supported? Only in that wherein its equilibrium is perfect independently of those three forces; for the slightest declination of the axis from that position would cause one or more of those equal rectilinear forces to preponderate over the rest, and upset the top. In short, in all such explanations as those afforded by "A.," or by M. Paris, the idea of a perfectly upright position or equilibrium of the top seems to have been unwittingly assumed, and the subsequent reasoning arranged to satisfy it. Thus it is only the maintenance of the position which enters into the question, and "equal tendencies" seem to satisfy it. But the real nature of the phenomena are such as require a very different solution. A top scarcely ever falls from the hand of the spinner with its axis in a vertical line. It (1) assumes that position; (2) maintains it; (3) can recover it again and again if disturbed; (4) it can prolong resistance (more or less according to shape) after it has finally lost the vertical position, to the final result of gravitation. "Equal tendencies" utterly failing to account for this conflict with gravitation, from first to last, I suggest to your readers that however advantageous a vacuum may be for the revolution of a body when the axis is duly provided with bearings, an experiment will go far to prove if the support of the spinning-top is not rather due to an elastic cushion of compressed air called into action by the resistance of the vis inertiæ of the atmosphere to the velocity of the rotation, and by the superior density of each lower stratum. Such a theory accounts, I think, for every phase of the phenomena. The proof, at any rate, is very simple, afforded by the air-pump. By withdrawing the atmospheric support, it must at once become evident how far that support is necessary. My three replicants all give specious (though, I think, unsound) reasons why it should spin better in vacuo; and it would seem, I think, that M. Paris's information "it is found" to do so has come to him from a theoretical rather than a practical source. I shall be much surprised to hear that a spinning-top will stand erect in vacuo for a moment, and I should expect that a few strokes of the air-pump would at once destroy the stability of its vertical position. In proportion to the fineness and smoothness of its point, the top shows less and less disposition to travel about. It requires only vertical support at that point up to the last moment of its struggle with gravitation. We see, therefore, that "A.," of Liverpool, in his sketch of a very simple form of the gyroscope, is showing us only a suspended top. The string remains plumb, I think, because the point only requires vertical support. In this suspended position the support of an air cushion to the body of the rotating instrument becomes still more probable.

A few more words on the atmospheric theory next week in my reply to "Philo" on the upward deflection of the bullet. I have satisfied myself, by experiment, that this upward deflection, more particularly in the case of the smooth-bore, is no imaginary thing. Finally, I would suggest, by way of showing that the atmospheric theory may prove of practical value, that the stable position of the bicycle-rider is due to the same elastic force when excited by sufficient velocity of motion.

J. M. TAYLOR.

Seer Green Vicarage, Beaconsfield.

ELECTRICITY—WHAT IS IT?

[4251.]—UNDER this title, in your last impression, Mr. B. Thomson refers, in a desultory manner, to the considerations which led some electricians to the crude *à priori* notion that since sound, heat, and light have been shown to be modes of motion, electricity might possibly be placed in the same category, and its effects explained analogically. He makes, however, no progress whatever towards answering the question with which he sets out; and the *petitio principii* with which he commences his second paragraph, and ends the present portion of his paper, must appear somewhat ludicrous to those who are acquainted with the present aspect of this question. He cannot, I think, be aware that I claim to have proved, by experiment, as well as by reference to verified and accepted principles, first, that electricity cannot, in accordance with our present knowledge, be regarded as a "force" or as a form of motion; and secondly, that in no case can it be shown that electricity is converted into heat or work (*vide* the *Engineer*, July 18, August 14, September 4, 1868, &c.).

I should, perhaps, have abstained from offering any remark upon Mr. Thomson's papers until after their conclusion; but I imagine that there is no probability of his strengthening his position by a fair consideration of the question as it stands.

DESMOND G. FITZGERALD, M. S. Tel. Eng.

6, Loughborough-road, North Brixton.

MAMERTUS AND FRENCH VOLCANOES.

[4252.]—THE statement that the "Rogations" (now called the Litany) and "Rogation-days" originated with prayers against the volcanic eruptions in Languedoc during three years (458-460) is quite correct, and Mr. Cooper Key will find the two contemporary authentications thereof in (1) the Epistles of Sidonius Apollinaris, Book VII., Epistle 1 (to Archbishop Mamert); and (2) the Homily of Alcimus Avitus (successor of Mamert) on the Rogations. Both are in Migne's *Patrologia*, tom. 57, p. 563, and tom. 59, p. 289. I do not see that these eruptions have any particular bearing on any current geological question, and they did not proceed from the Auvergne craters (as the correspondent of *Nature* and Mr. Key in "ours," p. 254, seem to imply), but from some of those in the two more south easterly provinces of Velay and Vivarais, as the ashes repeatedly reached the capital of the Burgundian monarchy, Vienne, then the most important place in the country, and Mamert's See. As no writings of St. Mamert himself are extant (unless his Litany), nor of any Gallic contemporary but those two, the phenomena stand in the singular position of being attested by literally *every* contemporary author; and yet, strange to say, passed into such oblivion that *no* chronicler of the next age, not even Gregory of Tours, mentions them, as Mr. Key found. It is a most instructive caution, and geologers would do well to read pp. 293, 297, of the late Sir F. Palgrave's essay entitled "The Conquest and the Conqueror," in the *Quarterly Review* of October, 1844.

E. L. G.

REVOLVING PUDDLING FURNACES.

[4253.]—"R. S." (let. 4172) has not succeeded in explaining away the facts already adduced in reference to Mr. Danks' claim to the invention of the revolving puddling furnace. Mr. Walker's experiments failed for the want of a proper chimney for his furnace—this was not his fault, but his misfortune; while even with the aid of a good chimney Mr. Danks' furnace is reported to be a "bad melter." As a manager of iron works and a practical mechanic, I consider Mr. Danks' furnace to be neither more nor less than a combination of the inventions of Messrs. Walker and Tooth; and, until Mr. Danks has otherwise proved his claims to this invention, "R. S." has no right to put forth his humble opinions as to the superiority of Mr. Danks' furnace. An invention lying in the pigeon-holes in the Patent Office is not lost, or a thing to be pirated with impunity; neither can a mere improver in any sense of the word be considered an original inventor. The Danks' furnace appears to me a second edition of the American reaping-machine. In 1825, if I mistake not the year, an English mechanic invented a reaping-machine; it was tested and did its work well. On the first public trial the machine was smashed to pieces and the inventor pelted with stones by an enraged mob of farm labourers. This invention lay dormant until the Great Exhibition of 1851, when the reaping-machine again appeared as a new invention from America, and, of course, patented. The trick was exposed, and the patent, like the revolving furnace, fell to the ground.

"R. S.'s" laudations of the Iron and Steel Institute are rather out of place. It cannot be admitted that that scientific body has acted fairly by rushing with an iron-melting-temperature zeal at Mr. Danks' furnace before the original invention at home had been practically tested. In the absence of this fair play on the part of this institution the pleasant trips across the Atlantic, the convivial dinners and speeches, the gushing votes of thanks from the lordly lips, the full-siced portrait of the noble President, certainly have that smack of egotism already described. The old proverb informs us that things dear bought and far fetched are greatly admired by fantastical ladies; even so, apparently, with the Iron and Steel Institute. Had the Iron and Steel Institute acted on the motto, "Fiat justitia, ruat cœlum," justice would have been done to Messrs. Walker and Tooth, without injury to Mr. Danks. G. S. (Civil Engineer).

A NEW MODE OF CONVERTING MECHANICAL FORCE INTO ITS HEAT EQUIVALENT.

[4254.]—IT has struck me that the following experiment, which, however, I have not tried, would be a fitting addition to those for the determination and illustration of the mechanical equivalent of heat. When a disc is made to revolve it may be noticed that it offers resistance to being turned in a plane perpendicular to the plane of its revolution. This is the principle of the sustentation of the disc in the gyroscope, of which instrument we heard so much of in the ENGLISH MECHANIC some time back. If I construct a machine so that while a heavy disc is made to revolve rapidly in one plane its axis is made to revolve in another perpendicular to the former, an amount of force will be absorbed independent of the friction of its parts. From the first principles of natural philosophy I think it follows that this force must appear as heat in the disc, and the amount could be measured by a thermometer inserted in the disc. If so, I do not think that the conversion of mechanical force into heat force is traceable to friction, percussion, compression, electrical, or chemical action, the usual means for the evolution of heat, as the machine can be imagined perfectly rigid in its parts, and frictionless without interfering with its principle. I am also curious to know if all discs of equal weight and diameter (the thickness, of course, being in inverse proportion to specific gravity), but of different materials, would offer the same resistance, and consequently evolve the same amount of heat worked at the same velocity. The arrangement of the machine is very simple, and if any one thinks of trying the experiment I should be happy to supply the design. A. R. M.

HOW TO USE A BOOK WITHOUT HANDS.

[4255.]—IT must be very gratifying to you, Mr. Editor, to know that the ENGLISH MECHANIC has been the means of procuring for the unfortunate man who had lost his hands the useful and very ingenious instrument described at p. 224, which "M. O." has been clever enough and generous enough to contrive and make for him. It is something like, but an improvement on, the instrument I saw many years ago for turning over music with when the hands are engaged; and it is likely, if "M. O." would make such for sale, that violin and flute players would be glad to purchase it, and I for one should be glad to know that its ingenious and kind maker reaped profit as well as the praise and thanks he is so justly entitled to.

PHILO.

RELIEF FOR CATARRH.

[4256.]—A FOREIGN (Dresden) correspondent says that the following has been found very effective in relieving cold in the head, and not unpleasant:—Fill a wide-mouthed stoppered bottle with cotton or asbestos, saturated with a mixture of pure carbolic acid, 5 parts; rectified spirit of wine, 5 parts; strong solution of ammonia, 6 parts; water 10 parts. The vapours are drawn into the nose and mouth frequently, it is said with great advantage. M. R. C. S.

ELECTRIC BELLS ANTICIPATED.

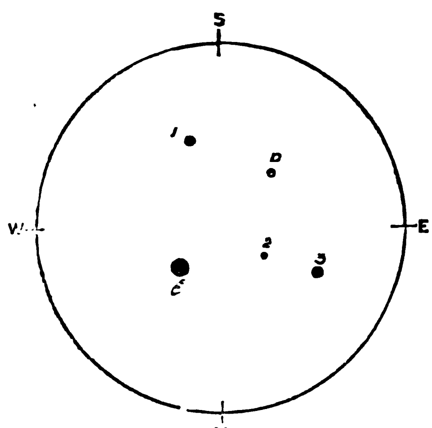
[4257.]—THERE is an account of a similar apparatus to that referred to in let. 4200, p. 253, as employed by the Moors of Grenada, where there was a certain armed figure which, on the approach of an enemy to the city, turned and pointed its spear in the direction from whence he was coming. But, useful as these figures must have been, we have equally well-authenticated accounts of far more valuable products of the wisdom of our ancestors, of which we have not yet recovered any reminiscences, even so faint as our electric telegraphs are of these ancient sentinels. For instance, our commissariat departments in their endeavours to accommodate our troops in the autumn manœuvres, fall very far behind the possessors of the tents described in several old works, which would fold up into a pockethandkerchief, and yet extend so as to shelter a whole army. Then, again, even our express trains and finest ocean steamers are miserable attempts at locomotion compared with the lost art of manufacturing carpets on which it was only necessary to sit and to be at once transported to any part of the earth at pleasure. Those, no doubt, were the good old days, and we mere moderns are poor pretenders. SIGMA.

NEW DOUBLE STARS.

[4258.]—I BEG to report the following double stars found with my 6in. Alvan-Clark refractor a few evenings since:—

CORVI = L 23488 . 12h. 26m. 7s., S. 15° 56′ : 8, 14 : 260° : 10″. This pair is 3m. f δ Corvi, and about 20′ further south; the northern of two 8 mag. stars, about 25′ apart. Probably a moderately difficult object.

BOÖTIS = L 27106 . 14h. 46m. 31s., N. 19° 16′ : 8, 10 : 180° : 1″. I would call particular attention to this exquisitely beautiful double in the immediate vicinity of the well-known pair ξ Boötis, f that star 1m. 6s., and declination 23′ less. I have only seen it once, and although on that occasion it was well separated with clean, sharply-defined discs, it cannot be a very easy pair with a 6in. aperture, except in very good weather. It is a little strange, however, that it should have escaped observation, when ξ has been observed and measured for so many years. It is certainly a very beautiful pair under favourable conditions, and sufficiently difficult with small instruments to make it an interesting object.



The accompanying sketch will enable any one to find this without an equatorial mounting, the star marked D being the pair in question. The stars marked 1, 2, and 3 are respectively Nos. 955, 989, and 1008 (= L 27137) of Weisse's "Bessel." The double is not included in that catalogue, but is No. 27106 of Lalande. Is 3 variable? Its magnitude in Lalande is 7, and in Weisse 6·7. It is now very plainly visible to the naked eye at any time. Argelander, whose "Uranometria Nova" is almost perfect in this respect, has not given it, from which some change might perhaps be inferred.

Will Mr. Knott give some later measurements than those made by Mr. Dawes, of OΣ 288, if any have been made? A few evenings ago I picked up this pair (R.A. 14h. 47m. 13s., N 16° 14′), and at first supposed it must be new, as my estimate of the distance was so much greater than that of OΣ. Looking at it again, just before finding the pair given above, I felt certain that the pair I had found was identical with OΣ 288. In Otto Struve's first catalogue it is marked "fortasse oblonga," and in the catalogue of 1843 the distance is given as 0·5″. Dawes measured it in 1847, making it 0·6″. Now, its distance is at least twice that. My estimate before identifying it was 1·5″, and it cannot be less than 1¼″. It is now a comparatively easy object. The new pair given above is apparently half a second closer.

The new pair $s. f.$ 6 Comæ turns out to be quite a delicate object, and more difficult than I at first supposed.

Chicago, May 6, 1872. S. W. BURNHAM.

IS LIGHT INVISIBLE.

[4259.]—SOME time since I saw an experiment described to prove the invisibility of light. I should like an explanation of the following:—The undulatory theory of light assumes that a subtle elastic fluid pervades and fills infinite space, all fluid, solid, and gaseous bodies, and is called luminiferous ether, which ether, in a state of rest, is darkness, and in a state of undulatory motion is light. This theory assumes that light is not in itself matter, but is a state of matter. Supposing, then, I cast my eye upon an object, I do not see the object, but the rays of light that are reflected from the object. Thus, when I look upon the green fields before my house, I do not see the fields, but the rays of light that are reflected from the fields, and the reason why they appear green is because they absorb all the colours of the spectrum, excepting the yellow and blue, which go to make up the green appearance. Here I am in a fix. In the first place, I do not see the object; in the second, it is asserted I do not see the light—what do I see? A simple experiment is enough to prove I do not see the object I cast my eyes upon. If I walk into a darkened apartment I see nothing. I light the gas and see, or imagine I see, everything. I have added nothing but a light, therefore it must be the light I see. It may be said that the waves of luminiferous ether strike the eye with inconceivable rapidity and produce the sensation of light. Well, be it so, the luminiferous ether then becomes visible, and it is light; if not visible in the ocular sense, it becomes visible to the touch—the touch upon the eye. JOHN HOPKINS.

ATOMICITIES.—ELECTROLYSIS AND MODERN CHEMISTRY.

[4260.]—HOWEVER simple the facts involved, it is not easy to clear away the muddle and confusion of diatomic philosophy. "Sigma" says we cannot escape from what are diatomic elements, such as zinc, copper, sulphuric acid, &c.; and, therefore, we are bound to consider electrolysis as subsisting with a linear chain of H_2, Zn, ϴu," &c. In other words, it is a circuit of molecules, and not of atoms. In this great assumption the whole secret is involved.

If a tension of 1 volt. (roughly the force of 1 Daniell cell) in a voltaic circuit involves an energy equivalent to 4,673 foot pounds per equivalent, and if this action is not through "chemical equivalents of matter," but a force "transmitted through the centres of attraction, or of atomicity by which the molecules are constructed," then I hold that this unit of force should be 9,346, and not 4,673. But wherefore this dire necessity—this thraldom, which "cannot escape" from diatomic or doubled atoms? One paragraph of diatomic evidence would be of more worth than pages of assumptive reiteration.

As to the unfortunate reasons which have led to this doubling of many atoms, I would refer to a paper "On the Atomic Weights" (*Chemical News*, February 9, 1872). Such great chemists as Berthollet, Bouchardat, and a host of others, look with dismay on their distorted alphabet. Then, as to the curious facts which have puzzled electricians, and led to "imaginary laws of electrolysis," what are the laws referred to I know not; but, if they are more imaginary than the atomicity electrolysis of "Sigma," I do not covet their acquaintance. As to the copper difficulty, I do not see that the diatomic device affords any enlightenment. "Sigma" has—

No. 1.	$\begin{matrix}H\\H\end{matrix}\!>SO_4 \quad H_2 = O$	$Cu<\begin{matrix}Cl\\Cl\end{matrix}$	$\begin{cases}Cu - Cl.\\ \mid \\ Cu - Cl.\end{cases}$
No. 8.	H_2O	$Cu\ Cl_2$	$Cu_2\ Cl_2.$

Now, taking No. 8 on the simplest chain, we have, first, a molecule of H_2 = 2 vols., connected with half a molecule of oxygen = 1 vol.! Secondly, we have a weight of copper which is both atom and molecule in one, associated with a molecule of chlorine = 2 vols. Thirdly we have a double molecule of copper connected with 1 molecule of chlorine; and, to the explaining power of all this, I would say—Prodigious!

The chemical peculiarity involved in what is called cupreous chloride, ϴuCl. or Cu_2Cl, I have pointed out in a paper "On Some New Sulphur Salts" (*Chemical News*, Vol. XXI., p. 123). On this occasion I would further illustrate this allotropic peculiarity by a somewhat similar action in organic chemistry. A new field of great interest is opening up in what are called "condensed molecules." The compound radicals, which act and react like elements, are found capable of condensation, so that two or three atoms condense into one, in which state they are truly single atoms, and volumetrically or chemically (and, might I not say electrolytically?) they comport themselves as such. They combine with one H and form characteristic hydrides, or with one O or one Cl and form corresponding acids or bases; they replace one H in varied ammonias, alcohols, glucosides, &c.

A clearer conception of this law of action will tend to remove certain anomalies in old mineral chemistry, as copper, and some other elements certainly share this affection. Here, then, is a problem for some inquiring electrotypist, for he may, in a given time, or with a given potential, deposit a double weight of allotropic copper!

I cannot enlarge here on the chemical evidence in this direction, and briefly compare this view with the molecular chain of "Sigma"—

HO | CuCl | ϴuCl.

Here we have one oxide and two chlorides, all strictly analogous, both in type and function.

"Eclecticus" is pained at the thought of "quarelling" with an accomplished chemist, who bids fair to rank high where only great ability and attainments can succeed. In descending to the level of an outside thinker, G. E. Davis is both fair and courteous, and commands only high respect and esteem.

ECLECTICUS.

CEMENT FOR AND ATTESTING MEERSCHAUM.

[4261.]—MANY thanks for the advice and suggestions in reply to my queries. To "Jack of All Trades," I attach the greatest weight, and from my own practical experience. The cement mentioned by "Saul Rymea," is very inferior to a mixture of double gum and plaster of Paris, and the mode for testing a meerschaum pipe mentioned by "A., Liverpool," is erroneous; rank imitations will float as stated by "C., Glasgow," in your issue of May 10. The cement mentioned by W. R. Donaldson will have my immediate attention, for which I must thank him. The Germans in town have now a neat way of mending meerschaum pipes broken in the middle of stem (some of which are as thin as tobacco pipes), by inserting a fine fitting bone or lead tube, 1½in. in length, to connect the broken part, which is also cemented, the broken part forming one side of a neatly carved buckle. I beg to add, for the information of your subscribers, the account given by Professor Smyth, M.A., of this mineral, in his course of lectures on "Mineralogy," to the students of the Royal School of Mines, Jermyn-street, and which lectures were not published. Meerschaum is a hydrated silicate of magnesium. Its chemical composition is ($Mg_2Si_3 + \frac{3}{2}$ H) and its percentage composition is—

Silica	62·6
Magnesia	28·3
Water	9·1
	100·0 (Nicol).

Several varieties are known, generally associated with hornblendic rocks. It breaks with a fine earthy fracture, that is, like fine grained chalk. Its hardness is about 2°, or, in other words, it may be scratched with the finger nail. Its specific gravity is 0·8, hence it will float in water, and it is from its being picked up at times floating on the sea that the Germans call it "foam of the sea," this being the meaning of the word meerschaum: meer, a lake or sea; schaum, foam or scum. It has a greasy or soapy feel, in common with most magnesium minerals. When a fractured surface is applied to the tongue it adheres strongly. It is brought principally from Asia Minor, Greece, near Madrid, and Toledo, Moravia, and Wermeland. Real meerschaum pipes are turned and carved from the solid mineral, and steeped in wax, inferior articles are made from compressed scrapings and steeped in oil, and generally heavier and less perfect than those made from the solid mineral. The Turks absolutely employ meerschaum as a substitute for soap in washing, for it is quite soft and soap-like when first dug from the earth, and it lathers in water and will remove grease.

Reading. ZETA.

CHLOROFORMING BEES TO REMOVE HONEY.

[4262.]—THINKING it may be useful to many readers of "ours," I subjoin a method for the above which has been practised several times with success. The quantity of chloroform required for an ordinary hive is the sixth part of an ounce: a large hive may take nearly a quarter of an ounce. Place a table opposite to, but about four feet distant from, the hive. On the table spread a thick linen cloth, in centre place a small shallow or soup plate, which cover with a piece of wire gauze to prevent the bees coming in immediate contact with the chloroform. Now quickly and cautiously lift the hive from the board on which it is standing, set it down on the top of the table, keeping the plate in the centre, cover the hive closely up with cloths; in five and twenty minutes the bees are not only sound asleep, but not one is left among the combs, the whole are lying helpless on the table. Now remove what honey you think fit as expeditiously as possible, and replace the hive in its old situation, and the bees, as they recover, will return to the domicile. A bright, calm, early morning is the best time. Be cautious at first, but practice makes perfect.

H. B. E.

INCUBATORS.—To "HATCHER," AND ALL READERS IT MAY CONCERN.

[4263.]—YOU are quite right in what you say on p. 229. The incubator does absorb the moisture of the eggs too much; I therefore advised you to damp the eggs well. I find it a good plan to float the eggs in warm water for a minute or two, a day or two before they are due. The hens, if set in a very dry place, get a small brood; I therefore set them in a cool damp place if I can, or I put two shovelfuls of fresh earth under the nest before I make it up, or a large sod fresh cut. I know this is contrary to most people's notion of keeping the hens warm, but it prevents the increase of vermin, and I get more chicks. I am corroborated in this opinion by Mr. Wright, in his "Poultry Keeper's Guide," and he is a trustworthy authority. In the incubator I now make a cotton bag, and put in a quart of damp warm bran, flat it down to about an inch thick, and put it upon the eggs under the glass; this gives the required pressure, and in a great measure prevents the absorption so detrimental to the welfare of the chicks in the eggs. This bran bed will require renewing about every third day or so; in this way you will get good results. If you are timid about it, try it on part only, and see the difference; with the bed they require no more damping. The floating the eggs the last day or two certainly assists in freeing the chicks from the shell or inner lining should they be gummed thereto, which you cannot ascertain until too late.

M. O.

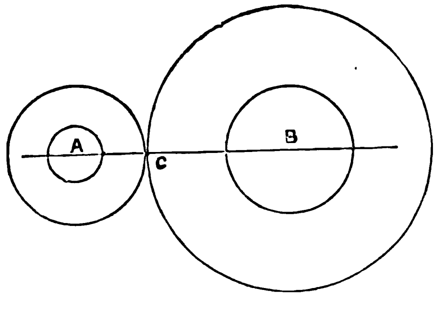
OF AUGUSTUS LE PLONGEON, M.D., ON THE COSMIC FLUID.

[4264.]—THE cosmic fluid or ether I suppose to rotate and revolve in orbit amidst the aërial atoms along with the great orbs of space. W. Matthieu Williams, F.C.S., in "The Fuel of the Sun," published in 1870, opines all space is filled with an atmosphere like the one we breathe except in its extreme rarity; that our atmosphere has no limit, but grows rarer and rarer as it recedes from its attracting centre until terrestrial gravitation is neutralised by that of some other orb at the point where the attraction from each is equal. Between the orbs A and B, for instance, the point C exists as a centre of equilibrium.

The point C, where the two atmospheres join, is distant from A and B in the ratio of their respective weights, thus—

$$AC^2 : CB^2 :: A : B.$$

Now we infer the moon has no atmosphere of nitrogen, oxygen, &c., like ours, but has the like cosmic fluid, which will rotate and revolve with it, and, I ask, are we, when it passes between Sol and us, to infer that the three atmospheres are crushed to that extent closer? A solar eclipse in such case displays its corona through an extraordinarily dense medium. Dr. Plongeon asserts the cosmic fluid opposes the orbit motion of the earth; that this front resistance causes diurnal rotation of the earth and its conical movement, occupying 25,868 years; its tide-producing vibration; and continuous friction throughout its surface, but mainly at the equator—a cause of heat at the earth's surface. Is not such result from interstellar fluid quite an over estimate? We see because objects rebound ether, but even this without force enough to disturb the equilibrium of a feather floating in the air; but were the ether equally dense in space, where, I ask, but in falling meteors or aërolites can there be friction? After the first impulse to motion each orb in motion creates a vacuum behind it, which is rushed into with an impetus to the orb, evidently as acceleratingly effective as anything in front is obstructive. What obstruction is there in front to an orb that carries along with it everything around it, especially in front of it, in an unresisted orbit? Suppose the earth, by some terrific collision, driven off from its atmosphere and orbit by suddenly acquiring a speed it could not all at once impart to its air, how would the air, once the earth's atmosphere, deport itself? Would not it gravitate to the nearest powerful enough orb unless held back by some centre of equilibrium? Why do not all the atoms of nitrogen and oxygen and all other fluids descend by the law of gravity to the surfaces of all their allied orbs, but because they vibrate molecularly to the creation or maintenance of vacuum which buoys them up? In so far as rotation causes easterly and westerly winds it produces friction and heat, but the easterly wind being mostly northerly, destroys much more heat than it imparts. I am quite afraid the doctor is importing into his theory more imaginary causes than he can adduce reasons to support. Did any one live to testify as to the temperature of a cannon-ball on leaving the cannon and its fire? If on splitting we find the interior hot and exterior cool, it seems to have cooled by its excursion. But enough: I wait to see if some veteran soldier in science do not tilt to discomfiture some of the over-brave utterances of a nevertheless clever M.D.



In my diagram the outer circles denote extension of the atmospheres within the bounds beyond which they would intersect each other; how far, beyond this, rotation influence extends, of course, is matter for speculation, and to be considered in results, in observations.

J. BARWICK.

SULPHUR AS A BLEACHING AGENT.

[4265.]—I HAVE looked forward with special interest to Mr. Bottone's papers on the sulphur compounds, in the hope that he would attempt some explanation of the manner in which sulphur acts as a bleaching agent. Chlorine we know, acts in this manner, in the presence of water, by uniting with the hydrogen and liberating the oxygen—the true bleaching agent: this is intelligible enough. When Roscoe and others, however, go on to tell us that the action of sulphur is just the opposite of this, that sulphur dioxide bleaches by deoxidation, what are we to infer with regard to the nature of its action? What is the true bleaching agent in the case of the sulphur compounds, and how does it act? Does it, like oxygen, form insoluble compounds with the vegetable colouring matter present? In what sense, again, are the colours said to be merely masked? If Mr. Bottone will kindly come to our assistance in this matter, I—and, I doubt not, other readers—will feel greatly obliged to him.

A. E. S.

"JACK OF ALL TRADES."

[4266.]—FEW of your readers have not admired, and many have profited by, the varied and accurate knowledge displayed by this contributor, which he has always been so kindly ready to communicate; and the very least we can do, now he is suffering from illness and the effects of it, is not merely to desire but to do our best to promote his recovery. It is not possible to form a very accurate opinion of a case by description alone, but "Jack" has said enough to show that he imperatively needs complete mental rest, and especially relief from worry, and, very probably, at least a temporary change of residence; he certainly needs that if he be still living in the place where he contracted his ague, unless, indeed, it be one which is free from ague during a great part of the year, and even in that case a temporary change of residence would probably be very beneficial. It often happens that doctors, in ignorance of their patients' circumstances, advise that to be done which is impossible, and that may be the case now. Our good friend may have been so ready to give his knowledge for the help of others as to have neglected his own interests, or his severe illness may have caused such loss and expense as to place mental rest and freedom from anxiety, which are essential to his recovery, out of his reach, unless some of the many whom he has often and so kindly helped will now join together to help to save a life so valuable. As I am in absolute ignorance of the sufferer's circumstances, this suggestion of aid possibly needed may appear to be an impertinent intrusion; but if the case be as I suggest as possible, I trust it will not wound our friend's delicacy to receive help in the only form in which most of us can offer it, and that he will feel under no painful obligation towards us, who feel ourselves that we are simply discharging a just obligation, and acting towards another as we would wish others to act towards us under similar circumstances. If, Mr. Editor, you think such aid is needed, my guinea is ready; and if all who have benefited by "Jack's" advice will pay for it, he will be freed from all anxiety on that score. It will be only payment of just, though not legally enforcible, debts.

PHILO.

[Mr. J. W. Hayward, of Tonnage House, Carrow, Norwich, has also written a kindly-worded letter on the health of "Jack of All Trades," and suggests that he should, if possible, visit Smedley's Hydropathic Establishment, Matlock, for a short time. "If," says Mr. Hayward, "'Jack of All Trades' is poor, I should be happy to forward him £1 to help to pay his expenses, if he would accept it." We may inform our readers that our versatile friend "Jack" is a hardworking man with a large family, and from what we know of him we believe that he is as ready to help his neighbour as he is willing to give the best advice he can to those who ask it in our columns. No doubt such a change as that suggested by Mr. Hayward would re-establish his health. If three other correspondents would imitate the unsolicited example of "Philo" and Mr. Hayward, making in all £5, the Editor would cheerfully double the sum, and we hope "Jack" would not be too independent to accept the present.—ED.]

DRYING PLANTS FOR HERBARIUM.

[4267.]—IN my juvenile days, being a great rambler amongst the fields and along a sea-shore margin, I collected a large number of plants of various kinds, and dried them by means of warm sand and sheets of blotting-paper, changing and drying both sand and papers very frequently. My press was the sacking-bottomed and loose-cushioned old-fashioned sofa (not old fashioned in the days I allude to), so that every one who visited us, and accepted a seat on the said sofa, was so far a contributor, unwittingly, to my *Hortus Siccus*. I still possess most of those specimens, almost fifty years old, and when I look at them, I can say, with Montgomery, "Days of my childhood, hail!"

H. O'B.

MARSH MALLOW FOR HARDENING PLASTER OF PARIS.

[4268.]—THE following may prove useful to your correspondents, on which subject I contributed a short article to the *British Journal of Dental Science* for April. Having suffered much inconvenience from the porosity of plaster of Paris, and having tried alum (subsulphate of alumina), salt (chloride of sodium), &c., and finding no improvement, I remembered that I had somewhere read of marsh mallow (Malva: a genus of the Monadelphia polyandriæ) as a remedy for the above defect; I therefore procured 1oz. of the above, half of which I placed in a pint bottle, on which I poured boiling-hot water, using half the above solution and half water to mix the plaster to the required consistency, and have since had no trouble whatever, it being quite hard and non-porous.

E. GRAHAM YOUNG, S.D.

HOW TO OBTAIN DOUBLE FLOWERS FROM SEED.

[4269.]—MANY years ago I was very fond of flowers, and had the advantage of a fine garden. I was very successful in obtaining double flowering plants of the different species of stock gillyflower. The plan I adopted was frequent transplanting the first year, with good rotten compost, generally taken from an old hot-bed. As the plants began to prepare for flowering, I stripped them of all side shoots, and selecting such as from the appearance of the buds would be likely to produce semi-double flowers, I first staked and secured them with a string of bass, and then with a sharp penknife took off a strip of bark, ¼in. deep, three-

REVOLVING PUDDLING FURNACES.

[4253.]—"R. S." (let. 4172) has not succeeded in explaining away the facts already adduced in reference to Mr. Danks' claim to the invention of the revolving puddling furnace. Mr. Walker's experiments failed for the want of a proper chimney for his furnace—this was not his fault, but his misfortune; while even with the aid of a good chimney Mr. Danks' furnace is reported to be a "bad melter." As a manager of iron works and a practical mechanic, I consider Mr. Danks' furnace to be neither more nor less than a combination of the inventions of Messrs. Walker and Tooth; and, until Mr. Danks has otherwise proved his claims to this invention, "R. S." has no right to put forth his humble opinions as to the superiority of Mr. Danks' furnace. An invention lying in the pigeon-holes in the Patent Office is not lost, or a thing to be pirated with impunity; neither can a mere improver in an sense of the word be considered an original invent The Danks' furnace appears to me a second edition the American reaping-machine. In 1825, if I mist not the year, an English mechanic invented a reap machine; it was tested and did its work well. On first public trial the machine was smashed to p and the inventor pelted with stones by an en mob of farm labourers. This invention lay do until the Great Exhibition of 1851, when the re machine again appeared as a new inventior America, and, of course, patented. The tri exposed, and the patent, like the revolving furn to the ground.

"R. S.'s" laudations of the Iron and Steel are rather out of place. It cannot be adm that scientific body has acted fairly by rushi iron-melting-temperature zeal at Mr. Da before the original invention at home had cally tested. In the absence of this fair part of this institution the pleasant tri Atlantic, the convivial dinners and gushing votes of thanks from the lordly sized portrait of the noble President. that smack of egotism already descr proverb informs us that things dear fetched are greatly admired by fantas so, apparently, with the Iron and Ste the Iron and Steel Institute acted on justitia, ruat cœlum," justice would Messrs. Walker and Tooth, with Danks. G. S.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

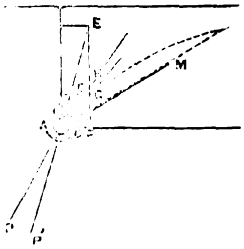
HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[10478.]—**Pork Diet.**—I am glad to find some one who thinks as I do, and congratulate the "Mother" on having had the courage to introduce the subject of "Pork Diet;" for it requires courage to again raise a question which has been discussed so often and so ably, and generally with the same result—which result is not satisfactory to non-pork-eating people. When in No. 356 there appeared a query on the same, I hoped it would have met with a more general response. "Philo" alone answered, and not to the point. It was disappointing, but what can one say to these older and wiser heads?—except, indeed, that "wisdom is not always with the mighty, nor understanding with the strong." Had "Philo" and the other gentleman worn out less carpet in lighting or not lighting electric sparks, we might have had some valuable reasoning from them. As it is, I hope that some earnest and capable mind will take the matter up, and so convince some others of the unfitness of the pig for food. Rabbits and shell-fish are equally rubbish. They are coarse, impure diet, and have a vile and lowering influence on the mind. It may be that much of the crime and misery among the lower orders originates from such a cause as this. I have frequently noted the effect of such food on those about me, causing irritability and peevishness in both young and middle aged, and if there be a "deaf grandmother" she will be more deaf because more crochetty. If such is the influence on refined and educated minds what can it be with the untaught but hurtful and debasing?—SARAH.

[10640.]—**A Reason Wanted.**—I beg to state, in reply to Mr. Taylor (p. 204) that it is in the act of breathing out that strength to lift weights is increased, and that I firmly believe breathing out air from the lungs is not the same thing as breathing in. I beg to add that, very often, I have found breathing out air from the lungs greatly help in ascending hills, giving a compactness and sense of lightness to the body, pleasant to experience, as well as helpful in the ascent. Breathing in reduces both the lifting and the ascending power. Such is the fact, and experience of—GERARD SMITH.

[10664.]—**Angle of Incidence and Reflection.**—I thank "Billiardist" for the illustrative case he has given on p. 204, and his explanation, so far as it goes, is correct, but still it does not account for the fact that both times the ball should take the same course after having struck. I am afraid I cannot explain it, but shall venture to hint at a probable reason. By the nature of the problem, the red ball having to return to its original position at the instant of striking the line joining their centres must be perpendicular to the end of the table, and if the balls were perfectly elastic, the result in all cases with any angle or velocity would be that the striking ball would proceed parallel to the end of the table; this is on the supposition that the balls are physical points. The elasticity not being perfect causes the ball coming from P to take the direction A D, $\frac{B\ D}{B\ C}$ being the co-efficient of elasticity, similarly a ball coming from P′ with a velocity A E should pass through a point G, $\frac{E\ G}{E\ F}$ being the same co-efficient of elasticity. But this co-efficient has been proved by experiment to be less with increased velocity; it should, therefore, pass in some such direction as A H, in place of which it appears it travels in direction A M. Now, I venture to suggest the following as a reason, but should be glad to have the opinion of more competent persons — viz., when the balls strike a whirling motion is imparted to them, the ball A rotating in direction represented by the arrow. The effect of this motion rubbing on the table must be to retard the motion of the ball on the one side more than the other, acting as a rudder, and causing it to describe a curve, such as indicated by the dotted line. Now, with a greater velocity, and at particular angles of striking, this rotary motion is increased, and, consequently, its deviating effect. I have no doubt some of your correspondents will be able to give a better explanation.—F. N.



[10731.]—**Fastening Escape-Wheel in Lever Watch.**—I have not the time nor the desire to enter into a war of words with "West Cornwall." I will tell him, in confidence, I do love soft solder, it is so very convenient. Last week I had a first-class lever watch to repair. It had three of the teeth and a part of the rim broken out of the fusee-wheel. There had been a fracture of the brass, done, I presume, when the metal was condensed, and unfortunately it was opposite the slit of the maintaining power spring. I recommended a new wheel, but the question was asked, "Can you not repair this one?" I said, Certainly I can. Now, dovetailing alone would not have done. Hard soldering would have softened the metal, therefore I made use of a dovetail and the convenient soft solder, and made a good job of it, which will stand as long as the watch will last. I will give "W. C." one of my practical wrinkles for soft soldering small jobs, which I have no doubt will be useful to many readers of the ENGLISH MECHANIC. Take a common German silver spoon, drill a small hole in the middle of bowl. Now take a spoonful of melted metal and run it along any cold surface, and you will make small solder wire, about the thickness of staff wire; run it into four or six-inch lengths. Cut a short piece of peg wood, make a hole in the end, press in the end of a length of solder-wire. Now take a piece of mainspring, press into the slit of a batswing gas-burner, close down to the bottom on one side and a little from the bottom of the other. Turn on the gas, and you have a small horizontal fine-pointed jet of flame. Now place the peg wood end of solder in your mouth as you would a blow-pipe; put a drop of spirit on to your work. You have both hands at liberty: bring the two pieces together you wish to solder, and let the tip of flame impinge upon it. By this method any amount of work can be done in a quick and neat manner. I use it for all kinds of common jewellery work. "W. C." says I entirely omitted Geneva watches. Why import them into the controversy? "S. H. L." asked to know how to collet an English escape-wheel. It could not be a Geneva, as the Swiss workmen do not employ collets, but seat their wheels on the pinions.—A YORKSHIRE PIVOT.

[11108.] — **Tilt Hammer.**—As Mr. Fennell still persists that his drawing of a tilt hammer is correct, I must again warn the readers of the ENGLISH MECHANIC that it is an ingenious impossibility, would cost five times the price of a proper hammer, and not do the duty expected. I have not time now to go more into detail or send a sketch, but will do so if wished.—A BARRISTER.

[11120.]—**A Question of Sight.**—To "E. L. G." —By "air under special mechanical pressure," I mean air subjected to pressure beyond that of the open air superincumbent and around it. As "E. L. G." will not accept my feeble illustration of a single needle reaching from the sun, let him suppose the cosmic fluid to be a dense solid (of course he drives me to suppose the "impossible") from the sun to the earth; then, if without a vacuum between any of its atoms, it would strike the earth when it itself was struck at the sun, how can he state such to be longer than light, which travels at less than 200,000 miles per second, whilst the sun is distant more than 95,000,000 miles. I think I never could be so abstracted as to put down 17,000 feet as the speed of light, though I may have let feet slip in for miles. I regret it, and will try to mend.—J. BARWICK.

[11275.]—**Darkening Walnut (U.Q.).**—Boil the husks or skins of walnuts when they are black and rotten to a jelly and use hot or cold. Will keep any length of time, and does not spoil the look of the grain. —F. J. G.

[11333.]—**Motive Power for Amateurs.**—I am sorry that "Zoo Andra" should be annoyed by my classing his plan with those fancies—plausible in themselves—which are the bane of young and enthusiastic mechanics. He will find the pendulum idea one of those proposals to gain or multiply power which are only varieties of the perpetual motion scheme. If "Zoo Andra" will refer to page 206 he will find the plan recommended there is for a single-handed saw—*i.e.*, one to enable a man to do the largest amount of work without assistance, and of course worked by a treadle. I have had some experience with circular saws from 4ft. diameter to 3in., and although I grant speed is advisable, it is of no use without sufficient power, and the plan proposed by me will allow much harder work to be done than can be managed by a saw fitted to a lathe in the usual manner. A circular saw will cut very well at a slow pace if sufficient power be applied to keep it going, and will, in many cases, cut more at a moderate than a high speed; the reason of this is that the teeth are frequently too close, and do not take proper hold of the wood. The teeth of all saws require to be enlarged as the speed with which they are driven is increased.—A BARRISTER.

[11386.]—**Crystals in Gas Tar.**—(To MR. BOTTONE.)—I have always taken the term artificial alizarine to mean the substance prepared from anthraquinone, as distinguished from the natural substance extracted from madder, and the term is certainly generally used in this sense: *vide* any of the scientific periodicals for the last two years. I am acquainted with the substance termed naphthazarine by Schützenberger, but I never heard of the term artificial alizarine being applied to this body, which, probably, has the same relation to naphthaline that alizarine has to anthracene.—ETHYL.

[11452.]—**Rain-water Tanks (U. Q.).**—"Rosso" had better construct his tank of galvanised iron, which is far preferable to bricks and mortar. I have a large tank made of it, and it has answered efficiently. The cover can be made on a hinge, or one with handle to lift right off. If "Rosso" requires the water clean for any special purpose, he had better have the tank in an fourths round the stalk, taking particular care to leave one-fourth of the circle of bark intact. The seed from the plants so treated produced nearly all double flowers. The principle on which I acted was, that the blood or sap of a plant ascends through the centre or pith, which may be called the artery; and again descends between the stem and bark, corresponding to the veins of a living animal. The partial stoppage of the descending current was to give the plant a sort of apoplexy. By this means the finest double anemones can be produced, and plants beautifully striped can be obtained by crossing. Thus select (say) a crimson for the male plant, to be crossed with a white (the female). As soon as you can carefully open the petals of the white flower, extract all the stamens with a small pincers, and immediately cover both flowers with a fine muslin bag. Examine frequently with a hand microscope the stamens of the red, and when they appear ripe, extract them carefully one at a time, and removing the bag from the white flower, gently rub the pollen dust over the pistils. Then cover the impregnated flower again with the bag for a few days until all danger of extra impregnation from insects is over.

From an old gardener who was celebrated for his stock gillyflowers I obtained the following information: His plan was to save seed from the semi-double plants only, and to carefully wrap up the seed in brown paper, not to be again opened for five years. He showed me his collection of seeds, and gave me some of white and crimson from packages, which he declared had been saved five years. I sowed those seeds, and the next year found nearly all the plants produced double flowers. E. J. D.

MICROSCOPE.

[4270.]—As the microscope trade is stocked with a class of instruments which are constructed merely to hold together while being sold, a few words on the subject may assist others besides "A Canadian Subscriber" in making a judicious bargain. First, then, where to purchase. If the buyer is disposed to contribute to the support of an expensive front shop he will find every facility for doing so, but let it be understood that he thus allows the shopkeeper a ruinous percentage for the mere trouble of selling. The majority of this class are mere salesmen, and their whole knowledge of microscopy might, as a rule, be condensed into the text, "Here are the instruments and I want to sell them." In support of this statement I quote Mr. J. F. Heather, who, speaking of microscopes in his well-known book, says that "many so-called opticians are mere sellers of articles, of the qualities of which they are totally ignorant." And I would add that an instrument bearing an eminent name often emanates from the hand of poor Bill somebody, who lives, works, and appears very likely to die, in some garret or kitchen.

In the mechanical part nothing is of greater importance than the focussing rack motion; and, therefore, it should be seen that it has a good, even, and parallel fitting, without the least "shake," false motion, or nasty grating, produced by the pinion being set too deeply into the teeth. Put an object under a ½in. power on the instrument and watch it (the object) as it gradually comes into focus; if it is seen to move about in the field the rack is imperfect, and should be rejected. Next, try the fine adjustment with a higher power, and the same rule applies to both. Notice that the "core" through which the rack bar slides is fitted by a separate plate, as many are made to fit by a gentle use of the hammer round the top. The pinion bearings are often packed up with leather, &c., which, on wearing away, leave the instrument as innocent of anything like "cobbling" as it is incapable of proper adjustment. If the object is in focus at one side and indistinct at another, the probable cause is that the stage is not at right angles with the optical axis of the instrument, though the object may be imperfectly mounted, so, to make certain, turn it upside down or try another, using a high power for this. Take out the objective and eyepiece, and looking straight down the tube turn the diaphragm round and see that the apertures are pretty central, as they appear successively in the field. See that the motions for mirror, &c., are reasonably tight, and that the whole is steady, proportionate, and well-fitted.

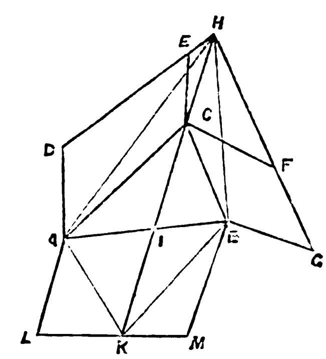
A set of French achromatics containing three powers (that is, in all, three pairs of lenses) will do excellently for all general purposes of interest, but in the deeper studies there are many things which cannot be properly seen without the use of first-class objectives, which are very expensive. Good test objects are the Navicula sigma, a minute shell found in fresh pools, which should appear completely covered with a number of longitudinal and tranverse lines, and the Podura flambea, or skip-tail, a small wingless cellar insect the size of a flea, which should appear covered with a number of delicate marks like notes of admiration. In choosing a binocular look first into the straight tube, and notice the exact position of the object in the field, and in what parts it touches the edge; then see the image in the side tube, and it should exactly correspond; should it not touch the edge at the same part the error may owe its cause to one aperture being larger than the other, so put the right side eyepiece into the left body, and *vice versâ*, when, if this fault is still apparent, the prism must be set wrong or the body at a wrong angle. The arrangement for raising or lowering the draw tubes should move smoothly, and both eyepieces at the same time, as, if one is higher than the other, that image will be the most magnified and an indistinctness will be the consequence; place both eyes over the instrument and adjust the tubes to their proper height by shutting the right eye and looking down the left tube, and then shutting the left eye and looking down the right tube, so that both images are seen at the same time; they should then appear stereoscopical and sharply defined, free from darkness and prismatic or other glare caused by the entrance of light between the bodies, the right one often being unavoidably lighter than the left, but there are many who fail to see the binocular effect. Now, if I have not exhausted the subject, I nevertheless must have exhausted the patience of those who read this letter, so conclude by informing "Canada" that the price varies from £4 to £400, but a very serviceable instrument may be had for about 14 guineas, with three powers, mechanical stage, condensor, frog-plate, polariscope, parabola, live box, neutral tint reflector (or camera lucida), forceps, and all accessories, but in one of the best kind double that amount may easily be given for the lenses alone. C. G. P.

NEW (?) PROOF OF PYTHAGORAS' THEORY.

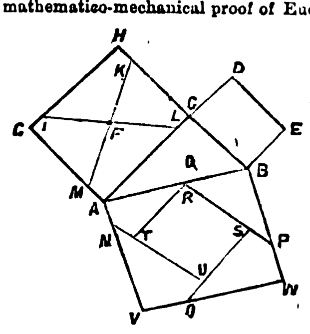
[4271.]—In your number of 10th inst., p. 203, Mr. Recordon has exhibited an old arrangement. I refer him to "Un Million de Faits" for a generalisation proved by Clairaut's brother (query, dating from the ancient Greeks)—viz., thus:—"On any $\triangle ABC$ erect any lateral parallelograms, ACDE, BCFG. Let DE, GF produced, meet in H. Join HC, produce it to cut AB in I, and extend to K, IK = CH. Draw AL, BM, parallel and equal to IK, join LM. Then shall AK = AE, BK = BF, and parallel AM = parallel AK + parallel BF." For, join AH, AK, BH, BK. Then $\triangle ACH$ is half AE (same base and same parallels); $\triangle ACH = \triangle AIK$, equal bases on same line HK, and same vertex; $\triangle AIK$ is half AK (same base and same parallels), whence LI = CD; similarly MI = CG. *Q. E. D.*

Very Special Case.—DAC = right angle = CBG, also DA = AC, GB = BC, AM = square. (Euclid 47, I.)

Is it possible that this diagram will illustrate the composition of oblique velocities, forces, moments, &c., as Euclid 47, I., does that of rectangular ones?



My friend Mr. Perigal many years ago gave a mathematico-mechanical proof of Euclid 47, I., as follows:—On right angle $\triangle ACB$ describe lateral squares AH, BD, AW. Bisect each side, AB in Q, P, O, N; draw QT, OS parallel to AC, and NU, PQ parallel to BC intercepted at R, S, T, U respectively. Through centre F of AC square, draw IL parallel to AB, and KM perpendicular to AB or IL. Then shall the eight four-sided figures IFKH, KFLC, LFAM, MFIQ, ANTQ, QRPB, PSOW, OUNV, be all equal and similar to each other; and RSTU is a square = CBED. Then AH may be cut up and its pieces placed round BD, so as to produce AW—proving it to the layman as well as the student of mathematics that $AB^2 = Ac^2 + Bc^2$.



S. M. DRACH.

RECURRENT VISION, &c.

[4272.]—The following fact may help to elucidate the "recurrent vision" of Professor Young (see p. 190): The image impressed on the retina, after looking at a contrast of colour, is reproduced alternately by each eye, and is not a continuous impression, as it ordinarily appears to be when the eyes are equal. This may be proved by any one who can combine the two views of a stereograph without a stereoscope (by directing the axes of the eyes parallel as in looking at a distant object, and yet focussing the eyes as for a near object). Thus, stick two discs of black paper (about half an inch diameter) on a sheet of white paper, the distance between them being equal to the distance between the eyes; then, holding the paper about a foot from the eyes, so that a line between the discs would be exactly parallel to a line between the eyes, combine the discs as a stereograph, so that the right eye looks at the right disc, and sees the left disc rather indistinctly, and the left eye sees *vice versâ*. After gazing at them thus in a strong light (keeping the eyes steadily fixed on the centres of the discs) for about half a minute, shut the eyes quickly and wait (sometimes for a few seconds) until the images appear, meanwhile shading the eyelids and gently pressing them if the images do not appear easily, or if they cease for a few seconds (a good impression, with pressure or rubbing, lasts off and on for about a minute), and if the trial be successful, there will appear a central strong disc image, formed by the right image of the right eye and the left image of the left eye overlapping, the second images of each eye alternately appearing one on each side, one becoming visible when the other disappears. Each of these transient images lasts about two or three seconds, sometimes five or six alternations being perceptible, as the images of each eye strengthen and diminish.

Now, whether Professor Young's recurrent vision results from a shorter period of recurrence of rather a different character, affecting both eyes simultaneously, or whether one of his eyes reproduces images far more vividly than the other, is uncertain, but the above phenomenon may throw some light on it.

While on visionary subjects, I may as well mention a remedy for the dazzles, with which many of your readers may be troubled, as was the late Sir John Herschel; by the dazzles I mean a quivering appearance of a dark and light, or coloured shade or impression of lines moving angularly or serpentinely, which commences at the extreme limits of vision, and gradually encroaches towards the objects of view, until in about five minutes the whole vision is affected, so that it is impossible to see anything distinctly, though the forms and positions of objects appear quite unaffected by it. A fraction of a grain of sulphate of quinine will remove this appearance in about ten minutes, though otherwise it will continue for some hours. This is the homœopathic consequence of the fact which was first perceived—namely, the production of the dazzles by a small quantity of sulphate of quinine, which is an effect any of your readers who are curious on the matter could doubtless produce, if not already drugged with large doses of that medicine.

W. M. FLINDERS PETRIE.

COMMUNICATING ROTARY MOTION TO BALL FIRED FROM SMOOTH-BORED GUN.

[4273.]—"PHILUS WARD" (letter 4159, p. 227) may perhaps not have heard of the Mackay gun, which was tried some few years ago near Liverpool, against a target of the "Agincourt" pattern, if I remember rightly. Mr. Mackay used a rifled gun, from which he fired cylindro-conoidal shot, without studs or any other contrivance to take the rifling. The shot was rotated by the gas escaping alongside the shot, through the grooves; hence it was called the "Windage gun." I remember seeing the target shortly after the experiments, and the shot seemed to have done good work upon it. The system soon afterwards sank into oblivion, for what reason I can hardly say, but there must have been something wrong somewhere.

ARTILLERY CAPTAIN.

CONCRETE MULTIPLICATION.

[4274.]—I HAVE no desire to be hypercritical, and only again object to "Sigma's" further explanation of "concrete multiplication" (let. 4188, p. 223), because I believe that, being erroneous, it may tend to produce confusion of ideas in others. It is worth while on some occasions to dispute about words; for nothing has occasioned greater conflicts of opinion than misunderstanding the terms involved in the subject in dispute. Now, what is the meaning of multiplication? It has either the simple arithmetical sense of repetition a certain number of times (integral or fractional), or it has a more general algebraical meaning.

In the first case, it refers to the arithmetical operation upon another number, abstract or concrete, in which case anything foreign to the idea of number cannot become introduced, and so there can arise no idea of squareness or solidity. In the second, results of a very general character may ensue, but in neither case is it a valid reason against the possibility of any operation that it has no meaning. We may, for instance, in algebraical operations arrive at the result $\sqrt{-a}$. This is an impossible, and itself an unintelligible, quantity, but it does not disprove the correction of the operation of which it is the result. Another explanation, then, must be given of the result of the so-called "multiplication of concrete" quantities, and I believe the correct one to be that which I have already given, that the unit is supposed to be changed before the multiplication takes place. If pounds cannot be multiplied by pounds there is no reason, either *à priori* or *posteriori*, why feet can be multiplied by feet. To say that "concrete multiplication" is an arithmetical dodge is quite beside the subject: what is so called is a straightforward and simple proceeding when rightly explained. Nor can I allow "the true explanation" to be that "concrete numbers are only susceptible of addition and subtraction." This can only mean, I think, that though we cannot multiply a pound by a pound, yet we may increase a pound by a pound, as if the pound were the arithmetical operation, and not the increase or addition of it. I need not pursue this question further, but I can discern no other reason for "Sigma's" assertion than this supposition. The fact is, that concrete, as well as abstract, quantities are susceptible of multiplication and division as well as of addition and subtraction. We do not in any case perform the operation by means of the concrete quantity, but with respect to it.

Lastly, I can see nothing impossible in "Sigma's" last example, which, I suppose, is intended for a "reductio ad absurdum." I should say "you" can "add a pint of water to a pound of flour, and produce paste, which a number compounded of these" (numbers, I presume, for to compound numbers, of water or flour, or even paste, would be "concrete multiplication" with a vengeance) "will represent." Now, 2 is a number compounded of two numbers, one and one, and I think we should not be far from the mark in saying that there would be 2 pounds, or 2 pints, of paste. If greater exactness is required—*fiat experimentum!*—let the unit be determined by experiments.

M. A.

A GIANT PLANET.

[4275.]—The article which appears in the *Cornhill Magazine* for this month (May) under the above title, and given, with the exception of a few preparatory sentences in No. 374, pp. 244 and 245 of "ours," bears evident marks of coming from the pen of Mr. Proctor, as surmised by the *Spectator* in the leading article of May 4, as stated in your foot-note, and if so, it will be a suitable appendix to his "Essays on Astronomy," lately published, a compilation of most of his previous papers in different serials, and, in its present connected form, well worthy the study of all students in astronomy.

As Mr. Proctor is always so accurate in his quotations of observations on which he bases his theories, I feel diffident in pointing out an apparent omission in the article. Where the satellites are regarded as photometers of Jupiter's luminosity, the writer quotes Mr. Lassell's observation of Dec. 30 last, of the fourth satellite in "dark transit," and also Padre Secchi's observation of Feb. 3 of the third satellite in "dark transit," and states "that the comparative darkness of all four satellites will have been established;" he omits, however, to give the instances of the first and second satellites in "dark transit," as the remark of Padre Secchi in his narrative that "this fact is not a new one for the other satellites," appears to apply to the immediate context as to the behaviour of the satellites close to the edge and not to their transit as dark spots across the remainder of disc. I was favoured, through much smaller optical means (a 4·28-in. refractor by Wray), to witness three "dark transits" during the late opposition of Jupiter—viz., the fourth satellite on Dec. 30 and Feb. 18, and the third satellite on March 24 last; in the latter case, the satellite not being on the disc at the same time as its shadow (as in Padre Secchi's observation of Feb. 3, I had not the means of judging so accurately the comparative darkness of satellite, but it appeared to be almost as black as its shadow, which came on afterwards. I would again call attention to the peculiarity I pointed out (No. 363 p. 608) in the observation of the transit of satellite 4 on 18th February last, the satellite showing itself as a dark spot nearer to the western edge than it did to the eastern edge of Jupiter after passing on at the commencement of transit.

There is no more interesting study with instruments of sufficient excellence than the observation of the changes in the tints of the equatorial zone of belts with the ever-varying changes of their form, and the great number of minute cloud-like markings sometimes seen, and which probably give to Jupiter the mottled appearance observed under less favourable conditions. By the way, Mr. Buckingham's fine 21-in. refractor is mentioned in the article as showing these minute clouds, and as I have seen that instrument noticed several times in newspapers without stating the maker's name, I think it is not generally known that, though the owner constructed the equatorial mountings and fittings, the credit of the optical part (the most essential), is due to Mr. Wray. As many of "our" astronomical readers may not have seen the quaint account of an observation of Jupiter given in the first number of the *Philosophical Transactions*, published in London on "Munday, March 6, 1664 5," I now append an extract from the original:—"The ingenious Mr. Hook did, some months since, intimate to a friend of his that he had, with an excellent twelve foot telescope, observed some days before he then spoke of it (viz., on the 9th day of May, 1664, about nine of the clock at night), a small spot in the biggest of the three obscurer belts of Jupiter, and that, within two hours after, the said spots had moved from east to west about half the length of the diameter of Jupiter."

LINBA.

Extract of Meat.—Professor Artus, of Jena, recommends a new method of making extract of meat which possesses the advantage over that of Liebig in retaining the albumen, gelatine, and fat, which are all removed by Liebig's process, and which would seem, from recent experiments, to be the only really nutritious elements of the meat. For this purpose, by a very simple apparatus, an extract of the meat is made first with cold water; this dissolves out the soluble salts, the albumen, and part of the gelatine and creatine. The meat, after extraction in this way with cold water, is then boiled for an hour in a Papin's digester, and the liquid pressed out. The fat is skimmed off the surface, and this extract is mixed with the cold extract. The mixed extracts are then evaporated down to a proper consistence in a sand-bath, or better, in a vacuum-apparatus. This certainly, says the *British Medical Journal*, seems a much better way of preparing an extract of meat than any of the methods which necessitate the throwing away of the most valuable constituents.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

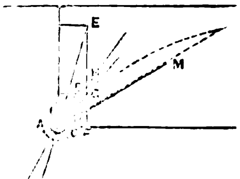
HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[10178.]—**Pork Diet.**—I am glad to find some one who thinks as I do, and congratulate the "Mother" on having had the courage to introduce the subject of "Pork Diet;" for it requires courage to again raise a question which has been discussed so often and so ably, and generally with the same result—which result is not satisfactory to non-pork-eating people. When in No. 356 there appeared a query on the same, I hoped it would have met with a more general response. "Philo" alone answered, and not to the point. It was disappointing, but what can one say to these older and wiser heads?—except, indeed, that "wisdom is not always with the mighty, nor understanding with the strong." Had "Philo" and the other gentleman worn out less carpet in lighting or not lighting electric sparks, we might have had some valuable reasoning from them. As it is, I hope that some earnest and capable mind will take the matter up, and so convince some others of the unfitness of the pig for food. Rabbits and shell-fish are equally rubbish. They are coarse, impure diet, and have a vile and lowering influence on the mind. It may be that much of the crime and misery among the lower orders originates from such a cause as this. I have frequently noted the effect of such food on those about me, causing irritability and peevishness in both young and middle aged, and if there be a "deaf grandmother" she will be more deaf because more crochetty. If such is the influence on refined and educated minds what can it be with the untaught but hurtful and debasing?—SARAH.

[10640.]—**A Reason Wanted.**—I beg to state, in reply to Mr. Taylor (p. 204) that it is in the act of breathing out that strength to lift weights is increased, and that I firmly believe breathing out air from the lungs is not the same thing as breathing in. I beg to add that, very often, I have found breathing out air from the lungs greatly help in ascending hills, giving a compactness and sense of lightness to the body, pleasant to experience, as well as helpful in the ascent. Breathing in reduces both the lifting and the ascending power. Such is the fact, and experience of—GERARD SMITH.

[10664.]—**Angle of Incidence and Reflection.**—I thank "Billiardist" for the illustrative case he has given on p. 204, and his explanation, so far as it goes, is correct, but still it does not account for the fact that both times the ball should take the same course after having struck. I am afraid I cannot explain it, but shall venture to hint at a probable reason. By the nature of the problem, the red ball having to return to its original position at the instant of striking the line joining their centres must be perpendicular to the end of the table, and if the balls were perfectly elastic, the result in all cases with any angle or velocity would be that the striking ball would proceed parallel to the end of the table; this is on the supposition that the balls are physical points. The elasticity not being perfect causes the ball coming from P to take the direction A D, $\frac{B\,D}{B\,C}$ being the co-efficient of elasticity, similarly a ball coming from P′ with a velocity A E should pass through a point G, $\frac{E\,G}{E\,F}$ being the same co-efficient of elasticity. But this co-efficient has been proved by experiment to be less with increased velocity; it should, therefore, pass in some such direction as A H, in place of which it appears it travels in direction A M. Now, I venture to suggest the following as a reason, but should be glad to have the opinion of more competent persons — viz., when the balls strike a whirling motion is imparted to them, the ball A rotating in direction represented by the arrow.



The effect of this motion rubbing on the table must be to retard the motion of the ball on the one side more than the other, acting as a rudder, and causing it to describe a curve, such as indicated by the dotted line. Now, with a greater velocity, and at particular angles of striking, this rotary motion is increased, and, consequently, its deviating effect. I have no doubt some of your correspondents will be able to give a better explanation.—F. N.

[10731.]—**Fastening Escape-Wheel in Lever Watch.**—I have not the time nor the desire to enter into a war of words with "West Cornwall." I will tell him, in confidence, I do love soft solder, it is so very convenient. Last week I had a first-class lever watch to repair. It had three of the teeth and a part of the rim broken out of the fusee-wheel. There had been a fracture of the brass, done, I presume, when the metal was condensed, and unfortunately it was opposite the slit of the maintaining power spring. I recommended a new wheel, but the question was asked, "Can you not repair this one?" I said, Certainly I can. Now, dovetailing alone would not have done. Hard soldering would have softened the metal, therefore I made use of a dovetail and the convenient soft solder, and made a good job of it, which will stand as long as the watch will last. I will give "W. C." one of my practical wrinkles for soft soldering small jobs, which I have no doubt will be useful to many readers of the ENGLISH MECHANIC. Take a common German silver spoon, drill a small hole in the middle of bowl. Now take a spoonful of melted metal and run it along any cold surface, and you will make small solder wire, about the thickness of staff wire; run it into four or six-inch lengths. Cut a short piece of peg wood, make a hole in the end, press in the end of a length of solder-wire. Now take a piece of mainspring, press into the slit of a batswing gas-burner, close down to the bottom on one side and a little from the bottom of the other. Turn on the gas, and you have a small horizontal fine-pointed jet of flame. Now place the peg wood end of solder in your mouth as you would a blow-pipe; put a drop of spirit on to your work. You have both hands at liberty: bring the two pieces together you wish to solder, and let the tip of flame impinge upon it. By this method any amount of work can be done in a quick and neat manner. I use it for all kinds of common jewellery work. "W. C." says I entirely omitted Geneva watches. Why import them into the controversy? "S. H. L." asked to know how to collet an English escape-wheel. It could not be a Geneva, as the Swiss workmen do not employ collets, but seat their wheels on the pinions.—A YORKSHIRE PIVOT.

[11108.] — **Tilt Hammer.**—As Mr. Fennell still persists that his drawing of a tilt hammer is correct, I must again warn the readers of the ENGLISH MECHANIC that it is an ingenious impossibility, would cost five times the price of a proper hammer, and not do the duty expected. I have not time now to go more into detail or send a sketch, but will do so if wished.—A BARRISTER.

[11120.]—**A Question of Sight.**—To "E. L. G." —By "air under special mechanical pressure," I mean air subjected to pressure beyond that of the open air superincumbent and around it. As "E. L. G." will not accept my feeble illustration of a single needle reaching from the sun, let him suppose the cosmic fluid to be a dense solid (of course he drives me to suppose the "impossible") from the sun to the earth; then, if without a vacuum between any of its atoms, it would strike the earth when it itself was struck at the sun, how can he state such to be longer than light, which travels at less than 200,000 miles per second, whilst the sun is distant more than 95,000,000 miles. I think I never could be so abstracted as to put down 17,000 feet as the speed of light, though I may have let feet slip in for miles. I regret it, and will try to mend.—J. BARWICK.

[11275.]—**Darkening Walnut (U.Q.).**—Boil the husks or skins of walnuts when they are black and rotten to a jelly and use hot or cold. Will keep any length of time, and does not spoil the look of the grain. —F. J. G.

[11333.]—**Motive Power for Amateurs.**—I am sorry that "Zoo Andra" should be annoyed by my classing his plan with those fancies—plausible in themselves—which are the bane of young and enthusiastic mechanics. He will find the pendulum idea one of those proposals to gain or multiply power which are only varieties of the perpetual motion scheme. If "Zoo Andra" will refer to page 206 he will find the plan recommended there is for a single-handed saw—*i.e.*, one to enable a man to do the largest amount of work without assistance, and of course worked by a treadle. I have had some experience with circular saws from 4ft. diameter to 3in., and although I grant speed is advisable, it is of no use without sufficient power, and the plan proposed by me will allow much harder work to be done than can be managed by a saw fitted to a lathe in the usual manner. A circular saw will cut very well at a slow pace if sufficient power be applied to keep it going, and will, in many cases, cut more at a moderate than a high speed; the reason of this is that the teeth are frequently too close, and do not take proper hold of the wood. The teeth of all saws require to be enlarged as the speed with which they are driven is increased.—A BARRISTER.

[11386.]—**Crystals in Gas Tar.**—(To MR. BOTTONE.)—I have always taken the term artificial alizarine to mean the substance prepared from anthraquinone, as distinguished from the natural substance extracted from madder, and the term is certainly generally used in this sense: *vide* any of the scientific periodicals for the last two years. I am acquainted with the substance termed naphthazarine by Schützenberger, but I never heard of the term artificial alizarine being applied to this body, which, probably, has the same relation to naphthaline that alizarine has to anthracene.—ETHYL.

[11452.]—**Rain-water Tanks (U. Q.).**—"Rosso" had better construct his tank of galvanised iron, which is far preferable to bricks and mortar. I have a large tank made of it, and it has answered efficiently. The cover can be made on a hinge, or one with handle to lift right off. If "Rosso" requires the water clean for any special purpose, he had better have the tank in an open place; to catch water from roof, have it made lip level with shoot. The water can be drawn off with a tap or bucket; I have a tap for mine, which avoids the necessity of getting to the top with a bucket. I know of no method to clean out, except drawing all the water off. Perhaps some correspondent of "ours" can give a plan for the edification of "Rosso," myself, and other subscribers.—H. B. E.

[11572.]—**Compressing Water.**—To the question asked by Mr. Westwood—viz., how it is when the pressure is pumped up and allowed to remain on for a quarter of an hour that the indicator never alters—I offer the following suggestions :—Mr. Westwood answers his own question thus : "That proves to me that the water is compressed." Now, I think, it is a proof that the water is not compressed, but is driven out of the cylinder, either through the joints or into or through the pores of the steel. It would require an enormous pressure, no doubt, to drive water into the ring of steel forming the sides of the cylinder, 8in. thick, but there seems to be a very great pressure in use. Deduct the weeping acknowledged from one gallon (277 cubic inches), and suppose the remainder driven into the pores of the cylinder sides—into, that is, something like 60,000 cubic inches of steel, or (say) one cubic inch of water into 200 cubic inches of metal, and the gallon of water is disposed of. I am supposing the conditions first stated to be perfectly accurate, viz., that the head and foot of the ram are perfectly immovable at the moment when the extra gallon of water begins to enter the cylinder. Otherwise there is nothing in the question, because it only requires a motion of less than ½in. in the ram to dispose of the whole gallon of water. To the extent to which water is compressible it probably is so because of the air it contains, and in that case would probably be equally as elastic as compressible; and, if so, the pressure indicator would necessarily rise, while the fact is stated to be that the indicator remains stationary. For this reason, I think, some other means of disposing of the extra gallon of water than by compressing the cylinder full to the extent of about a 220th part of its bulk must be sought. Water is supposed to be slightly compressible, but nothing like to this extent. A few trials with this machine, and very accurate records of the proceedings and result, would be of general interest.—C. S.

[11572.]—**Compressing Water.**—One million parts of water are reduced by 51 parts for each atmosphere of pressure—about 15lb. on the square inch. This is Colladon and Sturm's results, which Regnault, however, considers a trifle too high. Thus, suppose the hydraulic press to hold one million half-pints when the ram is driven up so as to just touch the head-block, we know that it is possible to pump in more water, and this amount will be in round numbers 50 half-pints for each "15lb. per square inch" of additional pressure. Regnault calculates the diminution in the bulk of water under the pressure of each additional atmosphere to be forty-seven millionths. The compressibility of water is greater at low than at high temperatures.—SAUL RYMEA.

[11589.]—**Dry Steam.**—According to Henri St. Claire Deville, steam gets dissociated into its elements at the temperature of 250° Centigrade, and not until it has reached that degree of heat. Now, it is not likely that, this being the case, steam has been split into its elements; but, being superheated, its molecules occupy a larger area, and being most tenuous, give up more readily their oxygen in presence of red charcoal, and, consequently, the hydrogen thus liberated burns also. That this is the probable influence of superheated steam may be concluded from a series of experiments made by Prof. Frankland, if I am not mistaken, and which prove that a candle, on burning at the top of a mountain, gives less smoke than at the bottom of a mine, although (and especially because) the air is more tenuous at the top of a mountain than in a plain and at the bottom of a mine.—F. T.

[11615.]—**Teeth.**—Tincture of iron will not cause the teeth to become loose. I should not recommend your correspondent to use alum (subsulphate of alumina and potash), as it contains sulphuric acid, which has a very injurious action on the teeth. There are many lotions recommended for restoring the attachment of the periosteum, but they are not to be much relied on. Have you been, or are you, suffering from salivary calculus? If so, that would account for the looseness of your teeth, as this is constantly gravitating from the salts of which the saliva is composed, and collecting about the necks (cervix) of the teeth, when it causes inflammation, and consequent recision of the gum. The only efficient remedy for this is to undergo the operation of having your teeth scaled, and then using astringent lotions, such as tincture of myrrh, or the following preparation :—Mastic (in powder) 2dr.; balsam of Peru, ½dr.; gum, 2drs. or grs.; orange flower water, 6 fl.oz.; tincture of myrrh, 2 fl.dr.—F. GRAHAM YOUNG, S.D., Bristol.

[11632.]—**Debility.**—Any one who discovers, or has discovered, "two *most noble* medicines" which effect the cure of all disease, and refuses to make them known, must not complain if he is looked upon as a quack. I do not say that he is not entitled to reap a pecuniary reward for his discovery, but there is a difference between inventing a new method of making steel and discovering a means of curing the diseases which afflict mankind. SAUL RYMEA.

[11687.]—**Speeding Machinery.**—Suppose that a pulley of 18in. in circumference is on the driving shaft. If we require (say) three revolutions of the driven shaft, its pulley should be $\frac{18}{3}$ = 6in. in circumference. If great accuracy was required, the thickness of the belt might require consideration, as a pound of water raised 1° Fahr., represents, theoretically, 772 foot-pounds.—PHILANTHROPIST.

[11697.] — **American Lathe Chuck.** — The Warwick or scroll chuck is extremely useful, also the twist drills, as they will cut rapidly to any depth in solid metal. As sold, however, they are ground with too much cut, which causes them sometimes to run in and stop, especially just as they are through the work. I should not now like to be without a set, as when properly ground they are by far the best drills I ever came across.—ROOK.

[11711.]—**Time at our Antipodes.**—This is a most interesting question, and is not yet disposed of, notwithstanding all that has appeared on the subject in your very valuable journal, so that I for one rejoice that you have allowed the discussion to be continued a little longer. Many communications addressed to you have not helped us a bit to solve the problem, but have rather tended to "darken counsel by words without knowledge." Amongst the latest of these I am sorry to have to reckon Mr. Birt's diagrams and explanation, which I have made three attempts to understand without success. One of the best letters is the one preceding this, by "T. S." If some of our "masters in Israel," to whom we look for help, will kindly answer the letter of "T. S." in as lucid a manner as it is written in, your readers will be greatly indebted to them. I have pondered this matter for years, and hail with joy the discussion of it. Will any of our savants kindly answer me this question? One of the Feejee Islands (Vuna) is exactly on the meridian opposite that of Greenwich, or 180°. On this island there are English missionaries. As I write it is exactly 12 o'clock by Greenwich mean time at midnight between Friday the 17th and Saturday the 18th of May. Consequently, at Vuna it is exactly 12 o'clock at noon. Is it with those Englishmen 12 o'clock at noon on Friday the 17th or Saturday the 18th? Which do they call it?—KELBY.

[11711.]—**Time at Our Antipodes.**—I have every reason to speak with respect of Mr. Birt, but this will not prevent me saying that he is evidently lost in a fog on this subject. In his letter which appears in this week's (May 24th) ENGLISH MECHANIC, he positively says that "T. S." is wrong in assuming that a message telegraphed from London at noon on Tuesday, May 7, would reach New Orleans at 6 a.m. on the same day, but that it will not reach that place till 6 o'clock on Wednesday, eighteen hours after its despatch. That is to say, that when it is 12 at noon at London on Tuesday, May 7, it is 6 a.m. Wednesday, May 8. Now, every tyro knows that the sun (in appearance and in effect) moves round the earth from east to west, passing over 15° in one hour. New York is about 75° to the west of London; therefore the sun reaches London five hours before it reaches New York; so that when it is twelve at noon in London it is 7 a.m. of the same day in New York. We verify this calculation every morning by reading the telegraphic messages from New York which are found on our breakfast tables. New Orleans is 15° west of New York. and, therefore, when it is 7 a.m. at New York, it is 6 a.m. at New Orleans. We are sure about the time of New York from the scores of messages which are flashed from New York to London, and from London to New York every day. Now, if Mr. Birt's theory be correct, when it is 7 o'clock a.m. of Tuesday, May 7, at New York, it is 6 a.m. of Wednesday, May 8, at New Orleans, which is a *reductio ad absurdum*. Further, if Mr. Birt's theory be correct, then it would happen that the news from New Orleans, New York, and other cities of the United States which appears in the morning newspapers of a Wednesday would be, not the news of the previous Tuesday, but of the following Thursday, or, at all events, of the latter part of the same day. Every newspaper reader knows this is not so. It is said that the manager of a theatre in New York, one evening before the performance commenced, addressed his audience thus: "Ladies and gentlemen, I am sorry to inform you that the —— Theatre, Paris, was burnt down this evening, at 12 o'clock." Such a feat might be accomplished in New York in speaking of Paris, but cannot be done in Paris or London in relating New York news.—KELBY.

[11715.]—**Testing Acetic Acid.**—CORRECTION.—I omitted when describing the mode of testing for free sulphuric acid, at p. 234, to state that after decomposing the surfeited sulphate of barytes by heating it, mixed with charcoal, by a blowpipe flame, that the sulphide formed must be decomposed by hydrochloric or other strong acid, when sulphuretted hydrogen will be formed. Of course, the carbonate of lead used must itself be quite free from sulphate, of which common white lead often contains a little.—PHILO.

[11731.]—**Hair Wash.**—It seems to me that a superabundance of scurf in any head—except in a diseased condition of the scalp—is simply, to use plain English, a case of dirt. Scurf is a natural healthy condition of the head. It is the continuous moulting of the scurf skin which occurs all over the body, but becomes entangled in the hair in flakes. Now all washes and messes that have not as their base a liberal supply of soap and water, are but aids to its formation. Would any bath-loving Englishman or woman consider such a concoction as any one of those recommended to "Excelsior," a cleanly substitute for his or her daily ablution? Fancy taking a bit of flannel soaked in glycerine, honey, borax, camphor, or quicklime, and with it anointing one's face, body, arms, and legs, and then saying, "I'm clean!" The absurdity is at once apparent. Why, then, treat the head to such disease-producing agencies? Has it not the same number of pores per square inch to be purified as other members of the body? In all these patent and home-manufactured washes the *modus operandi* and results are as follows: The wash is poured on flannel or sponge and briskly rubbed into the roots of the hair until the scurf is dissolved and the skin looks white; then the head is considered clean, whereas it merely melts the grease, scurf, and dirt into the hair, where it dries to form a trap for fresh scurf and dirt. As for the tooth-comb, it is a capital instrument of torture for such undue irritation of the skin as will produce a seriously diseased condition. I know many ladies object to washing their hair on account of its length and the time taken in drying; but is that an excuse for such a state of unhealthy hidden dirt as must exist after the use of these washes? No matter what length the hair may be, where it is regularly cleansed, five minutes for washing and about fifteen for drying with warm towels is ample. The use of soap and water, with a little ammonia to aid in dissolving the grease, regular brushing of the skin of the head with a moderately hard brush, and just enough pomatum to supply needed oil, will speedily remove unsightly scurf, except in the case of genuine skin disorder, when a doctor should be consulted.—M. POPE.

[11752.]—**Meerschaum Pipe.**—"F. G. C." cannot remove the black colour produced by a solution of caustic, for it is not only impregnated in the wax, but burnt in by smoking. The only plan is to have the bowl rewaxed, at any pipe-makers in town, which will cost about 2s. It is the thin coating of wax on all pipes that holds the colouring matter, and when warm from smoking is very susceptible of any liquid matter, and even the perspiration of the hand.—ZETA, Reading.

[11756.] — **Power of Water Wheel.**—Many thanks to Mr. Gillaird and "B. A." for taking notice of my queries respecting the power of water-wheel. I now send the particulars they required concerning it. There is at the bottom of the reservoir a conical plug 8in. in diameter, tapering down to 7in., raised by a screw to regulate the flow of water; the distance from this to the top of water-wheel is 110 yards, and diameter of the pipe 9in. inside; the fall from bottom of reservoir to the top of the wheel 6ft., and from the mouth of the pipe to the bottom of wheel-pit 14ft. 9in. The wheel is an overshot, and 14ft. in diameter; the width of the iron rim is 10in., and 1¼in. thick, made of six segments on each side. The wheel has 48 buckets, each will hold 5 gallons of water, the circumference is 44ft. 2in., and makes 6 turns in a minute in thrashing corn; the shaft is of iron 5ft. long, and rests on brass bearing; the diameter of the bearing 5in., and weight of shaft 10 cwt. Buckets and arms are made of wood.—WATER-WHEEL.

[11762.]—**To take Honey from Bees by Using Chloroform.**—If it is of any use to "W. T. B.," I will give him an account of an experiment I made with chloroform in the autumn of 1869. I selected three strong stocks, in common straw hives, weighing about 30lb. each. Before dusk I loosened the hives from the stools with a long knife, that I might lift them off quickly. After they were quiet, I placed a stool close behind the hives, on which I stood a common earthen pan large enough to admit the hive about two inches, and tapering to the bottom. In the bottom of this I placed a small bedroom candlestick, with the candle holder filled with cotton wool. On this I poured one-third of an ounce phial of chloroform, placed the hive over, and threw a wet cloth over the whole. In five minutes, after tapping the hives a few times, most of the bees were in the pan below. I then took about half the comb out, emptied the bees back into the hive, and placed it on the stool again, and repeated the operation with the other two. In neither hive were the bees quite stupefied, but could only crawl. All the stocks lived through the winter, but did not do very well the next swarming season. The honey was a much better colour and taste than sometimes it is when taken with the brimstone matches. It was a rather troublesome affair, and I thought it rather expensive, as, to the best of my recollection, they (the three stocks) did no farther good. I have not tried the experiment since. In the summer of '70 I wrote a few letters to "ours" on "Bee Management," and asked that some of my brother bee-keepers would tell me if any of them had made a trial of chloroform, but was only answered with a half-ridiculous half-sarcastic letter from "Receps" and though a constant reader have not since troubled "ours" with any of my experience, &c.—BERKS LATE OXON FARMER.

[11762.]—**To Take Honey from Bees by Using Chloroform.**—The quantity of chloroform required for an ordinary sized hive is the sixth part of an ounce; a very large hive may take nearly a quarter of an ounce. Set down a table opposite to, and about 4ft. distant from the hive; on the table spread a thick linen cloth, in the centre of the table place a small shallow plate, which cover with a piece of wire gauze, to prevent the bees coming in immediate contact with the chloroform. Now, quickly and cautiously lift the hive from the floor-board on which it is standing, set it on the table, keeping the plate in the centre; cover the hive closely with cloths, and in twenty minutes or so the bees will be sound asleep. You can now remove the honey you require, replace the hive, and the bees, as they recover, will return home.—J. W. RICHFORD.

[11789.]—**Effect of Temperature on Ale.**—I have noticed the same effect on ale brewed at home with soft, and almost chemically pure, water, so that hard water has, probably, little to do with the phenomenon. Most likely, water at low temperatures has less capacity for holding extraneous matter in solution, and hence turbidity may arise in wine and vegetable decoctions, as well as in ale. There seems to be no remedy but keeping the ale in a cellar of suitable temperature, and, indeed, if "W. A. N." could discover a method of brewing ale which would keep its qualities and appearance under all temperatures, cellars might speedily go out of fashion.—J. COLBY.

[11789.]—**Effect of Temperature on Ale.**—I am obliged to Augustus Avame for his answer. Does he mean me to understand that by the use of Beane's patent material such a thing as my ale going cloudy from cold will be entirely prevented? If the nature of the water is not the cause, how is it that a glass of bright ale drawn from a cask will, upon being exposed to cold, go cloudy and go bright again when brought into a warm atmosphere? and how does he account for the fact of the cold not having the same effect on other ales, mine being the only ale that I know of that is affected by cold in the manner mentioned? Of course, there may be plenty of other brewers labouring under this difficulty as well as myself, as in winter time it is a great drawback to my success in brewing. Will Augustus Avame say if he knows an instance of this difficulty having been got over, either by the use of Beane's material, or any other means? If I had to use this material would there be no insoluble matter in the casks, as I can scarcely imagine that to be the case?—W. A. N.

[11799.]—**Botany of Cornwall.**—Your correspondent will find a catalogue of the mosses and lichens of Devon and Cornwall, by Messrs. E. M. Holmes and F. Brent, in Vol. III., of the Annual Reports of the Plymouth Institution and Devon and Cornwall Natural History Society (Plymouth: Keys and Son). The best book with plates for naming flowering plants is Sowerby's "English Botany," now publishing in parts, but this is a very expensive work. Hooker's "Student's Flora" (Macmillan) is an excellent book for naming flowering plants, but has no plates.—H. F. P.

[11800.]—**Cool Air in Hot Climates.**—The danger of breathing unwholesome air, from which Mr. Bottone suffered by sleeping in a cellar when residing in Italy (see p. 285), will not be incurred if the cooled air be drawn from dry wells dug in the subsoil, below that which is charged with organic matter. There is a strong and very natural dread in many places—especially in those where the difference between day and night temperature is great, and the formation of dew therefore considerable—against admitting the night air into dwellings, and it is very common to attribute the injury often sustained to the coldness of the air, which is really caused by the mist, or rather by the organic matter, perhaps by the living organisms contained in the mist. That this is so is shown by the fact that those who sleep at a level above the mist suffer less than those who sleep near the ground level, and that even such a slight obstacle to the entrance of mist as a muslin blind is a considerable though incomplete protection against the effects of night air, which, it is evident, can scarcely affect either its temperature or its composition, except by intercepting floating particles, whether solid or liquid. It is highly probable, though not, I think, proved, that if malarious air were filtered through charcoal it might be breathed with impunity, and it is certain that danger from it would be much diminished.—PHILO.

[11810.]—**Colds in the Head, &c.**—If "X. Y." will pay attention to the following I think he will find relief:—Procure a pair of rough bath-gloves and rub the skin all over the body every morning until a burning sensation is produced; then rub briskly with a dry towel; if convenient, a cold sponge bath every morning with above would be better. Keep the bowels laxative (with a little castor oil), if necessary, and abstain from all stimulating liquors. This I have tried, and now enjoy perfect relief from some complaint, which was constantly annoying me. As a rule, I found drugs only gave me temporary relief.—A SYMPATHISER.

[11810.]—**Colds in the Head, &c.**—"X. Y.," if not now a daily bather, has a grand career and cure before him!—viz., the simple adoption of means to rouse the skin to healthy action; and this can be done only by a daily washing. In my younger years I was a victim to colds in the head; eyes, ears, and throat being continually affected, off and on, and worse in summer than in winter. At length, when I was about twenty years of age, my kind doctor lent me Coombe's "Physiology," with the remark that it would not suit him to lend it to all his patients to read. By his advice I then began the "daily sponge," using a long and rather coarse sheet as an enveloper from cold air, a small diaper towel to rub dry under said sheet; and now, after forty years' trial, I am more than ever thankful that I was so persuaded; and attribute a large portion of prolonged life to this regular daily cleansing of the skin, winter and summer alike, at home or abroad, from top to toe—not requiring to spend more than from five to seven minutes every morning at it; but I should not know how to dress without "sponging," and often am surprised at the muddy state of the water when the sponge has been well squeezed in it to get out the scales of "skin dirt." Already I have made scores of converts, and hope to have added to them many of "our" intelligent readers.—ONE WHO PREACHES AND PRACTISES.

[11814.]—**Lathe Queries.**—I have unfortunately mislaid my copy of the ENGLISH MECHANIC of the 10th of May; but from what I recollect of the query under this number (11814), "A., Liverpool," while taking the answer out of my mouth, has forgotten what the question was. My impression is that another and, if possible, simpler way of fitting a double-bearing mandril than Whitworth's from the drawing appears to be was the thing asked for. "A., Liverpool," has given the ordinary way of making a single collared lathe, not intended to be fitted up for self-acting sliding at all. The cone of the rear end of the mandril is commonly reversed, and the steel fixed collar also reversed, the movable collar being then bored through and ground out truly cylindrical, and fitted on a plain part of the mandril with a thin key to insure its turning at the same time, and with a nut fitted behind it to adjust it for tightness and wear. It is, perhaps, a little easier to make a mandril this way, as only one collar has to be welded on the mandril instead of two; but it involves an extra piece—viz., the adjustable cone, which must be made in the most accurate manner to fit very tight on the mandril, although, to be sure, I have seen one on a new lathe that would fall off of its own accord when the mandril was held perpendicularly. I have a very good head on my lathe with a homogeneous iron (mild steel) mandril, not hardened, running in Babbet's metal bearings, which were cast on the mandril in paper moulds with wooden bottoms, and turned on the mandril itself to fit the holes in the head-stock, into which they were afterwards forced by screw pressure, assisted by a big mallet, and the collars were afterwards eased a little inside by scraping with a penknife. It won't do to let these white metal bearings get dry. The mandril above-mentioned is fitted as described with reversed cones.—J. K. P.

[11816.]—**Fixing Balance Wheel on Verge.**—In reply to "S. H. L.," choose a verge the proper length, cut the pallet-leaves the right width; now put on to the pallet next the collet a screw ferrule. Prepare a bow in the following manner:—Take a piece of whalebone eight or ten inches in length, scrape it with a sharp knife until, when holding by one end, you can bend it by blowing at it. Now make a bow of it with a fine horsehair; put your verge into the turns, and run it backwards and forwards with the bow; bring the tool up to the work only when drawing the bow towards you. This requires a large amount of practice (it is an easy matter to write down here to do a thing, but the skill to do it only comes by practice). Turn down the collet till the hair-spring collet just fits tight on to it. Now turn down the seat for the balance, turn the bottom of seat flat, not hollow, else, when riveting on, the edge gives way, and your balance will not be true. Drive on the balance, and mark where it will want turning down; leave just enough to rivet (you can leave the top hollow, it is better to rivet when left so). Take pivot calipers and get size of bottom pivot of old verge, run down new pivot, right size, cut off proper length, round up and polish. The same with the collet pivot, except that you must turn up true before using pivot file. Now rivet on balance and finish up top—you will find it a much more difficult job than turning a collet on 'scape staff. Take off ferrule, put it into the turns, and see if the balance is really a balance; if it is it must not be left so (not in verge watches). When the balance is put in and in a state of rest, the point next the follower of crown wheel must be left a little the heaviest, as all verge watches lose a certain amount of the cross of the balance when the figure 12 is downwards, and therefore gain time. I have no faith in the isochronous properties of the hair-spring when applied to recoil escapements like the verge. I have always improved the time-keeping, without exception, of old verge watches I have so treated.—A YORKSHIRE PIVOT.

[11825.]—**Testing Bleaching Powder.**—I would have answered this query sooner, but I have been very busy with the manufacture of this article. The method proposed by our mutual friend, Mr. S. Bottone, would, I fear, be found rather expensive for general use, not to speak of the length of time required for each estimation. The following (Gay Lussac's) method will, I think, be found very satisfactory. It is based upon the circumstance that the contact of chlorine with arsenious acid, in presence of water, gives rise to the formation of arsenic acid and HCl:—$AsO_3 + 2Cl + 2HO = AsO_5 + 2HCl$ 1 eq. of $AsO_3 = 99$, requires accordingly 2 eq. of $Cl = 71$ for its conversion into AsO_5. Consequently, the amount of a solution of chlorine required to convert a definite quantity of AsO_3 into AsO_5, indicates at once the amount of chlorine present in that solution. To prepare the AsO_3 solution, dissolve 99grs. arsenious acid in 4,000grs. msrs. water. This strength will be found most suitable. Suppose you work upon 50grs. of the powder, and convert 1000grs. msrs. of the AsO_3 solution into AsO_5; then, as $4000 : 71 :: 1000 : 17{\cdot}75$grs. Cl in 50grs. of the powder. $17{\cdot}75 \times 2 = 35{\cdot}5$ per cent. Cl in the sample of chloride of lime. The powder must be triturated in a mortar with water, and the point of saturation will be known when the liquor ceases to give a purple colour with starch paper. I will be happy to give further particulars if this is not sufficiently clear.—AUGHRIM.

[11825.]—**Testing Bleaching Powder.**—The plan of acting on the powder with dilute sulphuric acid, and conducting the gases evolved into a solution of silver nitrate, as recommended by Mr. Bottone, is open to several objections, and is more calculated to mislead any who may try it, than aid them. In the first place, Mr. Bottone in his directions says, "the quantity of nitrate of silver must be equal to the amount of chloride of lime to be tested." Now, say we start with 100 grains of each; many samples of bleaching powder contain 35 per cent. of available chlorine, so that if all the chlorine were driven over it would require nearly 108 grains of pure silver, or 172 grains of nitrate, even to fix the chlorine; secondly, chlorine does not act upon silver nitrate so as to produce only silver chloride and nitric acid, but it also produces silver hypochlorite (Balard), a soluble, but very unstable, salt, which is soon resolved into a mixture of chloride and chlorate. The formation of silver chlorate would cause a loss, it being a soluble salt; thirdly, some of the chlorine would remain dissolved in the liquid in the vessel A, and there is no provision shown in the sketch for its final and total expulsion. In lieu of this process I should recommend the well-known and thoroughly reliable method introduced by Penot, which consists in adding to a definite quantity of a solution of the bleaching powder an alkaline solution of sodium arsenite till a point is reached when a drop of the mixture ceases to form blue spots when placed on paper imbued with a mixture of potassium iodide and starch. The mode of operating is as follows:—1. Dissolve 99 grains of pure arsenious acid with 350 grains of pure crystallised sodium carbonate in 6,000 to 7,000 grains of water with the aid of heat, allow to cool to the temperature of the air, and then make up the solution to exactly 10,000 grains measure with water; 1,000 grains measure of this solution represent 7·1 grains of free chlorine. 2. Take 50 grains good starch, and 4,000 grains water, raise slowly to boiling, and add 15 grains each of potassium iodide and crystallised sodium carbonate. Soak strips of good filter-paper with this and dry them. Keep them well secured from the air in a bottle. 3. Take 100 grains of the bleaching powder and rub it up in a mortar to a perfectly smooth paste; with water pour the liquid into a 10,000 grain flask, rinse the mortar well out several times with fresh water, and make up the whole to 10,000 grains. Agitate the whole well, and remove 1,000 grains of the turbid liquor by means of a pipette to a beaker. Arrange a number of small pieces of the starch paper on a plate, and from a 1,000 grain burette add carefully the arsenic liquor till a drop of the mixture just ceases to cause any coloured spot; the point can easily be hit to one drop. Suppose in an experiment 450 grains measure of the arsenic solution are consumed, then as 1,000 grains of the liquor are equal to 7·1 grains of chlorine, 450 grains are equal to 3·195 grains—that is, 10 grains of the bleaching powder contain 3·195 grains of available chlorine, or 31·95 per cent. If the arsenious acid and sodium carbonate are quite pure the standard solution will keep a long time unaltered. I believe this to be the only mode of proceeding which enables us to discriminate between the calcium hypochlorite and calcium chlorate; of this last salt, bleaching powder often contains several per cents., which in the ordinary way of testing, would indicate as chlorine, though really this salt is of no use practically in bleaching.—ETHYL.

[11826.]—**Tinning and Soldering.**—In my remarks on this subject, p. 261, "tin, &c.," has been substituted for the word "zinc."—W. T. M. D.

[11840.]—**Whooping Cough.**—The remedy recommended by "T. C. H." is also strongly recommended in Australia.—MANUS.

[11840.]—**Whooping Cough.**—The remedy for this complaint very much in use in Berkshire, and found effectual in many cases, is as follows: In a half pint of best vinegar put a new-laid egg (shell and all) at night, and leave it until dissolved the following day, when beat it up well and strain. Dose, a teaspoonful three times a day.—ZETA, Reading.

[11840.]—**Whooping Cough.** — Try Roche's enbrocation, to be used externally by rubbing in the chest every evening at bedtime. It can be bought of any druggist for a trifle, or may be made by mixing olive oil 2oz., oil of amber 1oz., and oil of cloves 1 drachm.—H. B. E.

[11841.]—**Human Relics.**—Yes—it is too true! In the Etruscan vase room of the British Museum, in the bottom compartment of a cheap glass case, with no external mark to call attention to it, or to distinguish the relics from the old pots and pans surrounding them, lie the well-preserved mortal remains of "Mykerinus the Holy," the pyramid builder, the cotemporary of Abraham. Even with the help of a catalogue you will not readily find it out. While mushroom monarchs of yesterday are thought worthy of glorious shrines, the British nation thinks this treatment good enough for the remains of a mighty monarch of the days when the earth was young, who has left his stamp on its face in the shape of a monument of exquisite taste, which Time seems powerless to destroy. His sarcophagus lies at the bottom of the Bay of Biscay, and it would be better for our credit if the body lay there also, decently buried within it. The object of the museum authorities appears to be to overcome the monarch's aversion to return to dust. "Dust thou art and unto dust shalt thou return," should be placed as a motto over the compartment. They seem to have about as much respect for the king as the historian of the khaliphs had, who records about the opening of the sarcophagus, "that they found in it nothing but the rotten carcase of an infidel," which, accordingly, they turned out on to the floor and left there. Would it be too much to expect that the remains should be at least removed to the Egyptian room and placed in an air-tight glass case, and that some pains should be taken to preserve them from the rapid destruction which exposure to the air must be bringing about? It would, I suppose, be too much to expect that anything in the way of harmonious surroundings should be added thereto, such as our neighbours would indulge in if they had it in the Louvre. The late Baron Bunsen made some sharp remarks, in his "History of Egypt," about our treatment of these remains, which should long since have shamed the authorities of the museum into some action about them; but it takes a deal of kicking to move us Britons.—T. C. H.

[11841.]—**The Oldest Human Relics.**—On what ground does Mr. Matthews (p. 286) regard the skeleton of Pharoah Mykerinus as the *oldest* human relic? Has he never heard or read of the Neanderthal and Engis skulls? If not, Sir John Lubbock's admirable work, "Prehistoric Times," will enable him to correct his ideas on this most important subject.—A Fellow of the Royal Astronomical Society.

[11847.]—**Curry.**—The recipes for true Indian curry are numerous, and vary much in proportion of ingredients. The total quantity of powder in each of the following recipes being nearly equal, the relative proportion of the different colouring, heating, and flavouring ingredients, will at once be seen. Dr. Kitchner complains that the proportion of cayenne is generally so large that a proper quantity of the powder cannot be used to obtain the benefit of the other ingredients; and the late editor of the *Pharmaceutical Journal* justly complains that many recipes contain too large a proportion of turmeric. All the ingredients should be of fine quality, and recently ground. No. 1, I think, will be found very nice.

[11857.]—**Gelatine Moulds for Plaster Ornaments.**—A mixture of good glue, not too stiff, with fine brown sugar, will give flexible moulds.—S. Bottone.

[11861.]—**Glove Cleaning.**—Put the hand in the glove, and while on the stretch, carefully rub with a fine piece of old flannel dipped in benzole. One night's exposure to the atmosphere will rid them of all smell. —T. I. Preston.

[11862.]—**Charcoal.**—The produce in charcoal is apparently at first sight very variable. The experiments undertaken by Junker, at the instigation of Berthier, at the smelting works at Planen, are of all others the most trustworthy. The woods burned were all 32 years old. Dry oak, peeled 2 years, yielded 25·7 per cent. charcoal, and ·84 per cent. half charred wood; unpeeled, yielded 24 per cent. charcoal, ·3 per cent. half charred wood; green oak, 22 per cent. charcoal, ·3 per cent. half charred wood; green oak with lops, branches, &c., yielded 18·5 per cent. charcoal, ·4 per cent. half charred wood. The wood was charred in heaps of 21ft. diameter. The commercial products that can be obtained are tar and pyroligneous acid. The sale of these is very much dependent upon the nature of the country in which you are, and is often exceedingly small, and yet various methods have been tried, though not always with success, for collecting them. The retort furnace admits of all the produce being completely collected, an advantage which is only counterbalanced by the necessity of employing small quantities of wood at once; for it is clear that the bad conducting power of wood and charcoal must offer an insurmountable obstacle to the penetration of heat from without, into the interior of a larger furnace, and that its full action cannot there be exerted. This kind of furnace is exceedingly appropriate for the production of tar, when charcoal is not the chief product required, but when the chief product required is tar. According to Stolze, the amount of tar in oak is from 10 to 20 per cent. When the retort begins to be at a red heat, the first gases which appear are combustible. At some furnaces there is a small fire kindled with twigs under the retort until it is at a red heat (it need not be upon a grate), and then the gases are lighted and turned into the furnace, which they will now entirely support without any stoking for about 16 hours. The gases are now to be turned off, and the retorts drawn. This is the most economical manner of disposing of the combustible gases. I don't think that the other gases arising from the contamination of the charcoal could be profitably disposed of.—P. W. H. J.

[11862.]—**Charcoal.**—"Prentice" would get about 8¼ cwt. of charcoal from a ton of oak tops dried in the air by burning them in a retort; and 5 cwt. by the process of pit burning. The gases evolved during the distillation in the retort are condensed. Pyroxilic spirit, and pyroligneous acid are produced, used by calico-printers and others.—Woodman.

[11864.]—**Rabbit Disease.**—I once had a rabbit affected in the same way as that of James King's, and I completely cured it by rubbing flowers of sulphur on its skin every morning, and it had no return of the complaint again.—J. W. Richford.

[11864.]—**Rabbit Disease.**—Let your rabbits have as much fresh air and as good food as possible. Rub into the bald patches every day a little of the diluted nitrate of mercury ointment; if this fails try the tar ointment.—T. I. Preston.

[11867.]—**Separating Tar from Wool.**—Pure benzole will easily remove tar or pitch from wool. It will also remove paint, if it has not remained too long on wool.—F. T.

[11867.]—**Separating Tar from Wool.**—Washing with benzine, turps, or coal-tar naphtha will effect this.—S. Bottone.

[11868.]—**Ash Timber.**—Ash timber felled in winter is best when cut into planks for seasoning as soon as felled; but I would advise "Ash" to let his timber stay with the bark on until next autumn, and then cut it up, as if done now, and hot weather sets in, it would crack and warp. I should advise him to put his timber in a shed, as it would keep it a better colour. Good ash timber is worth about a shilling a foot cube when within ten miles of a manufacturing town. When sold by the inch it is quoted at, say, 2d. per in. for 3in. plank—that is, 6d. per superficial ft. It is sometimes sold by the lineal yard of 9in. wide—thus, 9 superficial ft. equal 4 lineal yards.—Woodman.

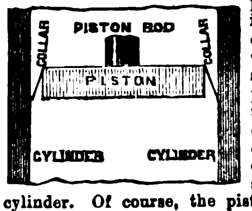
[11869.]—**Zinc v. Coal.**—Coal can unite with a greater quantity of oxygen during the process of combustion than zinc does, and, therefore, gives out more heat, the amount of heat given out being in the proportion of the quantity of oxygen combined with. I extract the following from "Recent Improvements in the Steam Engine," by Bourne, p. 5:—"In the animal economy a given quantity of carbon produces its equivalent of power with far less waste than in the best steam-engine, although the temperature is not great; and the same result takes place in a voltaic battery—the electricity generated by which may be made to work an engine with far less loss than its equivalent quantity of heat. It does not, however, appear to be in the least probable that electro-magnetic engines will be brought into use to supersede steam-engines, unless some means should be discovered of obtaining the electricity from coal instead of zinc . . . A pound of coal consumed in an engine will produce more than twice the power produced in a galvanic battery by a pound of zinc, and the cost of the coal will also be very much less." In the best steam-engines only about one-tenth of the value of heat is obtained as power.—Philanthropist.

[11872.]—**Carbonic Acid Gas and the Atmosphere.**—The pressure of the air is 14·75 (say 15lb. on the inch. It varies at different places at different times, as we see from the fluctuations of the barometer. Calculate the weight of the atmosphere by finding the number of square inches on the earth's surface, and multiplying this by 15, 8,000 miles is the diameter of the earth approximately. $(8,000)^2 \times 3·1416$ = area of earth in square miles (say) 200,000,000. There are 63,360 inches in a mile, or $(63,360)^2$ inches in a square mile. In round numbers 4,000,000,000 square inches.
200,000,000
400,000,000

80,000,000,000,000,000 pounds is the weight of the atmosphere, or about 35,600,000,000,000 tons. I am not sure of the proportion of carbonic acid in the air in its normal state—perhaps, one part in 10,000; if so divide by 10,000. If the carbonic acid were increased tenfold or less, animal life would suffer seriously.—Philanthropist.

[11875.]—**Spectrum Colours.**—It is almost impossible to get a pure white with our known pigments, the nearest approach being a light gray. Divide your disc into 4 equal parts, colour two divisions with the best Prussian blue, one with carmine, and one with gamboge yellow.—S. Bottone.

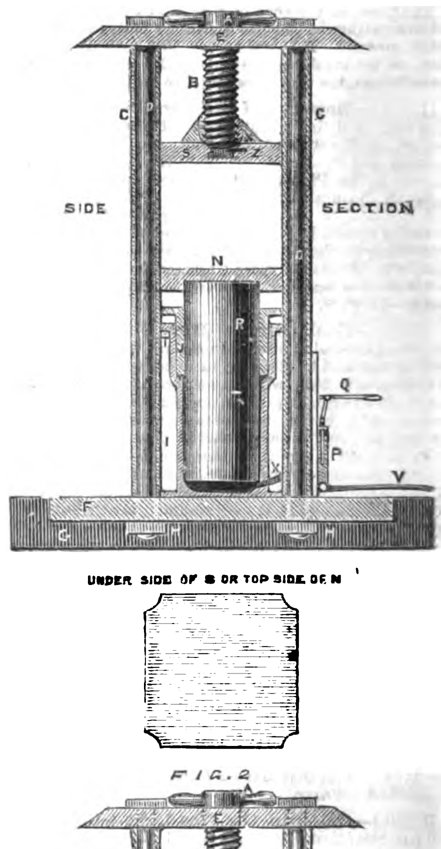
[11876.]—**Hydraulic Press.**—I could send you a drawing, or a calculation; I cannot go much into the workmanship. The great difficulty, which was to



prevent the water escaping past the piston, was obviated by Mandsley, who used a leather collar secured round the upper part of the piston, so that the greater the pressure of the water the more closely the leather collar or flap was pressed against the inside of the cylinder. Of course, the piston is made to fit very accurately. I gave a sketch showing the piston too small to indicate the action of the collar.—Philanthropist.

[11876.]—**Hydraulic Press.**—I inclose sectional drawings of the press. The size that I have calculated for is, I think, about the smallest size that can be made, and yet show its effects practically. This press can be used for experimenting upon the crushing strain of wood and metal, and if well got up, will form an appropriate and ornamental machine to receive prizes at the local industrial exhibitions. The barrel of the ram would bear a pressure of three tons per square inch, and the pillars will bear about the same amount of tensional strain, if made of the dimensions specified. I have introduced a novel feature in the hydraulic press, which extends its range of action to nearly double of what it would otherwise be. This is more important in small machines than in large ones, as it is difficult to make screws of relative size for large ones, and easy for small ones. The modification consists in the screw B, Figs. 1 and 2. If "Ricardo" prefers otherwise, he can dispense with the screw, and use my other dimensions. Now for the specification. The ram to be made of a piece of solid brass rod, turned to 1in. diameter, and about 3½in. long; it must be turned truly parallel, and polished as bright as possible, as by so doing it will save much friction. Thickness of barrel to be ¼in., no less, and if possible, thicker; it is to be made of gun metal, or very fine brass. It would be best to make a complete casting of the bottom of the ram with the top and body with a wide ledge or flange at the bottom, as shown in drawing; this flange to be ¼in. thick, and 3½in. diameter. This must then be turned on the exterior, and bored just where the stuffing-box gland has to go in. The stuffing-box gland had best be a casting 2½in. diameter at the top, or greatest diameter, and turned to 1½in. at its other exterior diameter, and ¾in. deep, as at J, in the drawings. It must now be put into its place and drilled with the five holes for bolts. The bolts are to be made of one-eighth or three-sixteenths iron wire, at least 1½in. long. The bolts having been put into their places, the gland and the ram barrel are to be bored together; this will be best done by a workman. The cross plates S and N are to be ¼in. or ⅜in. wrought iron, finished off bright with semicircular holes filed or drilled in them so as to be able to slide smoothly.

FIG. 1



UNDER SIDE OF S OR TOP SIDE OF N

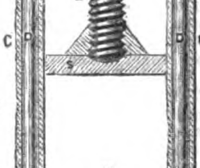


FIG. 2

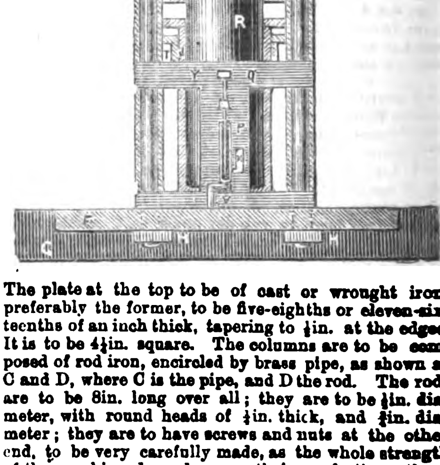
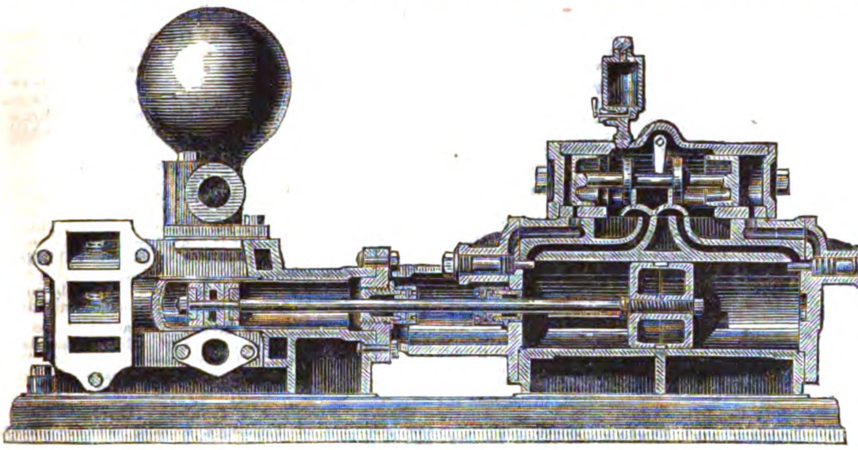


The plate at the top to be of cast or wrought iron, preferably the former, to be five-eighths or eleven-sixteenths of an inch thick, tapering to ⅛in. at the edges. It is to be 4½in. square. The columns are to be composed of rod iron, encircled by brass pipe, as shown at C and D, where C is the pipe, and D the rod. The rods are to be 8in. long over all; they are to be ⅜in. diameter, with round heads of ¼in. thick, and ⅝in. diameter; they are to have screws and nuts at the other end, to be very carefully made, as the whole strength of the machine depends upon their perfection—those with bad screws should be rejected; the nuts to be hexagonal, ¼in. thick, and 1in. diameter. All these columns to be carefully turned to fit the brass pipes. They are to be placed 3½in. distance from each other. The screw B would be best chased with a coarse chasing tool with a square thread, and, if possible, it should be made of steel, if not of wrought iron. The screw should be ⅝in. diameter, if of wrought iron, and about ⅝in. diameter if of steel (not hardened, as it diminishes its tensile strength, and it will last long enough without). The small wheel at the top is to be cast of brass, without arms, but one solid piece, 1¾in. diameter. It might be milled at the edge, and if so, would do without handle; the handle to be of rod copper, ⅜in. thick, and ¾in. high, turned to some ornamental pattern. The foundation plate to be ⅝in. thick, and 5in. diameter, to be turned out of a piece of boiler plate, and polished; this is to be let into a square mahogany plinth, 6½in. or 7in. square, and 1in. thick. The cross plate N can be soldered to the top of the ram R, as there will be no strain tending to separate them. The directions for making a force-pump were given some weeks back, and by altering the dimensions, the same plan of construction could be used in this case. The plunger can be made out of a piece of brass wire, screwed into a little brass block for the pump lever to work in. The pump plate is to be made of a piece of plate brass, ⅛in. thick, 3in. high, and 4in. wide, sawn out to shape, shown as Y in the drawings. The pump can be screwed, or if screws are not obtainable, hard soldered to the pump plate. The pump lever is to be made out of a piece of brass or iron wire, ¼in. thick, and 2¼in. long, having three holes, one ¼in. from one end, and the others at ½in., 1in., respectively distant from it. There is also a short connecting rod between plunger and lever; this is to be made of two sides of brass plate, soldered together in the middle, the holes drilled at the ends, and the ends bent apart, so as to allow the top of plunger and the lever to slip between and be pinned on; it is then to be finished off bright. For the stuffing boxes, I would not advise "Ricardo" to use leather, but well-greased hemp strands.—P. W. H. J.

[11876.]—**Hydraulic Press.**—It is almost impossible to give "Ricardo" any information, as his question is in such general terms. If he will give some idea of the size he wishes to make his model press, and what amount of actual work he wishes it to do, I will try and help him.—ROOK.

[11877.]—**Slide Valve Question.**—The slide valve is moved by a small piston, the steam for actuating which is admitted alternately at each side by means of spindle valves in the covers of the main cylinder, and which are opened by the piston just before it reaches the end of each stroke. I send a longitudinal section showing internal passages.—ROOK.



[11878.]—**Photography.**—"Camera" will find a soft lead pencil applied to the varnished surface of the negative as convenient as anything for retouching. The parts so treated will not require varnishing again; but my advice is that he should try and get his pictures as perfect as possible by photography alone, and not trust to retouching, as only bad negatives are at all improved by it. The cause of the difficulty mentioned in the second query is over-exposure, the light being so much more intense out of doors than in. —DÆDALUS.

[11878.]—**Photography.**—It is a sign of bad management if a negative requires "touching." Try to make perfect negatives; without this you will never be a successful photographer. The reason why your outdoor pictures "flash out" is because they are "over exposed." In the open air expose only one-tenth of what you do under glass.—S. BOTTONE.

[11878.]—**Photography.**—Your landscapes flash into view the moment the developer is applied because you have probably not taken into due consideration that landscape negatives require considerably less exposure than pictures taken indoors. Indeed, under favourable circumstances, landscapes require little more (if any) than instantaneous exposure.—QUERCUS.

[11878.]—**Photography.**—I presume "Camera" means spots and pin-holes in his negatives; if so, they should be stopped with Indian ink, applied with a small brush. The negative will not require varnishing again. For outdoor work he should use a weak developing solution, and be sure not to over-develop or he will fog his picture. As soon as he can see the detail in the shadows when looking through the negative he should wash off the developer and clear (fix) the picture.—C. S. W.

[11883.]—**Sustaining Power of Cast Iron Column.**—The column may be, practically considered, as one of 7½in. diameter. At all events our error will be on the safe side, and I don't see that such a small difference in the top and bottom diameters could create much difference in the result. Hurst gives in his tables, the safe load = one-tenth breaking weight. He gives for that diameter of column, the safe load to be 164·8 tons, but there is a correction to be used when the length of the column is less than 30 diameters. Let S be the strength for long columns given in the table; and C = 49 times the sectional area of the metal in inches. Then strength for long columns = $\frac{S\,C}{10\,S + \frac{3}{4}C}$. Then substituting S = 164·8 and C = $49 \times (7\frac{1}{2})^2 \times {\cdot}7854 = 2164{\cdot}76$. $\therefore \frac{164{\cdot}8 \times 2164{\cdot}76}{1648 + \frac{3}{4}(2164{\cdot}76)}$ = 273 tons about.—P. W. H. J.

[11884.]—**Power of Water Wheel.**—As "R. S." has not told me the number of buckets, I shall use Fairbairn's rule for finding them. Let D be the diameter of the wheel in feet, and N the number of buckets. Then for wheels of from 25ft. to 40ft. diameter, N = D × 2·3 = 25½ × 2·3 = about 56, and the circumference of the wheel = 80·1ft., therefore the buckets are at a distance of $\frac{80{\cdot}1}{56}$ft. = $\frac{801}{560} \times 12 = 17\frac{1}{4}$in. nearly. Then suppose that each bucket contains upon an average 8 cubic feet, then the number of cubic feet consumed by the wheel = 56 × 8 = 448 per revolution. Then the proper velocity of periphery I find by tables to be for that head of water = 6ft. per second, or 6 × 60ft. per minute = 360ft., and the circumference of the wheel = 80·1ft. ∴ the number of revolutions per minute = $\frac{360}{80{\cdot}1}$, or nearly 4½ revolutions. ∴ quantity of water consumed per minute = 448 × 4½ cubic feet. Then let P = effective horse-power, Q = quantity of water in cubic feet per min., and h = head of water in feet. Then P = ·00113 Qh in high breast wheels. Then substituting Q = (448 × 5), and h = 19ft. ∴ H.-P. = ·00113 × 448 × 4½ × 19 = 43·28352, so that the wheel would work about 40 horse-power economically.—P. W. H. J.

[11884.]—**Power of Water Wheel.**—Had "R.S.", given the depth of shrouds to the water-wheel name any practical millwright might have answered his query. Water-wheels are usually formed so as to work at full power with the buckets three-fourths full. The horse-power of the water to be applied in this case will be

$$\frac{\text{cubic feet per minute} \times \text{fall in feet} \times \frac{3}{4}}{528} = \text{H.-P.—S. J.}$$

[11884.]—**Power of Water-Wheel.**—The data is insufficient; you do not say how much water passes over to the wheel per minute, nor how much water a bucket holds. The buckets should be large enough not to be completely filled, as in that case a deal of water is lost by running out of them before the level of the tail race is reached.—PHILANTHROPIST.

[11885.]—**Power of Boiler.**—If the tank were jacketed in wood or some other non-conducting material less heat would be required.—PHILANTHROPIST.

[11886.]—**A Thick Soled Shoe.**—If "Wee Pet" intends making a sewed shoe, the best way is to put on a thick welt made thin inside; fill up with a piece of cork afterwards; sow on sole, on top of which peg a clump sole, this will give him about ⅜in. sole. Unless "Wee Pet" has made a sewed boot before, I would say, "Don't try."—COBBLER.

[11887.]—**Hair Dye.**—Let me advise "Gray Beard" to sedulously avoid nitrate of silver as a dye; it is injurious to both hair and skin; he will find the solution of the terchloride of gold more useful and more efficient; the latter produces a light brown colour. But if he will use the silver dye here is a formula:—Nitrate of silver, 40gs.; glycerine, ½oz.; rain water, 20 fl. oz. Mix, and preserve in a blue-glass stoppered bottle.—T. I. PRESTON.

[11889.]—**Hedgehog.**—The hedgehog will require little looking after. A box with some shavings, placed in a cool place, where it can use it at pleasure, and a saucer of milk occasionally, is all it requires. It will crack beetles like nuts, also destroy spiders and mice, but beware how you leave eggs in its way, for they will assuredly vanish. It soon becomes tame enough to be handled and have its cheeks stroked. One I had took up its abode in the cellar, and was sometimes invisible for days, though it was always on night duty, as it entirely freed the house from beetles. I see "G. W. C. H." and "Emily" recommend cucumber rind and phosphorus paste. The former will do well enough where beetles can be counted by the dozen; but, from experience, I can say it is useless against such brigades of the "varments" as sometimes swarm into our kitchens. As for the latter, surely no one with children or live pets would venture to use it.—M. POPE.

[11889.]—**Hedgehog.**—I hope Mr. Pope will not think it presumptuous of me in answering "F. S.," but I have had a hedgehog for the same purpose, and I thought "F. S." would be glad of all the information he could get. He will find it a most amusing pet, and it will get very tame in a few days. They are very fond of warmth; mine used to get under the kitchen grate in the cold winter evenings, and occasionally sleep with my dog (who is a curly one) to the no small annoyance of Tiny. They will eat meat raw or cooked (which must be cut small), as they like a change of diet, and are very fond of milk, but will drink water. They will require a bed of hay to sleep in during the day. I used to keep mine in a cage till night, and then let it out to devour those London pests, and they will not refuse a few crickets.—J. W. RICHFORD.

[11891.]—**Contents of Cistern.**—We can regard the cistern as half a cylinder. The first step will be to find the number of cubic feet in the cistern. Let D be the breadth at the top of the cistern, and L the length. If the contents of a cylinder, having a diameter of D be found, then one-half of that will be the contents of cistern. The contents of cylinder are $D^2 \times {\cdot}7854 \times L$ cubic feet, and then $\frac{D^2 \times {\cdot}7854 \times L}{2}$ number of cubic feet in cistern, and as there are 6·2355 gallons in one cubic foot, ∵ the number of gallons in the cistern is $\frac{D^2 \times {\cdot}7854 \times L \times 6{\cdot}2355}{2}$.—P. W. H. J.

[11891.]—**Contents of Cistern.**—Multiply the area of the base in square feet by the depth of water in feet and this product by 6·23 for the contents of the cistern in gallons.—S. J.

[11898.]—**Tempering Cast Steel Chisels.**—The easiest way to harden and temper steel chisels is to heat the chisel to a bright red about half-way up, and then cool it about an inch up, which will harden it; now you want to let it down to the required temper; you must now rub the cooled part with a piece of brick or rough stone till bright. The brightened part will now change colour, beginning at a light straw till it gets to a purple. The best colour for "Inquirer" is between the two; cool it when the required colour comes.—R. WELBANK.

[11899.]—**Etching on Glass.**—"Un Irlandais" can buy the hydrofluoric acid much cheaper and stronger than he can make it, but if he would like to try, here is the process:—Heat some calcic fluoride (CaF_2) with twice its weight of sulphuric acid (SO_2HO_2) in a leaden retort, and pass the gas evolved through a U-shaped lead tube, surrounded by a freezing mixture, a volatile and colourless liquid is obtained. To etch on glass, heat some white wax or beeswax in a beaker, and apply it to glass, to be etched with a feather or small brush; now, very gently warm the glass over a Bunsen or a gas jet, and well float the wax until it lays even, pouring off any excess; after cooling, take a needle and write on any design, and flow on the acid; the result will be that the glass is etched where not protected by the wax.—LICTOR.

[11900.] — **Electro-Plating.**—With "Sigma's" permission, I beg to inform "Un Irlandais" that he will get all the information he requires from a cheap manual, published by Virtue and Co. I believe it is called "Electro-Metallurgy Practically Treated," by Alex. Watt. It is one of the well-known Weale's series.—QUERCUS.

[11901.]—**Grip Chuck.**—To "F. G. T."—You only want one tap to make your left-handed jaw with; dies are of little or no use for such a job, as the screws ought to match perfectly, and you cannot make sure of getting them to do so when marked out with dies; they should be done in a screwing lathe. From the way in which you speak of Whitworth's "set of four right-handed" taps, I guess you are rather a young hand. I don't approve of the right and left-hand screw grip chucks for general purposes. They are useful in manufacturing where you have a great number of things from the same pattern to do, but for jobbing give me a four jaw chuck.—J. K. P.

[11902.]—**Chlorine.**—The gas evolved from hypochlorite of lime is undoubtedly very injurious, and if long continued would produce serious consequences to the mucous lining of the throat, mouth, and lungs. The irritation would set up a low form of inflammatory action.—T. I. PRESTON.

[11902.]—**Chlorine.**—The gas evolved from the substance commonly called chloride of lime, or bleaching powder, is not chlorine, but hypochlorous anhydride, which is removed from the above compound by the carbonic anhydride present in the air of the room. That gas, as well as chlorine, becomes injurious when it is in a moderate quantity. The quantity of bleaching-powder put in a room ought never to exceed two or three ounces, especially at night, as there is not sufficient ventilation. Great precautions must be taken as to chlorine, or hypochlorous anhydride, as they exercise a most suffocating and offensive action on the lungs.—F. T.

[11902.]—**Chlorine.**—I speak from five years' daily or rather nocturnal, experience. Chlorine, in modera tion, is not injurious in a sleeping-room; on the contrary, I have found very great benefit from it.—S. BOTTONE.

[11903.]—**Quinine.**—Sometimes adulterated with the salicine, and phloridzine group of alkaloids; sometimes with the less active cinchona alkaloids.—S. BOTTONE.

[11903.] — **Quinine.** — When the adulteration is white sugar, it is detected by the solution of the suspected salt in as much potassic carbonate as will saturate the sulphuric acid. If sugar be present it will then be detected by the taste. If the adulteration be starch, a portion of the suspected salt will remain insoluble in cold water; and if the mixture be heated to 170° Fahr., then cooled, and tincture of iodine added, the starch will be made evident by the blue colour. Boracic acid is detected by dissolving the salt in alcohol and setting fire to the solution; if boracic acid be present, the flame will be green. It is more difficult to detect the sulphate of lime, which is manufactured in acicular crystals, expressly for the purpose of adulterating the sulphate of quinine. It may, however, be detected by exposing the suspected salt to a red heat; the sulphate of quinine is decomposed, but the sulphate of lime merely loses its water of crystallisation, and when mixed with water, it rapidly absorbs the fluid, and will solidify in a few seconds. If the adulteration be an anhydrous sulphate of lime, it will remain insoluble in water while the sulphate of quinine dissolves. 10 grains of sulphate of quinine, with 10 drops of diluted sulphuric acid, and ½oz. of water, form a perfect solution, from which ammonia throws down a white precipitate. This redissolves on agitating the whole with ½oz. of pure ether, without the production of any crystalline matter floating on the lower of the two strata, into which the agitated fluid separates on rest; this indicates the absence of quinidine and cinchonine. It is doubtful if quinine can of itself cause salivation; a condition, known as cinchonism, has been met with, the chief symptoms of which are intense headache, accompanied by running at the eyes and nose. As it is not an uncommon procedure to commence a course of quinine by taking purgatives, the salivation might have been produced by calomel. Amorphous quinia may be produced by dissolving the disulphate of quinine in dilute sulphuric acid, and evaporating to dryness.—T. I. PRESTON.

[11911.]—**Lathe Head Mandril.**—In answer to "Anglo-America," I don't see how such bearings as he sketches would be applicable to an eccentric chuck, and I think they would be much more troublesome to fit than the ordinary ones to a lathe mandril, and, therefore, less likely to be well done.—J. K. P.

[11912.]—**Chemical.**—For the purpose of initiating the student into the changes brought about by modern theories, I can recommend Hoffman's "Introduction to Modern Chemistry," 1851; and Odling's "Manual of Chemistry."—S. BOTTONE.

[11912.]—**Chemical.**—Fowne's "Chemistry," published by Churchill.—T. I. PRESTON.

[11929.]—**Chemical.**—Nothing.—S. BOTTONE.

[11951.]—**Photography.**—Procure a small keg or cask, stand it on end, insert a small tap at lower extremity. Place your cask in some convenient mode, so that the waste water may run down some sink. Fill your cask with water, place your prints in a dish just below the tap. Now turn on the water in a fine stream, not exceeding the thickness of a straw. The superfluous water will flow over the sides of the dish, while the prints will remain in it. From six to ten hours will be required to remove entirely the hyposulphite.—S. BOTTONE.

[11961.]—**The Leclanche Cell.**—I believe that the crystals which form on the porous cell and on the zinc are a double chloride of zinc and ammonium. They are easily removed by soaking in warm water, and their production may be prevented by using only a half saturated solution instead of a saturated one, as usually directed. For such purposes as bell-ringing I do not think there is any cell to compare with the manganese, of which the Leclanché is the most readily obtained form. The zinc need not be amalgamated, but the force is somewhat higher with amalgamated zinc.—SIGMA.

[11963.]—**Brass Springs.**—Brass can be tempered by hammering. Take a stout brass wire, place it on a smooth steel anvil, beat it to the required thinness with a round-faced hammer, and you will get it as "springy" as you please.—S. BOTTONE.

[11965.]—**To Blacken Brass.**—Pass over the surface to be blackened with a sponge dipped in a dilute solution of bichloride of platinum.—S. BOTTONE.

[11966.]—**Dandelion Roots.**—Is in perfection now. Cannot recommend the wine for medicinal purposes. The extract, or even the simple decoction, is preferable. Flowers much used by druggists to make extract. Capital tonic, bitter and aperient, especially recommended in cases of torpidity of the liver.—S. BOTTONE.

Carbonic Acid in Charcoal.—Dr. H. Vohl, of Cologne, supposes he has proved that the carbonic acid obtained by heating charcoal is not derived from the charcoal itself, but is carbonic acid occluded by that substance, being derived from the atmosphere. He states that charcoal freed from carbonic acid, and made to absorb oxygen, does not show a trace of the former gas, even when heated to 680° Fahr.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "F. J. G." has answered 11275; "H. B. E.," 11452.

QUERIES.

[11984.]—**Tea Testing.**—Being anxious to test my daily manufacture of tea—in cup or infusion, for strength, flavour, pungency, and briskness; as to good quality; and sourness, mustiness, and flattishness, when of bad quality, throughout the season—but not knowing how to set about it, would any of your readers put me in the way of doing so, as to requisite chemicals (if any) and instruments for the tests, together with detailed information as to operations for the different qualities? Is there no instrument, or cannot one be introduced for testing tea in strength, in the same manner as they tell spirits? If so, where is it to be had, at what price, and is it efficient? If not, could any one suggest a suitable instrument? We generally test by tasting as the brokers do, but it is not at all times satisfactory; for one's stomach may be out of order, or may be, sickness may prevent one, or one's mouth may be out by having attended a dinner party, &c., the previous night.—ANON.

[11985.]—**Machine to Cut Leaves.**—I wish to cut 240lb. of green leaves daily (from 3in. to 8in. in length) as chaff is cut. Can any one suggest a simple and suitable machine, to be worked by a couple of boys (one feeding the machine, and the other working it)? A detailed illustrated explanation will oblige—ANON.

[11986.]—**Chemical Properties of Tea Leaves.**—What properties are there in tea leaves, to give the manufactured tea therefrom strength, briskness, pungency, and flavour? How do the chemical actions take place to secure the above qualities?—ANON.

[11987.]—**Draft Holes in Fireplaces.**—Of what use are draft holes in fireplaces, and why? Previous to my arrival here some fifty fireplaces were erected for drying the green tea leaves, but without draft holes. I wish to know whether this has any effect on the fires, and what effect? and why would draft holes in them remedy them in any way? I forgot to say over each of these fireplaces there are five trays for drying the leaf in, and a sixth for catching the tea dust, to prevent it from falling into the fire.—ANON.

[11988.]—**Dyeing and Fixing.**—Wishing to dye with Judson's dyes, can any one inform me what are the several mordants for fixing the different colours sold, and how the operation for the different colours is to be carried on?—ANON.

[11989.]—**Extract of Tea.**—How can I make the extract of tea, so as to be used in the same manner and proportion as the essence of coffee? Explanatory illustration of instruments and operation will oblige—ANON.

[11990.]—**Ice Making.**—It is 97° thermometer in the shade, water lukewarm. Can any one suggest a compact, portable, and cheap machine, for making from one to two pounds of transparent or other ice at a time? The materials to make it with I should like to be procurable in India, and of that description as to be used over and over again without much loss of them. The machine to be capable of cooling a couple of bottles of liquor when ice is not being made; and the machine to be as small as possible. An invention of a machine was advertised in the *Lancet* of February 6, 1864, procurable for a few shillings, by which transparent ice could be made, and supplied by Brown Bros., of 43, Cranbourn-street, W.C., London. An explanatory and detailed illustration of this machine will greatly oblige.—ANON.

[11991.]—**Focal Length of Lenses.**—What is meant by the focal length (as 4½in. or 3in.) or focus of a lens in camera or telescope? How is it ascertained, and why is it necessary to know it?—ANON.

[11992.]—**Edwards' Graphogenic Apparatus.**—An illustrated explanation of this apparatus in detail, with the working of it, will oblige—ANON.

[11993.]—**Photographic Process.**—Is any one acquainted with a process of a dry nature (as dry plates) which is as good or at all approximate to the wet collodion processes, in certainty, perfection of detail, and rapidity of action? The process, if possible, must admit of any number of plates being prepared at one time, keep for weeks and months (the longer the better), not needing to be developed for days after exposure. The plates must bear carriage for the use of a tourist, and, if practicable, prepared on mica instead of glass, so as to involve as little weight as possible. Information on the preparation of plates, exposure, development, with chemicals, &c., necessary, and operations of working, will greatly oblige. I want it for one of Murray and Heath's miniature photographic apparatuses for moving objects.—ANON

[11994.]—**Instrument for Measuring and Recording the Amount of Light for Photographic Purposes.**—Is there any portable and cheap instrument invented for the purpose of recording the differences of light (sun) on different occasions or days, which could be temporarily fitted to a camera and taken off and on in a moment, so as to aid photographers (amateurs) for a certainty, as to the time requisite for exposure of the plates? Of course it must be procurable, with information as to the differences of light, when using lenses of different sizes and qualities, and size of opening used.—ANON.

[11995.]—**Patent Rights.**—Somewhere about ten or twelve years since, I made a machine (which is still in use), and I have noticed that recently a patent has been granted for one similar to another firm. Can you or any of your correspondents kindly inform me whether this patent affects me in any way?—MATTHEW COUCHMAN.

[11996.]—**Deafness Arising from Cold.**—Will any of "our" readers kindly inform me of some effectual remedy?—R. C. Y.

[11997.]—**Warming Greenhouses with Gas.**—"Houblon" will greatly oblige by giving a drawing and fuller description of his apparently excellent plan for the above, mentioned in reply 8735, p. 44, Sept. 29, 1871, and say if it stood the test of winter.—H. B. R.

[11998.]—**Dry Solder.**—What is meant by dry solder?—W. T. M. D.

[11999.]—**Chuck.**—Will any one give a description of the interior of the American chucks, as advertised in the ENGLISH MECHANIC?—W. A. M.

[12000.]—**Insects in Tables and Chairs.**—How can I stop these? They are, I presume, what is commonly known as wood lice; the holes are numerous and about as large as pinholes. I should be glad of a recipe for arresting further depredations.—FOX.

[12001.]—**Hair Turning White.**—To "AULD REEKIE."—Will "Auld Reekie" (reply 11811, p. 261) say whether I am to put the cantharides to the glycerine and lemon as well as oil and lime-water or not? Also I should like "Auld Reekie's" advice or opinion upon the following: My hair turned white, also one eyebrow, at the age of sixteen, present age twenty, is there any cure? If not, is the above recipe the best I can use to prevent its extending or turning all my hair white?—J. A. A.

[12002.]—**Zinc for Aquarium.**—Will any of your correspondents kindly inform me if an aquarium partly constructed of zinc be detrimental to fresh water fish, or the best means of constructing an aquarium?—A THREE YEARS' SUBSCRIBER.

[12003.]—**Keeping Dust from Turret Clocks.**—A valuable turret clock is being erected in a position where there will always be a good deal of dust: a glass case has, therefore, been ordered for it, which is to be made as dust-tight as possible. There seems to be some danger (when a case is nearly air-tight) of moisture condensing on the works of the clock in damp weather. (See "Clock and Watchmaking," Weale's series, p. 218, 5th edition.) Of course this must be prevented from happening in some way or other. Would it answer to put a jar half full of strong sulphuric acid into the case? Or would a jar full of pieces of calcium chloride be better? Could not the jar full of the same pieces be used for a long time if it is heated in an oven occasionally, to drive off the moisture which the chloride has collected? Sulphuric acid gives off no corrosive fumes at ordinary temperatures, is calcium chloride equally harmless?—E. G. LODER, Trinity College, Cambridge.

[12004.]—**Nitrate of Soda.**—Can any correspondent inform me concerning nitrate of soda, whence does it come, and is the supply likely to be permanent? When genuine what is there in it which causes such extraordinary effects on the wheat plant?—A FARMER.

[12005.]—**Fleming's Locking Corks.**—What is the principle of Fleming's locking corks?—PHILANTHROPIST.

[12006.] — **Liquor Oils.** — Would some of your numerous readers who understand chemistry well (and they are many), confer a favour on me, by giving, through your valuable journal, the process of manufacture of the different liquor oils, or essences, that are used by brandy, gin, rum, cider, and wine makers, with the different articles used? also, the whole process of manufacture? If some one would confer this favour, and the editor not consider too much space occupied, they would very much oblige—R. R.

[12007.]—**Purification of Iron.**—Can any of your readers inform me whether a stream of superheated steam with atmospheric air has ever been used in the puddling of iron, with a view to separating the sulphur and phosphorus—as sulphuretted and phosphoretted hydrogen—and would some of your readers practically and chemically acquainted with the subject, give me their opinions on the matter?—WM. U. BUEL.

[12008.]—**Cork Cutting.**—I should feel obliged if some kind reader would furnish information through the MECHANIC regarding the best cork-cutting machine, and price of same. Also whether it can be worked by a person unacquainted with cork-cutting, and if the corks so cut are quite as good as those cut by hand.—CORTEX.

[12009.]—**Photographic Lens.**—Will some photographic friend kindly inform me whether it is possible to take a picture by the calotype process, with a single double-convex lens? If so, what would be the right size and focus for pictures 4½in. × 3¼in.?—A BEGINNER.

[12010.]—**Bee Management.**—I am sure we all appreciate Mr. Abbott's letters on bee management. I have, like him, been obliged to have recourse to feeding, having noticed several dead larvæ at the mouths of the hives, which were strong and would have swarmed ere this, but for the wet and cold weather. But I would ask Mr. Abbott to explain what he means by "Some fitful hours of sunshine made them believe in the almanack." By them he means the bees, I suppose, and again, "they have exhausted their store of honey through faith in the infernal almanack." Now, I have kept bees several years, and have never heard that bees have anything to do with almanacks, nor can I find any by searching in the hive. The Rev. J. G. Wood, in his excellent work on bees, says: "Would one could look at a few of the bee blue-books." Now, by this letter, it would seem that there are such things as books used, and faith put in by the bees. I am sure the Rev. J. G. Wood would like (and so should I) to see an almanack that the bees have read and have such faith in, even though it was an infernal one.—COLNEY HATCH.

[12011.]—**Magic Lantern Effects.**—Can any correspondent inform me how to make a slide to exhibit falling snow in the dissolving view lantern?—likewise moonlight effect?—DRAWDE T. REHCTELF.

[12012.]—**Water Power.**—"Ignoramus" would be pleased to learn what actual power he could procure from a 3in. run of water (through a 3in. pipe) constant? and what would be best medium of power, water-wheel or turbine, and cost of each, and how made? Fall 6ft. at least.—IGNORAMUS.

[12013.]—**The First Watch and Clock Made.**—As it happens to be my lot to make a living by watches and clocks, I have been anxious for years past to get some information regarding when, and by whom, the first watches and clocks were made; also on their improvement up to the present time. Will any reader kindly inform me through the ENGLISH MECHANIC if such is in print?—A GLASGOW HIGHLANDER.

[12014.]—**Organ.**—To "J. D."—Will "J. D." or some other correspondent kindly answer this question. The pipes of the organ are placed, are they not, upon long boxes connected with the bellows, with a small pallet to each pipe, inside the "box." How are these pallets connected to the trackers coming from the keys? If you bore a hole through the bottom of the "box," I fancy you will lose a large quantity of wind, for you could never get them air-tight, and yet be able to move easily enough.—E. C.

[12015.]—**The Gyro Pigeon.**—Can any of your readers inform me if the gyro pigeon, described on p. 222 of the MECHANIC, No. 373, can be made to describe its flight, right, left, or straight forward, by any arrangement of the apparatus? What is the price? Can the shot marks be readily effaced after one good hit, so as to show clearly the result of the next shot? and how far does the pigeon fly before reaching the ground? As I want a little practice before August 12, I shall be greatly obliged for a little information.—A DEAD SHOT.

[12016.]—**Cutting Cardboard Mounts.**—Will any correspondent tell me how the white Bristol board used for putting over water-colour drawings, &c., is cut? The cut is so clean, and the bevel usually so true, that it looks as if it were done by machinery. Is this work done by a machine or by hand? What tool is used, how is the board kept steady, and on what is it placed for cutting?—J. K. W.

[12017.]—**Electro Iron.**—Can any of your readers tell me how to deposit electro-iron? I do not mean the steel facing of copper, but a fair deposit of reguline iron. I have specimens of electro iron from Russia (by Jacobi's patent) but can not find any one in England who will do the work. I have myself deposited a thin film of bright iron, but it then turned to mud.—BAFFLED.

[12018.]—**Star Distances.**—Will Mr. Proctor or "F. R. A. S." kindly inform me what are the distances of stars, from the 1st to the 12th magnitude, inclusive?—DORSET.

[12019.]—**Damp Walls.**—A wash is frequently used to prevent damp walls, consisting of a solution of soap, allowed to dry, and followed up by a solution of alum in water. Sometimes soap, linseed oil, and alum, are mixed and applied at once, and the efficacy of both processes is, I believe, well attested. Will "Sigma" or Mr. Bottone kindly tell the chemistry of this?—A. C. G.

[12020.]—**Tireing Cart Wheels.**—Could any one oblige by informing me the way to tire a dished cart wheel? Say a wheel 3ft. 8in. high, 1¼in. dished, how much should the bar be hollow on the edge, to come the same dish or bevel as the wheel? Any information will oblige.—U. V. W.

[12021.]—**Turning.**—What is the best kind of chuck to be used for turning down castings of model engines?—GLATTON.

[12022.]—**Forest and Rainfall.**—It is asserted that the destruction of forests causes a diminution in the rainfall. Where can the best information on this subject be found?—ELM HIRST.

[12023.]—**Dissolving Bone.**—Will any of "our" readers kindly inform me by what means I can dissolve bone, so as to mould it to any shape required?—A. S. A.

[12024.]—**Photographic.**—Will some reader kindly tell me how to get out of this fix? I have a ½in. plate portrait camera and lens which is quite light-proof, but when I take a portrait I focus the face, and I find it nice and sharp, but all round—hair, neck, hands, &c., are very dull. I photographed a large placard the other day, and the letters in the centre of it were plain, but those above and below and each side of the centre are almost invisible. Are the glasses of the lens in wrong, as they have been taken out to be cleaned? If wrong, how should they be put in, or what else can cause it?—TOM IN A FIX.

[12025.]—**Chiding Stone.**—I have a print representing a large boulder lying on a large square slab of stone, with the name "Chiding Stone" under. Can any one tell me where it is?—J. K. P.

[12026.]—**Greenheart Timber.**—At a sale of surplus stores at one of the Government dockyards, I purchased a considerable quantity of greenheart plank. Not knowing what to do with it, and being utterly ignorant of its specialties, I laid it down for a granary floor, screwing, not nailing it down. Happening to take a strip sawn from the edge to get the planks straight and square, I was much struck with its wonderful elasticity, almost equal to whalebone. I had a rod of 1in. square prepared; this I supported on trestles 2ft. 8in. apart, and weighted with bricks in the centre. To my surprise this 1in. square rod took no less than 413lb. to break it. Under this load it gradually gave way, breaking up in long fibres almost like hemp in a rope yarn. I tried with other woods of equal size, and under similar conditions. Among the rest the heart of pitch pine; this broke short (without warning) under a weight of 323lb. My object in writing this is to get from "Jack of All Trades" or some other of your knowledge-imparting contributors, some account of this wood and its specialities. What is its action under the influence of the sun? Is it fit for outdoor work, in the shape of field-gates, &c., or for indoor work? Would it do for cattle-feeding troughs, or purposes where it is alternately exposed to rain, sun, or moisture? It is rather expensive working it for rough purposes, as it will not stand nails; splitting up so readily. Perhaps at the same time I might get a similar answer as to the specialities of Santa Maria timber, of which I bought one or two lots, and which I have been using up for door and window cills, and also with advantage for cart shafts. Any kind friend among your contributors who will give information on the above will greatly oblige—KHODA BUX.

[12027.]—**Albert Durer's Engravings.**—Will any one give some information on the distinguishing marks of original etchings by Albert Dürer? Where can undoubted originals be seen? Is the water-mark of the paper any guide? I have three; one, "The Anointing of the Body," has for the water-mark of the paper "A. M." Another, apparently a subject from the Apocalypse, is marked, as well as I can make out, "D. Riaw." The third bears the water-mark "Vienne."—KAPPA.

[12028.]—**Dimensions of Balloon.**—Can any correspondent give me the dimensions for a balloon to carry 120lb.? it would be inflated with pure hydrogen. Also I should be much obliged for the names and price of any good books on the construction of balloons.—THE ROLLING STONE.

[12029.]—**Object Glass.**—Why are some object-glasses balsamed? Is it to correct defects or merely to hold the lenses in place? Do balsamed glasses perform as well as those not balsamed? Would observing the sun disturb the balsam, thereby spoiling the view?—C. B.

[12030.]—**Sun Screen.**—If Rev. E. L. Berthon (letter 4037, p. 150) will oblige by stating the way to deposit the silver on the field-glass of telescope and proportions of chemicals required, I shall esteem it a favour.—C. B.

[12031.]—**Hot Peas.**—The hot-pea hawkers have a mode of cooking their peas that makes them very savoury, soft, and swollen, as big as, if not bigger than, when full grown, unplucked from the stalk. If any brother reader could and would describe how they are done, he would greatly oblige—POOR TEETH.

[12032.]—**Fishing Nets.**—Can any one give the particulars of process used by the French fishermen for tanning or barking their nets, thereby rendering it unnecessary to dry them occasionally, or re-bark so often as the fishermen of this country do? Cutch catechu and Gambier are the ingredients used here, but they do not seem to answer the purpose, as the nets require re-barking and drying often, whereas the French can be fished with for months without either.—ERIN.

[12033.]—**Waterproof Fishing Socks.**—Can any fellow reader tell me how I can make a cheap pair of waterproof socks? I have thought of indiarubber solution laid on canvas, but I am afraid it would be too sticky. Any information on the above subject will oblige.—WADER.

[12034.]—**Ordnance Map of London and Environs.**—The altitudes are given in feet above the approximate mean water at Liverpool. Can any of your readers inform me what difference there is between mean water at Liverpool and high water at London-bridge?—ROOK.

[12035.]—**The University of Turin.**—Will our kind friend Mr. Bottone give a little information as to the University of Turin? Whether Englishmen can be educated free, and any particulars suitable to a young man who desires to go there to learn the languages, &c.—SILEX.

[12036.]—**Engine.**—Would any of your correspondents favour me with an answer to the following? What would be considered the proper dimensions of a boiler for a small horizontal engine 1in. bore, 2in. stroke? and what would be the power of an engine of the above sized cylinder, and length of stroke?—F. GRAHAM YOUNG, S.D.

[12037.]—**Mining Query.**—What is fire-setting, and how is it applied?—WM. MCCULLOCH.

[12038.]—**Atmospheric Electricity and Magnetism.**—Will "Sigma," or some other kind reader, state how the amount of atmospheric electricity can be registered, what apparatus is required, and can it be procured at a moderate cost? Also, how is terrestrial magnetism observed? Can instruments for testing intensity be purchased of ordinary scientific instrument makers?—R. C.

[12039.]—**The Pressure of the Wind.**—Perhaps some of your correspondents might inform me if any experiments or observations have been made from which the following point may be determined. Suppose two polished plates, a foot square each to be placed, the one vertically, at right angles to the direction of the wind, and the other horizontally on the surface of the ground. Suppose the pressure of the wind, urging the vertical plate forward, to be equal to one pound, what is the amount of pressure exerted on the horizontal plate tending to move it forward along the ground, the wind, of course, being assumed to act only on the upper surface of the plate, and not on its edges? The particles of the air strike the surface of the horizontal plate obliquely, consequently the pressure of the wind is exerted obliquely in the plate. Conceive the pressure decomposed into two components, the one vertical to the surface of the plate, and the other horizontal. The question to be determined is, what is the amount of the horizontal component?—JAMES ELLIS.

[12040.]—**Navigation.**—Will some practical reader—say the mate of a ship—kindly tell me the best books to read, and the easiest way of picking up sufficient knowledge of this science to interest one, and to fill up some of the weary hours on board ship? Although not a sailor by profession, I have, in common with many others, often regretted my ignorance during the many long voyages I have made?—A. B. C.

[12041.]—**Burnishers for Brass-work.**—Will "Jack of All Trades," or any other of our readers, kindly inform me what kind of burnishers brass finishers use for burnishing their brasswork, either before or after it has been lacquered?—J. W. CARD.

[12042.]—**Boiler.**—I have a 1 horse-power tubular boiler, and will be glad if some of your kind correspondents will assist me in answering two questions. 1. It has two pipes inside from the bottom, each side meeting in junction, or T piece to a thin casing close up and under steam dome. I want to know the use of them. 2. The boiler plates are three-sixteenths of an inch in thickness in sides, one-eighth of an inch in back, and copper riveted. I want to know at what pressure I may work it with safety.—STEAM.

[12043.]—**Poultry Breeding.**—Could any of "our" readers inform me if there are any places in England where they breed poultry on a large scale for the purpose of profit? and if so, would they kindly say where, and any other information they could give me, as I want to inspect one, to enable me to commence operations myself?—C. H. C.

[12044.]—**Rosin Grease.**—Can any of your readers tell me how rosin grease is made, the materials used, quantity of each, and the process of manufacture?—INQUIRER.

[12045.]—**Analysis.**—Will G. E. Davis, or S. Bottone, or any other chemical reader, assist me in the following difficulty? I have a substance which I was told consisted of beeswax and sulphur, but I want to know the exact percentage. I was told by a Professor of Chemistry that beeswax could be dissolved in ether and alcohol, and that the sulphur would be left behind; but on trial I had no residue. I next tried dissolving in bisulphide of carbon, and then allowing to evaporate; but no crystals of sulphur were left. I think that the substance has been melted together, and then ground to a fine powder. I am very anxious to be able to get at its proportions. I may say it is used in the construction of telegraph cables.—LICTOR.

[12046.]—**Endorsing Ink.**—Will some reader of "ours" oblige me with a receipt for endorsing ink for brass stamps? The desiderata are that it shall dry rapidly on the paper, but not dry on the ink pad.—F. V. H.

[12047.]—**Radius of Sector.**—Will "E. L. G.," "V. B.," "J. K. P.," or some other kind person show me, as simply as possible, how to find the length of radius of a sector (like figure in query 11166, p. 650, Vol. XIV.) when the measurement is given as chords; also, when given as curves?—T. E. G.

[12048.]—**Trip to Ireland.**—I intend, during July, spending a week in and about Dublin. I shall go from Liverpool direct to Dublin and places about Wicklow, Bray, and Parsonstown. I would like a reliable guide-book. I would also be glad of a good map, geological preferred.—A WANDERER.

[12049.]—**Aerated Water Machines.**—Would any reader inform me if there is a book on the construction and management of the above machines?—A MECHANIC.

[12050.]—**Socotrine Aloes.**—Will any of your readers inform me why it is this drug when ground varies in colour from a dark rich brown to a light drab?—B.

[12051.]—**Fire Engines.**—Will "Philanthropist," who, in No. 370, proffers further information in connection with Shand and Mason's steam fire engine, say what advantage is obtained from an air vessel being fitted to the suction side of the pumps in these engines?—A. GRAY.

[12052.]—**Rust in Brewing Water.**—Will any of of your numerous readers inform me how to construct a cheap filter to separate rust from water, imparted to it in passing through cast-iron pipes? I should require to filter about 1,500 gallons (say) in three hours. The distance from tank to inlet pipe overhead is 8ft., so I could not insert a thicker filtering medium.—CROMWELL.

[12053.]—**Canaries.**—I have a hen canary that is at present sitting on rotten eggs. She is constantly wheezing and sniffing as if she had a bad cold. Can any one inform me what is the cause of this? May this not have something to do with the rotten eggs? What is the cure for this? I have also a cock canary similarly affected. He is only now beginning to whistle, although he was a splendid whistler not long ago. I have given them egg and maw seed "with a muchness." Would it do them any harm to be put out in the open air for a few hours daily?—BED OF STONE.

[12054.]—**The Needle Lock.**—Can any kind reader give a detailed description of the needle unpickable lock?—A STRUGGLING ORGANIST.

[12055.]—**Works on Pedal Playing.**—Can any musical reader give the names of some of the best works on pedal playing for the organ?—A STRUGGLING ORGANIST.

THE *ENGLISH MECHANIC* LIFEBOAT FUND.

Subscriptions to be forwarded to the Editor, at the Office, 31, Tavistock-street, Covent-garden, W.C.

	£335 9 7

Water of the Deep Sea.—An apparatus for obtaining water from the depths of the ocean has been invented in Germany. An open vessel of suitable form and size is lowered by means of a rope, and when the desired depth has been reached an electrical current is transmitted through a wire that accompanies the lowering rope, and this current, inducing activity in an electro-magnet attached to the apparatus, releases powerful springs, which act upon stop-cocks, thus inclosing the water at any degree of depth. Some useful experiments in the determination of the carbonic acid in sea-water have been made through the agency of this apparatus.

Raphael's Cartoons.—With a view to preserve accurate copies of the cartoons of Raphael, the Lords of the Committee of Council on Education, acting through a committee, propose to select nine artists to make preliminary studies of given parts of three of the cartoons. Artists will first be required to complete an accurate copy either in water-colours, tempera, or oil, of a photograph, full size, of a head selected from the Beautiful Gate. These will be sent in to the Secretary of the Science and Art Department by the 31st of July, 1872. From the candidates so competing, nine may be selected to make accurate coloured copies from the cartoons themselves of portions set out by the committee as a final test.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, May 28, and unacknowledged elsewhere:—

T. T. Greg.—Stephen Reay.—J. P.—Arthur Monckton.—G. A. W.—J. A. R.—Guillaume.—James Best.—The Harmonious Blacksmith.—H. Franklin Parsons.—P. Santalinus.—Well-wisher.—James Gillingham.—John Wilkins.—S. Deacon and Co.—Jabez Francis.—Wm. Bowles.—Robt. W. Armstrong.—F. R. A. S.—Amateur.—Fitzgerald Kenny.—W. J. P.—Plumbago.—B. C.—Mechanic's Wife.—A Subscriber.—One in Need.—A. A. A.—A Silversmith.—Rev. H. C. Key.—Monte Cristo.—R. O. Berry.—Emily Jane.—R. A. B.—Philo.—T. A. A.—Maugh.—M. Paris.—S. M. Drach.—John Parsons.—Caloric.—J. H. Schucht.—G. C.—J. W. Fennell.—F. J. M. Evans.—X. Y. Z.—Cymro Glân.—John.—H. W. J.—W. R.—"Sir Roger."—Louisa.—Hautboy.—J. Barwick.—M. Y.—An Engine Driver.—A., Liverpool.—Lovatt.—T. Smith.—Thos. Fletcher.—Ashley Dakin.—J. Jeffcock.—J. E. Anderton.—H. W. Cartes.—J. Sheldon.—E. W. Braithwaite.—N. Jocelyn.—W. H. Neal.—Rev. C. R. Holmes.—W. H. Skelton.—W. M.—Gwastad.—M. Carter.—Points and Crossaways.—Joe.—M. A. Simmonds.—Outside Labourer.—Bed of Stone.—Beacon Lough.—Ko Jo.—H. B.—G. E. L.—G. J. C.—T. A.—George Richardson.—Joseph Arrowsmith.—E. W. S.—En Avant.—Hope.—J. H. L.—P. H. Holland.—Separator.—P. H. D.—J. T. Oakley.—E. N. Piers.—T. L.—B. F.—Sarah Lewis.—Jacques.—Erick.—J. W. Abbott.

J. BARWICK.—The errors in your letter on the alcohol question are your own. We cannot spare the space you require to correct them.

B. THOMPSON.—Yours on "Electricity" next week.

MINERVA.—Consult the *Times* advertisement sheet.

J. W. HAYWARD.—Forwarded to "Jack of All Trades."

E. L. G.—Your "More Proofs of the Deluge" next week.

A. BULL.—See "Philo's" letter on "Jack of All Trades."

W. D. L. writing from Wigan, says: "It is now Monday noon and I have not got Friday's paper. Please attend to it." We have nothing to attend to in such a matter. The ENGLISH MECHANIC is invariably published at ten o'clock on Thursday mornings, and if not delivered to subscribers in time, the fault is not ours.

CHARLES ROCHE.—Yours on "Debility" next week.

AN OLD READER.—If an old reader you are a negligent or forgetful one, or you would have known and remembered that your questions appertaining to chucks have been answered in various ways.

E. B., J. WILLIAMS, AND ELSMORE.—Queries too trivial.

E. L. D., J. JUDSON, and E. D.—The controversy on "How we see a Distant Object" is closed.

G. PINNINGTON.—We have no desire to withdraw our assertion in reference to "perpetual motion and perpetual fools," neither can we consent to a rediscussion of the subject, or any aspect of it, in our pages. You say you have "been working at the problem for thirteen years." We are sorry to hear it, as your time has been wasted. You cannot get more out of your "model machine" than you put into it, if you try till doomsday. We don't know Mr. Dirck's address.

F. J. GODDEN.—See reply by "Berks late Oxon Farmer," on removing bees.

HYDROLOGIST.—Can't you send something more substantial and definite on the question.

J. W. BODWELL.—Try to write on thicker paper and in a plainer hand, and we should probably insert.

W. C. M.—See "Sigma's" letter this week. The one paragraph we have given from the hand-book must suffice.

ISLA, A Pattern Maker, A. Z., Schoolboy, R. B., R. J., J. C., F. Stockwell, and Inquirer, are referred to indices to back vols.

ARTILLERYMAN.—Very often it is the case, but if you have anything really good, *make* the department listen to you.

E. E. DUNN.—Your request could not be complied with, except by a great and useless sacrifice of our space.

PULSE.—Ask your medical man, if you *must* imagine yourself ill.

DÆDALUS.—For information on mounting microscopic objects in damar, see pp. 183, 343, and 380, Vol. XIII.

E. L. G. AND THE POPE.—Mr. J. Birmingham writes:—"I see 'E. L. G.' has transferred his wrath from Lyell to the Pope. It is all very well to laugh at his theories and the literary style in which he tries to set them forth, but I put it to you as a gentleman whether you ought to publish his insults to a large class of your readers and contributors, and to the vast majority of civilised and Christian men." Perhaps "E. L. G." will take the hint.

W. C. M.—You have only sent part of the description of the watch-key. We hardly think its insertion would be worth the space it would occupy.

J. DIXON.—Please do not send us "one or two more communications" unless you treat the question more scientifically that in the present instance, for which we cannot find space.

J. D.—It is impossible to make out the impression of the coin sent.

TROUBLESOME.—None.

A. M.—Incubators have been frequently treated of in our columns, see, for instance, pp. 517, 566, 609, 668, 671, of our last volume, XIV., and a few replies in recent back numbers.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING MAY 21, 1872.

1385 O. Schulze, Finsbury-circus, for new and improved modes of using cork. A communication.

1386 T. Morris, Carlton-chambers, Regent-street, for improvements in domestic hydraulics.

1387 J. Clark, Belmont-terrace, North Kensington, for improvements in railway brakes.

1388 L. Engel, Mumford-court, Cheapside, for attaching thermometers to the handles of umbrellas, parasols, sticks, whips, and fans.

1389 W. J. Perkins, Baker-street, Portman-square, for a new or improved portable pneumatic apparatus or bracket for supporting music or books, and for any analogous use.

1390 T. A. Ashton, Sheffield, for an improvement in the manufacture of coal, coke, and other similar baskets or "skips."

1391 F. G. Fleury, Merrick-square, Southwark, and A. Tylor, Newgate-street, City, for improvements in apparatus for measuring and recording the flow of liquids or fluids.

1392 F. J. Hamel, Avenue road, Regent's Park, for improvements in machinery for the compression or consolidation of blocks of fuel or other material.

1393 I. Brown, Edinburgh, for improvements in utilising the substance or material known as the green sand of the lias formation, such as that found in coprolite beds.

1394 F. L. H. Danchell, Horwich, Lancashire, for an improved filtering medium.

1395 A. Slater, Liverpool, for improvements in printing from photography.

1396 H. Turner, Sheffield, for improvements in the application of wire to building and other purposes.

1397 B. Looker, Kingston-upon-Thames, for improvements in hollow ventilating bricks or slabs, and in arrangements to be used for ventilating horticultural and other structures.

1398 E. Watteen, Middlesbro'-on Tees, or improvements in machinery or apparatus for driving holes or drift-ways in rocks. A communication.

1399 E. Brook, Huddersfield, for improved machinery for facilitating the application of labels to bobbins and other articles.

1400 H. D. Plimsoll, Gordon-square, Middlesex, for improvements in miners' safety lamps.

1401 W. Loy and J. Pinker, Liverpool, for an improved packing for steam and other motive-power engines.

1402 S. P. Longman and E. C. Alderman, Islington, for registering the issue of tickets in public conveyances and elsewhere.

1403 H. H. Mawhinney, Massachusetts, for new and useful improvements in eyeletting machines. A communication.

1404 J. Arnold, West Smithfield, for improvements in "enemas" or injection apparatus.

1405 J. Howard and E. T. Bousfield, Bedfordshire, for improvements in the construction of ploughs and other tilling implements.

1406 A. Wilbaux, Paris, for improvements in the manufacture of paper hangings, and printing on stuffs or other similar materials.

1407 G. Newsome, Rochdale, for improvements in emery rollers for grinding cards.

1408 W. R. Lake, Southampton-buildings, for improvements in apparatus for producing compression upon metallic articles. A communication.

1409 J. H. Johnson, Lincoln's Inn-fields, for improvements in the treatment or ores, more particularly iron ore, for the manufacture of cast iron, wrought iron, and steel therefrom, and in the apparatus to be employed therein. A communication.

1410 J. H. Johnson, Lincoln's Inn-fields, for improvements in the manufacture of artificial manure. A communication.

1411 F. Trotman, Zoological Gardens, Regent's Park, for improvements in reflecting apparatus or fittings for use in lighting up theatres and other buildings.

1412 M. H. Larmuth, Salford, and F. Norton, Manchester, for improvements in standards or supports for telegraph-wires.

1413 S. Swain, Bradford, for improvements in gas fittings.

1414 W. Ross, Glasgow, for improvements in water-closets.

1415 B. French, Rochester, U.S., for improvements in lubricating compounds.

1416 S. Crabtree, T. Crabtree, and J. Crabtree, Manchester, for improvements in apparatus for singeing or firing cotton or other fabrics.

1417 J. H. Johnson, Lincoln's Inn-fields, for improvements in traction engines or road steamers, and other vehicles. A communication.

1418 W. R. Lake, Southampton-buildings, for improvements in mules for spinning. A communication.

1419 J. C. Browne, The Cedars, Hampton-wick, for improvements in the construction and in the form of vessels and boats.

1420 K. H. Cornish, Market-street, Mayfair, for improvements in apparatus used for the manufacture of gas, applicable also to that employed for the distillation of paraffin and other volatile fluids.

1421 J. Robey, Manchester, for a new or improved filtering medium, suitable also as a disinfectant and deodoriser.

1422 G. T. Bousfield, Loughborough Park, Brixton, for a new and useful improvement in apparatus for puddling and melting iron. A communication.

1423 P. Jensen, Chancery-lane, for improvements in the construction of coke ovens, in the utilisation of the waste heat therefrom, and in apparatus connected therewith. A communication.

1424 W. F. Henson, Cavendish-street, and H. Poole, Princes-street, Cavendish-square, for an improved manufacture of certain textile fabrics.

1425 W. R. Lake, Southampton-buildings, for an improved clamp for joining and securing ropes and for other like purposes. A communication.

1426 W. Glover, St. James'-road, Old Kent-road, and H. Sykes, Bankside, Southwark, for improvements in governors for motive-power engines.

1427 H. B. Fox, Oxton, Cheshire, for improvements in jugs for filtering and cooling liquids.

1428 K. Highton, M.A., Putney, for improvements in electric telegraphs.

1429 J. G. Briggs, Gracechurch-street, City, for improvements in the manufacture of stereotypes, and in apparatus for use therein.

1430 E. Grinerd, jun., Bernard-street, Russell-square, for an improvement in portmanteaus.

1431 A. Dereguancourt, Lansdowne-road, Hackney, for an improved method of manufacturing "cutters" for cutting out leather, cardboard, paper, textile fabrics, metal, and other materials, applicable also to the manufacture of spades, shovels, picks, hoes, pitchforks, and similar articles, and also to the manufacture of handles for such tools.

1432 J. Sutherland, Glasgow, for improvements in furnaces for puddling and re-heating iron.

1433 J. G. Hughes, Sunderland, for improvements in propelling steam ships.

1434 J. Carter and J. E. Carter, Halifax, Yorkshire, for an improved means or apparatus for moulding and casting lead, siphon-pipes, or stench traps, or other bent pipes or tubes.

1435 J. Sheffield, Glasgow, for improvements in furnaces for melting glass.

1436 T. Maynard, Dawley, Middlesex, for improvements in the manufacture of bricks and in the kilns employed therefor.

1437 J. V. P. Lagrange, Paris, for improvements in the treatment of saccharine juices and syrups.

1438 F. P. Preston, J. T. Prestige, E. J. Preston, and W. A. Prestige, High-street, Deptford, for improvements in apparatus for regulating the supply of water to water-closets and other places.

1439 A. Ray, Guildford, for the instantaneous transmission of telegraphic signals by the employment of two currents. A communication.

1440 Sir F. Blackwood, Marlborough Club, Pall Mall, for improvements in signal lanterns.

1441 A. Stewart, J. Stewart, and J. Wotherspoon, Coatbridge, Lanarkshire, for improvements in steam boilers.

1442 W. Gossage, Widnes, Lancashire, for improvements in the manufacture of certain alkaline carbonates for the purpose of obtaining carbonic-acid gas therefrom.

1443 G. Davey, New Cavendish-street, Portland-place, for improvements in the manufacture or artificial or imitation ivory, bone, horn, coral, malachite, and tortoise shell, applicable also to the production of a variety of substitutes for ornamental and decorative objects.

1444 J. Oldroyd, M. Olyroyd, jun., and E. Johnson, Dewsbury, Yorkshire, for a new or improved textile fabric, and the means or method of producing the same.

1445 J. Hall, Chancery-lane, for improvements in window-sash fasteners.

1446 G. J. Cross, New Cross, and A. Macgillwray, Camberwell, for improvements in means and in apparatus or appliances for clearing or cleaning tramway rails and the groves therein.

1447 J. A. Désgoffe, Paris, for improvements in the construction of telegraph posts and in the apparatus in connection therewith.

1448 E. Lofts, Cambridge, for a new or improved apparatus or arrangement for washing and rinsing bottles.

1449 G. B. Lewis and W. M. Ward, East Boston, U.S., for improvements in machinery for the manufacture of fishing and other nets.

1450 J. J. Kern, Oxford-street, for an improved combined cot and carriage or perambulator.

1451 J. C. Ellis, Piccadilly, for a convertible day and night railway carriage.

1452 W. R. Lake, Southampton-buildings, for improvements in pneumatic signal telegraph apparatus, chiefly designed for use in steam ships. A communication.

1453 T. A. Edison, Newark, U.S., for improvements in printing telegraphs.

1454 T. Sheehan, Dunkirk, U.S., for an improved process for steelifying iron.

1455 D. Johnson, Wrexham, Denbighshire, for an improved process and apparatus for washing, drying, decolorising and deodorising wheat and other grain or seed.

1456 W. Clark, Chancery-lane, for extracting the whole (or nearly the whole) of the anthracene contained in coal tar, and the pitch accruing therefrom, without either carbonising or decomposing the pitch. A communication.

1457 W. Morris, Deptford, for an improved mode or method of and means for establishing a communication with water or gas mains.

1458 W. R. Lake, Southampton-buildings, for an improved vehicle for painting. A communication.

1459 W. R. Lake, Southampton-buildings, for improvements in pianofortes. A communication.

1460 E. H. C. Menckton, Fineshade, Wansford, for improvements in the construction and arrangement of furnaces suited for smelting and fusing every description of ores and metals and glass, for heating gas and other retorts, and for other useful purposes, and in the means and appliances necessary thereto.

1461 W. G. Fearnley, Eardley-crescent, West Brompton, for improvements in apparatus for making illuminating gas, heating apartments or chambers, and other purposes.

1462 J. H. Weibel, Geneva, Switzerland, for improvements in apparatus for warming railway carriages.

1463 I. Liebich, Church-street, Camberwell-green, for an apparatus adapted to pianofortes for the purpose of varying the tones produced in playing.

1464 L. A. E. MacKinnon, Great St. Helens, London, for improvements in means or apparatus for use in extinguishing fire by the aid of carbonic acid gas.

1465 B. T. Newnham, Bath, for improvements in carriages and parts connected therewith.

1466 E. G. Brewer, Chancery-lane, for improvements in the manufacture of steel, steely iron, and homogeneous metal. A communication.

1467 A. Jaynor, Clapham-road, and M. Low, Lee, for improvements in steam boilers and furnaces for consuming smoke and gases.

1468 J. Spratt, Camberwell, for a new or improved food for cats.

1469 G. Bedson, Manchester, for improvements in puddling furnaces.

1470 J. H. Johnson, Lincoln's Inn-fields, for improvements in the manufacture of shoes, and in machinery and apparatus connected therewith. A communication.

1471 W. A. Hubbard, Ramsgate, for an improved level.

1472 C. G. Wilson, C.E., Royal Exchange-buildings, City, for an improved ordure road cleaner.

1473 C. H. Siemens, Great George-street, Westminster, for improvements in the supports, fastenings, and joints of underground telegraph wires.

1474 P. Jensen, Chancery-lane, for improvements in the construction of bridge piers, wharves, docks, and other hydraulic structures, and in apparatus therefor. A communication.

1475 R. Allan, Glasgow, for improvements in reflectors for gas and other lights. A communication.

1476 R. C. Menzies, Valleyfield, Scotland, and A. E. Davies, Worcester, for improvements in the manufacture of pulp for paper-making.

1477 A. Fryer, Manchester, for improvements in the treatment of cane sugar, and in machinery or apparatus to be employed in connection therewith.

1478 H. A. Bonneville, Piccadilly, for improvements in the production of motive power, and in the apparatus connected therewith. A communication.

1479 H. A. Bonneville, Piccadilly, for improvements in the construction of two-wheeled vehicles for the conveyance of passengers or goods on common roads. A communication.

1480 W. E. Gedge, Wellington-street, Strand, for an improved vertical hammer. A communication.

1481 A. V. de Mignot and J. Ganter, Bordeaux, France, for an improved generator of expanded gasses, intended to replace steam generators, and applicable to all kinds of engines.

1482 C. M. Lloyd, South Lambeth, for new or combined machine for sawing, moulding, planing, tenoning, and cutting out various forms of wood.

1483 C. Anderson, Bradford, for an improved apparatus for indicating the time or period at which passenger tramway cars or "busses" are due at various stages, or the route from starting point to terminus, and vice versa, and for indicating the clearing of pillar letter-boxes.

1484 J. Waddington and W. Garside, Halifax, for an improved grate-bar.

1485 S. Russell, Bayswater, for improvements in means and apparatus for stoppering bottles containing aerated and other liquids.

1486 W. Ashcroft, Wolverhampton, for improvements in presses and in "bale ties" relating thereto.

1487 J. Goodfellow, Blackburn, for improvements in metallic pistons.

1488 C. Richardson, Gracechurch-street, City, for improvements in looms for weaving.

1489 J. Imray, Southampton-buildings, for improvements in means of transit across rivers, estuaries, and other waters, and apparatus therefor. A communication.

1490 J. W. Whinyates, Liverpool, for improvements in propelling and steering ships and other vessels, and in machinery or apparatus therefor.

1491 W. Laidlaw and T. Fairgrieve, Galashiels, N.B., for improvements in carding and carding machinery.

1492 T. Christy, jun., and A. Bobrownicki, Fenchurch-street, City, for improvements in the treatment of ammoniacal liquors of gasworks, in order to obtain valuable products therefrom.

The English Mechanic
AND
WORLD OF SCIENCE AND ART.

FRIDAY, JUNE 7, 1872.

ARTICLES.

MR. PROCTOR'S ESSAYS ON ASTRONOMY.*

MR. PROCTOR is a puzzle to us. Scarcely are the sheets of one of his books dry from the press than he is again before us with another. *Uno avulso non deficit alter.* Each of his works appears contemporaneously with the announcement of its successor, and "the cry is still, they come." Our difficulty would be decreased did our author exhibit any signs of having overwritten himself, or of being guilty of mere bookmaking; but, assuredly, none such are apparent, each essay in the volume now under review bearing marks of the same careful study and deliberate preparation which have characterised all his former productions. Emphatically it may be affirmed of Mr. Proctor that his utterances are those of a man who has something to say, and not merely of one who has to say something. For, after all, the chief charm and merit of his writing lies in the evidence which it contains of earnest and original thought on the subjects which he discusses; it being as refreshing as it is novel, in these days of compiled scientific "Handbooks," "Manuals," &c., to find a writer to whom paste is as an occult compound, and scissors as unknown as they were to our progenitors in the Flint Age.

The ostensible object of the author of the volume now before us is to collect in it those essays to which he has had most frequently to refer in his "Sun," "Other Worlds," &c.; but it would be doing him an injustice to suffer it to be imagined that the present work is of interest only to the readers of his previous ones. Viewed merely as an independent contribution to astronomy, there are very few pages in it from which the student will not derive both pleasure and instruction; and, collected, as its contents are, from widely diverse sources, much in it must necessarily be perfectly new to any reader. The advantage of obtaining many valuable contributions to the proceedings of the Royal Astronomical Society—otherwise practically inaccessible to him—is one which many a young astronomer, especially, will appreciate.

The first three essays have reference to the life and work of that great astronomical philosopher who has but recently passed from among us, Sir John Herschel; and it is not uninteresting to us to note, in passing (implying, as we conceive it does, a tacit compliment), that the one with which the book opens is the *éloge* which first appeared in our own columns (ENGLISH MECHANIC, Vol. XIII., p. 195). On the whole, we may regard these three essays as conveying a very fair notion of Sir John Herschel's distinctive intellectual peculiarities, and of the kind and nature of the work which he did so bravely and honestly. More merely flattering notices of his labours may have appeared, but certainly no more impartial one has yet been given to the public. But, in saying this, we must not be held to subscribe wholly and unreservedly to all Mr. Proctor's dicta; for, to take a simple (even if it may appear a trivial) instance from pp. 36 and 37, it does seem to us somewhat "hypercritical" on our author's part to object to the very harmless pieces of pleasantry which he there quotes. Granting, which we do at once, that they would have been wholly out of place in formal papers, intended to be read before any of the learned societies, we really must take exception to the assumption that trivialities must, *ex necessitate*, be excluded from popular exposition; since we believe that, to a certain order of minds, these homely illustrations bring conceptions with an amount of force and vividness that no merely rigid enunciation of facts ever succeeds in doing. That "*Dulce est desipere in loco*" is as true now as it was when Horace wrote it, 1900 years ago; and it is a little hard upon the man of science to deprive him of an instrument which is wielded with effect in the Senate, at the Bar, and even in the Pulpit. Before dismissing the particular papers which we are now discussing, we would invite the especial attention of astronomical amateurs to the remarks and protest made on pp. 43 and 44. It would be well if these could be reprinted on a large card and hung up in every telescope-room in the kingdom. Notably would we recommend the Observing Astronomical Society to reproduce them in a pamphlet form, and circulate them among its members. Real service might, in that way, be done to science.

The fourth essay is on Mars; one of the subjects which Mr. Proctor has made peculiarly his own. This gives a mass of detail as to the physical structure of the planet's surface; and the means adopted by the author to determine, with very refined accuracy, his precise rotation period. In connection with this essay we would point to the diagram of the orbits of the Earth and Mars, in the plate facing p. 51, as an example of the *thoroughness* of all Mr. Proctor's work. If there be one thing rather than another which is executed in a perfunctory manner in popular works on astronomy, it is the drawing of diagrams; a series of concentric circles, with the most absolutely hap-hazard proportion subsisting between their radii, mostly doing duty for delineations of the various planetary orbits. The particular diagram of which we are now speaking presents an extraordinary contrast to this slipshod kind of work, being most carefully and elaborately drawn to scale; and, the nodes being marked and the inclination of the orbit of Mars to the ecliptic given, we would suggest to the student that it would be a profitable exercise to obtain a couple of sheets of cardboard and reproduce the plate under discussion in, as it were, a solid form. He would hence gain a more vivid idea of the relations subsisting between us and our neighbour in space than he could derive from almost any amount of reading.

The three succeeding essays relate to the planet Saturn. With reference to these, it will be sufficient to note that they are by the author of "Saturn and its System;" the frontispiece of which grand monograph, by the way, decorates the present work also.

The next four papers, on the November shooting stars, and on meteors generally, will be read now with considerable interest in connection with Schiaparelli's extraordinary discovery (for which the Royal Astronomical Society granted him its gold medal in February last) of the correlation of these marvellous luminous streams and comets.

From meteors to the zodiacal light, and hence to the solar corona, the transition is natural, and these subjects are treated in the sequence indicated. How thoroughly Mr. Proctor crushes the hypothesis of the terrestrial origin of the corona, the reader must go to his book itself to learn; and it must, we think, be a source of some gratification to him to have found how absolutely and entirely the recent Indian eclipse observations settled the question of the character of this stupendous solar appendage, and justified the views which he advanced, on theoretical grounds, so, relatively, long ago. Surely this power of vaticination is the glory, as it is the crucial test, of true science; the future is opened to him who will read it aright, and the prophet and the philosopher are one!

"The Sun's Journey through Space" deals with a problem which has successively engaged the attention of Sir William Herschel, Otto Struve, and the present Astronomer Royal; of which, however, all that can be fairly said is that that existence and direction of such motion is demonstrated. "Coloured Suns" has reference to those exquisitely tinted gems which spangle our night sky; and "News from Sirius" to a subject which was treated in a popular form in our eleventh volume (p. 361) by one of our own correspondents.

The succeeding essay on "Equal-surface Projections of the Globe," is but a quasi-astronomical one; but it appears as a necessary introduction to its successors, which contain the author's speculations on the physical structure of the sidereal heaven. Every word of these will repay perusal. There are, further, three appendices, two having reference to subjects discussed in the main body of the work, and the third treating of the approaching transit of Venus in 1874. Here, again, we have some of Mr. Proctor's exquisite and admirably accurate delineations of the aspect of our own world, as viewed from the Sun during the passage of Venus across his face.

Regarding the work as a whole, it is impossible to speak of it otherwise than in terms of very high commendation; but we here and there come upon statements, or modes of expression, to which it is difficult, unhesitatingly, to subscribe. As examples to illustrate this assertion we would refer to a foot-note on p. 181, in which the hypothesis is advanced that the earth, as viewed from Venus or Mercury, must sometimes look green, and sometimes "dun or fawn coloured;" this opinion being founded on the assumption that the ocean would appear bluish green, and the land on the average of a brownish tint. Now, excluding altogether the mass of cloud, which covering as it does no inconsiderable portion of the earth's visible hemisphere, would reflect a brilliant faintly yellowish white light, we would merely observe that the larger oceans are of a black-blue tint, rather than of a bluish-green one; and that, considering the enormous area of land covered with vegetation, it is very improbable that it should (save over relatively minute areas) exhibit a *brown* hue. Portions of the earth's surface, like the African deserts, would no doubt look buff or dun coloured, *assuming the superincumbent atmosphere to be free from cloud;* but it surely cannot have escaped our author's recollection, that during the very eclipse (the one of 1870) with reference to which he calls in his conjectural terrestrial tints to account for an observed greenness of the Moon's dark body, a very large proportion of the visible hemisphere was covered with cloud, and that to an extent which was very nearly rendering all observation nugatory. Certainly the African continent seems to have been shrouded in an impenetrable pall. *Mutatis mutandis*, the same observations would apply to the eclipse of 1860; since, if we have reason to expect any continent to look green, as viewed from external space, it would be that of America, with its virgin forests and millions of acres of prairie and savannah. Yet we are told that during the eclipse of 1860 the Moon "presented a brown hue," she then being mainly illuminated by earth-shine from America. Again, on p. 280, we find a reference to Mädler's theory of the orbital motion of our system round Alcyone, a motion which we conceived had long been held to have had its only warrant in that astronomer's imagination. And further, in the essay on "A Novel Way of Studying the Stars," on pp. 308 and 309, we find our author using the words "higher" and "lower," as applied to star magnitudes, in a way which we think open to question. In ordinary parlance we should call 2 a *low* number, and 520,000 a *high* one. Why, then, a star of the first magnitude should be spoken of as of high magnitude, and one of the tenth as of a low magnitude, is not, at first sight very apparent. Even admitting that reasons may be advanced in justification of this nomenclature, we cannot but regard it as decidedly perplexing to the student.

Five misprints, and as far as our somewhat careful examination has extended, five only, disfigure the present volume. The first is on p. 72, where "line of light" appears for line of sight. The next on p. 89, where the compositor has spoken of examining Saturn "with a powerful microscope!" the third, on p. 91, where "Handibook" stands for Handbook; and the fourth is in a foot-note on p. 185, where "superior conjunction" is printed for inferior conjunction. The blackness of Venus's disc in contrast with the surrounding sky during her *superior* conjunction, would, we are tempted to think, astonish observers very much indeed. The last we have noted is on p. 256, where the northern horizon is called the "southern horizon."

We can only, in conclusion, express a hope that our rapid survey of the leading features of this, Mr. Proctor's latest work, and our curt summary of its contents, will induce the earnest astronomical student to go direct to its pages for trustworthy information concerning the most recent results of cosmical investigation. From them he may learn, in a popular and most attractive form, what has been accomplished towards the solution of some of the very grandest problems which the human intellect has ever attacked.

We have reproduced on another page one of the essays, as a sample of the interesting contents of the book.

* *Essays on Astronomy.* By RICHARD A. PROCTOR, B.A. Camb. (Honorary Secretary of the Royal Astronomical Society). London: Longmans, Green, and Co., 1872.

TELESCOPIC WORK FOR MOONLIGHT EVENINGS.

BY W. R. BIRT, F.R.A.S., F.M.S.

THE GREAT SIRSALIS CLEFT.

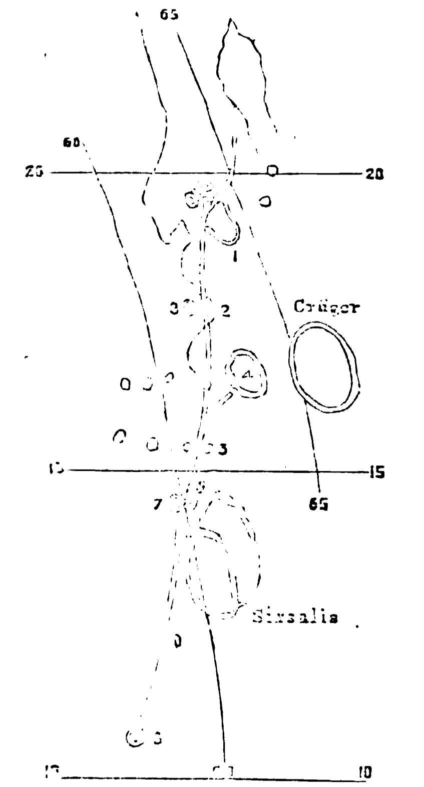
THE study of lunar clefts is increasing in interest, and, embracing as it does, a cl[illegible] of objects that differ so exceedingly from [illegible] broader features of the moon's surface, too [illegible] attention cannot be bestowed upon it. A cleft may be described as a narrow channel running through every variety of surface, sometimes penetrating and dividing mountain ranges or cutting down cliffs and headlands, at others traversing plains or existing in the interiors of craters, having tunnelled beneath the surrounding wall or pierced it to its foundation with a deep ravine. The appearance of such an object as viewed with a powerful telescope is not easily forgotten, the sharp linear character which it exhibits among the surrounding diverse forms rivets the attention and creates a desire to know what purpose so singular a feature subserves in the lunar economy. Often commencing and terminating with a small craterlet, clefts have been supposed in some way to connect distant openings. Our business, however, is not with conjecture, but with facts.

In No. 311, March 10, 1871, p. 577, we presented to our readers an account of a system of *ramifying* clefts which appeared to originate in the Crater Triesnecker. We have now the pleasure to notice a *single* cleft situated in a region of a different character to that in the neighbourhood of Triesnecker; it is known as the *Great Sirsalis Cleft*. The earliest notice of this cleft which we have been able to find is of the date 1824, by Lohrmann, who gives on his map, constructed from observations made in 1822 to 1836, a cleft commencing at the parallel of 20° S., passing northward partly through the crater 204, and thence to a small crater (No. 7 on the sketch accompanying this article), on the S.W. of the double crater 205 (Sirsalis). With the exception of an interruption by the crater 204 the cleft is *continuous* on Lohrmann's map. In the year 1832, October 8, Beer and Mädler observed and figured in their map the southern part of the cleft of a curved form *not figured by Lohrmann*, which they treated as a separate cleft, designating it Eichstadt γ. It is No. 64 in their catalogue. On October 26, 1833, they detected a portion of the northern part, terminating near Sirsalis, which they termed Crüger ε. It is No. 49 in their catalogue. It is likely the instrument which Mädler was then using was inadequate to show the intermediate portion figured by Lohrmann. In 1866 Julius Schmidt published his "Rillen auf dem Mond," in which he refers to Lohrmann's notice of 1824, and Mädler's of October, 1832; but he does not mention No. 64 Eichstadt γ, except as the strong southerly curved γ, having, as he says, seen the *whole* in 1850 and 1851. The length he gives is 45 German miles, or 207 English miles.

We are in possession of three unpublished series of observations of the *Great Sirsalis Cleft*. One by Messrs. Knott and Birt, made with Mr. Knott's Alvan Clark refractor of 7·3 inches aperture, on October 2 and 3, 1865. One by M. Gaudibert, with his silvered glass reflector of about 8in. aperture, on Nov. 6, 1870; and one by Mr. Knobel, with his 8½in. speculum, on May 21, 1872. As the study of this cleft is interesting on more accounts than one, and it can be well observed from thirteen to fourteen days of the moon's age, we shall give the observations principally as recorded by the several observers, illustrated by a drawing, in which each object specially referred to is numbered; the scale is that of Beer and Mädler's large map, the positions of the larger objects being taken from it.

The cleft is designated in the symbolic nomenclature III C ϖ^1, III Cσ^9, and III C μ^5, according to the areas in which its portions are situated. On October 2, 1865, it was observed to take its rise from the N.W. rim of the crater III C σ^1 (No. 1 in the drawing), the rim of which it cut through. On Lohrmann's map it is seen as extending S.S.E. from the S.E. rim of No. 1, a portion of it being figured as on the S.E. floor of this crater; according to Lohrmann it is *interrupted* by the S.E. rim. Beer and Mädler do not figure No. 1 *as a crater*, but as two nearly parallel mountain ranges with an oblique range between them on the north and nearly open on the south, and they bring the cleft *through the S.E. rim across the floor* to the W. rim, which is not disturbed. In M. Gaudibert's sketch of November 6, 1870, the cleft is shown as given by Lohrmann, the rim interrupting it, and it is described as passing *under* the wall. In Mr. Knobel's drawing of May 21, 1872, it is shown and described as cutting clean through the *walls* and floor of the crater. This is a point of no ordinary interest. Lohrmann and Gaudibert agree in its *not* cutting through the S.E. rim, Beer and Mädler and Knobel in the rim being separated by it. As regards the N.W. rim, Lohrmann and Mädler show it entire. Knott and Birt and Knobel speak of it as separated by the cleft, and Knobel alone shows both rims separated. In the earlier observations the rim appeared to be unaffected by the cleft, but in 1865, 1870, and 1872 it appeared as cut through. This sequence does not, however, characterise the S.E. rim at the epoch of Lohrmann, 1824, and in 1870 the rim was seen entire, but separated at the time of Beer and Mädler, and also in May, 1872. The alternation of the two appearances precludes the idea of the rim having existed in two different states, and it would be an interesting matter for inquiry as to whether Libration will account for these appearances, but the small number of observations will not allow of a solution. No. 1 has two craterlets on the S.W., they are both in Lohrmann and in Beer and Mädler. Mr. Knobel's N.W. crater is *double*, M. Gaudibert gives neither of them.

From the crater No. 1 the cleft was traced on October 2, 1865, through a depressed portion of the moon's surface, III C σ^2, cutting a headland III C σ^3 (No. 2 in drawing), which projected into the depression. In cutting through the headland the cleft grazed the east side of a somewhat conspicuous but small crater III C σ^4 (No. 3 on drawing). The depression, headland, and crater are shown by Lohrmann, but not by Beer and Mädler, and the crater is shown by Gaudibert and Knobel exactly as described above. The course



of the cleft was noticed in 1865 to be west of a crater III Cσ^5 (No. 4 in drawing) marked *a* by Beer and Mädler: it is in a line with Crüger and Fontana. On May 21, 1872, Mr. Knobel found a small craterlet *on the cleft* opposite to No. 4. From a point a little north of this craterlet Mr. Knobel observed a delicate offshoot from the main cleft towards No. 4. Returning to the observations of 1865 the cleft was seen to pass through a cliff III C σ^6, which is shown by Lohrmann, with the cleft to the east of it; Beer and Mädler also show the cliff. North of the cliff the appearance of the cleft was exceedingly distinct, as it crossed an elevated plateau, III C σ^7 to the west of a craterlet, III C σ^8 (No. 5 on the drawing), where it is terminated on Beer and Mädler's map. This craterlet is given by Lohrmann, who gives another close to and west of the cleft, which is given by Beer and Mädler, the E. craterlet being omitted by them. The W. craterlet was not seen by Gaudibert and Knobel in 1870 and 1872. From the point at which Beer and Mädler mark its termination its continuation was observed in 1865 along the N.W. slope of the plateau, III C σ^7, to near the south edge of the craterlet, III C μ^3 (*f* of Beer and Mädler, and No. 6 on the drawing) where it disappeared. It reappeared at the north-western border of the crater, III C μ^3 (I of Beer and Madler, and No. 7 on the drawing) descended, the slope was continued on the south-west of a ridge of mountains, III C μ^4, and finally terminated at the crater III C μ^1 (No. 8 on the drawing).

The craters Nos. 6 and 7 are shown by Lohrmann, and given by Gaudibert and Knobel, and in connection with them we have a repetition of the phenomena presented in the case of No. 1. Lohrmann, in 1824, showed the cleft as terminating at No. 7. Knott and Birt, in 1865, speak of its disappearance at No. 6, and reappearance at the north-western side of No. 7. Gaudibert, in 1870, delineated and describing it as crossing No. 7, and in Knobel's drawing of May 21, 1872, it is shown as interrupted by the east side of No. 7; indeed, its appearance is much as described by Knott and Birt. A careful determination of the circumstances of Libration, under which these different appearances are presented will go far to make us acquainted with hypsometrical and other relations.

On the 3rd of October, 1865, some further observations on this cleft were made by Messrs. Knott and Birt, the portion south-east of the crater No. 1, and designated III Cϖ^1, was seen to run along the foot of the cliff III Cϖ^4, the cliff forming the west side of the cleft which then *crossed* the crater No. 1, its course being diverted by the crater III C σ^{10} on the south-western part of the floor. It does not appear that either M. Gaudibert or Mr. Knobel saw this crater on the floor of No. 1 at the epochs of the later observations. It is desirable to include in the study of the clefts the search for craterlets on the lines of fracture, if such they be, and also to ascertain if in *any* instance a cleft really partakes of the nature of a tunnel.

BEDDING-OUT.

THE time for planting out the flowers which it is now the fashion to employ for ornamenting our gardens during the summer and autumn months having arrived, it may be as well if we say a few words on the subject, for many of our readers are amateur gardeners, and the present plan of "bedding-out," as it is called, is so much the rage that one of our daily contemporaries has actually devoted a column to the important question. Time was when our gardens, while presenting just as pleasing an appearance in summer as they now do, were not the blank deserted patches of black mould which is their chronic state under the fashionable régime during the most cheerless part of the year. Then we had flowers of some sort nearly all the year round, and, at least our parierres looked green, and gladdened the eye with vegetation if they did not exhibit the exuberant rejuvenescence of the genial and growing spring. Now all this is altered, and our public and private gardens are bare of bloom from October to May. It is true that our changeable climate is the cause in a great measure of this state of things, for the inclement springs of the last few years have done much to retard the "bedding-out" time even under the present system. But this shortening of our flower season is not entirely due to the treacherous weather of May, which was formerly the chief planting-out month; but is in a great measure occasioned by the vicious system of "coddling" in vogue with gardeners, amateur and professional. Geraniums, calceolarias, verbenas, and heliotropes are now forced along at such a pace that slight frosts in May, and even in June, affect their weak frames and unconsolidated tissues to an extent that a month of warm weather almost fails to repair. Instead of strong, healthy, autumn-struck cuttings, the market is glutted with cheap plants that a few months previously were merely shoots on the parent stem; and the consequence is that a cold, wet spring makes such wretched objects of them that the purchaser is disappointed, while no credit and, ultimately, no gain accrue to the producer. The present system is the most expensive style of gardening that can be adopted, and if the result is worth the candle it is worth while to insure obtaining it after the candle is burnt. The *Daily News* essays to prove that English gardeners are not masters of their profession, and that a considerable reduction in the first cost might be effected by the plan of propagating bedding-out stuff it recommends. "Ask an ordinary English gardener," says our contemporary, "to turn you out at the end of every May (say) three thousand plants, and he will be sure to ask you where is your greenhouse. Failing that, in his eyes, absolutely indispensable appendage, he will not be ashamed to own himself absolutely powerless to meet your wishes. In vain will you point to three or four large stout frames, solid at the sides and well-glazed, and inform him that he has at his disposal any amount of rotted leaves and stable manure. He will tell you that he can do nothing with them. They are cucumber frames in his eyes, and nothing more. Yet no better appliances, nine times out of ten, are at the command of the gardeners who decorate the beautiful villas that surround Paris with floral beauty from May till November, as they can testify who saw them deserted, but in all their beauty, when the Germans invested the great capital. If an Englishman wishes to attain the same results by the same small means, he must either become his own gardener, or he must break his gardener's will to his own. Given such a frame as we have spoken of, and four or five hundred of the hardier geraniums—such as Tom Thumb, Tom Thumb's Master, Lady Constance Grosvenor, and the Duchess of Sutherland—may with care be carried through the coldest and, even what is far more trying, the wettest winter. What are termed the foliaged pelargoniums, such as Mrs. Pollock, Bijou, and Star of Spring, will not, it is true, or but rarely, endure this simple treatment; but if the bright and flowering geraniums are preserved, the exquisite charm and variety that are given by foliaged plants can be still more easily obtained by other means. Abundance of white is a *sine-quâ-non* in the bedding-out style of gardening; and white may be secured to an unlimited extent without the aid of so much as a pane of glass. *Cerastium Tomentosum*, with its beautiful silver-gray leaves, is as hardy as common grass, and can be propagated by division either in the late autumn or the early spring. It is to be seen in almost every cottage garden, only there it is allowed to flower, as it must not be when intended to serve the purpose of which we are speaking. Another most useful and lovely white plant is the *Cineraria Maritima*, which has only to be sown under a south wall, from seed, in September, to be left out all the winter, and to be potted in spring, to make a famous show by the end of May. After white in importance comes blue; and the best, indeed the only good blue, unfortunately, the Lobelia, can be grown by any one who can make a hotbed of stable-manure in February. By its side, in the same manner, may be raised the Oxalis, that lovely bronze-coloured clover; the tall Perilla; and last, but anything but least, the Pyrethrum, or Golden Feather. Only, in all these instances, care has to supply the place of extravagant outlay; whereas extravagant outlay is just the one thing that delights the English gardener most."

Now, as a matter of fact, a greenhouse will cost no more to construct than the requisite frames to preserve and propagate an equal number of plants; while it is immeasurably more convenient for the gardener, requiring less labour and time for the due performance of the various attentions necessary for the health and welfare of his patients. Besides, frames with their fermenting masses of leaves and stable manure can be made to yield a more profitable return from early vegetables than "bedding-out" stuff would give—doing this, moreover, while the latter is in "winter quarters," and then coming in handy for the "hardening-off" process.

So much for the expense of the system. There is another side to the question as to the advantage of the present arrangement of flowering and brilliant foliaged plants. The gorgeous masses of colour are, no doubt, pleasing when set out in a harmonious manner, but they require to be surrounded with large masses of green, as much to exhibit their full beauty as to relieve the eye, which is apt to be dazzled by the glaring lines of yellow and scarlet—the *heat*, in fact, of the "painted carpet" produced by "solid planting." For this reason the "solid" style is utterly unsuited to small gardens where grass is conspicuous by its absence; and the plants should therefore be so placed that they may develop their foliage and permit the earth to be seen between them. Independently of all this, the aspect of the subject which we are most inclined to look at is left out in the cold—the individuality of the plants is utterly destroyed, and the mental pleasure which might be derived from a study of their physiology and life-history is lost in the mere sensual gratification of harmoniously arranged colours. The principal value of a garden to our readers consists in the facility which it affords for the study of vegetable physiology and the refining influence which a contemplation of the works of Nature must always exercise upon the mind. How this may best be carried out, with the further advantage of having flowers all the year round, we shall probably explain at some future time.

ELECTRICITY: WHAT IS IT?—II.

By B. Thompson.

ELECTRICITY A MODIFICATION OF THE MOTION OF HEAT.—In the second part of this communication it is my object to try and show that the motion which I think has been proved to constitute a current of electricity is only a modification of that of heat. Let us follow out the experiment touched on in the latter part of the former paper. When the current of electricity is increased, of course more electricity passes in a given time, but if no more matter be given for the electricity to be conducted by, the rapidity of polarisation must be increased, which, if it be motion, will show itself, as we have found it does, by increase of heat. Increasing the current still more we obtain further evidence of the increase of motion, for if the radiation from the wire be submitted to the action of a prism (of rock salt, because of the absorbing power of glass), we get no visible spectrum, but heat is found to exist greatest where it would had there been a visible spectrum—viz., just beyond where the red becomes visible, when the current, and therefore the heat, is still further increased. The fact of the spectrum becoming visible and extending is very significant, for it shows that more rapid vibrations have been compelled by the increased current, and it may be increased until the spectrum includes the actinic rays only shown by the phenomenon of fluorescence.

This similarity in nature between heat and electricity which we are discussing affords a ready explanation of the fact that a good conductor of heat is also a good conductor of electricity, and a good insulator of electricity a good insulator of heat: the same substance which stops the motion of heat stops that of electricity.

The phenomena of electrolysis, too, have an important bearing on this part of the subject, inasmuch as they present tangible evidence of the changes electricity works in compound bodies: so we will now consider them.

We know that no other forces, save heat and electricity, can effect the decomposition of any compound by apparently destroying the affinities of its elements for each other; we likewise know that electricity will decompose substances that defy any other means of analysis; and that electricity is convertible into the most intense artificial heat and light known. Can we fail to see the significance of this fact, which distinctly points to their similarity of nature? Even the simple evidence of their being convertible into each other is sufficient to show that they have a common origin, and beyond this we find they act in the same way, and have a connection so close that it is impossible to produce the one without the other.

Heat destroys the affinities between the constituents of compound bodies, or at least suspends them, by removing the atoms beyond the sphere of each other's attraction; and taking any example we may, the heat required to decompose a compound body is exactly the same in amount that was given off in its composition. For example, take the gases, oxygen, (O) and hydrogen (H); like all gases, they contain a large amount of latent heat. When they combine to form water OH_2, the greater part of this is given off, because the latent heat of water, and indeed all liquids and solids, is considerably lower than that of a gaseous body; but it will be seen at once that to again pass into the gaseous state, the oxygen (O) and hydrogen (H_2) must be supplied with the same amount of heat that they gave up when forming water, and with less than this amount they will not be decomposed, *except* when electricity is employed; that the electricity has given them a different force to that which they possessed before cannot be admitted, for they will yield just the same heat on again forming water as in the first case.

Again, if a current of electricity which produces the greatest heat and light known to us can also decompose substances which no other agent will touch, and that this decomposition can only be effected by an amount of heat being supplied to the molecules sufficient for their constituents to exist in an uncombined state—so far as we are able to discover—would it not be a remarkable thing if electricity suspended the affinities of an electrolyte by other means than that of heat (or motion) which it can supply of such great intensity?

I believe I am right in stating that when the temperature of water is raised to about 200° C. it is decomposed; this being the case, we may with reason conclude that virtually a heat of 200° C. is given out in the combination of oxygen and hydrogen, and forms water, and therefore that a motion corresponding to this heat must be supplied by the electric current when it effects the decomposition of water, and this supposition is perfectly consistent with fact, for a very powerful current is required to decompose water alone; and the heat developed in a bad conductor, such as water is, increases enormously with the augmentation of battery power. Here, then, I think, we can approach nearer to the theory I am trying to explain than we have hitherto done; for, besides having the conditions necessary to produce the required heat for the decomposition of OH_2 (water)—a powerful current and poor conductor, itself a proof almost of the agency by which the water is decomposed—we can (retaining the same arrangement of decomposing cell) apply heat direct, instead of the electric current, with exactly the same result. Thus, if the platinum electrodes of the voltameter or decomposing cell be heated by the oxy-hydrogen flame, the water is decomposed the same as with a battery; showing, again, how intimately connected the two modes of motion, of heat and electricity, are.

The influence of pressure in the decomposing cell also tends to confirm this theory, for, if an electrolyte in a decomposing cell be submitted to pressure, the decomposition is entirely suspended. The expansion consequent upon increased temperature and ultimate decomposition being prevented, the current manifests itself as heat, instead of being rendered latent; observing exactly analogous laws to those of heat in relation to constant pressure and constant volume.

Following the above course of reasoning, I think we shall be able to comprehend more clearly what occurs in a decomposing cell or ordinary voltaic battery. The first effect of the voltaic current is to polarise the molecules of the electrolyte, which, I think we have proved, is accompanied by a motion of them; this motion represents, or is virtually, a certain amount of heat; indeed, a great part is manifest to us as heat; and if the rapidity of vibration is sufficient, the heat is supplied requisite for the constituents of the compound to exist separately; of course, this amount varies with the compound being decomposed. In the case of water, as we have before shown, the heat required is very great. When, however, a small quantity of sulphuric acid (SO_3HO_2) is added, the water is decomposed readily by two or three batteries, on account of a secondary action. O being liberated at one pole and H_2 at the other, the SO_3 (sulphuric anhydride) combines with another molecule of H_2O (water) to form again SO_2HO_2 or H_2SO_4, and so the action is continued.

I have taken all along water as the example to work with, but any other compound will answer just as well, and the same reasoning apply to it; for instance, take $CuSO_4$ (sulphate of copper), where we have a compound in which the base Cu (copper) gives out very little heat in combining with H_2SO_4 (sulphuric acid): indeed, it does not combine very powerfully at all, but is easily displaced by other metals; in this example of weak affinity we might reasonably suppose that a weak current would effect their decomposition; such is the case, $CuSO_4$ is even decomposed by one cell of a battery.

Going a step further to the voltaic cell itself. I think it is very generally admitted now by scientific men, that "chemical affinity" is identical with "electrical attraction;" indeed, modern chemistry divides the elements into chlorous and basylous, or + and —; and it will be admitted that all bodies vary in their susceptibility to electrical action; or, if we may use the term, in their affinity for it. Friction is the readiest method of developing it, and when developed in this way is called statical electricity.

The theory to account for this which finds most general acceptance is, that the development of electricity is the result of the separation and renewal of contact between dissimilar bodies, and electricity is distributed amongst them in quantities proportional to their affinity for it (or may we not say to their power in rendering it latent?). Now, let the affinity of glass for it be represented by 4, and the affinity of a rubber of silk by 6, making together 10. When these bodies are brought together, this relative affinity may be supposed to be charged, the electricity being nearly equally distributed over the two bodies; the affinity of the glass, then, in this case, would be increased from 4 to 5, the affinity of the rubber decreased from 6 to 5, the total, 10, remaining the same; when we separate the rubber from the glass, or break the contact, the original affinities, 4 and 6, are restored, whilst the new distribution, 5 and 5, remains; the quantity of electricity in the glass, therefore, has been increased by 1, and hence is positively electrified and the rubber negatively.

The same kind of reasoning must be employed to explain the effect of contact between the dissimilar metals in a voltaic battery. It was this behaviour, probably, that led so many of the earlier electricians to believe that contact alone was necessary to generate a *current* of electricity.

Now, taking one of the simplest voltaic batteries—a plate of amalgamated zinc and a plate of copper immersed in dilute sulphuric acid—so long as the plates remain unconnected no current circulates, nor does any decomposition occur, at least, very small in amount, if any, due to the ordinary affinities of the plates for the elements of the compound; but when the two metals, zinc and copper, are connected by a conductor, powerful chemical action ensues, accompanied by a current of electricity, which, indeed, it has generated. The strength of the current, too, is always proportional to the amount of zinc dissolved in a given time, and it is one of the important points which should be noticed, as will be seen afterwards.

The amalgamated zinc has little power of itself to separate the constituents of the liquid in which it is immersed, but on receiving additional assistance from its connection with the copper by the new distribution it has its affinity or electrical attraction increased sufficiently to overcome the existing affinities between the elements of the solution in which it is placed, and thereby decompose it. But we have said that the same amount of heat or motion is required to decompose a compound that was given off in its composition; applying this to the point in question, I should say that the affinity of the zinc now represents an amount of heat or force equal to that required by the elements of the electrolyte to exist in a separate state—*i.e.*, the H_2 has an amount of heat given to it, *must have*, to enable it to take the gaseous state as it does; and so must the O, or the O and H_2 would not part company. Indeed, any body in passing from the solid or liquid state to the gaseous absorbs large quantities of heat. From whence does this heat come? We are obliged to refer it to the new affinity obtained by the contact of the two dissimilar metals.

If now it be admitted that chemical affinity—the affinity we have to do with here—is only electrical attraction, and that attraction can only exist where there is an excess of electricity, we have a ready explanation as to how the decomposition occurs when the metals are connected; that is, when the new distribution takes place, for it has been shown that electricity, if not a form of heat, represents in its effects this heat.

The oxygen, however, liberated in the battery we have been speaking about, does not continue in the gaseous state, as the H_2 liberated at the copper plate does, but combines with the zinc, forming oxide of zinc (ZnO), and in doing so, of course, gives up again, more or less, the force which it absorbed when parting with the hydrogen. What is this force? Where does it go? I think we cannot fail to see that it is this force which, when supplied with suitable conditions to circulate through a conductor, is called the electric current, though, of course, it must have undergone some modification from the true form of heat. If the suitable arrangement is not supplied, no sign of electricity is present, but the chemical action manifests itself as heat. It must be remembered that part of the current must return to the zinc to again render it electro-positive, otherwise all action ceases.

This theory, if I may call it such, I think we shall find applicable to all the phenomena observed in a battery, for the strength of a current produced by a given expenditure of zinc is always proportional to the amount of work it does in overcoming the resistance of its conductors, and if the current loses strength by the interposition of work its equivalent is always found in the work done, whatever that may be, whether to induce magnetism in iron, work machinery, or circulate through a long conducting wire; just as there is with heat, so is there with electricity a true mechanical value.

Another important thing for us to notice here is, that if there is not sufficient work for the battery to do, the surplus force turns directly into heat, the behaviour being exactly analogous to that observed in machines where heat is the motive power. If the machine is made to work, an amount of force or heat is lost proportional to the work done; but if the machine is not working, the force or heat is found to be distributed over all the parts of it.

(*To be concluded in another paper.*)

SMELL.

THE *Moniteur Scientifique* contains a paper by M. Papillon on this subject, having reference to recent discoveries in chemistry and physiology. We extract from it the following:—

The seat of the sense of smell is, as we know, in the lining membrane of the nostrils. This membrane has a mucous and irregular surface, over which spread a number of nerves, with delicate terminations. It secretes a lubricating liquid. By means of muscles, the apparatus of smell is dilated or contracted, like that of sight.

The mechanics of smell are, simply, the contact of odorous particles and the olfactory nerve. These particles are carried by the air into the nostrils. If, on the one hand, the nerve is injured, or even compressed; if, on the other, the air is prevented from passing into the nostrils, there is an absence of smell. The upper part of the nostrils is the most sensitive as regards odour. The sense of smell varies much in different people. Some are entirely without it. Others are quite insensible to certain odours: a case similar to that of Daltonism, in which some eyes fail to perceive certain colours. It is recorded of a certain priest that he perceived no odours but those of smoke and decayed cabbage, and to another person vanilla seemed quite inodorous. Blumenbach speaks of an Englishman who could not perceive the fragrance of mignonette.

Smell is sometimes voluntary, sometimes involuntary. In the former case, to obtain a lively sensation, we close the mouth, and make a long inspiration, or a series of short and jerking ones. The muscles contract the orifice of the nostrils, and thus increase the intensity of the current of air. On the other hand, when we wish *not* to smell, we *expire* through the nose, so as to drive away the odorous air, and inspire by the opened mouth.

Smell and odours are closely connected with the phenomena of taste or gustation. Most savours perceived by us arise from a combination of sensations of smell with those of taste. There are, indeed, only four primitive and radical kinds of taste—acid, sweet, salt, and bitter. This may be shown by experiment. If we close our nostrils on tasting any sapid substance, the perceived taste will come under one or other of these four heads. Thus, when the olfactory membrane is diseased, the savour of food is altered.

How do odorous substances act with reference to the matter which separates them from the organ of smell? Prevost, in 1799, showed that if an odorous body were put in a saucer full of water, the emanations from it agitated the molecules of the water visibly. These motions, of which camphor gives a very good example, have been recently studied by M. Liegeois.

He found that some substances caused movements of gyration and translation over the water surface, similar to those of camphor. Of this class are benzoic acid, succinic acid, and orange bark. In the case of others, this motion ceases very soon, as they become encased in an oily layer over their surface.

He thinks these motions are due, not to a disengagement of gas, causing something like recoil, but to the separation and rapid diffusion of the odorous particles in the water. The fluid shows affinity for these. Similarly, a drop of oil falling on water sends out an infinite number of very small globules, which spread through the liquid, while the volume of the drop is not sensibly diminished. So with aromatic essences. Though insoluble in water, the small odorous particles tend to disperse themselves in it. A small quantity of odorous powder will thus impart perfume to a large body of water.

It is these same odorous molecules which are carried to our nostrils. And the action of water is thought by M. Liegeois to assist in the formation of them. In the morning, when the ground is moist, and the flowers are covered with dew-drops, there is a large exhalation of perfume. Similarly, after a shower of rain. In gustation we have something analogous: the saliva is fitted to diffuse the odorant principle; by the motion of the tongue in the cavity of the mouth, this diffusion is promoted, for the surface of evaporation is enlarged. Now, in the same way as the small particles diffuse themselves in water, do they diffuse themselves in air, which then becomes the vehicle carrying them to our nostrils.

Some odorous substances have a very great diffusibility. Ambergris, newly cast on the shore, is smelt a long way off. Bertholin states that the odour of rosemary off the Spanish coast is perceptible long before the land comes in sight. The degree of division of the particles is in some cases marvellous. A grain of musk will perfume an apartment for a whole year, without sensibly losing weight. Haller mentions having kept for forty years some pieces of paper perfumed with a grain of ambergris, and at the end of that time they still retained their odour.

It is to be noted that the odorous particles are *sent out*, and the body emitting them does not act as a centre of agitation, giving rise to vibrations. It is thus a different case from those of light and heat. The odour is the odorous molecule itself; whereas light, as perceived, is not the luminous body.

We cannot tell whether oxygen has some chemical influence on the particles; nor what kind of action takes place on contact of the particle with the nerve, whether a mechanical agitation or a chemical decomposition. But the distinction of the senses into *physical* (sight, touch, and hearing) and *chemical* (taste and smell) is a just one. In the latter, contact is always implied.

An able writer has recently tried to prove a kind of music in odours. That is, different odours, according to him, affect the olfactory nerve in various degrees, corresponding to those in which sound affects the auditory nerve. Thus we may have octaves of odours. He enumerates various substances that produce the same impression, but in different degrees; *e.g.*, these four, almond, heliotrope, vanilla, and clematis. By combination he obtains semi-odours, corresponding to semitones; *e.g.*, a rose with a geranium. He points out principles of harmony in perfumes corresponding to those in colours, and thinks it possible to produce a desired perfume from a mixture of others.

The theory is ingenious and worthy of attention, but it is open to grave objections. For the harmony in colours and sounds depends on exact numerical relations, which may be accurately determined; whereas, in the case of smell, the criterion is capricious and uncertain, and it is not possible to reduce to formula what our sense reveals.

There are many cases of hallucination as regards smell; united, generally, with insanity on other points. Lunatics have been met with who constantly complained of a fetid odour; others rejoiced in the most delicious, though imaginary, perfumes. M. Lelut tells of a patient in the Salpetrière, who was continually troubled with the smell of dead bodies, which she thought to have been buried in the establishment.

Capellini mentions the case of a lady who could not bear the smell of a rose, and fainted one day when a friend came in with one that was artificial in her hand. Many other instances could be given. It seems to be well authenticated, that in lunatic asylums these delusions as to smell are very frequent.

The intensity and delicacy of the sense of smell vary in different individuals and races. In some it is wonderfully sensitive. Woodwart tells of a woman who predicted storms several hours in advance, from the sulphurous odour (due to ozone probably) which she perceived in the air. A young American who was deaf, dumb, and blind, became a good botanist, simply by the sense of smell. It is, however, in some of the lower animals that we find the sense most highly developed: ruminants, pachydermous animals, and, above all, carnivorous mammifers. Smell is, with some of them, like an eye, which sees objects, not only where they are, but where they have been. The keen scent of the dog is well known.

Humboldt mentions that when, in his travels in South America, it was desired to attract condors, all they had to do was to slaughter an ox or a horse, and in a short time the odour attracted a number of these birds, though none were visible previously. Of birds, waders have the largest olfactory nerves, and their sense of smell is most highly developed.

The olfactory organ in reptiles is large. Fishes also have an olfactory membrane; and fishermen have observed that they are driven away when certain odorous substances are thrown into the water. Sharks and other voracious fishes often gather from great distances when a carcase is thrown into the sea. Crustaceans are not insensible to emanations which come in contact with their olfactory fibres.

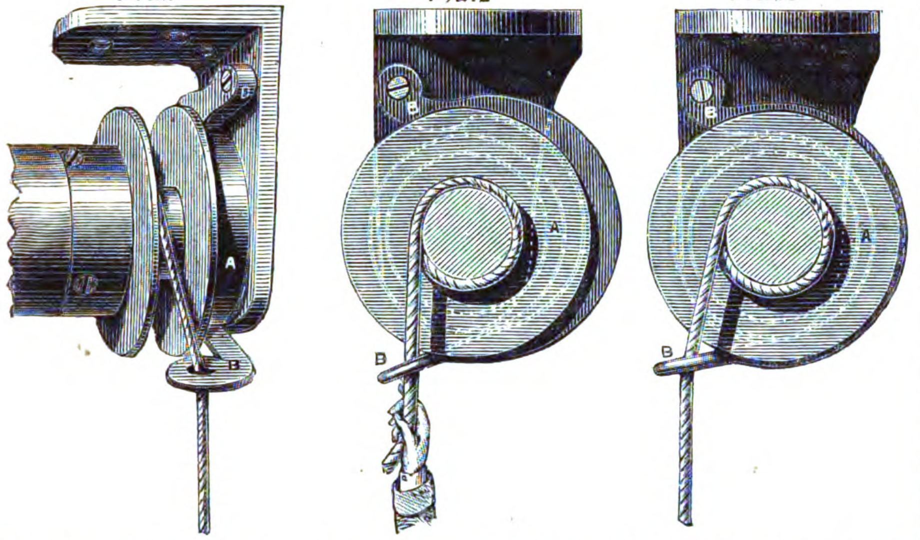
Entomologists say that the sense of smell in insects is very subtle, but it is difficult to determine the seat of it. When meat is exposed in the air, flies soon appear in great numbers, though none were seen before. The carcases of animals left on the ground attract hosts of insects, which find nourishment in them, and deposit their eggs. This will often happen when the object is concealed, so that their search cannot be guided by sight.

The flower of the cuckoo fruit gives forth a fetid odour, and a number of flies and other insects are often seen moving about on the corolla, in search, it is said, of decayed matter, from which, they imagine, the odour proceeds.

SELF-ACTING BLIND ROLLER.

A SIMPLE form of self-acting blind roller has been recently patented by Messrs. J. Manuel & Son, which will be readily understood from the engraving and the following description. The principal feature of the invention consists in the application of a friction brake, which prevents the roller turning except when released by the single cord which is found sufficient for moving the blind to the different positions required. On an ordinary blind roller, between the drum or pulley on which the cord is wound and the bearing bracket, a washer, consisting of a ring of rubber, guttapercha, leather, cork, or any substance capable of causing friction, is fixed. On the window frame or jamb, at a point above the washer, a lever brake, consisting of a curvilinear pendant, is secured by a pin or screw in the frame, bracket, or jamb, so as to bear against a portion of the circumference of the washer. This friction lever may be made of metal or wood or other combination of materials, and may be lined internally to enable it to exercise speedy friction on the washer, by its own gravity and contact always tending to cause it to press on the side periphery of the washer. The pendant lever or brake when in position rests with its lower extremity (through which the cord is passed (projecting forwards from the vertical line drawn from the centre of its pivot, and consequently the cord from the drum or pulley is held forward at a tangent, as shown in Fig. 3; consequently when the cord is pulled by the operator it becomes vertical by tension, and thus throws back the projecting under-point and prevents the friction brake bearing against the roller washer. The cord can then be pulled to raise the blind wholly or partly, and immediately the cord is released the swinging lever hangs forward and holds the roller exactly in the position required. When it is desired to lower the blind it is only necessary to slightly depress the cord, so as to throw the brake out of friction and to let the cord slip through the hand till the blind has wholly or partly descended, the release of the cord allowing the brake to act without the use of any rack or spring or other equivalent. Fig. 1 represents an elevation of the blind roller; Fig. 2 an end view with brake released; and Fig. 3 an end view showing the blind at rest, the hand having left the cord. In each figure A is the washer ring and B the brake.

FIG. 1 FIG. 2 FIG. 3



THE WESTINGHOUSE ATMOSPHERIC RAILWAY BRAKE.

THE railway brake invented by Mr. Westinghouse, which has during a period of three years proved itself to be the best mechanism for the purpose in use in the United States, has at length been tried by two railway companies in this country, with a result very gratifying, though not, we imagine, unexpected by its ingenious inventor. The principle of the brake consists in the application of the elastic force of compressed air to actuate the ordinary brake blocks, the control of which throughout the train is left entirely in the hands of the driver. The remarkably short distances in which long trains can be stopped by its means was made apparent on its introduction to the American railways, and the results there regularly obtained in practice have been reproduced here. In the trials recently made on the Caledonian line near Glasgow, with a train consisting of twelve carriages and two vans drawn by one of the powerful fast four-coupled engines belonging to the company, stoppages were made in 19 seconds and in 264 yards on the level, when previously going at the speed of 50 miles per hour. While travelling at the same speed, and running down an incline of 1 in 130, a dead stop was come to in 20 seconds and in a space of 268 yards; and when running down a gradient of 1 in 68 at 60 miles an hour (29⅓ yards a second) the train was brought to a standstill within 308 yards in 23 seconds. These results are amply sufficient to show the value of the new (as far as this country is concerned) brake, even when examined solely in the light of the figures thus obtained, but there is another point of view which appears to have been overlooked by the chroniclers of the experiments. Under the present system, as our readers are aware, the driver or the stoker has the immediate control only of the brake attached to the tender. In order that the other brakes on the train may be applied he is obliged to whistle to call the attention of, and signal to, the guards, who, it is to be hoped, always pay prompt attention to the commands of the driver thus conveyed. As many of our readers will not require to be told, however, long acquaintance with danger renders those callous who have to face it; and although we are inclined to be reticent in insinuating that guards do not always pay that attention to the whistle of the driver they are supposed to do, there cannot be the slightest doubt that far too much is left to their care; in other words, that the command of the train is taken out of the hands of the man best capable of governing it, to an extent which should not be allowed when a remedy is pointed out. But granting that the guards are always on the *qui vive*, with their hands on the brake wheel, ready at the first intimation of danger to apply the means of stopping the train under their control, it must be acknowledged that with trains travelling at 50 miles per hour even fractions of a second are valuable amounts of time, and it is only too true, having been proved in numerous instances, that the waste of these fractions of time in whistling and in getting the brakes put down, has often resulted in accident, or rather has failed to prevent what would have been, under a better arranged system, preventible. With the Westinghouse air-brake, on the contrary, the application of every brake on the train may be almost simultaneous with the intimation of danger, depending solely on the quickness or smartness with which the driver puts in operation the means at his disposal. Under the present arrangement the time occupied in whistling and getting the brakes on often means just the difference between a collision and its avoidance, for although the time thus occupied may seem almost inappreciable, it is frequently of sufficiently lengthy duration to be a trifle too long.

It is time, however, that we proceeded to describe what experience has shown to be the best arrangement for stopping trains yet put into practice. The most important part of the Westinghouse system is the method of compressing the air and storing it up for use when required. This is accomplished by an ingeniously contrived engine and pump secured to the outside of the locomotive, between the driving-wheel and the trailer; in fact, on one side of the fire-box in a similar position to that frequently occupied by the Giffard's injector. The piston of the little cylinder and that of the pump are connected together by a rod of a somewhat peculiar section, obtained by cutting or filing down the ordinary circular rod on four sides. The object of this is to prevent the turning of the pistons, which, owing to the peculiar arrangement of the steam-valve, and the absence of guides, &c., would otherwise be free to rotate. The arrangements for the admission and regulation of the steam to the pump engine are of a very ingenious character, and we shall probably illustrate them at a future time; suffice it to say, that the steam-valve is contained in a cylindrical chamber, and is made to rotate to admit and exhaust the steam. This rotatory movement is obtained from a very small piston actuated by steam, situated on the top of the cylinder and working at right angles to its axis. The main piston-rod is hollow for more than half its length, so as to permit the insertion of a rod connected with a valve which admits steam to the small piston employed to rotate the valve-rod. Thus the motion of the piston-rod actuates this valve-rod, and the steam being caused to act upon the same piston, the valve is rotated to the required positions. The air-pump is double-acting, takes its air through a strainer, and also draws in a supply of the lubricator at each stroke—mineral oils being used for the purpose, owing to the great heat developed by the forcible compression carbonising all other lubricating materials. The compressed air is forced from the pump to a strong cylindrical receptacle carried under the foot-plate of the engine, and it is found in practice that the pump is self-governing, working when the air chamber is full at just sufficient speed to supply the small leakage which unavoidably takes place, but when the pressure which thus opposes its movements is reduced on applying the concentrated force to the brakes, it immediately springs into rapid action and restores the normal pressure. The small engine and pump is capable of a speed of 100 double strokes per minute in the event of any extraordinary leakage, less than one-third of that speed being found amply sufficient, however, under ordinary circumstance. The reservoir is provided with a small safety-valve, so that whatever the pressure of the steam in the boiler of the locomotive may be, the pump may be allowed to work as fast as it can against the pressure of the air in the reservoir, generally from 60lb. to 70lb. per sq. in. The compressed air is led by a pipe from the reservoir to a three-way cock placed conveniently to the hand of the driver, which communicates by one pipe with a three-way cock situated beneath the foot-plate, and by the other pipe with the atmosphere. In connection with this second three-way cock are inch iron gas-pipes, fixed beneath each carriage one on each side, the joints between the carriages being made with stout specially prepared indiarubber tubing and an ingenious coupling, the air-tight fit of which is secured by means of the compressed air itself. The object of having two sets of pipes is partly to insure against mishap to one set of tubes, in which case the other would be sufficient for all the purposes required, and partly to facilitate the connection of the different carriages; for the couplings, being provided with male and female screws respectively, and all the carriages being fitted alike, it is obvious whichever end of the carriage it is desired to couple will present the pipes in the required position, which could not be the case if only one pipe was employed. The coupling is fitted with two valves, which, when the connection is perfect, are both open and allow of the passage of the compressed air, but in the event of rupture of any of the couplings by accident, or if the connection through carelessness has not been made, the valves close the end of the pipe and prevent the escape of the air. Besides this self-acting arrangement the driver can, by means of the three-way cock beneath the foot-plate, shut off the compressed air from either or both of the pipes.

The air being thus led throughout the whole length of the train is conveyed by branch pipes to an air cylinder under each carriage. This cylinder contains a piston packed by a cup-leather, and connected with a rod, to the outer end of which is attached a conical cup, which receives the thrust rods employed to actuate the brake-shaft. A small pipe is inserted in the front cover of the cylinder to permit the escape of air when the piston is going forward, and to admit it when the piston is going back. Thus the whole operation is readily understood. The driver by means of the three-way cock placed near his right hand admits the compressed air to the pipes and the cylinders, where it moves the pistons, and by means of the thrust-rods and gear forces the brake-blocks against the wheels with a degree of pressure entirely under the control of the driver, who can thus by a mere turn of the wrist lock every wheel in the train, or bring just sufficient friction into play to check the speed and retard a train when running down an incline or through a station where numerous points and dangerous crossings render 50 miles an hour a hazardous speed. By another turn of the wrist the compressed air which has done its work is permitted to escape into the atmosphere, and spiral springs immediately draw away the brake-blocks and push back the pistons in the air cylinders. The existing brake-gear can be made available for the application of compressed air, but where new gear has to be provided Mr. Westinghouse prefers to adopt an arrangement of swing brake which possesses the valuable properties of equalising the pressure on the blocks, however unequally they may be worn, and of preventing all jar and vibration, none being perceptible, it is said, in the first-class carriage to which it has been applied on the Caledonian Railway.

Mr. Westinghouse has also devised a simple system of signalling between passengers, guards, and driver, which depends on the adoption of the atmospheric brake, however. It consists in fitting each carriage with a small reservoir, which is supplied with compressed air every time the brakes are applied. Wires lead from the different compartments to a lever in connection with a valve in this reservoir, which lever also works a kind of semaphore indicating the part of the carriage whence the signal was made. The valve being opened, the air rushes along the pipes and sounds whistles near the driver and in the guards' vans. These whistles are also unavoidably blown when the brakes are put on, and to prevent the continuance of the sound longer than is required, a peculiar form of whistle is adopted, consisting of a cylindrical pipe containing a loosely-fitting piston, which permits sufficient air to pass to sound the alarm, but which is driven up so as to close the outlet as the volume of air increases. All the details of the mechanism seem to have been well and carefully thought out, as regards both the brake and the signalling apparatus, each of which answers its purpose in an admirable manner. When we further consider that the cost of application cannot amount to a very great sum, that the coupling of the pipes occupies but a few seconds, and that the power of the driver over his train is considerably increased (which means, as we take it, increased safety for the passengers), we are curious to see what action will be taken by railway companies, who have some regard for the money they pay away in damages if they have no respect for the lives of the public.

THE PRODUCTION OF CHLORINE AND HYPOCHLORITES.

ANY improvements in the manufacture of chlorine must be, as the majority of our readers are perfectly well aware, of considerable importance to sundry industries of the United Kingdom. We gave an account of an improved process on p. 55 of Vol. XII., and we are now enabled to give the details of the method recently patented by M. Tessié du Motay. According to that distinguished chemist, the processes hitherto employed to produce chlorine continuously by means of oxygen or of air and hydrochloric acid in the presence of certain metallic peroxides or dehydrating salts have never given practically valuable results, because the excess of oxygen or air and nitrogen mixed with the chlorine generated partly prevents the condensation of this chlorine or its combination with the alkalies and alkaline-earthy bodies intended to produce hypochlorites suitable for practical use in bleaching. The object of M. Tessié du Motay's process is while wholly or partially utilising the hydrochloric acid employed, to generate pure chlorine in an isolated state which can combine without waste with the alkaline or alkalino-terrous bodies in the form of bleaching chlorides; and to accomplish this the inventor has discovered two methods.

1. Into a retort heated to a deep red, containing peroxide of manganese or a mixture of peroxide of manganese and lime, a current of hydrochloric acid is caused to pass; chlorine and steam are produced and disengaged, and there remain in the retort non-decomposed peroxide of manganese and chloride of manganese, or a mixture of peroxide of manganese, chloride of manganese, and chloride of calcium. The chlorine is collected in the water or led away into a chamber for the production of dry hypochlorites. Over the mixture remaining in the retort a current of air or oxygen of the same temperature is caused to pass, which, in the presence of peroxide of manganese decomposes at once the chloride of manganese alone or the chlorides of manganese and calcium regenerated from the sesquioxide of manganese alone into sesquioxide of manganese mixed with lime, and sets at liberty the chlorine contained in the chlorides. This chlorine mixed with air and azote or oxygen is led into vats containing a mixture of lime and protoxide of manganese which has been previously produced by the decomposition of chloride of manganese by an excess of lime, the soluble chloride of calcium produced in this reaction having been previously run off. In presence of the oxygen of the air and of the chlorine it produces immediately sesquioxide of manganese and hypochlorite of lime, which in reacting upon the sesquioxide produces finally the hydrate of peroxide of manganese and chloride of calcium. The excess of lime remaining having no longer to act upon the sesquioxide remains in the state of hypochlorite of lime. Upon this mixture composed of hydrate of peroxide of manganese, chloride of calcium, and hypochlorite of lime, liquid hydrochloric acid is made to react in the ordinary manner. Chlorine is at once disengaged by the reaction of this acid on the one hand upon the hydrate of peroxide of manganese and on the other upon the hypochlorite of lime. This chlorine is led into the chamber for the production of hypochlorites. After this reaction it remains in the vats of the chlorides of manganese and calcium. Upon the chlorides of manganese and calcium an excess of lime is again caused to act, which reproduces the mixture of protoxide of manganese, chloride of calcium, and lime already referred to. The soluble chloride of calcium is then run off, and there remains in the insoluble state a mixture of protoxide of manganese and lime, which will serve for other similar operations by repassing under the action of chlorine and air to the state of hydrate of peroxide of manganese, chloride of calcium, and hypochlorite of liquid lime.

It therefore follows, first, that by the reaction of gaseous hydrochloric acid upon air and oxygen in retorts heated to redness containing peroxide of manganese or a mixture of peroxide of manganese and lime, a first quantity of pure chlorine is produced, which is led away into condensing chambers, and for the production of dry hypochlorites; secondly, that by the decomposition by means of air or oxygen of the chloride of manganese alone, or the chlorides of manganese and lime contained in the said retorts, gaseous compounds are produced containing at once oxygen and chlorine. These compounds in their passage across the vats containing the protoxide of manganese and liquid hypochlorites of lime produce pure chlorine by the action of liquid hydrochloric acid, the chlorine in its turn being led into the chambers for the production of dry hypochlorites. Instead of the mixture of protoxide of manganese and lime in excess, over which the chlorine mixed with air and oxygen is caused to pass just as it comes from the retorts, a milk of lime may be employed, which is transformed into hypochlorite of lime. This hypochlorite as well as the mixture of hydrate of peroxide of manganese and hypochlorite of lime treated by liquid hydrochloric acid regenerates pure chlorine suitable to be taken to the chambers for the production of dry hypochlorites.

The chloride of calcium remaining from the operation is collected in vessels wherein carbonate of magnesia, or magnesia and carbonic acid, are caused to react simultaneously, carbonate of lime and chloride of magnesium being produced. This distilled chloride of magnesium regenerates the hydrochloric acid, which is again employed for the production of a fresh quantity of chlorine. The magnesia remaining serves again for another operation. Thus the reactions which constitute the process are shortly as follows:—1, the oxides of manganese serving for the production of chlorine are ceaselessly regenerated; 2, the hydrochloric acid is utilised completely for the production of chlorine; 3, all the chlorine generated is in a pure state, and consequently suitable for the production of dry hypochlorites.

2. The second method only differs from the one just described in the substitution of magnesia for lime, the chlorides of magnesium produced being without transformation, and capable of re-engendering hydrochloric acid by simple distillation.

COLOURED SUNS.*

IF a brilliant star be observed when near the horizon, it will be seen to present the beautiful phenomenon of "coloured scintillation." The colours thus exhibited exceed in purity even those seen in the solar spectrum or in the rainbow. By comparison with them the light which flashes from the ruby, the emerald, the sapphire, or the topaz, appears dull and almost earthy. There are four or five stars which present this phenomenon with charming distinctness. The brilliant Vega in the constellation Lyra, which rarely sets in our latitude, is one of these. At midnight in winter, and earlier with the approach of spring, this splendid steel-blue star may be seen as it skirts the southern horizon, scintillating with red, and blue, and emerald light. Arcturus twinkles yet more brilliantly low down towards the north-east in our spring evenings. Capella is another notable scintillator, seen low down towards the north during the summer nights. But these, though they are the most brilliant northern stars, yet shine with a splendour far inferior to that of Sirius, the famous dog-star. No one can mistake this noble orb as it rises above the southern horizon in our winter months. The vivid colours exhibited by Sirius as it scintillates have afforded a favourite image to the poets. Homer compares the celestial light which gleamed from the shield and helmet of Diomed to the rays of "Sirius, the star of autumn," which "shines with a peculiar brilliancy when laved by ocean's waves;" and, to pass at once from the father of poetry to our greatest modern poet, we find in Tennyson's "Princess" the same image, where he says of Arac and his brothers, that—

> As the fiery Sirius alters hue,
> And bickers into red and emerald, shone
> Their morions, washed with morning, as they came.

It is difficult to persuade oneself that these ever-changing tints do not really belong to the stars. But there is now no doubt that they are caused by our own atmosphere. Unequally warm, unequally dense, and unequally moist in its various strata, the air transmits irregularly those coloured rays which together produce the light of a star. Now one colour prevails over the rest, and now another, so that the star appears to change colour. But it is only low down towards the horizon that these changes take place to their full extent. In the tropics, where the air is more uniform in texture, so to speak, the stars do not scintillate unless they are quite close to the horizon, "a circumstance," says Humboldt, "which gives a peculiarly calm and serene character to the celestial depths in those countries."

But the stars are not wanting in real colours, caused by peculiarities in the quality of the light which they emit towards us. In tropical countries the colours of the stars form a very obvious and a very beautiful phenomenon. The whole heaven seems set with variously coloured gems. In our latitudes, none but the brightest stars exhibit distinctly marked colours to the naked eye. Sirius, Regulus, and Spica are white stars; Betelgeux, Aldebaran, Arcturus, and Antares are red; Procyon, Capella, and the Pole-star are yellow; Castor exhibits a slightly green tint; while Vega and Altair are bluish. Antares, which we have described as a red star, presents, when carefully watched, a greenish scintillation so peculiar as to have early attracted the notice of astronomers. The green tint of Castor had been found to arise from the fact that the star is double, and one of the components green. But, for a long while, powerful instruments failed to exhibit a companion to Antares. At length General Mitchell, with the great refractor of the Cincinnati Observatory, detected a minute green companion to this brilliant red star—the Sirius of red stars, as it has been termed.

But, as we have said, the stars which present distinctly marked colours to the naked eye in our latitudes are few and far between. It is in the telescope that our observers have to seek for a full

* From "Essays on Astronomy," reviewed on p. 291. The essay on "Coloured Suns" appeared originally in *Frazer's Magazine*.

view of the delicate phenomenon of coloured stars. When a survey is made of the heavens with a powerful telescope, peculiarities well worthy of careful attention are revealed to the observer. We have seen that there are no stars visible to the naked eye which are *decidedly* blue or green. The ancients, also, recognised only red and white stars. In the telescope, this peculiarity is still observable when single stars only are looked at. We meet with some telescopic stars, the depth of whose red colour is remarkable. There are stars of a fiery red, of a deep blood-red, and of a full orange colour. There is a well-known star entitled the "garnet star." And, in fact, every variety of colour, from white through yellow and orange to a deep, almost dusky red, is met with among the single fixed stars. But there is no instance throughout the whole heavens of a single green, blue, or violet star.

The case is altered when we come to examine those double, triple, and multiple stars, the observation of which is one of the most pleasing employments of the amateur telescopist. Amongst these systems we meet with all the tints of the rainbow, and with many colours which are not seen in the rainbow, such as fawn-colour, lilac, gray, and so on. "The attentive observation of the double stars," writes the celebrated Struve (who detected 3,000 of these objects) "teaches us that, besides those that are white, all the colours of the spectrum are to be met with." "Here we have a green star with a deep blood-red companion, there an orange primary accompanied by a purple or indigo-blue satellite. White is found mixed with light or dark red, purple, ruby, or vermilion." Sometimes a single system offers at one view many different colours. Such is the case with the remarkable group detected by Sir John Herschel within the Southern Cross. It is composed of no less than 110 stars, which, seen in a telescope of sufficient size, appear, Herschel tells us, like "a casket of variously coloured precious stones."

It will be well to examine some of the collocations of colour, that we may trace the presence of a law of distribution, if such exist.

We have said that blue stars are not met with singly in the heavens. Among double stars they are common enough. But they are generally small. When the larger star or primary is not white, it is usually either red or yellow; then the smaller star —or satellite, as we may term it—is frequently blue or green. But this is so far from being a law without exception that the more common case is to find both stars similarly tinted. Amongst 596 bright "doubles," Struve found 375 whose components were similarly coloured, 101 whose components presented colours belonging to the same end of the spectrum, and only 120 in which the colours were totally different.

Amongst double stars whose components are similarly tinted, by far the greater number are white, yellow, or red. But there are some instances of double blue stars; and in the southern heavens there is a group containing a multitude of stars, *all blue*.

It is impossible, therefore, to suppose that the blue colours seen in multiple systems are due to the mere effect of contrast. In some cases this may happen, however; or at any rate the effect of contrast may intensify the colours of each component of a "complementary double." There is one very charming instance of complementary colours in a double star which may be separated with a telescope of very low power. We refer to the star Albireo on the beak of the Swan. The components of this star are orange and blue, the tints being well pronounced. It has been found that when one of the components is hidden, the other still preserves its colour, though not quite so distinctly as when both are seen together. Another "complementary double" is the star γ Andromedæ. The primary is red, the smaller star green. In very powerful telescopes the smaller component is found to be itself double, and doubts exist among astronomers whether the two minute components of the lesser star are both green, or one blue and the other yellow. There is another double star very beautiful in a powerful telescope. This is the star ϵ Boötis, on the Herdsman's belt; it is called also Mirach, and, on account of its extreme beauty, Pulcherrima. The components are nearly equal—one orange, the other a delicate emerald green.

One of the most startling facts revealed by the careful observation of the fixed stars is that their colour is not unchangeable.

We may begin at once with the brightest of the fixed stars—Sirius. This star was known to the ancients as a red star. To its fiery hue may doubtless be ascribed the peculiar influence assigned to it by ancient astronomers. At present Sirius is brilliantly and unmistakeably white.

We have not such decisive evidence in the case of any other noted star. But among telescopic stars, there have been some very remarkable changes. There are two double stars, described by the elder Herschel as white, which now exhibit golden-yellow primaries and greenish satellites. That careful observer, Admiral Smyth, records also that one of the components of a double star in Hercules changed, in twelve years, from "yellow, through gray, cherry-red, and egregious red, to yellow again."

The questions may well be asked: Whence do the stars derive their distinctions of colour, and by what processes do their colours change? To these questions modern discoveries have supplied answers which, if not complete, are well worth listening to.

It had long been suspected that the stars are in reality suns. It had been shown that their distance from us must be so enormous as to enable us to assign to them an intrinsic brilliancy fully equal, in some instances, and in others far superior, to that of our own sun. Nothing remained but that we should have some evidence that the kind of light they emit is similar to that which we receive from the sun. This evidence has been supplied, though only of late years.

We cannot here enter at length into an account of the important discoveries of Kirchhoff and Bunsen, which have enabled astronomers to analyse the light emitted from the celestial bodies. It will be sufficient to remark that in the solar spectrum there are observed fine dark lines breaking the continuity of the streak of light, and that these lines have been proved to be due to the presence of the vapours of certain elements in the solar atmosphere. The proof depends on the exact correspondence of numbers of these lines, grouped in a complex manner (so as entirely to eliminate the possibility of a mere chance accordance) with the bright lines seen in the spectra of light from the vapours of those elements. When once Kirchhoff and Bunsen had proved the possibility of exhibiting the same set of lines either as bright lines on a dark ground or as dark lines on a brilliant spectrum, all doubt as to their meaning in the solar spectrum disappeared at once.

It has been found that in the sun's atmosphere there are present the vapours of iron, copper, zinc, and nickel, besides calcium, magnesium, sodium, and other metals. But the vapours of tin, lead, silver, and gold do not appear to be present in the solar atmosphere. One of the most remarkable dark lines is due to the presence of hydrogen.

But it has been found possible to extend these researches to the fixed stars. Drs. Huggins and Miller have done this successfully, and their discoveries afford a means of assigning very sufficient reasons for the colours of the brighter stars. By analogy also we may extend a similar interpretation to the colours of stars not bright enough to give a spectrum which can be satisfactorily examined.

Let us take first the brilliant Sirius. This star belongs to the southern half of the celestial sphere, and although it becomes visible at certain seasons in our latitude, it never rises very high above the horizon. In fact, at its highest—that is, when due south—it is only twenty-two degrees above the horizon, or less than one-fourth of the way from the horizon to the point immediately overhead. This peculiarity somewhat interferes with the observation of the star by a method so delicate as that applied by the celebrated physicists we have named. On the other hand the exceeding brilliancy of Sirius makes some amends for the effects of atmospheric disturbances. By selecting very favourable opportunities, Huggins and Miller were able to analyse the star's spectrum, with the following result:—

The atmosphere around Sirius contains sodium, magnesium, hydrogen, and probably iron.

The whole spectrum is covered by a very large number of faint and fine lines, indicating a corresponding variety in the substances vapourised in the star's atmosphere.

The hydrogen lines are abnormally strong as compared with the solar spectrum, all the metallic lines being remarkably faint.

This last circumstance is well worthy of notice, since it is *a peculiarity characteristic of white stars* —so that we begin already to find a hint respecting the source of colour or of the absence of colour in stars.

Take next an orange-red star, the brilliant Betelgeux. The spectrum of this star was very carefully analysed by Huggins and Miller. They marked down the places of two or three hundred lines, and measured the position of no less than eighty. They found that sodium, magnesium, calcium, iron, and bismuth are present in the star's atmosphere, but the two strong lines which note the presence of hydrogen are wanting.

Take next the yellow star, Pollux. The observers were not able to obtain very satisfactory measures of this star; but they established the presence of sodium and magnesium in the star's atmosphere; and again the strong lines of hydrogen were found to be missing.

But we are not entitled to assume that red and yellow stars are characterised by the absence of hydrogen from their atmospheres. On the contrary, the noted red star Aldebaran, the spectrum of which was very carefully analysed by Huggins and Miller, was found to exhibit the two lines of hydrogen with perfect distinctness. This star exhibited a richness in the construction of its atmosphere not presented by any other. The elements proved to be present are sodium, magnesium, calcium, iron, bismuth, tellurium, antimony, and mercury. It must not be supposed, in this or any other case, that other elements might not by a sufficiently laborious scrutiny be proved to exist in the star's atmosphere. The observations required, says Dr. Huggins, "are extremely fatiguing to the eye, and necessarily limited to the stronger lines of each spectrum."

It is clear, however, from the above short list of examples, that a considerable variety exists in the physical constitution of the fixed stars. This of itself affords a suggestive hint respecting the true explanation of the variety of colour which we have described. And the peculiarity that in the white stars the hydrogen lines are singularly strong, while the metallic lines are as singularly weak, is yet more to the point. Sirius *was* a red star. Was it at that time unlike present red stars? Does it not seem more probable that, if there had existed in those days a Huggins or a Miller, and the instruments used so successfully by these observers had been invented, it would have been found that Sirius did not—when a red star—present peculiarities now observed only in white stars?

We recognise, then, the influence of time upon the spectrum of this celebrated star, as probably tending to render the lines of hydrogen more distinct than of yore, and the lines of the metallic elements less distinct. But what is the meaning of such a change? Suppose a chemist, for example, observing the spectrum of the flame produced by the combustion of a compound body, should notice that the lines of some elements slowly increased in distinctness, while the lines of others grew fainter, how would he interpret such a phenomenon? If we remembered only that the dark lines are due to the absorptive effect of the vapour they correspond to, on light which is trying, so to speak, to pass through the vapour, we might readily jump at a conclusion, and answer that the extent of absorptive vapour is increasing when the lines are growing more distinct, and *vice versa*. But we must also consider that these lines are partly the effect of contrast. The limelight held before the sun's disc appears *black*, though so dazzling when seen alone. It may be, therefore—or rather we may say it certainly is the case—that those parts of the spectral streak which seem dark are in reality luminous; or—which is merely another way of saying the same thing—that the vapours which absorb light from the solar beams, send us light of their own. And so with stars. Therefore, we have this difficulty to contend against—that there is no power of determining whether a change in the intensity of a line, or of a set of lines, is due to a variation in the light-giving power of the corresponding vapour, or to a variation in the quantity of vapour whose absorptive effects produce the lines.

But, inasmuch as it resulted from Dr. Huggins' examination of a temporary star which appeared last year, that the increase of light—for it was only the abnormal brilliancy of the star which was really temporary—was due to a sudden outburst of inflamed hydrogen, it seems on the whole more probable that the incandescent vapours of stars burn with variable brilliancy, than that they vary in quantitative distribution.

As regards the constant colours of different stars, we are enabled at any rate to deduce negative results.

For instance, we may dismiss at once the theory started some years ago by the French astronomer M. Doppler. He supposed that the colours of a star are due to the proper motions of the star, acting so as—in effect—to lengthen or shorten the waves of light proceeding from the star to the earth, just as the apparent breadth of sea-waves would be greater or less to a swimmer according as he swam with or against their course. It is quite clear that the effects of a motion rapid enough to produce such a change would be to shift the position of the whole spectrum,—and this change would be readily detected by a reference to the spectral lines.* Apart from this, the colour of a star would not be changed by such motion, the spectrum being merely displaced, not affected in its characteristics of colour. (See p. 275.)

Another theory—that the orange and red tints indicate a lower degree of temperature—must also be dismissed. For we have seen that the spectra of red stars indicate the presence of the vapour of iron and other metals, and nothing but an exceedingly high temperature could vapourise these.

It seems clear that the difference of tint is due to the different arrangement of the dark lines—in other words, to an absolute difference of physical constitution. "There is a striking difference," remarks Huggins, "between the effect on the colour of a star of such closely grouped and very dark lines in the green and blue part of the spectrum of Betelgeux, and of the corresponding part of the spectrum of Sirius, in which the dark lines are faint, and wholly unequal to produce any noticeable subduing of the blue and green rays."

But we have still to consider the peculiarities presented by the double stars. We have seen that

* I may be permitted to notice that this was among the earliest *published* references to the possibility of determining motions of recess or approach by the displacement of the spectral lines. Very shortly afterwards, Dr. Huggins had succeeded in applying the method, which he had been endeavouring to do for some months before. I was, however, quite unaware of this when I wrote the above lines. I believe, in fact, his researches were carried on altogether privately.

amongst the components of these there are observed some which present a distinct blue colour. It has been found possible to analyse some of these with the spectroscope. We have spoken of the charming double star Albireo, the components of which are orange and blue. Both have been analysed—with this result, that the spectrum of the orange component is remarkable for the great strength of the lines in the green, blue, and violet, while the spectrum of the blue component is equally remarkable for the great number of groups of fine lines in the orange and yellow.

It would seem, then, that the complementary colours observed in certain double stars indicate a sort of complementary distribution of elements which in our own sun are associated equably and intimately.

And we must note here, in passing, that it is not absolutely necessary, as some have supposed, that, if there are systems of worlds circulating around such double suns, there should be any remarkable difference in the quality of light distributed to the planets, as compared with that which we receive from the Sun. Sir John Herschel has spoken of "the charming contrasts and grateful vicissitudes —a red or a green day, for instance, alternating with a white one or with darkness, according as one or other or both of the stars should be above the horizon." But if the dependent orbs swept in very wide circuits about their double sun, they would receive white light during nearly the whole of each of their days, since it would only be during a brief interval that either sun would be visible *alone* above the horizon.

Of the deeply coloured stars which are visible with the telescope, none have been found sufficiently brilliant to admit of exact analysis.

A peculiarity has been remarked by a distinguished modern observer which is worthy of careful attention. Many of the regularly variable stars, when passing into their phase of minimum brightness, exhibit a ruddy tinge which is very conspicuous in instruments of adequate power. It does not seem easy to explain this as due to any change in the vaporous constitution of a variable star—since it seems difficult to show why such changes should occur at regular intervals. Yet this would appear to be more probable than that these changes are due, either to the rotation of the star itself and the presentation in a cyclic order of the different parts of an unequally illuminated globe, or to the revolution round the star of an extensive vaporous mass whose interposition cuts off from us at regular intervals a portion of the star's light.

It is remarkable that a large number of the known variable stars are red or orange. There is one notable exception, however, for Algol—the celebrated variable in Medusa's head—is a white star.

It is probable that a careful examination of the stars with any efficient "colour-tester" would lead to the discovery of many cases of variation in colour. Admiral Smyth adopted a chromatic scale of colour—but a test of this sort is not very satisfactory. Opaque colours generally vary with time, so that it is impossible to say that two observers, even if they have used the same strip of coloured discs, have really made observations fairly comparable *inter se*. And it is further to be noted that there are many persons who find a difficulty and uncertainty in the comparison of stars, or brilliants, with opaque colour-scales. An ingenious student of science has suggested the use of chemical solutions, which can always be reproduced with certainty; and he has described a method for forming an artificial star in the field of view of a telescope, and for gradually varying the colour of the star until it should coincide with that of a fixed star whose colour we may desire to determine. The great objection to the plan is its complexity. Coloured glasses, through which a small white disc within the telescope might be illuminated (just as the wires are illuminated in the ordinary transit telescope), would serve the same purpose much more simply.* The inquiry is an exceedingly interesting one, and Sir John Herschel has expressed the opinion that there is no field of labour open to the amateur telescopist which affords a better promise of original discoveries than the search for such variations as we have described.

WOOD VENEERS FOR COVERING WALLS.

THE following particulars of the method of preparing veneers of wood for use in place of paper-hangings, are sent by a correspondent to the *Gardeners' Chronicle* :—

Some time since, Dr. Asa Gray presented to the Museum at Kew a series of thin veneers, or rather sheets of wood, such as had been introduced into America for covering the walls of rooms instead of paper. These wood papers, if we may so call them, are exhibited amongst the American woods in the timber museum (No. 3), and though the specimens there shown are not more than from 2ft. to 3ft. long, and 18in. wide, they are, we understand, to be had in America in lengths of 10ft. and of the entire width of the trunk from which they are taken. They are of a uniform thickness throughout, and scarcely, if at all, thicker than ordinary wall paper. They are produced by a kind of gigantic planing-machine, the papers being simply huge shavings. In most of them the grain runs longitudinally, the trunk of the tree being fed against the plane, or the plane being worked along the trunk in that direction, but by a further development of this wood machine much wider veneers are obtained. A wider blade is, of course, necessary, and the trunk of the tree being cut to the required length, it is made to revolve like a cylinder, and by a very even and uniform pressure against the edge of the plane, a continuous shaving or veneer, of any desired thickness or length, is produced by what might be likened to a kind of unrolling of the vegetable tissues. Though these wood papers are of comparatively recent introduction in America, it appears the patent for their production is only a development of a French patent obtained so long ago as 1826, by which the patentee covered a piano with sheets of ivory so produced. For the veneering of small objects, such as telescope tubes, sword canes, &c., the wood shavings are usually backed with thin papers; the backing or lining is applied by means of a machine very similar to that usually employed for making cardboard, by which two sheets, supplied from rollers, after being brought into contact with a revolving brush, dipping in liquid paste or size, are passed together between compressing rollers, and then taken up on the receiving roller. At first the wood sheets were used for walls without any lining or backing, but before being applied they were thoroughly soaked in water to make them pliable; when lined with paper, however, they are much stronger, and are used exactly as ordinary wall papers by pasting the sheets, or if preferred the wall itself. The sheets are so thin that the edges can be lapped over each other as readily and neatly as actual paper. After being properly fixed the walls can be either left untouched, rubbed down with oil, or varnished, and in either case look well. Amongst the woods cut for this purpose, and exhibited at Kew, are bird's-eye maple (*Acer saccharinum*), red maple (*A. rubrum*), swamp curly maple (*A. rubrum*), mahogany (*Swietenia Mahagoni*), black walnut (*Juglans nigra*), button wood (*Platanus occidentalis*), hornbeam (*Carpinus Americanus*), &c.

* This plan was proposed by me in the *Quarterly Journal of Science*, for October 1867, in the "Chronicle of Astronomy.' An instrument of some such sort had been constructed earlier by Mr. Birt, who called it the *homochromatoscope*.

NATURE PRINTS BY PHOTOGRAPHY.

THERE are probably but few of our readers who have never seen the beautiful pictures produced by skilful manipulators of the ordinary nature-printing processes. Probably the best method of producing these elegant pictures of leaves, ferns, and grasses is the most neglected of any, although it is possibly the most simple of all. We allude to the utilisation of photography in this connection, and extract some interesting details of the process from the *Photographic News*.

Our contemporary has more than once called attention to the very interesting, but singularly neglected, branch of photography, the production of copies of ferns, leaves, grasses, and other botanical specimens, by printing direct from the freshly gathered plant without the intervention of a negative. The production of these "leaf prints," as our American neighbours have styled them, is an occupation at once simple, elegant, and interesting, and may be adopted either for the purpose of securing pretty floral pictures and decorative designs, or for the more important purpose of aiding botanical studies. Where decorative results only are required there is abundant opportunity for the exercise of taste in arranging the leaves, stems, and blossoms of various plants in pictorial bouquets in graceful wreaths; ferns, and the leaves of various creeping plants, such as the ivy, the linaria, various grasses, the graceful plumous foliaged milfoil, and a hundred other of the most common wild plants growing by the hedge side, will yield endless varieties of effect. Where aid to study is the aim, the plan in question is not less full of interest and value. One of the first objects of the botanical student is to acquire a distinctive knowledge of the appearance of plants and their likeness to, or difference from, each other, which can only be acquired by constant comparison. When the student turns to the dried specimens in his flora, he finds that he has lost much of the characteristic of the fresh plant. By skilfully using the plant, or portions of it at a time, as a negative, he can retain many qualities utterly lost in the dried plant, however carefully preserved. Where the student, besides securing self-prints of the leaves and other portions of the plant admitting such treatment, will also take the trouble to photograph the whole plant, either the size of nature or in some definite relation to the size of nature, he will gain an enormous advantage in his studies. A set of such photographs accompanying his preserved specimens would give a flora more perfect than any other we know.

Treating of the subject for decorative purposes, Mr. Gaffield, of Boston, gives the following hints :—

1. The leaves and ferns should not be dried, as the dried leaves do not permit the light to delineate their beautiful and delicate venation. They should be freshly gathered and pressed between the leaves of a book, just enough to extract the excess of moisture, and then used before the delicate veins have become dry and opaque to light. The finest impressions are those from the fresh leaves and ferns.

2. They are not placed on sensitive paper, but fastened by mucilage to a sheet of glass in the form of the design required. This glass is then placed in a pressure-frame, and used as a negative from which to print. The sensitive paper placed upon this negative must be exposed to sunlight from ten minutes to half an hour, according to the season of the year, or the intensity of the chemical rays. The pictures can then be toned, fixed, and mounted like other photographic prints.

3. It is not true "that it requires but little skill to arrange the leaves and sprigs of fern, and none to print them." As the chief part of my work has been done by other and gentler hands than my own, I can, without a charge of immodesty, assure you that the work requires great taste and skill, and the expenditure of much time, labour, and patience.

Again, great care is necessary in printing not in injure or start off the delicate ferns from the glass. After the print is made, a sheet of white letter-paper should always be placed over the ferns, and the back-board put in position again to protect them from injury, and to keep them from drying and coming off the glass.

For the help of those who may desire to adopt this method as an aid to botanical studies, we reprint a few hints from Professor Hime's excellent work on the subject :—

In gathering leaves for photographic purposes, some care should be taken to procure perfect and characteristic specimens. The margins should be kept as free from overlapping as possible when the leaves are placed in the printing frame or pressed. Some are more easily managed if very slightly wilted, but generally the sooner they are subjected to a slight pressure the better. A portfolio or ordinary atlas, supplied with sheets of printing-paper, should be taken to the woods, in which the most delicate one—as the maiden-hair, fine-haired mountain fern, &c.—can be placed as soon as plucked. Many leaves can be printed from without pressing or drying—as forest leaves, many ferns, columbine, anemone, black currant, &c., but when the pines of the leaf may be expressed by the pressure used in printing, and stain the sensitive paper, it will be necessary to subject them to some pressure between the folds of bibulous paper. They should not, however, be dried as for an herbarium.

The ribs and veins in prints made from undried leaves appear as sharply-defined dark lines, and the whole appearance of the prints is superior to those made from dried leaves, in which the ribs and veins are represented by comparatively ill-defined white lines.

The reason of the difference alluded to lies in the fact that the ribs and veins, whilst filled with the fluids which they convey, are transparent, and allow the light to pass through and make a record of them in dark lines. When dry and empty they are opaque, and, by preventing the action of light, produce white lines.

Dried leaves may be made to give prints in all respects equal to, and sometimes even superior to, those obtained from freshly-gathered ones, by soaking them for several hours in water until the veins become expanded and filled. They must then be pressed between the folds of bibulous paper until dry enough superficially to print from. After this treatment they will only remain in good photographic condition several days, but the operation can be repeated as often as desired. A little glycerine added to the water will cause the veins to remain transparent longer, and a little hydrochloric acid will facilitate the filling of the veins in some cases.

When it is desired to print from several leaves upon the same piece of paper at the same time, it will be found convenient to fasten them to the glass by means of dilute gum-water. Immediately after being fastened to the glass in this way, they should be subjected to the pressure of the clothes-clip as in printing from them. In some cases it is best to place the leaves—especially dried ones—between folds of writing-paper, and subject them to as great a degree of pressure as can be obtained by means of an ordinary letter-press, before fastening them on the glass. If the leaves are not of the same intensity, the most intense—those that require the longest time to print—may be bleached as much as necessary by means of Labarraque's solution, or those least intense may be stained light yellow by means of turmeric. Small plants with flowers that preserve their shape somewhat in pressing—as violets—can be photographed entire.

As all prints taken from the leaves themselves must consist of a light image on a dark background, Professor Himes suggests that for many purposes an improved effect will be produced by using the print first obtained as a negative, first treating it with wax to render it transparent. The following is the method recommended ;—

Melt some pure white wax by placing it in a shallow dish placed in a pan of boiling water. Immerse in the melted wax sheets of blotting-paper. As these sheets will absorb much more wax than is required, a pile is to be made of (say) half-a-dozen of these with half-a-dozen clean sheets of blotting-paper, placing alternately waxed paper and clean blotting-paper, a few extra sheets of the latter being placed at top and bottom. The whole pile is then pressed with a flat iron heated to about the temperature of boiling water. By this treatment a series of uniformly waxed sheets of blotting-paper will be obtained. When a print is to be waxed for use as a negative, it is placed upon a sheet of blotting-paper, and then upon its face is laid a sheet of the waxed paper; this is then covered with two or three sheets of blotting-paper, and the whole pressed with the hot iron. The negative is thus uniformly waxed, and made sufficiently transparent for printing purposes.

Silver prints will, of course, be found to answer every purpose, and carbon prints, in suitable colours, still better. Blue and brown prints may be obtained as follows:—Prepare—

Ferridcyanide of potassium (red prussiate of potash)	100 grains
Water	1 ounce

Apply the solution with a tuft of cotton to a piece of Saxe paper pinned to a board. This will give paper of a uniform yellow tint. This, on exposure to light, becomes blue; the only fixing process necessary being copious washing in water until all trace of yellowness is removed. A saturated solution of bichromate of potash produces brown images by similar treatment, excess of washing having a tendency to decompose the image of brown oxide of chromium, and leave a pale green image of sesquioxide of chromium.

FLUID MEAT.

A SOLUBLE preparation, under the above title, has been perfected by Mr. Stephen Darby, F.C.S., which is likely to become of some economic as well as medical importance, says *Food, Water, and Air*. Mr. Darby recently gave some interesting particulars respecting this article to the Food Committee of the Society of Arts, from which we glean the following:—

"Fluid meat contains all the constituents of lean meat, including fibrine, gelatine, and coagulable albumen. By the process pursued these are all brought into a condition in which they are soluble in water and are not any longer coagulable on heating—in which state they have been designated peptones. This change is effected, as in ordinary digestion, by means of pepsin and hydrochloric acid. Lean meat, finely sliced, is digested with the pepsin in water previously acidulated with hydrochloric acid, at a temperature of 96° to 100° Fahr., until the whole of the fibrine of the meat has disappeared. The liquor is then filtered, separating small portions of fat, cartilage, or other insoluble matters, and neutralised by means of carbonate of soda, and finally carefully evaporated to the consistence of a soft extract. But this process, whatever care may be taken, leaves the fluid meat with a strong bitter taste. This bitterness attaches always to meat digested with pepsin; and this, in the opinion of medical men, would wholly preclude its acceptance and adoption as an article of food. In order to remove this bitter taste, and to obviate the objection to fluid meats on that ground, I have made many experimental researches, and have at length discovered that the purpose is completely and satisfactorily effected by the addition, in a certain part of the process, of a small proportion of fresh pancreas. The fluid meat so prepared is entirely free from any bitter flavour."

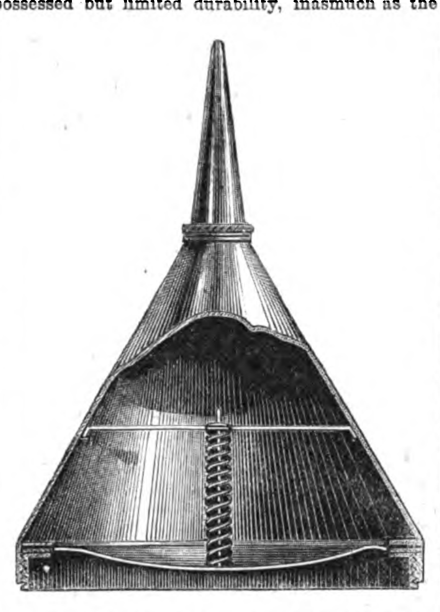
Mr. Darby regards these changes as exactly analogous to the action of the pepsin and pancreas on food in the body. 1lb. of soluble extract is obtained from 20lb. of lean meat, and he considers that even by using English beef economy is effected in certain cases, while, of course, the employment of the process in places where meat is much more plentiful would be attended with an equivalent increase of profit.

A NEW ANILINE VIOLET.

M. CLAVEL, of Basle, Switzerland, has published an account of the preparation of a new violet, obtained by heating magenta and iodide of ethyl without pressure. He calls it the "night violet," and obtains it by means of a condenser connected to the apparatus with a glass tube, in which the iodide of methyl, as fast as it is volatilised by the heat, is recondensed and falls back as a liquid. The apparatus is a common cast iron boiler heated by means of a steam jacket. The cover has two openings for two glass tubes in connection with a worm for condensation. The vapours rising out of the boilers pass into the worm, are there condensed, and from thence run as a liquid into the second glass tube which leads back the iodide of ethyl in a regular stream. For the preparation, he takes magenta crystals, solid caustic soda, and iodide of ethyl, with a suitable quantity of wood spirit; or the iodide of methyl can be used, and alcohol used as a solvent. The magenta and the soda are put into the boiler together, and well stirred till the mixture becomes uniform. Half of the iodide of ethyl is then added, the lid closed, and the condenser connected. Heat is now applied for six hours. The apparatus is then cooled, the remaining half of the iodide of ethyl added, and heating resumed for six hours more. After this time the connection between the condenser and the second or return glass tube is closed by means of a tap, and another tap is opened to allow the condensed iodide of ethyl to run off into a receiver. Heat is again applied, and maintained until all the iodide of ethyl and wood spirit are distilled over and preserved for use on another occasion. The mass which is left behind in the boiler is then taken out, and boiled for a considerable time with a strong lye of caustic potash. This removes all the iodine in the form of iodide of potassium, while the "night violet," is deposited as a cake. This is now in the state of an insoluble base. To render it soluble in water, it must be combined with an acid. For this purpose, the cake is dissolved in dilute sulphuric acid. When this has been done, the colour is thrown down by neutralising with a solution of soda. It is then washed in cold water, dissolved in boiling water, and finally reprecipitated by the addition of common salt. Unlike the ordinary aniline violets, which, when seen by artificial light, seem of a reddish brown colour, this dye retains its beautiful blue tone. A variety of shades may be obtained by varying the proportions of magenta, soda, and iodide of ethyl.

IMPROVED PATTERN OIL-CAN.

AN improvement in mechanics' oil-cans recently patented in the United States relates to that class of oil-cans in which the oil is ejected by pressure on a piston or a portion of the can made elastic for the purpose. Such cans have hitherto possessed but limited durability, inasmuch as the



bottom generally became worn out before the body; and as it formed an integral part of the latter, the destruction of the bottom caused the loss of the whole; the necessary repair not warranting the expense. This is obviated in the improved can by making the bottom readily detachable, so that when necessary or desirable it can be replaced by another, and as several bottoms are sold with the can the cost of repair is reduced to the minimum. The can is of the usual form, but provided at its base with an annular piece of brass or other metal securely soldered in place, and furnished with a screw thread on its interior surface; at the upper edge of this fixed ring or base-piece is an internal flange, *a*, on which a washer of leather or like material is laid; the flexible bottom is then placed with its edge on the washer just mentioned, and a second washer is laid upon the edge of the opposite side of the bottom. The annular nut shown, being provided with a screw-thread on its outer surface corresponding to that on the ring forming the base, is then screwed home, and firmly clamping the edge portions of the bottom, together with the washers, tightly fixes the bottom in position. The annular nut, is, in practice, fitted with internal projections in order that it may be easily turned. The bottom has the usual swelled or bulging contour, and may be fitted with a spring, as shown in the figure, arranged between it and the fixed transverse bar, but this can of course be dispensed with when desired, without impairing the advantages secured by the essential feature of the invention.

BITUMEN AS A PHOTOGRAPHIC MATERIAL.

A FRENCH photographer, M. Despaquis, recently exhibited to the Société Photographique of France, specimens of a new photographic agent which is likely to yield valuable results for photo-engraving and photo-lithographic purposes. This is bitumen of Judæa, which is used for sensitising either sheets of paper or mica. In calling attention to this new process, M. Despaquis said that the paper may be preserved for an indefinite period, if screened from light and protected from the effects of moisture. The manipulations necessary to its employment are of the most simple character, and are confined to placing the paper under a negative in the ordinary manner, exposing to light (a very long exposure is necessary) and washing subsequently in essence of turpentine.

The samples of paper are of various kinds. No. 1 is as transparent as glass, and is covered with a sensitive film of bitumen; it serves for the production of transparent positives, and for reproducing clichés, which may be put into the frame reversed if desired, according as the image is required for photo-engraving or carbon printing.

No. 2 is also transparent, but possesses more the appearance of ground glass. It is suitable for making transparent prints for stereoscopes, transparencies, &c., at a low price. With prints of this kind, the stereoscope needs no glass, and is, therefore, very light and portable. This same material answers well for the preparation of so-called photo-miniatures, which are produced by means of two prints superposed, the lower one being vigorously coloured; the tints, when viewed by transparency through the upper print, possess very fine gradations. The upper print is produced upon this No. 2 paper, which will doubtless be found to answer the purpose much better than albumenised silver paper rendered transparent by varnish.

No. 3 has a matt or opal white surface, formed by means of oxide of zinc and starch. It serves very well for the production of the second or lower print required for the object previously mentioned, and is also suitable for the preparation of transparencies.

All three papers may be attached or mounted upon cardboard like ordinary prints. To do this, the print is put upon a glass plate and covered with thin card slightly moistened; the two surfaces are then passed through a rolling press, and complete adhesion takes place.

The fourth material, which is likewise sensitised by means of bitumen, is, however, capable of more important applications. It is prepared specially for the transfer of photographic prints, with all their half tones, to stone or zinc, for working up with fatty inks, and printing upon wood, glass, enamel, painter's canvas paper, &c.

In this last named material, a film of gum is placed between the gelatine film and the film of bitumen, and as no washing in water is required for developing and fixing, it is attached while still wet with essence. If already washed and dried, the print is again treated with the essence upon the stone, zinc, wood, &c.; then by the aid of a sheet of thick and moist blotting paper, which is placed upon it and pressed down to chase away air bubbles, the print is allowed to dry under a slight pressure, as in carbon printing. The blotting-paper should somewhat overlap the print. One or two dry sheets of the same kind are placed over the wet paper, and these are then covered with a few glass plates. After the lapse of a few hours, the dried sheets are removed by means of a sponge and water applied to the last sheet of blotting-paper, and the gelatine being softened the gum is dissolved; the blotting-pad is then lifted off, carrying with it the gelatine, and leaving the bitumen upon the glass or metal surface. The image is thus transported to the block, and nothing is then necessary but to etch the same in the usual manner with acid.

The preparation of bitumen paper is, of course, no novelty, but it is the special employment of gelatine that is new. This renders the application of water unnecessary in development, and the film does not cockle or roll in washing; by the addition of starch, carbonate of baryta, oxide of zinc, and various colours, it is possible to impart to the film any degree of transparency desirable. The two principal points of importance are the application of bitumen of Judæa to a support of gelatine, which, not being dissolved in the liquids used as solvents for the bitumen, is not modified or changed in any way during the process of washing; and the special preparation of the bitumen, whereby it is very adherent to its basis, and of so solid a nature that it will allow of the application of a layer of printer's ink by means of a roller. Acid for etching may be employed with impunity.

This is a very important matter for photo-engraving or photo-lithographic purposes. Maps and drawings have been prepared upon glass by M. Despaquis in the manner indicated, and in these cases not only is the etching of extraordinary depth, but the fineness of detail is perfect, proving beyond doubt that the hydrofluoric acid which had been employed for etching had in no way attacked the film. These same qualities are only to be seen upon metal engravings; and although M. Despaquis is himself but an indifferent operator, he has been enabled to obtain these results very easily.

As to the transparent pictures produced by means of this material, they are certainly very beautiful when mounted between two plates of glass, forming very charming illuminated designs. The manipulations are exceedingly simple: there is no sensitising, no fixing, and no toning, inasmuch as the whole operation consists in placing the prepared material under a cliché, in exposing to light, and washing it in essence of turpentine.

SCIENTIFIC SOCIETIES.

CHEMICAL SOCIETY.

The Atomic Theory.

AT a recent meeting of this Society a paper was read by Mr. Atkinson, entitled "An Examination of a recent Attack upon the Atomic Theory," having reference to a paper by Dr. Wright "On the Relations between the Atomic Hypothesis and the Condensed Symbolic Expressions of Chemical Facts and Changes known as Dissected (structural) Formula," recently read before the Society, and published in the April number of the *Philosophical Magazine*, which led to an animated discussion. Mr. Atkinson said that Dr. Wright, notwithstanding his having asserted that the atomic theory is unnecessary, invariably uses it, arguing that we must either accept the atomic theory, in order to revise the approximate results obtained in any given analysis, or adopt the actual number obtained, instancing Roscoe's analysis and determination of the vapour density of tungsten oxy-chloride and other tungsten compounds. Dr. Wright refers to the law of multiple proportions as one of the facts of chemistry, but experiment does not lead to numbers which are multiples of his combining numbers, that is, the law of multiple proportions is not an experimental fact; thus, the vapour density of ferric chloride would lead to the atomic weight 112 for iron, and that of aluminium chloride to 55 for aluminium. Dr. Wright's analysis of hydrobromate of bromocodide would lead him to the formula

$$C_{18}\frac{1}{7}, H_{22}\frac{1}{6}, Br1\frac{15}{16}, No._{2};$$

instead of $C_{18}H_{21}Br_2$ No. $_2$, the one he had adopted; instead, however, of accepting the numbers obtained by analysis, he rejects them, and takes the nearest numbers which yield a formula containing only integral multiples of atomic weights. He also said that Dr. Wright had not attempted to explain the cause of isomerism, which can be readily done by the notion of the existence of atoms associated in different relative positions.

Dr. Wright said it was somewhat difficult to reply to a large number of objections which he had only just heard for the first time. He was afraid Mr. Atkinson had failed to understand the object of his paper, which was to distinguish between the employment of certain symbols to express certain facts, and the adoption of the atomic hypothesis to explain these facts. One of the charges was that of denying the atomic theory, and yet of employing that theory; the instance adduced being that the approximate results obtained by his analysis of hydrobromate of bromocodide would lead to the formula—

$$C_{18}\frac{1}{7}, H_{22}\frac{1}{6}, Br1\frac{15}{16}, No._{2}.$$

He need only say, that taking into account the errors of experiment, such as the presence of water, &c., the nearest whole numbers which represent his results lead to the formula $C_{18}H_{21}Br_2$ No_2; and that in assigning this as the formula, he did so quite independently of the atomic theory. With regard to his observations that the determination of the vapour density of ferric chloride and aluminium chloride would lead to the numbers Fe = 112 and Al = 55 he seems to have forgotten that the speaker had especially stated that compounds that dissociate, or are believed to do so, must be excluded in the determination of the combining number of the element. It is quite possible to express symbolically the difference between isomeric compounds without reference to any theory whatever: the two isomeric propylic alcohols, for instance, when treated with reagents, give rise to different products, and these facts can be recalled by the employment of symbols apart from all theoretical considerations. The speaker could scarcely see what great advantage was gained by the discussion of such a purely theoretical question as the constitution of matter, the important point being to express symbolically the facts with which we are acquainted. At present sufficient distinction was not made between Dalton's proposal to represent the results of his quantitative analyses by symbols, and the theory founded on these results—namely, that matter is built up of small particles or atoms, and these again are united to form molecules. The latter was a subject which admitted of much discussion. The use of symbols to represent facts quite apart from any theory gave us a power similar to that which the symbols in algebra gives to the mathematician.

Mr. J. Newlands remarked that it was very important to distinguish between the two proposals of Dalton—namely, the law of multiple proportions and the theory of the existence of atoms founded on it. Dr. Divers said there was one point he would like to refer to, and that was whether in sodium chloride, for instance, the sodium and the chlorine existed as such. On bringing together chlorine and sodium, the two united with production of intense heat, and formed a compound as different from either sodium or chlorine as these were from one another. True, we could obtain these elements from the compound, but we could not say they exist in it as such. We know nothing of the structure of coupled substances except that by certain reactions they yield certain products. It is quite possible, therefore, that although we get out the same elements from two isomeric bodies, these may differ in the amount of force they contain.

Dr. Williamson said that although it was a question of very great difficulty to decide upon facts so remote from our senses as these minute particles of which matter was built up, yet it was no more unreasonable to do so than with the enormous masses in the remote regions of our planetary system. He must say that those who consider it simply the part of science to record the results of observations, and not to endeavour to connect them with one another, know not what science is. A theory different from the atomic theory would be very valuable by reason of its giving us another point of view from which we might behold the facts with which we are acquainted. He would hail such a theory with delight.

Mr. Atkinson said it would be unnecessary for him to reply, as most of the points raised had been refuted by subsequent speakers.

The Chairman, Dr. Debus, was inclined to think that the representation of facts by symbols, without connection with some theory, was very like a body without a soul; the human mind could never rest satisfied simply with the outside representation of things, but would look for the causes which connect them. From about 1808 to 1820, in Germany, the dynamical theory advanced by Karl was generally employed, and it is remarkable that no great discoveries were made there, and that no eminent chemist existed during that period; whilst in England and in France, where the atomic theory was adopted, science advanced rapidly; when, however, Germany adopted the atomic theory, chemistry at once began to improve. These things spoke for themselves.

USEFUL AND SCIENTIFIC NOTES.

Force and Energy.—By "force" in rigid signification is understood the power of producing "energy;" by "energy," the power of performing work. To give an illustration: powder has force, the cannon-ball energy; but to speak of the force of the cannon-ball is inexact. It may also be remarked that the words "actual" and "potential" are in frequent use to qualify the state in which energy is met with. By actual energy is meant energy in an active state, energy which is doing work. By potential energy, energy at rest—energy capable of doing work, but not doing it. In a bent cross-bow there is potential energy—energy in a state of rest, but ready to become actual or to manifest itself, when the trigger is pulled. Again, actual energy is evolved from the sun. By vegetable life this is made potential in the organic compounds formed. In these organic compounds the energy is stored up in a latent condition; potential energy is reconverted into actual energy when they undergo oxidation during combustion, or in their utilisation in the animal economy.

Meerschaum. — At the Berlin Geographical Society's December meeting, M. Ziegler described the sources whence the considerable annual supply of meerschaum for meerschaum pipes is derived. Large quantities of this mineral, so highly esteemed by smokers, come from Hrubschitz and Oslawan in Austrian Moravia, where it is found imbedded between thick strata of serpentine rock. It is also found in Spain at Esconche, Vallecos, and Toledo; the best, however, comes from Asia Minor. The chief places are the celebrated meerschaum mines from six to eight miles south-east of Eskischehr, on the river Pursak, chief tributary to the river Sagarius. They were known to Xenophon, and they are now worked principally by Armenian Christians, who sink narrow pits to the beds of this mineral, and work the sides out until water or imminent danger drives them away to try another place. Some meerschaum comes from Brussa, and in 1869 over 3,000 boxes of raw material were imported from Asia Minor at Trieste, worth 345,000 florins. The pipe manufacture and carving is principally carried on in Vienna and in Ruhla, Duchy of Saxe-Coburg-Gotha. The commercial value of meerschaum carvings at these places may be estimated at £100,000 annually. However, very large quantities of them are not made from genuine but from artificial material. The waste from these carvings is ground to very fine powder, and then boiled with linseed oil and alum. When this mixture has sufficient cohesion, it is cast in moulds and carefully dried and carved, as if these blocks of mineral had been natural. It is said that about one-half of all pipes now sold are made from artificial meerschaum.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

**** In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

THE UNDULATORY THEORY OF LIGHT—FOCUS OF A LENS—AND CEMENTED OBJECT-GLASSES.

[4276.]—MR. HOPKINS (let. 4259, p. 280) has either taken singularly little pains to acquaint himself with the undulatory theory of light, or he is indebted to his own imagination for what he puts forth as such. It is simply ridiculous, to say nothing of its being untrue, that "the undulatory theory of light assumes" that what "is called luminiferous ether . . . in a state of rest is darkness, and in a state of undulatory motion is light!" The function of the ether is *to transmit vibrations* from the source of what we call light to the human retina, which is then itself set into a state of inconceivably rapid vibration. *It is this vibration of the retina which affects us as light.* It is mere nonsense to talk of the medium which transmits it "becoming visible." Perhaps a rough illustration may help to show Mr. Hopkins the error into which he has fallen. I assume that he is familiar with the fact that the scratch of a pin made at one end of a long beam of wood, or felled tree, is quite audible to any one who will put his ear against the other. Evidently, then, what happens in this case is that the vibrations caused by the scratching of the pin are transmitted along the fibres of the wood, that they set up corresponding vibrations in the tympanum of the ear, and that, in common parlance, we thus *hear* the sound. No writer on acoustics, however, that I have ever heard of, has yet attempted to enunciate the theory of this action by saying that the *wood* in a state of rest is *silence*, and in a state of undulatory motion is *sound*; and yet I fancy that even your correspondent must admit that this is no caricature of his own mode of exposition of the undulatory theory of light.

"Anon." puts a query (11991, p. 288) which he might have answered from, or found answered in, any fourpenny catechism on "Optics;" and I really must crave your indulgence, sir, for wasting the space necessary for a reply to so ridiculous a question. The focal length of a lens, then, is the distance from it at which the image of a distant object, like the sun, is formed. It "is ascertained" by holding the glass up in the sun and moving a sheet of cardboard to and fro until his image is perfectly sharp and well-defined upon it. A divided rule will then measure the distance between the lens and the card. It is "necessary to know it" (among other trifling reasons) because the eyepieces in a telescope and the plate-holder in a photographic camera have to be placed in this focus. In this reply I have dealt wholly with the principal focus of a lens, and said nothing about conjugate foci. I, moreover, expressly disclaim any attempt to give a scientific answer to such a query.

"C. B." (query 12029, p. 289) will find that, as a rule, terrestrial telescopes only, have their object-glasses cemented with balsam. I fancy that the makers do it to prevent that internal decomposition which will take place with lenses exposed to much damp or (especially) sulphurous vapour; and I think that they claim a slight increase of light from this arrangement. The sun ought not to melt the balsam, as it transmits heat rays pretty freely.

A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

DISTANCES OF THE STARS.

[4277.]—IF there be one man in England who knows more of the sidereal depths than another, indubitably that man is Mr. Proctor; but even he, I am afraid, will find "Dorset" (query 12018, p. 289) a trifle too much for him. If our querist will turn to p. 35 of your last volume (XIV.) he will find the parallax of nearly every star whose distance has yet been determined (there are about a dozen of them) in a letter by the present writer. In perusing this list "Dorset" will be struck by the curious fact that *the smallest stars are some of the nearest*; as, from the way in which his question is framed, he would appear to be under the impression that the smaller stars are, the further they are off. Your correspondent must forthwith obtain, read, mark, learn, and inwardly digest Mr. Proctor's last work, the "Essays on Astronomy." Its perusal will enlighten him most astonishingly as to the structure of the sidereal universe.

A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

PRACTICAL METHODS OF INCREASING THE LOUDNESS OF PIANOFORTE TREBLES.

[4278.]—FOR the purpose of increasing the loudness of the treble sounds of pianos only the subjoined means seem applicable.

1. The carrying out of any improvement in the soundboard, which is, or may become, known. I fear there is but little to be hoped for in this line, when I see that very little change or alteration has been made, for more than a quarter of a century, in pianoforte soundboards.

2. Increasing the force with which the hammer strikes the strings. This seems much more promising, for it is universally admitted that no piano with a weak action can yield powerful sounds, however large it may be, or however thick its strings are. The force of the blow may be increased by two methods. We may make the hammers heavier, or we may impel them with greater velocity. A hammer double the weight of another, which moves with the same velocity, must strike the strings with double the force the lighter hammer can strike them; but this (although a very great improvement in the bass) is unsuitable for the treble, because it is found to be impracticable to cause a very heavy hammer to rebound from the strings quickly enough after striking them to prevent it from partially damping their vibrations, and thereby (besides preventing the full power of sound from being developed) producing what is termed a "blocky" quality of tone. When a light hammer is impelled with great velocity, we obtain a sufficiently powerful blow without inducing "blockyness," because it rebounds from the strings instantly after striking them; in a word, it don't sensibly "damp" their vibrations, and suffers their full power of sound to become developed. Considering that there is no practical limit to the force with which a comparatively light hammer may be made to strike—except inducing objectionable weight of touch, also that sufficient force for any practical requirement may be obtained long before the touch becomes unpleasantly heavy—I think there can be no doubt that this method (which produces sounds of the greatest power and clearest quality) ought to be preferred.

3. Another method, which may be employed in conjunction with the above, is reducing the thickness of the covering of the hammers, or, what is preferable, covering them with harder material. Probably, there is not much further to be done in this way. I think it is already carried out pretty nigh as far as it well can be to advantage in ordinary English-made pianos, so long as their strings be not increased in thickness and length, in which case the hammers may be much harder than any we can employ to strike ordinary strings without inducing a disagreeable quality of tone. In this respect, many pianos of foreign make differ much from those of home production. Instead of, like most of the latter, having their hammers too hard, they are usually much too soft—at least in the treble—and most of them would be greatly improved by re-covering their treble hammers with thinner and harder felt, or even with doeskin leather, the tones produced by which I prefer to any I have yet heard produced by felt-covered hammers, but which material requires renewal too frequently to be suitable for general use. I may remark, however, the weakness of the trebles of foreign-made pianos—like the same defect in many of those home produced—is often caused by defects in the soundboard and in the action, as well as by the treble hammers being too soft.

Having thus pretty well exhausted every means which seems likely to be adopted in practice—excepting an improvement in the scale, for, I believe, extending the soundboard beyond, or, as in an upright piano, above the hammer line, as carried out by Godwin, Nosworthy, Alfred Wornum, and others—does not sensibly augment the loudness, however much it may improve the timbre or quality of the treble sounds of a piano, also dismissing Mr. Jenkinson's plan, on the ground that it must be too costly to execute and keep in order to be adopted for general use, not to mention that it can hardly be termed an improvement on the ordinary treble (it being, in truth, constructing two treble pianos with one action common to both, and placing them in the same case with one tenor and one bass piano), I now proceed to state what may be effected by altering the scale—*i.e.*, the lengths and thickness of the strings employed to produce sounds of given pitches.

Thalberg once said that, *cæteris paribus*, "the loudness of a pianoforte must be in proportion to the mass of matter we can put in motion to produce sound; doubtless, this is quite true within the limit "to produce sound," also that in practice that mass is only limited by the amount of force our fingers are able to impart to the keys of the instrument. Could pianists play on instruments with "tuppenny and threepenny touches" (see my article on harpsichord touches, p. 176, No. 371), which tuppenny and threepenny touches became sixpenny and ninepenny, *alias* six and nine ounces touches when the jacks plucked all the strings, simultaneously, they might put a very much greater mass of matter into sonorous vibration; but, I suppose, our fingers are not so strong as those of our forefathers, or even those of little Fanny Burney—the race is said to degenerate—so we can effect no useful purpose by augmenting the mass of the vibrating parts indefinitely. The force of a modern pianist's fingers is a limited quantity, which fact practically limits the mass they can put into sonorous vibration; and this, combined with the mechanical difficulties of executing modern pianoforte music, prevents us from making our piano-touches much heavier than the threepenny touch formerly employed on one harpsichord jack; in other words, we are limited to about 3oz.; nay, 2¾oz., or even 2½oz. touches, are generally preferred to 3oz., even in strong-handed Great Britain, and most continental pianists complain if the weight of touch exceeds 2oz., or 2½oz. at most.

This necessity for comparatively light touches also partly limits the number and thickness of unisonous strings which may be advantageously employed for a single note. The force of the blow being limited by the admissible weight of touch, it is, of course, quite useless to employ a mass of material in the form of strings greater than the blow can vibrate properly; consequently, even if pianoforte makers were not limited, as they practically are, by considerations of commercial requirement and practical convenience, from increasing the number of the strings for one note beyond three or four at most—I believe very few instruments have so many as four, even if made in France—they would soon arrive at the condition of failing to obtain any increase in the loudness of the sounds produced, because of the failure of the hammer's blow to vibrate so many strings properly.

So long as the number of strings be limited to three, there is no danger of being unable to strike them with sufficient force, both the actions engraved in No. 368 being quite able to do this, however long and thick we can make the strings. Indeed, long before the force of the blow could become too weak, relatively to the mass of three strings, the want of tensile strength of their material compels us to limit their length, and I fear the quite unavoidable consequent production of sounds of very unpleasant quality prevents us from very greatly increasing their thickness. Probably, wires from two to four sizes larger than those usually employed is quite as great an increase of thickness as can be allowed for treble strings; besides which, it should not be forgotten that every increase of length and thickness must be attended by a proportionate increase of rigidity, which soon more than compensates for any advantages increased length and thickness afford if the latter be carried to excess.

At first sight M. Thalberg's dictum might suggest increasing the superficial area of the soundboard in the treble, as well as increasing the length and thickness of the strings, and if *cæteris paribus* could in practice be maintained, it would be perfectly legitimate and probably successful, for our purpose to do this; but, alas! *cæteris paribus* cannot be maintained. Thalberg said "maintained in vibration," which a larger soundboard hardly can be if it cannot first be put into vibration, and that is just the thing very short strings cannot do. It is very easy to make your treble soundboard larger, at least beyond the bridge; but *cui bono*, if you cannot even make it vibrate (much less "maintain its vibrations"), at least not sufficiently for those vibrations to generate audible sounds; I fear we never shall be able to cause the necessarily short strings in the treble of a piano to induce the sonorous vibrations of its belly for any distance much farther than double the length of each string beyond each side of the bridge which supports them, or above and below that bridge in upright instruments; and, as any extension of the soundboard beyond that distance which the strings can (audibly) vibrate must be quite incapable of increasing the loudness, however much it may affect the timbre or quality of the sounds produced, we are soon practically estopped from increasing the superficial area of our soundboards in the treble by the utter inutility of doing it, consequently for the purpose of increasing the loudness of the treble sounds of pianos we seem to have no other resources than increasing the number, the thickness, and the length of their strings, and the force with which we impel the hammers which strike them. Practically, as commercial considerations prevent any increase in their number, we are reduced to the three latter methods.

How to carry out those methods I have given very full—perhaps it might truly be said very prolix—instructions in my articles on pianoforte actions in Nos. 338, 339, 367, 368, and 370, especially in those printed in Nos. 368, 369, and 370, illustrated by the engravings in No. 368, also in the illustrated article on an improved scale for the lengths of piano strings printed in No. 372. Regarding the latter I may, *en passant*, remark that the lengths shown in the figure are only two-thirds the full lengths of the strings from C above the lines to E, 30 semitones, so a workman, when making his gauges, will have to make each note exactly half as long again (both above and below the hammer line) as it is represented in the figure, which need not be a difficulty to the "skilled labourer." In that paper I purposely omitted specifying the thickness of the strings, because this must, in practice, be determined by the quality of the tone you desire to produce, and in this matter individual tastes differ greatly. For the same reason I omitted to specify the distance from the bridge at which I should prefer to make the hammers strike the strings; for this, again, ought to be varied according to the thickness of the strings (of any given length) employed to produce a sound of given pitch; also, perhaps, according to the number of unisonous strings struck by one hammer, for it is obvious the thicker and more in number the strings be, the more they must resist the blow a hammer of given weight, moving at a given velocity, can strike. That three strings whose total mass is fifty per cent. greater than the mass of two strings, must resist the same hammer's blow half as much again as two strings possibly can, is indisputable. Now, I see no possible method of even partly compensating for this increase of resistance—so long as the force of the blow be not augmented—but causing that blow to be delivered on a portion of the string which is less rigid, in other words, somewhat farther from the bridge.

Probably few persons who manufacture pianofortes for sale will be induced to string them so heavily as I prefer doing. I think they would prefer employing No. 17 wire for C above the lines, No. 18 for pitch C, No. 19 or 20 for middle C, and No. 20, 22, or 23 for tenor C, in which case, supposing the lengths of the strings of those notes to remain unaltered, it might be preferable, instead of causing the hammers to strike them at the same distances from the bridge, as I have specified below, that they should be struck at ⅞in., 1¼in., 1⅞in., 4¼in., and 7½in., therefrom.

For strings of the thickness I prefer using I have already stated the distance from the bridge I should cause the hammers to strike them, but to save the trouble of reference to back numbers—some of them rather far back—I again specify the sizes of the wires and the striking distances for the G and C's below the longest note in the scale printed in No. 372. Commencing at the top note E, I should employ wire of the sizes specified below:—

6 notes of No. 15		6 notes of No. 21
7 „ 16		5 „ 22
8 „ 17		4 „ 23
8 „ 18		3 „ 24
7 „ 19		2 „ 25
7 „ 20		2 „ 26

Assuming the instrument thus strung to be trichord down to fiddle G, I should strike its strings at the distances from the bridge specified below:—

C 8in. long, 1in. from the bridge.
(As shown in diagram p. 202, No. 372.)
G $10^3/_4$ in. long, $1^1/_4$ in. from the bridge.
C 15in. long, 2in. from the bridge.
G 19in. long, $2^7/_8$ in. from the bridge.
C 26in. long, $5^3/_{10}$ in. from the bridge.
G $35^1/_4$ in. long, $6^1/_2$ in. from the bridge.
C 50in. long, 8in. from the bridge.

Probably, it would be preferable to strike the strings of F♯ immediately below fiddle G, a trifle nearer the bridge than the distance this scale would afford, because that note having but two strings, each of which is only one size larger than those of fiddle G, might be a trifle deficient in firmness if struck so far from the bridge by an equally heavy hammer. Personally, I should much prefer that note to be strung with wire one size larger, say with No. 25, instead of No. 24, in which case it might be desirable to string the two lowest notes, C and C♯, with No. 27, also D and D♯, with No. 26 wire. If this be done, the striking distances for those notes may very safely remain unaltered, and, provided the hardness of the hammers be carefully regulated—in other words, the instrument's hammers be well "toned"—no offensive break in the loudness or quality of its sounds will be distinguishable where three strings are succeeded by two.

I rather think, Mr. Editor, that on the subject of pianofortes I have pretty nearly written myself out. Excepting the article on bracing and soundboard making which you have, and one on the various methods of tuning which have been employed, I don't think I have much more to say on this subject, so I intend to rest, and trust that yourself and my fellow readers will be thankful that these long-winded epistles which have extended over more than two years have nearly reached their terminus. Sooth to say, the subject of pianoforte improvement seems to the writer to be well nigh exhausted. However, should any fellow reader find a difficulty in understanding what I am but too conscious is very imperfectly expressed, I can only add I shall be most happy to afford them any assistance in the way of explanation—either through the columns of "our" journal or privately—which my small brains may enable me to give; also to reply to any questions, addressed either specially to myself or generally to my fellow readers, which my very limited experience will enable me to answer. A reply to the last of these, addressed to me by "H. D. W." (No. 11766), I have already written and will send soon.

THE HARMONIOUS BLACKSMITH.

INTERNAL RESISTANCE.—MANCE'S METHOD.

[4279.]—I HAVE to thank "Pi," p. 276, for describing this process, which I had overlooked, if even I had seen it. The process is good, particularly as it is applicable to other purposes; but for its special purpose it is scarcely so simple and convenient as the plan with a shunt given by Mr. Fitz-Gerald, which I should always use myself, if for no other reason than for this, that no calculation is required, and that the apparatus, once prepared, a single operation is all that is necessary at any after time, and the resistance of a single cell or battery is read off at once from the resistance instrument. Besides, in single cells it is important to have as small resistances as possible in the circuit, as the resistance sought must hold proportions to this, and the closer they approach in relative quantity, the greater the accuracy attainable.

SIGMA.

MEERSCHAUM.

[4280.]—IN answer to let. 4261, for meerschaum repairs, take a shank bone and make small tubes. Bore your pipe out with a twisted drill, and file your tube a nice fit; make that hot and cover with white wax or beeswax that all the oil has been pressed out of, and, heating the pipe, pass it through. This is the best and only way I have found to make a job of them, and if the joint is kept clean it will scarcely be seen. I have used this method for years. The pipes being treated to a bath of wax when manufactured, there is no way of cementing that ever I have found.

JACK OF ALL TRADES.

A SIMPLE METHOD OF HEALING WOUNDS.

[4281.]—I SEND, for the benefit of your numerous readers, many of whom often find some trouble in healing wounds from cuts, burns, &c., the following simple plan recommended by Dr. James Braithwaite, of Leeds, in the current number of the *British Medical Journal*. The plan is especially applicable to ulcers or festered wounds which have failed to heal by first intent through the entrance of dirt or some foreign substance. Dr. Braithwaite says: The application of an aqueous solution of carbolic acid (one drachm to eight ounces of water) to an ill-conditioned ulcer cleans it from all purulent matter, and causes it to assume a healthy red appearance, with each granulation distinctly visible. If a wound in this state be freely exposed to warm dry air for some hours, it becomes glazed and dried on the surface. It becomes covered by what is practically an impervious transparent membrane, closely applied to the surface of the granulations, and exercising a certain amount of mechanical pressure upon them. In many cases, no matter forms underneath this membrane, and cicatrisation goes on underneath it with great rapidity. In time, the membrane assumes the appearance of a thin dry scab, and drops off. If matter form under the membrane, it is at once visible through it; the lotion should then be reapplied, and the wound dried by exposure, as before. Immediately this is done, the inflamed edges of the ulcer commence to pale in colour, and in twenty-four to thirty-four hours have nearly the tint of natural skin. This treatment is especially of value in the cure of ulcers on the leg, as no confinement to bed is necessary; and what is required in the application of the lotion and subsequent drying can be done in the evening, after the conclusion of the day's work.

Disinfectant.—From the same authority I learn that Mr. T. L. Phipson, F.C.S., says: "The simplest, most effective, and most agreeable" method of disinfecting houses consists in spreading a little chloride of lime along the ledges at the top of every door in the house, outside the rooms. This, he says, should be done in the evening, and the next morning the whole atmosphere of the house will be found to have an odour resembling that of the sea. He says, when this odour is slightly perceptible it indicates that the disinfectant has been used in sufficient quantity. The reason for placing this substance upon the ledges over the doors is that the chlorine gas given off is a heavy gas, and falls to the ground.

I doubt, however, whether chlorine gas is given off unless the chloride of lime is treated with an acid. Some of our chemical contributors will perhaps say.

L. T. F.

AMATEUR ORGAN BUILDING.

[4282.]—WILL you find space for the following questions on amateur organ building. First, I want information to enable me to progress with my own organ; and, secondly, I am anxious to see whether it is not possible to make an altogether cheaper instrument than many of those advocated in the columns of the ENGLISH MECHANIC. I am half-way through a large organ—that is to say, for such a class of amateur as myself; my ideas being so enlarged by reading of the pedal bases, two rows of keys, swell box, &c., that it did not occur to me at the onset that a swell box really meant a case, say 6ft. × 3ft., × 4ft. 6in. high, of 1¼in. stuff, or that the mere fact of uniting principal as a stop instead of uniting coupler, meant the cutting of paper patterns for a week, and about 1cwt. of metal extra. I agree with Dr. Usher, now too late, that for the majority of amateurs a 4-stopped organ is quite enough. If the letter is too long, please omit it and insert the queries only.

Stockboards, or upper board, for an organ of C stops, soundboard 6ft. 1in. by 2ft. 8in.—I propose to make it in three parts, of 1¼in. pine or deal (mahogany cannot be afforded), as by so doing two stops can be placed upon each. How can I avoid the boards curling, as if braced with cross-wood, screws and glue they will perhaps curl? And a shifting brace like a drawing board I do not think will act upon a width of 11½in. Is it better to make it in three parts, with rack to each, or to make one board full size of soundboard to take all the pipes?

Will some of "our" readers send a few hints with a view of cheapening an organ, substituting (say) pine for mahogany. What can be the use of specifying 1in. or 1¼in. mahogany for a wind-chest, and covering that part of the soundboard not covered by the wind-chest with parchment? As both are subject to the same pressure, provided construction can be carried out, I conceive that the scantlings could be reduced to the strength of the parchment. Provided the middle board of the bellows is made strong and firm, say 1in. or ¾in. stuff, the bottom, top board, and frame of ¼in. stuff, why not make the ribs as light as possible, say ¼in. or ½in. pine, and covered with paper, or rag and glue, or perhaps of millboard, the object being to reduce the necessity for fine woodwork and expense? Is not the reservoir only an air-tight bag? I am a worker in metals and a draughtsman, but not a worker in woods, and thereby can be conceived the necessity to reduce the woodwork as much as possible.

Having got all the metal pipes to theoretical scale, what is the next operation before placing in the organ for voicing and tuning, and what are the lengths in practice? "J. D." gives 1in. shorter than the scale for a stopped wood pipe. If I so understand, this will give about 3in. or 4in. shorter on account of length of plug for the 12 basses CC to C. Is it the practice to voice and time the octives, and from these lengths to strike a new curve to cut the rest to?

DRAUGHTSMAN.

ELECTRICITY.—WHAT IS IT?

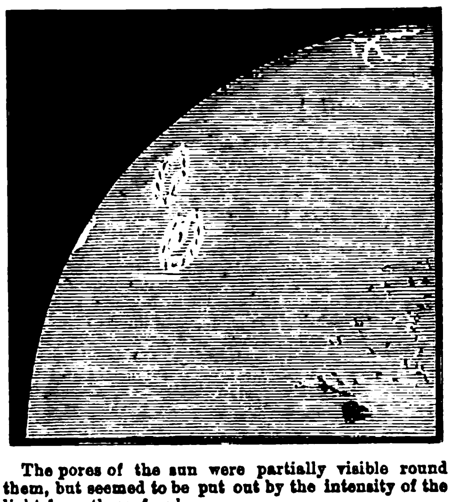
[4283.]—IN reply to Mr. Fitz-Gerald (let. 4251), I think he is peculiarly sharp on those who hold opinions contrary to his own with regard to electricity, for if I remember right, a similar letter to the one he referred to appeared in the ENGLISH MECHANIC when "Sigma" began his papers on electricity. I forget (if I ever knew) what theory Mr. Fitz-Gerald proposes to replace those which he claims to have upset, but if it had been a satisfactory one, and generally accepted, I cannot imagine that I should have been ignorant of it for so long.

The desultory nature of the first paper which Mr. F. complains of will, I am afraid, be shared by them all, though by the others, perhaps, to a less extent than the first; indeed, I could see no way out of it without increasing their length considerably.

Besides being very premature in his comments, I think Mr. F. is very much out of place in calling the paper ludicrous because contrary to his belief; for, in spite of his exhaustive investigations, which I have never seen and only once before heard of, many eminent philosophers still regard electricity as a force—indeed, the things he claims to have proved are directly opposed to the belief of some of our first philosophers (see "Tyndall on Heat," page 198), so that I certainly need not be *petitio principii*. B. THOMPSON.

SOLAR FACULÆ.

[4284.]—WHILE observing the sun at 6 p.m., on the afternoon of the 27th, I noticed two large and brilliant faculæ at the south-eastern part of the disc. They were then close to the edge, and consequently considerably foreshortened. The one farthest away from the edge was rather the larger of the two, but not so intensely brilliant as the second. I was at this time observing with a glass of 2¾in. aperture, and power of 80. On changing the latter for one of 200 I was instantly enabled to see further details. The upper one was composed of three masses, a larger one, and two much smaller, which were contained, as it were, by it. The second presented somewhat the appearance of a lunar crater, and the interior gave a fair idea of its floor. Both the faculæ were composed of small flakes, not unlike the feathers of a bird's wing. There was no spot in the immediate neighbourhood, and not one of any considerable size within 50,000 miles distance.



The pores of the sun were partially visible round them, but seemed to be put out by the intensity of the light from these faculæ.

It is worthy of notice that the shape of both of them was decidedly round, and there were no waves running sharply out from either, as is usually the case in large outbursts. I may mention that on the 26th, I had noticed a small patch of light in exactly the position these would have occupied had they followed the usual rotation. The annexed drawing will probably render the explanation clearer. PAUL W. WYATT.

Harpur-place, Bedford, May 30.

"THE HARMONIOUS BLACKSMITH'S" FUNNY FIRST FIDDLE.—To "F.R.A.S."

[4285.]—I BEG to assure "F.R.A.S." that he is totally mistaken regarding our relative positions—I was going to write in the scientific world; but, alas! instead of position I have not even the entrée. So far from I being head partner soliciting forgiveness, or rather advice from the Co., it is he who is certainly, at least, one of the heads of our scientific Co.—I mean cooperative for mutual instruction—journal. Hence, it is not at all surprising that the 'umble blacksmith desireth to "sit at the feet" of so scientific a Gamaliel as the "F.R.A.S.," who, although much the "Blacksmith's" junior, was, as the writer well remembers, devoted to the pursuit of science at that early period of "F.R.A.S.'s" life when it was my misfortune to be "earning my bread"—a thing "F.R.A.S." never had to do—by manufacturing and commercial enterprise, which, by the way, seldom sow the "seeds" of science.

I fear my rather long article on this fiddle is hardly clear; in fact, it can't well be if anything like a bridge is deducible. I never had any intention of employing a bridge proper, using that word to denote something on which strings rest, and which connects them with the soundboard. The piece of hard wood, 4½in. × 1in., which I proposed should be glued on the under surface of the soundboard, can hardly be termed a bridge, for it simply reinforces soundboard No. 1, and prevents it from becoming split between the holes bored in it for the reception of the strings, which I distinctly stated were attached to soundboard No. 1 just like those of a harp. Considering that, for facilitating performance, the strings cannot be far apart, it follows the holes for the strings must be bored pretty near each other, say as near or a trifle nearer than the strings of an ordinary violin are to each other on its bridge; consequently, if No. 1 soundboard be not reinforced, it would almost certainly be split by the tension of the strings.

The reason why I prefer placing the strings a trifle closer than usual is simply to bring the first string more conveniently within reach; were it not that there must be five instead of three strings behind it, closer spacing would be unnecessary. It will be noted that the first four strings are the same length (say 13in.) as those of the ordinary violin; consequently, the stopping will be as easy on my fiddle as on "any other man's fiddle," barring that to reach them we must reach over the two C strings, by which its compass is extended.

In regard to the length of the latter—to borrow the language *Punch* alleges Mr. Gladstone applied to Cerberus—I might have treated them "under three heads," more properly in three different ways. I could have made tenor C string, say, 14in. long, which is about its length in the viola. This would have required it to be "stopped" in planes differing from those of the violin to the same extent the "stops" are further apart in the tenor than they are in the violin. I might also have designed it the same length as the strings of a violoncello, thus making the CC string its usual length. Probably, doing this would produce the most powerful sounds of the finest timbre or quality; but as I didn't hope to rival Dragonetti or Bottesini, Lindley or Piatti, nor even to surpass my late friend J. A. Turner on the tenor C string, from which I have often heard him elicit sounds of great power, rivalling even those of the French horn in purity, I, like a true Englishman, chose a middle course; in a word, like all practical politicians, I accepted a compromise, and designed both the C strings only 2ft. long, which, assuming they be properly loaded so as to induce sufficient tension, will, I little doubt, afford sounds quite powerful enough for ordinary chamber music performed in the domiciles of her Majesty's subjects, who are oddly termed by Mr. Gladstone the upper middles; also in those of who might, quite as appropriately, be termed the "great middle middle class," for not many of their residences have rooms whose cubic capacity exceeds 10,000ft.

Why the holes in soundboard No. 1, which receive one end of each string, should be disposed on the segment of a circle of unusually small radius I cannot conceive. For anything I can see to the contrary, the radius of that circle may be quite as long as that of which the bridge of an ordinary violin is a segment. Provided the finger-board be posited somewhat nearer to the strings than usual, the radius of the arc might even be lengthened, because, so long as there be no danger of the bow touching other strings than those we desire it to act on, it would seem to be of little practical importance how flat the finger-board may be made, or how long the radius of the circle, on a portion of which the strings are disposed, may be. This appears to be a mere matter of practical convenience, and these considerations seem to me to dispose of the objection that my funny first fiddle would "necessitate a peculiar style of bowing." Were that objection well founded it would, in my opinion, be a very grave one. Although myself one of the "peculiar people"—I don't mean the religious (?) sect so-called, but merely an odd fellow—I yet, being also a rigid Conservative, deem all unnecessary departures from ordinary practice exceedingly unwise. Now, such a departure as necessitated the bowing of only one string at a time instead of (what we can now accomplish) the bowing of two strings together, would, I opine, be extremely objectionable, because it would deprive us of one of the greatest charms of good solo performance—to wit, the duet—although, perhaps, calling a duet rendered by one performer a solo seems rather Hybernian nomenclature. This deprivation would, however, be an abomination, which deserves to be accursed with bell, book, and candle, or even some yet stronger anathema, if such "great medicine" can (with clerical assistance, for priests are the principal manufacturers of curses, although lay assistance is often rendered) be prescribed and dispensed.

Probably, the fingering might, for a time, be "a bit of a puzzle." Any variation in the lengths of fiddle strings must be "a bit of a puzzle" to performers accustomed to their ordinary lengths. To render this puzzle as little complex as possible, I avoided designing the one or two thickest strings of the violin portion of my fiddle any longer than usual, although strongly tempted to do so by considerations of superior tone. Were the G and D strings made 2ft. long they would doubtless yield more powerful sounds of finer quality than they can do if limited to 13in. of length, even were they both loaded by wire wrapped round them—which, according to my experience, greatly improves both the power and the timbre of the sounds of the D string. Had I made them 2ft. long I fear my friend "Fiddler" and most of his fellow fiddlers would find their performances stopped by the "stops" on those strings becoming so much wider apart than usual and in different transverse planes to the stops on the A and E strings. It would, indeed, be very inconvenient to perform on an instrument which has two different scales within the compass of an ordinary violin. Of course, the same objection must apply, although with much less force, to making the two C strings longer than the G string; but I thought it preferable to encounter this evil—although it is far from an inconsiderable one—than the, perhaps, unavoidable consequence of bad tone, which, I fear, must necessarily result from the employment of C strings no longer than the G string. In this instance, as before, that true conservatism Disraeli has taught myself and the rest of the great Conservative party is "compromise."

THE HARMONIOUS BLACKSMITH.

SUN SCREENS.

[4286.]—WILL "A Fellow of the Royal Astronomical Society" allow me to point out that his suggestion (let. 4228, p. 278) in reference to smoking instead of silvering the field lens is not theoretically so perfect: indeed, the principle can hardly been said to be the same. They are both dependent on the effect of "minute solid particles, in the one case of carbon, in the other of silver," it is true, but the former act by absorption, the latter by reflection. The field lens would consequently be much warmed in the first case, and hardly at all in the second. With a large aperture, the heating of the field lens from this cause might be considerable, although the actual focus is formed some little distance beyond it. But there is another consideration—viz., that though a sufficient thickness of lampblack will undoubtedly absorb all light and much heat, yet a considerable portion of the heat is transmitted through it, as much, I think, as 38 per cent. for a film of ordinary thickness. The carbon particles are not by any means so athermanous as they are opaque, and I need not say that transmitted heat is unpleasant to the eye of the observer. In the case of a bright silver surface everything, heat as well as light, is reflected back and away up the tube again. I hope "F.R.A.S." will excuse my calling to the attention of his readers these to him well-known, though possibly overlooked, facts.

By the way, I remember that a short time ago one of your correspondents raised an objection to Mr. Berthon's plan of silvering the lens, on the ground that the reflected rays would converge and form a hot focus on the object side of the lens, which might produce a disturbance from convection currents. Eliminate the word hot, and the closing clause dependent thereon, and the sentence is correct; the focus is undoubtedly formed, but it is not hot. In the intense focus of an electric light, the air might be actually at a freezing temperature, while a piece of blackened platinum placed in it would be instantly rendered incandescent. If a substance does not absorb heat, it cannot be warmed by any quantity passing through it. Pure air is almost perfectly diathermanous, and consequently is quite unaffected by the passage of radiant heat, however intense.

A very striking experiment in proof, or rather illustration, of this is the following, devised by Dr. Tyndall. Take an air thermometer with a single large clear thin bulb, so sensitive that momentary contact with the finger will notably depress the column of liquid (I say *depress*, because in these instruments the bulb is at the *summit* of the stem). Place this in the rays of the electric light converged with glass lenses, so that the intense focus may be formed in the centre of its bulb. Although the glare is intolerable, not a motion of the liquid ensues, the rays pass through the air without communicating any warmth to it. As Tyndall observes, "A person on first seeing this can hardly believe his eyes." Of course, if the glass be slightly lampblacked, or even if a little tobacco smoke be introduced into the bulb, a most violent depression of the column is instantly produced.

SIRIUS.

IS LIGHT INVISIBLE?

[4287.]—JOHN HOPKINS (let. 4259) some time since saw an experiment described "to prove the invisibility of light." I presume it was the beautiful experiment shown by Professor Tyndall in his lecture on "Atmospheric Dust;" but our correspondent is not satisfied with the deduction therefrom that light is invisible, and proceeds very neatly to state the dilemma or "fix;" but I think he will find that the dilemma arises, as in most other cases, from an ambiguous meaning attached to one of the terms employed—in this case I think the ambiguity is in the word visible. If the visibility of light only meant that light proceeding from incandescent or reflecting bodies in the direct line of vision of the spectator excites the optic nerve and produces in the brain the sensation of light, then the visibility might be admitted. But visibility means more than this.

Before light can be pronounced to be visible, it must be shown that it can be seen in whatever line it is proceeding, even though that line should be vertical or at right angles to the line of vision. For instance, let the spectator stand in a square chamber, his back to the wall. In the wall on his right hand is an opening admitting the sunlight, which falls upon the wall on his left. He is conscious that the wall on his left is illuminated, because the light is reflected to his eye, and excites the optic nerve accordingly; but the light passing through the chamber from right to left is invisible. He may, perhaps, perceive a faint pathway of apparent light; but this would be only illuminated atmospheric dust. He cannot see the sunbeam, but only "the gay motes that people the sunbeam." Now, if a spray of water, or a jet of steam, or a cloud of smoke were passing from right to left, it would be visible, and would obscure the view of the wall of the chamber immediately in front of the spectator; but light in its transit is invisible, and the wall opposite is distinctly discerned, which it would not be if the light were visible; and it is well for us that light is not visible, if it were we might almost as well be blind, for we should see nothing else distinctly. I think we must conclude that although light is the exciting cause of vision, it is in itself invisible.

BOBO.

MAGNETO-ELECTRIC MACHINE.

[4288.]—IT has been asked from time to time through the medium of the ENGLISH MECHANIC how a magneto-electric machine can be constructed: although there are many contributors better able than myself to answer this question, I venture in a humble way to do so. The Figs. 1, 2, and 3, will assist me to describe its various parts. There are many kinds of magneto-electric machines, but the principle is the same in them all. Fig. 1 is a representation of one most commonly in use; A is a powerful horse-shoe magnet; B B are reels which are generally made of boxwood, on to which is coiled a quantity of moderately fine, insulated wire; in the centre of each reel is placed round soft iron, joined to C C, which is also soft iron; but as this part of the machine is the most difficult to understand, I will go more into details directly. D is the armature of the magnet A, made of soft iron, which can be moved to regulate the current. E represents a grooved wheel for the use of a gut band, communicating motion to another grooved wheel seen in Fig. 2, E. F is a toothed wheel running in another wheel attached to E, to increase

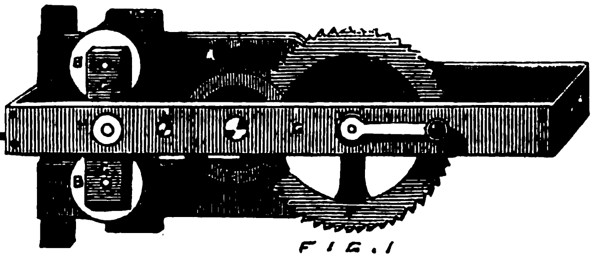


FIG. 1

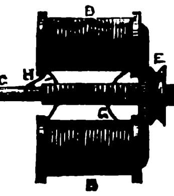

FIG. 2

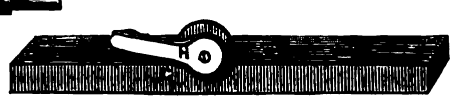

FIG. 3

its speed; a handle is screwed on the axis of F. G represents the framework made of brass to suit the requirements of the machine. I will direct attention now to Fig. 2; the secret of these machines depends materially upon the construction of the spindle which carries the reels of wire. D is a round piece of iron, filed flat on two sides at F, but not at the end beyond F. One part of the spindle is electrically insulated from the other, which may be done in the following manner:—Let a moderately-sized hole be drilled into D horizontally, and insert a piece of ivory or vulcanite; a hole is then to be drilled into the ivory to admit the thin part of the spindle C; care must be taken not to drill the hole in the ivory deep enough to allow C to touch D. The wire must be wound on the reels as follows: Each reel is filled separately, a length of wire must be left to come outside of each; let the wire in the first reel be wound on from right to left under the reel, and of course left to right above, but the second reel in an opposite direction; the two ends from the inside of the reels are soldered together not to touch D, then one of the free ends is soldered to D, shown at G; the other end to C at H which must not touch D. The reels when fixed in the machine are shown in Fig. 1. The C end of the spindle runs in a hole in a plate parallel with the magnet; the end F comes through H, which is a bit of box-wood fixed in plate G to insulate F from the other part of the machine. This leads me to explain Fig. 3, which shows the top and behind of plate G. H is a stiff spring screwed to the projection at the top of G, and made to bend to the back, that it may press on the spindle at F, Fig. 2, but the spring must not touch the flat sides. The machine complete is put into a suitable box, a binding screw goes through one end and into I, Fig. 1, another through the other end, but a spring must be attached to this, and not touch the machine except the F end of the spindle D, against H, Fig. 1. I think a little attention to the diagrams, &c., will give some idea how these machines are constructed, but it must be understood who ever constructs one should use judgment at every stage of his progress, as success depends upon exactness in every part.

J. THOMPSON.

"E. L. G.'s" COMET.

[4289.]—"HAVING no case, abuse the plaintiff's solicitor." "E. L. G." is getting out of temper, and therefore out of judgment, or he would not have written the first paragraph of let. 4239, p. 276, in which he ignores some of my arguments as though they were mere unsupported assertions, as is the case with too many of his own. He must remember, however, that if I replied to one of his extraordinary fallacies, "This is absurd," I did not do so as an *ex cathedrâ* condemnation, but gave the reason why it was absurd, a reason to which he has given no reply.

So also as to my argument as to the pressures resulting from the supposed fall of 10ft. per minute of water; he actually goes so far as to falsify my argument by saying that I "invent some unknown law whereby water that fell on land would not remain thereon long enough to press it." I did nothing even resembling this, but pointed out the self-evident fact that if the earth is coated with a mere elastic film, which "E. L. G." asserts would be disturbed by this pressure, then the water falling all over the surface would press *equally* on sea and land, and therefore not produce the result stated, but would produce the opposite as soon as the water ran off the land. Nor is it at all reasonable that "E. L. G." should foist his responsibilities upon me by asking how I got the water back from the sea. I never put it there, I do not believe it ever was there, but as "E. L. G." asserts that it was, and in quantity sufficient to cover sea and land, it is for him to show how the drainage was effected. I see how he means to do this; he proposes to lower the sea bed, and so make a cavity, and to raise the Andes, Himalayas, Alps, and other great ranges, so making space for water. But, as he tells us he is the "defender of natural law versus miracles," he must show where the force came from to effect this. He has brought the water in a comet, and so arranged things that the whole earth is submerged; it is, therefore, on his showing a mass of fused minerals covered with a film of solidified materials, and again by a stratum more or less deep of water, of course in the form of a spheroid of rotation. Now, what new force disturbed this condition of equilibrium, depressing one portion and elevating others of the covering film? Ordinary earthquakes and volcanoes may be accounted for by gradual cooling and contraction of the mass, but not this sudden and enormous change.

Again, "E. L. G." permits his wrath to overmaster the most ordinary courtesy, when he ventures to say he "does not believe" Roscoe or Huggins made a remark I quoted, and the source of which I named, copying and giving it as a verbatim extract. The words will be found on p. 253 of the first edition of Roscoe's "Spectrum Analysis;" nor can I see that, whether Roscoe was playing the buffoon or no in making the statement, I was doing so in quoting it in reply to the ridiculous assertions and baseless assumptions with which "E. L. G." fills page after page.

One would really suppose that those who object to this cometic dogma were a mere ignorant minority; that no one who really knows "the chief points yet discovered respecting comets, the earth, and the properties of fluids," can possibly require any evidence in support of it, for with charming *naiveté* "E. L. G." remarks, "No one so acquainted *would*, I conceive, ask for proof of anything so obvious." But as "E. L. G." also says he stands "alone, unless Mr. Gosse or some other physicist likes to help" him, therefore, it is evident that "E. L. G." is alone acquainted with these discovered laws. That *is* the case; the comet is his own discovery, unless he got it as a legacy from Whiston.

Now, "E. L. G." commenced this discussion at p. 91, with a characteristic threat of demolition to every one not inclined to adopt his views, and with a distinct promise to "show that every kind of evidence that could be fancied on this point exists. There is no conflict of evidence; all is harmonious." I have just measured the space he has taken up—just 11½ columns; and having given us one evidence (as he considers it, but no one else)—viz., the rounded form of hills and "sweep vales;" he again tells us "there is abundant evidence of a *steam* comet-fall 50 centuries ago, but not one of gas, for at least many thousands." Now, if there is *any* evidence either of the occurrence or the period, let us have it, in as few words and as plain a statement as "E. L. G.'s" peculiarities will permit—but let us have nothing else. I protest against page after page being filled up with magniloquent phrases meaning nothing. It is almost impossible to discuss the subject at all without shocking many people's feelings, and possibly injuring some people's faith in matters of first importance, but it is quite impossible to discuss it in the absence of a single particle of evidence; and, for my own part, these are my last words upon it, at all events till some evidence is forthcoming, as I have no wish to have a mere sparring-match with "E. L. G.," which is very much like fighting a cloud.

SIGMA.

"E. L. G." AND THE PROOF OF THE DELUGE.

[4290.]—I TOO would wish heartily to thank "E. L. G." for his excellent letters on this subject, though I feel my doing so may expose me to our "F. R. A. S.'s" sneer, and to our friend "Sigma's" scorn. But I am one of those old-fashioned people who have not yet been so far "educated" as to have come to regard the Deluge as a "myth," a "grand old legend," and its recorder, though "learned in all the knowledge of the Egyptians," as no more than "a semi-barbarous Hebrew." But, then, I am only an Irishman, trained in the Irish University of good Queen Bess, where the professors, as a rule, do not swallow all Lyell. This may be my misfortune; but, be that as it may, I have not given up "the tales of my childhood," and though I do not go with everything

"E L. G." says, I think there is a great deal in what he has brought forward which no one has as yet proved false, or shown to be less likely than what they would themselves substitute.

"E. L. G." is right well able to cope with either "Sigma" or "F R. A. S.," who, I regret to think, consider all who differ from their dicta as regards a flood 5000 years ago to be "playing deliberately into the hands of the infidel and scoffer." I cannot see how this need be, and, therefore, I venture to point out one or two weak points in "Sigma's" answers, as it appears to me, and trust he may reconsider what he has written, or found his objections on something else.

In "Sigma's" letter (4086, p. 196), he finds objection to "E. L. G.'s" illustration of the effect of rain in forming "furrow vales" in the earth, and says that its effect on a heap of clay is not at all applicable to the form, past or present, of the earth's surface—for that if any thing is certain it is this, "that the original condition of the earth was not that of a mass of clay, mud, or sand," that "clay, mud, and sand are the products of the wearing away of old solid rocks, and are again passing into solid rock."

Now, from this one would suppose that "E. L. G.'s" theory was based on the supposition that at the time of the flood which he contends for there were no rocks, that the earth was only a lump of clay, sand, and gravel. Starting, then, with this unfounded supposition, which he seems to wish to father on "E. L. G.," he proceeds to smash it to bits, and tells us that the effect of "E. L. G.'s," comet on this earth (which he "Sigma" has made for himself) "would be to reduce it to a true spheroid of rotation covered with water over its whole surface."

Now I have read very carefully all that "E. L. G." has written on this subject, and it seems to me he has never once given ground for such an unfounded supposition to be attributed to him, and has in more than one place stated that it is the "drift gravel," or "boulder clay" (let. 4157, p. 226), the then loose earth or disintegrated rock, which he believed the Deluge had formed and alone could form into "sweep vales."

A flood could not in a few days or hours smooth down a hard jagged rock, and make it into a gentle sweep, but it might gather around it and over it a mass of mud, sand, and gravel, and thus form a gentle slope. If any one doubts this let him walk along the bank of a river where there has lately been a flood, and he will see so many instances of its effects in forming of mud, sand, and gravel, sweep vales and sloping hills in miniature, that I will venture to say he will not regard a flood which once covered the whole earth at the same time as a mythical event, but rather as the most natural way of explaining the numberless facts he cannot shut his eyes to.

"Sigma" seems to think it a more rational explanation to believe that there were a number of local floods—which to produce the effects must have been greater than any recorded in profane history or in the memory or experience of later times, and these great local floods "constantly happening" (let. 4086, p. 196)—than to believe possible the one great flood recorded in a book which some still regard as divine, and of which one flood there is traditional record more or less distinct found amongst all nations even the most barbarous, and not amongst the merely "semi-barbarous Hebrews."

"Sigma" (let. 4193, p. 252) says a mass of water falling over the whole surface would do the reverse of what "E. L. G." states—*i.e.*, the sinking of the highlands, and rising of the sea beds, or as records call it, the breaking up of all "the fountains or foundations of the abyss."

Does "Sigma" forget the little but important fact, that the general surface of the land is somewhat above the sea level, and therefore, though the water might run into the sea, it could only do so if the land did not sink under the weight of water, which, because of the difference of level would first fall on it? The question, then, is, would there not have accumulated on the land and into the hollows a weight of water sufficient to entirely overturn the balance before a single drop had fallen on the sea. I think there is no doubt "E. L. G.'s" comet would effect what he contends for, and not the reverse.

Now, does "Sigma" think that he is arguing honestly for the truth when he says "the 10ft. on the area of the land would be balanced by the 10ft. per minute on the sea"? Is he so poor a mathematician as to think that the water will run as quickly off an inclined plane, and at the same time do the work of transporting mud, sand, and gravel, uprooting trees, shrubs, and everything, and carrying them along a winding course, and yet only take the same time as it takes to fall through the height of the inclined plane—*i.e.*, in other words, does he believe that there would be accumulated on the land no more than 10ft. water, by the same time there was 10ft. on the sea? How else could the 10ft. on sea balance the 10ft. on land? It would have to balance many times 10ft. on the land.

"Sigma" has only to look again at his reasoning in letter 4193, and he will see he is all wrong, and that a mass of water falling over the whole surface would certainly increase the pressure on the land more than it would on the sea, and first on the land.

Let us take "E. L. G.'s" rainfall of 10ft. per minute; there are, I imagine, many inland plains or valleys, call them what you like, and of large extent, whose level is some thousand feet above the sea. Now the rain which fell on the highest mountains would run down into these valleys and then form lakes, and thus there might be concentrated at one point on the land a pressure many hundred times greater than it had to bear but a minute before, and this might and would in certain places be the case before a drop of rain had fallen on the sea. Of course, till the land began to sink, the water would tend to run off; but still it would be retarded sufficiently to form the elevated lakes I have spoken of. But further, even let us suppose that the rain began to fall on the sea at the same time as on the land, or at a period of time so shortly after as to be inappreciable; and so if it were possible to have 10ft. on sea balancing the 10ft. on land, it would not have the effect "Sigma" supposes, for 10ft. on the sea surface would be equal to the pressure of a column of water 10ft. high distributed equally over all the bottom of the sea, and this it could bear without any sinking. Now, in the second minute, 10ft. more would be added to the pressure on sea's bottom, but it would be equally distributed—it would not be 20ft. at one place and 60ft. or 100ft. at another; it would be 20ft. plus whatever in the second minute might have run down off the land, which would not be more than a foot over the whole sea, if it would be so much. But what state of things would obtain on the land at end of the same second minute? In many places there would be an increased pressure of many hundred times greater than it had to bear but a moment before, and under this it might begin to yield, and if it once began it would take some time to stop it and set it going in the opposite direction. "Sigma" may know this from his chemical balance—if he puts too much in one scale and it begins to descend, a greater weight in the opposite scale will not at once make it commence to rise again. Thus the land would first sink, and could only do so by raising the bottom of the sea, whose waters would rush in on the lands, and thus help to flood and sink them. Derf Errac.

P.S.—I trust "E. L. G." will give us some more proofs. He has many a one who sympathises with him in his desire, in this and other matters, to have the truth known and acted on. Let him manfully, yet humbly, fight, and the victory will not be uncertain, though, perhaps, delayed. If he were not so well able to hold his own against all comers, more friends would speak out. Till help is wanted, it is oftentimes better withheld. D. E.

THE DELUGE.

[4291.]—While endeavouring to avoid infringing the law laid down for the exclusion of theological discussions (a law which, however, I much regret, as I long to break a lance with several of your correspondents), I wish to address a few words to "E. L. G." on the subject of his recent letters on the Deluge. Why does he give himself the trouble of trying to explain such an impossible phenomenon as a universal Deluge, deep enough to submerge the hills all over the earth, when there is at hand a far easier solution of the question? There had not been time enough since the Creation for men to have spread themselves very far from their first dwelling place, and, in all probability, their wanderings were confined to the level valleys, where the existence of themselves and their herds could be maintained with little or no exertion; therefore, what is more natural than to suppose that the Deluge, which was really universal as regards man and his possessions, should have been only partial as regards the whole earth? Provided that it accomplished the destruction of every human being, this awful instrument of the Divine wrath had done its work, and further ravage was unnecessary. God's wisdom in adapting means to an end will not allow us to suppose that in order to destroy man, He drowned the whole earth, where man had never yet come. We may, therefore, conclude, until it is proved to the contrary, that the Deluge was not universal, but partial, and confined to those regions inhabited by man.

Apologising for having occupied so much of your valuable space with these notions of mine, I leave "E. L. G." to explain to us what became of the water from his comet, and when that is satisfactorily done, how specimens of all the creatures of the earth could have been got into the Ark and preserved from destruction. If he cannot do this his theory falls to the ground. Vertumnus.

MORE PROOFS OF THE DELUGE.—II.

[4292.]—"As lakes and river systems," says Darwin, in his famous work on "Natural Selection," chap. xii., "as lakes and river systems are separated from each other by barriers of land, it might have been thought that fresh-water productions would not have ranged widely within the same country; and, as the sea is apparently a still more formidable barrier, that they would never have extended to distant countries." Certainly that seems, on any Lyellist view of Geology, very obvious. Of the three mansions of terrestrial creatures, land, sea, and fresh-water, the second alone has free connection round the globe, or over most of its face, having but a few detached outliers, as the Caspian and minor salt lakes. The first, the land, is mainly in two masses, but neither exceeding its half, and the outliers (of which our Britain is only about the twelfth largest) vastly more numerous than those of salt water. But the fresh-water mansion, widely different in plan from either, is in countless thousands of separate chambers, the largest barely holding a fraction of a tithe of it, and all of them as separate and permanently inaccessible now to their inhabitants, each from each, even when as near as the Thames and Medway, as are the earth and moon. Assuredly, few things could be plainer than that as long as "causes now in action" were uninterrupted, the mansion most uniformly stocked must be the sea; next to it the continents, and possibly some or many islands to which their land creatures and plants (or eggs and seeds of them) might be occasionally carried on driftwood, by birds, or even on ice; but that the fresh water, in its myriad isolated systems, each locked up in its own valley, must have the diverse, localised and peculiar stocks. Now hear Darwin proceed:—"But the case is exactly the reverse. (!!!) Not only have many fresh-water species, belonging to quite different classes, an enormous range, but allied species prevail in a remarkable manner throughout the world. I well remember, when first collecting in the fresh waters of Brazil, feeling much surprised at the *similarity* of the fresh-water insects, shells, &c., and at the *dissimilarity* of the surrounding terrestrial beings, compared with those of Britain."

"With respect to plants," he adds, "it has long been known what enormous ranges many fresh water and even marsh species have, both over continents and the most remote oceanic islands. This is strikingly shown, as remarked by Alph. de Candolle, in large groups of terrestrial plants, which have only a very few aquatic members; for these latter seem immediately to acquire, as if in consequence, a very wide range." That is, in such a group or family the majority of the members, those of *dry* habitat, with their free run of all their continent's uplands and connected frame, these are all *localised*; but the *fewer* branches of the family that need marsh or even constant water, and so are locked in by hills, each to its particular vale or basin, "these latter seem immediately to acquire, as if in consequence (!), a very wide range," or "enormous ranges, both over continents and the most remote oceanic islands"! !

Now, surely, if "the distribution of living beings" is to prove anything at all (as "Santalinus" and your other correspondents tell us it must, though I have demolished any connection between their facts and their dogma about deluges), here is a startling world-wide class of facts, according to Darwin and De Candolle, than whom I know of no higher "authorities" on this distribution, that must go to prove *something!* The trouble taken by Darwin, as detailed in the rest of that chapter, is truly worth reading. Nothing less could impress on minds like our "F.R.A.S.," M. Paris, "Osa," &c., the transcendent irreconcileableness of the above general facts with his baseless Lyellian dogmas All these elaborate experiments with duck's feet, &c., to prove what? Only barely to make out a *possibility* of some *occasional* transfer of fresh-water seeds or ova from one country to another over sea, or over hills (though the latter, indeed, the commoner problem, is not solved at all)—a bare chance of *some* fresh-water organisms happening now and then to obtain diffusions approaching or distantly imitating what is general to most of the sea and dry land ones. This is the utmost the experiments establish (if so much), when, by Darwin's own account, as you see above, the thing to be explained is not a diffusion of *some*, nay, not even of all or the generality of fresh water species, partly, or even quite *as well* as most sea or land species; but a diffusion of them as a *general rule*, *wider* and over *more* "enormous ranges" than the sea and land ones!

In short, if such things are evidence at all, while there is absolutely *no* evidence of all or the generality of *land* having ever, in any geologic period, been connected, or even the whole of the salt waters having been so, it is quite otherwise with the fresh. There is just *all* the evidence the nature of the case would seem to admit of, that the *fresh* waters have been connected, and this in quite the modern geologic period, that of the existing (not extinct) plants and animals. No shadow of evidence, indeed, for any of the many "partial deluges" of "F. R. A. S.," and others—(can none of the geologers, by the way, tell us the limits of even the very last? I do not even ask for the last but one of these deluges)—no single fact for any one of these uncaused and, as far as they have shown, sheerly *miraculous* deluges, baseless myths of their imaginations; but, on the other hand, *all* the evidence that could well be imagined (consistently with known laws) that once, in recent ages, a layer of fresh water has covered both our continents and oceans at once.

And so, if it be known, as M. Paris tells us, p. 255 (but it is still unknown to me), that mere freshets of Indian rivers kill "millions of sea fish," then, probably, their mourner has to mourn the death, at that deluge (the sole traceable one), of still more of his marine friends; unless there be reasons (as there may be plenty neither known nor knowable) for a vertical accession of fresh water killing fewer than a lateral. But whether more or fewer, billions or tens, I fail to trace any connection of their deaths with our argument.

Now, being in this twelfth chapter of Darwin, we may as well quote his other grand puzzle, that of the beings on "oceanic islands." First, he tells us, "The species of all kinds which inhabit oceanic islands are few in number compared with those on equal continental areas. Alph. de Candolle admits this for plants, and Wollaston for insects." Of this he proceeds to give very striking examples; all New Zealand, for instance (equal in extent and climates to Italy and Sicily together), having fewer species than a bit of most continents of a hundredth its size and but one uniform climate—nay, than a civilised isle as small and uniform as Anglesea! This *fewness* of species (in either kingdom) on each single pelagic island, and, moreover, their *separateness* on islands even within sight of each other (which astonishes Lyell in the case of Madeira and Porto Santo, two very ancient isles, long, long ante-Noachian)—these two facts, especially coupled, as he says, with great *similarity* in their fossil extinct species, are two quite general facts, for which neither he nor any of his school have suggested the slightest explanation; indeed, have tacitly quite given it up; though, of course, there *is* a theory, that of the "semi-barbarous Hebrews," that so obviously fits pat into both, that it would be an insult to the common sense of your readers to give its explanation of either.

The same, of course, applies to the following of Darwin's *facts*—"Oceanic islands are sometimes deficient in animals of certain whole classes. . . All such differences in number, and the absence of certain whole groups of animals and plants on islands are generally accounted for" (*i.e.*, said in other books to be so) "by supposed differences in their physical conditions; but this explanation is not a little doubtful. With respect to the absence of whole orders of animals on oceanic islands, Bory de St. Vincent long ago remarked that Batrachians (frogs, toads, newts) are never found on any of the many islands with which the great oceans are studded. . . . This general absence of frogs, toads, and newts, on so many oceanic islands cannot be accounted for by their physical conditions. Indeed, it seems that islands are peculiarly well fitted for these animals; for frogs have been introduced into Madeira, the Azores, and Mauritius, and have so multiplied as to become a nuisance. . . . But why, on the theory of creation, they should not have been created there, it would be difficult to explain." Certainly, I agree with the eminent naturalist, very difficult indeed! especially as it seems plenty of fossil extinct species of such absent orders *did* exist even on islands!

"Mammals," he proceeds, "offer another and a similar case. I have carefully searched the oldest voyages, and as yet I have not found a single instance free from doubt, of a terrestrial mammal (excluding domesticated animals kept by the natives) inhabiting an island situated above 300 miles from a continent or great continental island; and many islands situated at a much less distance are equally barren. . . Yet it cannot be said that small islands will not support at least small mammals, for they occur in many parts of the world on very small islands, when lying close to a continent; and hardly an island can be named on which our smaller quadrupeds have not become naturalised and greatly multiplied. It cannot be said on the ordinary view of creation" (what on earth is the ordinary view of creation?—I am at a loss to conjecture) "that there has not been time for the creation of mammals; many volcanic islands are sufficiently ancient." (! ! !) What precise antiquity this requires, I cannot find the learned creationist to have anywhere told us. According to Milton, the only other authority at hand, not a great period:—

> The grassy clods then calved; then half appear'd
> The tawny lion, pawing to get free
> His hinder parts.

But Darwin proceeds: "Although *terrestrial* mammals do not occur on oceanic islands, *aërial* mammals *do* occur on almost every island. Why, it may be asked, has the creative force produced bats, and *no other* mammals on remote islands? On my view this can be easily answered, for no terrestrial mammal can be transported across a wide space of sea, but bats can fly across." Certainly, that is a ready explanation on *one* view, but I was not aware Darwin's view was the one to yield it. "No terrestrial mammal can be transported across a wide space of sea"! But what need, O Darwin, on *your* view, to be *transported* to the island any more than bats? Why not be *developed* there? Since *you* say, "it cannot be said there has not been time," and "many volcanic islands are sufficiently ancient, as shown by the stupendous degradation which they have suffered, and by their tertiary strata." You explain indeed "easily" (and by nothing peculiarly Darwinian) the presence of the bats, but not the larger fact, the absence of all the other mammals!

But we have not exhausted, we have not yet come to the climax of, Darwin's diluvian proofs. "He who admits the doctrine of the creation of each separate species will have to admit that a sufficient number of the best adapted plants and animals have not been [later edition, "were not"] created on oceanic islands, for man has unintentionally stocked them far more fully and perfectly than has Nature" (later edition, "than did Nature"). Assuredly! Then you see, Nature, or Creation, or natural Selection (which ever of the three terms you prefer), if acting in regard to islands, has been a stupendous blunderer indeed! Widely different from what it has done on continents, and in seas, and even the now infinitely separated bits of fresh water, more numerous and even smaller than islands on the whole! Just observe! In one or two centuries only, our ships merely happen, by blind chance, to carry into most islands, plants or animals so vastly fitter to their physical conditions than the native species that have been there, according to Darwin's present faith—faith in the Lyellian priesthood—for thousands of centuries at least, as to starve out, crowd out, and exterminate, in a single century, these ancient, million-year-settled possessors of the soil! Oh, blundering natural process! With all this unlimited bank of "Time, time, time" (as Scrope hath it), to draw upon, natural selection is unable (according to the very prophet thereof), unable in all these million ages, either to develop *in*, or get *into* these islands, a stock half so fitted to them as man unintentionally (*i.e.*, man's ships, by pure chance) happens to introduce in one short century!

And this same process observe, infallible, as all admit, in stocking regions where it once *operates*, even for a generation or two! A crux indeed for Darwin, under Lyellian bonds, all this insular misdistribution! But taken in connection with all else, with the uniform age of deltas, and waterfalls, and peat-bogs, the universal diluviation, the flood-scoured surface, the boulder-drift, swept and lodged in every isle and every river-vale alike, the iceberg-dropped trains of "grey wethers," and other erratic blocks—what can be plainer? Between land and land, *no* such cause as natural selection, no *regular* or *continuing* cause, *has operated* at all in the present distribution of life. It is found, as regards islands, to be mere *mis*-distribution; therefore, the work of nothing regular or long continued, but of sheer *accident*, the sudden accidents of some quick, sharp, sudden catastrophe.

E. L. G.

A BATCH FROM MR. BOTTONE.

[4293.]—(4265.)—SULPHUR AS A BLEACHING AGENT. —Sulphurous acid and its congeners are powerful reducing agents, but they require certain favourable circumstances to bring their deoxidising powers into play. Sulphurous anhydride *cannot* of itself absorb oxygen from the air, but in contact with steam and an oxide of nitrogen it does so readily. A strong solution of sulphurous acid in water is tolerably permanent, *if air be excluded*, but after the lapse of some weeks part of the water is decomposed, hydrogen is set free, and sulphuric acid is formed, thus:—

$$H_2SO_3 + H_2O = H_2SO_4 + H_2.$$

The presence of organic matter seems particularly favourable to the production of this effect, and in many cases the organic matter absorbs the hydrogen liberated. Cases however occur in which the hydrogen is *not* absorbed. It by no means follows, however, that the result of the deoxidation is *insoluble*, as "A. E. S." seems to infer. The following equations may be acceptable, as illustrative of the effect of sulphurous acid in several cases:—

$$\overbrace{2C_8H_5NO}^{\text{Blue Indigo.}} + \overbrace{H_2SO_3}^{\text{Sulphurous Acid.}} + \overbrace{H_2O}^{\text{Water.}} = \overbrace{H_2SO_4}^{\text{Sulphuric Acid.}} + \overbrace{C_{16}H_{12}N_2O_2}^{\text{White Indigo.}}$$

$$\overbrace{C_{20}H_{19}O_3}^{\text{Rosaniline.}} + \overbrace{H_2SO_3}^{\text{Sulphurous Acid.}} + \overbrace{H_2O}^{\text{Water.}} = \overbrace{H_2SO_4}^{\text{Sulphuric Acid.}} + \overbrace{C_{20}H_{21}O_3}^{\text{Leucanaline.}}$$

$$\overbrace{2C_4H_2N_2O_4}^{\text{Alloxan.}} + \overbrace{H_2SO_3}^{\text{Sulphurous Acid.}} = \overbrace{H_2SO_4}^{\text{Sulphuric Acid.}} + \overbrace{C_8H_4N_4O_7}^{\text{Alloxantine.}}$$

NEW METHOD OF OBTAINING POTASSIUM (p. 273).—This is by no means a novelty. In 1865, while at Novara, I prepared both potassium and sodium by the action of iron filings on the respective sulphides. The mode of operation quoted last week is, however, far from being the best. I found that a straight gun-barrel, with the nipple plugged, and inclosed in fire-clay, is the best retort to be got. This is charged with the alkaline sulphide and iron filings, laid transversely in a furnace, while a short U-shaped tube, carrying a globule of mercury, and fitted with a cork, is kept in readiness. More than three-quarters of the gun-barrel must project from the furnace, and be kept cool by artificial means. When the body of the gun-barrel has attained a cherry red heat, the bent tube and cork is to be inserted into the cold end of the barrel. The heat must now be increased and kept up for about an hour. The glass tube may now be corked and the gun-barrel allowed to cool. When *quite* cold the mercury tube is to be removed, and the potassium, which will be found condensed at the cool end of the gun-barrel, quickly removed by a bent scraper, and preserved under naphtha. If the heat be sufficiently high all the potassium will be expelled from the sulphide.

S. BOTTONE.

ANALYSES FROM GEORGE E. DAVIS.

[4294.]—I DARE say "S. S.," who inserted a query in the ENGLISH MECHANIC some time since, must have thought I did not mean to reply, seeing that I had let such a long time slip over without taking any apparent notice. I promised to perform the analyses when I had sufficient leisure, and now that time has arrived, I hasten to publish the results, so that "S. S." may publish the analyses he has received from the "leader" already spoken of.

A qualitative analysis only has been made, and therefore to say how the bases and acids are combined would be simply an absurdity. I give them separately; but if "S. S." particularly requires a qualitative analysis made, I will do so for a consideration, which, in the present instance, will be rather high.

To proceed with the bottle marked "No. 1 Liquid," I found as follows:—*Acid Radicles*: Chlorine, phosphoric, sulphuric, carbonic. *Basyls*: Aluminium, sodium, trace of iron. *Neutral Substances*: Water, with a very small quantity of a fatty acid.

The following is the analysis of the liquid contained in the bottle marked "No. 2 Liquid:"—*Acid Radicles*: Chlorine, hyposulphurous, sulphuric, carbonic, phosphoric, silicic. *Basyls*: Aluminium, sodium, potassium, traces of iron. *Neutral Substance*: Water.

The tin canister containing a paste, and labelled "Composition Paste for Analysis," gave, on examining the contents, the following result:—Partly decomposed organised substance, sodium humate, with traces of copper sulphate.

Having now given the results of the qualitative examination, I should like to know what my friend "W. R." has done. I should like him to write me personally, especially if "W. R." should happen to be "R. W." GEORGE E. DAVIS.

Radcliffe, near Manchester, May 30.

AN IMPROVED BEEHIVE.

[4295.]—THOUGH "Bee-Keeper," in his interesting letter (4187, p. 251) does not expressly say so, no doubt one reason for making the sides of his hive so thick and durable is to protect his bees from cold, which is advantageous not only to save them from danger, but for economy of food. Mr. Pagden, of Alfriston, in his clever little book, called "£70 a year: How I Made it by my Bees," says at p. 29 that he has proved by weighing hives containing few and many bees that nearly as much honey is consumed in winter by a small as by a large number, a fact mentioned by many writers, though "no one," he says, "has been able satisfactorily to explain how this mysterious fact is to be accounted for."

Though it is unsafe to conclude that a general rule is established by one experiment, however apparently satisfactory, I believe that it is true that many bees in a hive do require much less honey in proportion to their numbers than few, and that the explanation is that when many are together they keep each other warm with less proportionate consumption of food as fuel (which honey chiefly is) when not used up in the secretion of wax. It is well known that all animals eat less whenever they are less exposed to cold, and bees when warm and not needing wax require but little heat-producing food. If this be the correct explanation, it follows that hives should be very well protected from cold in winter, and fortunately the same means will be effectual in protecting them from heat in summer if sufficient ventilation be provided for, but they will at all times need a great deal more air than "E. L. G." queerly thinks enough for us—namely, "just as much as is breathed, neither more nor less," and if they do not get far more, they will soon want none at all, neither should we if silly enough to confine ourselves to his allowance.

I do not know whether the experiment has ever been tried, but it is, I think, worth trying, if it would not pay to reduce the consumption of honey by bees in winter, by very gently warming their hives, or the air entering them artificially. It would have to be done very cautiously, lest warmth should stimulate them to unnatural activity. Possibly some of your correspondents may know if the experiment has been tried, and with what result. I know that hives are sometimes warmed to remove damp, but can heat be used to save food? PHILO.

REVOLVING PUDDLING FURNACE.

[4296.]—THE question as to Mr. Danks being the original inventor of the revolving puddling furnace will from present appearances have to be decided in a court of law; but as to who has the credit of perfecting the invention there is no doubt Mr. Danks is entitled to it. A similar manner of puddling was tried years ago at Dowlais and failed; since then Mr. Danks informs the trade that he has succeeded in what the Dowlais Company failed in, which in a great measure he has done by using a new description of "fettling." This has been proved by the commission sent out by the Iron and Steel Institute (of which "G. S." seems inclined to speak disparagingly), one of the leaders of the commission being from the very place where the invention was originally tried. If Mr. Danks's invention is adopted generally, and the economical working which is claimed for it proved to satisfaction, then the Steel Institute has performed a service for this country, which, perhaps, "G. S." may probable in the future acknowledge. Trevithick invented and patented the first locomotive made, but George Stephenson made the locomotive a success.

The remarks of "G. S." about the new Institute are very undeserved; they are doing a good work, which is acknowledged by foreigners of the highest distinction in the iron trade, such as M. Schneider and others; and as to his remarks about "gushing votes of thanks from lordly lips," when "G. S." can benefit mankind by writing such an inaugural address as the late noble President did at the first meeting of the Institute, he will be listened to as an authority. "G. S." must remember he belongs to an honourable profession, which deservedly boasts of an institute in connection with it similar to the Iron and Steel Institute to the iron trade.

A MEMBER OF THE IRON AND STEEL INSTITUTE.

ENTOMOLOGICAL.—(II.)—ON LARVÆ.

[4297.]—THE apparatus required in collecting larvæ is a metal larva-box, a large cotton umbrella, a strong wire ring-net, a stick, and a box to put food in to bring it home. Some collectors prefer chip boxes to metal ones, but they are liable to break in and kill the larvæ.

Thus equipped, the collector may set out. When a suitable locality is reached, he should proceed to beat the trees and bushes, holding the umbrella underneath to catch the larvæ that fall, which may then be boxed with some of their food plant. Many larvæ will contrive to elude observation by being quite still, and others, such as that of the Brimstone Moth, look more like pieces of stick than anything else.

Another method of collecting larvæ is to sweep over the herbage with the net, and so obtain many larvæ which could be found in no other way.

Concerning the best time of the year for collecting larvæ, I think all seasons are good, but early in the spring, in February or March, many otherwise unobtainable larvæ may be found on grassy banks. The next best season is about the end of May or beginning of June, when the trees have been in leaf some time. Lastly, many hybernating larvæ may be found just before the leaves drop off. Just before a just after sunset are the best times, though the collector will meet with success all day long. Some larvæ are great wood borers, such as *Cossus ligniperda* (Goat), but the collector may be deceived by the borings of beetles, when he expects a good lepidopterous larva; the different appearance of the holes must, of course, be learnt by experience. Other larvæ, such as that of *Catocala nupta* (Red Underwing), rest during the day on the bark of their food tree (willow), artfully concealed from general observation by the similarity in their colour to the bark of the tree, and by their filling up the hollows in it.

Lastly, the presence of birds, such as tits and creepers, shows that larvæ—which are their food—are close at hand, and this ought to make the collector even more active in his search. Ento.

BONES AS MANURE.

[4298.]—Some of your correspondents appearing interested in the question of manures, especially artificial and dissolved bones, I forward a clipping which may be found useful.

The complaint of fraud in the manufacture of commercial manures gives rise to many questions concerning the manufacture of bones into some available form by the farmer himself. Bones and coprolites are almost the only reliable sources of supply to replace the phosphates; but bones broken into fragments of not more than an ounce in weight each will, under ordinary circumstances, remain in the soil undecomposed for half a century, and consequently but little benefit will be derived from their use. Bones, to be of immediate value, must be ground fine; but this with "raw bones" is a very difficult process. When subjected to the action of high steam they lose all their oil and a large portion of the gelatine, thus becoming brittle, and easily ground in a common mill. The same end can be reached more directly by burning the bones, the waste being merely the animal matter contained in them. The phosphate of lime is unaffected by either steaming or burning. The mineral part of the bones thus separated, will be found to consist substantially of 45 per cent. of phosphoric acid and 55 of lime. This compound is insoluble in pure water, and but very sparingly soluble in rain water charged with carbonic acid. If we take this "bone phosphate" and add to it a little more than half its weight of sulphuric acid (commercial oil of vitriol), we shall in a few days produce a new compound, in which the sulphuric acid has removed two-thirds of the lime from the bones, combining with it to form gypsum, supplying the place of the lime thus removed with water. This is a true soluble superphosphate. Its elements are:—Phosphoric acid, 60·69; lime (calcium), 23·93; water, 15·38.

This mass will be found very tenacious, and somewhat difficult to handle. To remedy this it should be mixed, in sufficient quantities to render it dry, with some good absorbent, such as dry swamp muck reduced to a powder, or with ground charcoal, or even with road dust. Lime or ashes should never be used for this purpose.

Several farmers might co-operate in the construction of a mill, and thus produce the bone meal which they use at prime cost. From this, they can make their own superphosphate, and use it either by itself or mixed with composted manure.

But bones may be reduced to a very fine state of division by the use of strong wood ashes, and thus, presenting a large surface to the solvent action of water and carbonic acid in the soil, may be of great value in maintaining fertility. The following formula has been suggested for using bones with ashes:—

	Pounds.
Ground bones	100
Strong wood ashes	400
Soda nitrate	70
Epsom salts	10

Dissolve the soda nitrate and Epsom salts in sufficient water to thoroughly moisten the ashes and bone meal. Mix well, and let it stand ten days, stirring it daily. Use some absorbent, such as dry muck pulverised, to dry the mass and reduce it to powder. Kainite may be substituted for the ashes, in whole or in part. This amount used on an acre will have a marked effect on the crop.

In some parts a difficulty will be found in obtaining the quantity of wood ashes here mentioned, but it should be remembered that almost any vegetable refuse will answer the purpose—the haulm of potatoes and the clippings of hedges and trees being possibly more serviceable than the ashes of burnt wood.

Many persons who have studied the question are firmly convinced that the stimulating manures, such as contain ammonia are rarely required, that plants will obtain all of this that is absolutely necessary from the atmosphere, and the rain which brings it down into the soil; and all that the farmer need do is to supply phosphoric acid, and the special salts, which an analysis of the soil may show to be necessary—*e.g.*, potash for potatoes. B. T. R.

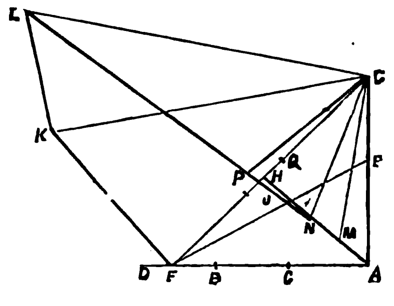
PURE GEOMETRY OF 113 : 355.

[4299.]—Since in this approximation to circumference $355 = 15^2 + 9^2 + 7^2$, and $113 = 8^2 + 7^2$, I find this permits of a geometric result excluding arithmetical divisions, *e.g.*, $MN = 11\,PQ = \frac{1}{7}RS$, &c.

On diameter A B of a circle, radius A C = 1, extended to B D = B C, erect perpendicular A E G, A E = E G = side inscribed square = $\sqrt{2}$. From E, radius A D = 3, cut A D in F $\therefore AF^2 = EF^2 - AE^2 = 9 - 2 = 7$, $AG^2 = 4 . 2 = 8$, hence G F is cut by perpendicular A H in ratio 8 : 7 :: G H : F H = G Q on G F, whereon H J = Q H gives C J = 9.

Next, on H A make H M = H F, G M = $\sqrt{113}$ in same units: then F K ⊥ G P = G J gives G K = $\sqrt{306 = 15^2 + 9^2}$; K L ⊥ G K = F H gives G L = $\sqrt{306 + 49} = 355$; G N ⊥ G L = G M; G P ⊥ L N, whence N P ; P L :: 113 : 355.

Further, $\frac{AH}{AC} = 2\sqrt{\frac{7 \times 8}{15}}$, $FH = \sqrt{\frac{7 \times 7}{15}} = HM$, $\therefore$ M falls between A and H.



I append some appropriate fractions, devised by my late friend, C. J. Willich (*Philosophical Magazine*, May, 1863), and resolved by me. Note specially the cube root of $\frac{1}{6}$ of π.

$$\pi = \frac{355}{113} - 0·000002 = \frac{5 \times 71}{64 + 49 + 72}$$

$$\frac{\pi}{360} = \frac{7}{802} - 0·000001,6 = \frac{7}{784 + 18}$$

$$\pi^2 = \frac{227}{23} + 0·000039 = \frac{441 + 9 + 4}{36 + 9 + 1}$$

$$\pi^3 = \frac{23200}{763} - 0·000022 = \frac{200}{7} \times \frac{100 + 16}{100 + 9}$$

$$\sqrt{\pi} = \frac{296}{167} + 0·000001 = \frac{100 + 196}{100 + 49 + 18}$$

$$\sqrt[3]{\pi} = \frac{331}{226} - 0·000010 = \frac{225 + 81 + 25}{2(113)}$$

$$\sqrt{\frac{1}{\pi}} = \frac{145}{257} - 0·000012 = \frac{144 + 1}{256 + 1}$$

$$\sqrt[3]{\frac{\pi}{6}} = \frac{457}{567} - 0·000000,5 = \frac{441 + 16^*}{21 . 27}$$

$$\text{Hp. log. } \pi = \frac{87}{76} - 0·000007 = \frac{3}{4} . \frac{29}{19}$$

$$\text{Mod. log.} = \frac{195}{449} + 0·000004 = \frac{15 . 13}{400 + 49}$$

$$\text{Base h. l.} = \frac{1264}{465} + 0·000002 = \frac{16 . 79}{15 . 31}$$

*Hence $(8 - 3)(8 + 4) : 8^3 :: 1 - \sqrt[3]{\frac{\pi}{6}} : 1 : + \sqrt[3]{\frac{\pi}{6}}$ nearly.

I find number of times every digit of π occurs in the first six hundred decimals of Mr. Shanks' value to be as follows:—

To dec.	0	1	2	3	4	5	6	7	8	9
100th	8	8	12	11	10	8	9	8	12	14
Add	11	12	12	8	12	12	7	4	13	9
200th	19	20	24	19	22	20	16	12	25	23
Add	7	10	11	12	15	7	15	7	9	7
300th	26	30	35	31	37	27	31	19	34	30
Add	11	13	9	8	10	12	11	7	10	9
400th	37	43	44	39	47	39	42	26	44	39
Add	6	16	9	12	7	11	5	12	10	10
500th	43	59	53	51	54	50	47	38	54	51
Add	13	4	11	13	10	6	15	8	5	15
600th	56	63	64	64	64	56	62	46	59	66

Here the same number is repeated as follows:—

No.	4	repeated	2 times	8
„	5	„	2 „	10
„	6	„	2 „	12
„	7	„	7 „	49
„	8	„	7 „	56
„	9	„	6 „	54
„	10	„	6 „	60
„	11	„	7 „	77
„	12	„	11 „	132
„	13	„	4 „	52
„	14	„	1 „	14
„	15	„	4 „	60
„	16	„	1 „	16
		Sum	60	609

For 500th, repeat 1 . 1 . 1 . 7 . 6 . 6 . 5 . 6 . 11 . 2 . 1 . 2 . 1 times. S. M. Drach.

DETERMINING THE SPECIFIC GRAVITY OF POROUS SUBSTANCES.

[4300.]—The plan suggested by Dr. G. E. Morse, described at p. 220, appears to be well suited for the purpose; but not better, I think, than the old one—proposed, I believe, by Sir John Leslie—of inclosing in the upper part of a glass tube a known weight of the substance whose bulk has to be determined, so that its specific gravity may be calculated. The tube, which must be more than 15in. long, is placed in a larger tube filled with mercury till the surface of the liquid metal corresponds with a mark on the inner tube; the top of this is then closed air-tight, and the tube raised until the mercury in it stands half the height at which the barometer is standing at the time; of course, the air in the tube being thus relieved of half the compressing force of the atmosphere, expands to twice its original volume. As half of the expanded air occupies the part of the space above the mark which is not occupied by the solid matter, and half the space between that mark and the top of the mercury. the space occupied by the mercury, which stands in the tube higher than it would do if no solid matter were contained in it, is equal to the space occupied by such solid matter, less any air or other elastic fluid that may be united with it mechanically. This volume may be estimated with very small error by weighing the mercury, its weight being great in proportion to the bulk it occupies. There may, however, be some objection to the use of this simple instrument not known to me. Philo.

DR. CARPENTER AND PERSPECTIVE.

[4301.]—The reason, I think, why a picture does not embrace so many degrees vertically as horizontally is because it represents a scene more or less defined, viewed by an eye directed to one point. The natural shape of a picture is, therefore, an ellipse, of which the major is to the minor axis as 3 to 2. "B. D. T." (let. 4190, p. 252), whose previous letter I was not so uncourteous as to reply to without reading, will see that our tower need not be made up of parallel lines to suit a rectangular representation of the scene. "E. L. G." (let. 4189) gives the better reason, but as he adds that pictures are not always viewed from the point of sight, it is unnecessary for me to say more than this, that as they are to be the best representations possible, under all circumstances we may be surer of the real truth by following what must be depicted on the glass plane of projection—namely, convergency. I do not quite agree about the correction of the eye, although quite aware that we really see not by the eye, but by the brain. A plane of projection being an entirely artificial matter is changed by the slightest movement of the eye. I have never seen the book referred to by "E. H." (let. 4191). To him, as to "E. L. G.," I reply, a picture is not mathematically arranged, but is a compromise, and is painted for effect. Architectural photographs are simply horrible. M. Paris.

PAINE'S MAGNETIC ENGINE, &c.

[4302.]—On p. 611 of your last volume "Sigma" asked in a very pointed way, "*Where's* the peck of pepper Peter Piper picked?" I have just come across a piece of "intelligence" which will supply him with the not unexpected information. According to the New York *Telegrapher*, the "peck of pepper" cannot be found; for it seems the Electro-magnetic-wood-sawing-and-driving-men-of-war-across-the-Atlantic-for-nothing Company has "gone up"; that Peter Piper himself has "left for the East, where the wise men came from," and that the stockholders have experienced an electric shock in the shape of a total loss of their money—3,000,000 dollars.

In other words, Mr. Paine has failed to do what he publicly stated, with much show of offended dignity and injured innocence, he had done and could do, and has retired from the country to "perfect the details" of his machine in quiet. So far Mr. Paine. What has become of Mr. Slater's engine, of which at one time we heard so much from Mr. Highton? The latter gentleman appears to have given up attempting to perfect its details, as his attention is now devoted to telegraphing through uninsulated sub-marine wires, which of course would be much cheaper than the rather costly cables found necessary in practice. Mr. Highton surely owes it to science to make as full a report of his failure as he did of the "facts" by which he thought to overthrow the experiments of Joule. I would also ask Dr. Packman how he is progressing with his steam-engine, mentioned on p. 253 of Vol. XIV., and when the promised description is likely to delight the hearts of "our" readers. Saul Rymea.

SUPPORT OF SPINNING TOP.—UPWARD DEFLECTION OF BULLET.

[4303.]—It is a misfortune that many men of great talent waste their time and energies in attempting to prove why some particular effect is produced, without in the first place ascertaining what the fact really is. Many of us have heard of the glass globe puzzle, the question being, "How is it that a live fish added to a globe partly filled with water does not increase its weight?" The learned of the time entered freely into the discussion, which came to an untimely end by a cynic requiring the globe to be weighed before and after the addition of the fish. Mr. Taylor says he "shall be much surprised to hear that a spinning-top will stand in vacuo for a moment." Would he be very much surprised to hear that Faraday kept a top spinning in vacuo for one hour and forty minutes?

Amidst all the plausible theories and speculations to account for the movements of the top and gyroscope, none as yet appear to afford any satisfactory solution of the problem.

With regard to the bullet rising from the gun, this again is a popular fallacy, of which it is easy to trace the origin. When a gun is fired from the shoulder the point of resistance not being in a straight line with the force exerted by the ignited powder, but several inches below, the muzzle naturally rises. It has been well ascertained from the experiments of Whitworth and others, that if a gun-barrel be firmly fixed to a slide-rest in such a manner that it can only recoil in a direction parallel to itself, the bullet will not rise. To give a more homely illustration, every one accustomed to pistol practice knows that pistols throw very high as a rule, but if the hand be turned sideways, the bullets will not rise, but the deviation will be horizontal instead of vertical. A BARRISTER.

SPINNING TOP.

[4304.]—I CANNOT just now lay my hands on the number "E. H." (let. 4191, p. 252) refers to. It appears to me, a perfect top in a perfect vacuum, and the peg being unaffected by friction, would spin for ever, being equally on all sides affected by gravity; let there be friction, rotation sooner or later stops, and the top falls. Let "E. H."—not resorting to any dodge *à la* Columbus—set up a top on its peg, and tell us what, if not gravity, causes it to fall. Let him then spin it; the top remains upright because its motion counteracts its tendency to find a position of rest. Perhaps I do not understand "E. H." The particles are moving in a plane, and cannot get out of that plane by themselves; gravitation, however, unequally affects them, as the top is not a theoretical top, and at last is too strong for the other force. M. PARIS.

[4305.]—I CANNOT refer to the MECHANIC of January, 1870, consequently know not what the "old fallacy" is, which M. Paris and myself are accused of reviving by "E. H.," let. 4191, p. 252, but I have a strong notion if "E. H." tries the following experiment, that he will withdraw his authoritative fiat as to which is right. Take a weight suspended to a cord; let it go, and it falls to the ground from the effect of the attraction of gravitation; pick it up and cause it to revolve rapidly and vertically, then let it go as it passes the highest or lowest part of its circuit. It will not then fall to the ground, but will travel in a tangent to the centre of gyration as long as the velocity is maintained, and if the "force of gravity" is not overcome then write me down an ——.

As it seems that I have not conveyed my meaning clearly upon the point to J. M. Taylor, I will endeavour to do so thus:—When any body is made to revolve, its centre of gravity is not, mathematically speaking, in a vertical line with the point of rotation. As a consequence, there is an unequal attraction, which is greatest at the lowest side of the circle, but is instantly conveyed to the highest part, which has the effect of raising the one side and lowering the other until the attraction of gravitation is equal all round; he will plainly see this by using a teetotum, as the motion becomes so slow as to cause his air-cushion to "fade like the baseless fabric of a vision." He will observe the heavier side dip, but being immediately whisked to the higher side counteracts the attraction until the velocity becomes too slow. Does he compare a bicycle rider who keeps erect, although going at merely a foot pace, to a bullet from a gun? Surely he is poking fun at us. I would like to know particulars as to how he satisfied himself that a ball fired horizontally always rises. I don't say that it does not, but I have not seen it proved, although often asserted.

Liverpool. A.

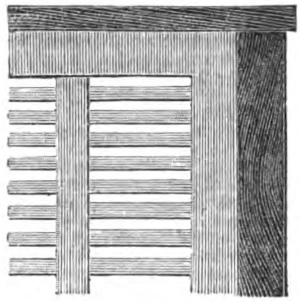
[4306.]—I CAN assure your correspondent J. M. Taylor that I have seen a top spin for one hour and ten minutes in vacuo. This was a top made, I believe, by Troughton, of black glass, with a steel point in a sapphire cup, now at the observatory at Armagh, in Ireland, and assuredly it did not wobble. It was made as an attempt to afford an artificial horizon at sea, which failed. The rising of a top and the gradual steadying of its motion depend upon the spherical shape of the so-called point. There is a good diagram of the forces, I think, in the *Saturday Magazine*, but I have it not. Let Mr. Taylor spin a seal ring on a table with the seal sideways: the seal, or the heaviest part of a ring when made symmetrical, but of different materials, will rise to the summit. VIS.

CABINET FOR MICROSCOPIC OBJECTS.

[4307.]—THE following is a description of a strong, light, and commodious cabinet for microscopical objects. Let a case be made having a door back and front measuring inside 10in. high, 8in. wide, and 6½in. from door to door, and let a vertical partition ⅛in. thick divide the case into two compartments; each will be 10in. high, 8in. wide, and 3¼in. deep. At ¼in. from both sides of partition fix a zinc plate of the same dimensions as inside of case, perforated as shown in sketch, and 2in. from each of these a second plate, perforated in precisely the same manner. Each pair of plates, instead of being fixed, may be in one sheet, doubled over so as to be 2in. apart, and soldered at the bottom; they could then be drawn in and out if necessary.

The perforations are to be made thus: Draw ½in. margin all round each plate, and let the middle space thus inclosed be divided into five vertical columns, nine-eighths of an inch wide, having a space between each of ⅜in. Each column is to have lines ¼in. apart, ruled from top to bottom, and the space inclosed by every other two cut away.

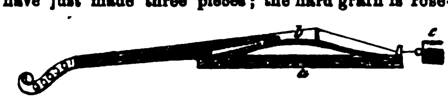
The mode of arrangement is as follows: The glass slides are to be passed through the slits in the front plate into the corresponding slits in the back plate, as far as the partition allows. This will leave about ¼in. of each slide projecting in front quite sufficient to admit of their being easily withdrawn. In the space between the slides the name of the object may be written, or a number may be placed at the side through which easy reference could be made to a list. The doors must be glazed with rather thick glass, and made to fit nearly close to the slips, to prevent them falling out should the cabinet become tilted; or the doors might be of wood, padded inside.



A cabinet this size would hold five slides horizontally and thirty-six vertically, equal to 180 in each division, equal to 360 in all. Every slide would lie flat, and be perfectly easy of access without disturbing any other. Some of the slits might be left farther apart than others (for deep cells), having the front aperture cut to correspond with size of cell. These cabinets can, of course, be made larger or smaller than the above, and as there is not much work in them need not be very expensive, nothing like 50s. or 60s.—the price the makers charge for a case to hold this number of slides. I have said nothing about outside ornamentation, which may be left to individual taste. The front plate might be electro-gilt, and would then present a handsome appearance. LOVATT.

HOW THE TONES OF A VIOLIN MAY BE INCREASED.

[4308.]—"FIDDLER" (let. 4197, p. 253) says, "I thought at first (and do now in part believe) that the pressure of the strings on the bridge interfered with the vibrations of the breast." I have made the experiment, and come to the conclusion that in a good violin the up-pressure of the breast is just so much more against the strings—say 8 to 7—as the down pressure, so that the pressure of the fingers and the bow on the strings make it nearly equal. However, "Fiddler" may try the experiment himself by hinging a neck of a violin on a piece of wood *a*, and centreing seven or eight pieces together, *b* representing the breast, which must be centred with one end on the neck, and with the other on the piece of wood. Then passing a string over the bridge as usual, putting it through a loop, and fastening it to a weight *c*, he will find that the pressure of the breast is not only more against the strings near the middle where the bridge is, but also on every centred piece, which he has to keep down separately. Besides this, in the violin, after the breast and strings are in what I may call proper tension, they act as a support against the neck, and from this support or breast the neck forms a lever connected with the back of the violin; this lever is pulling the back (if arched) straight, or a small portion towards it, and forces the soundpost against the breast also. Whether the law of vibration was known to the first makers of violins, or whether it was found out bit by bit, I cannot answer; but the fact is, the instrument constructed strictly in accordance with it, and if I may say so, just reversed from instruments which ring after the action ceases on the strings, for it is bound and compressed where ringing instruments must be free, except the strings. The only way I can see to get a little more tone out of such a small breast (for it is less than a square foot, and we cannot make it larger) is to construct the breast of pieces of wood (I have just made three pieces; the hard grain is rose-



wood, beach, and Virginia pine respectively, and barkwood in each of them, representing the soft grain. Trying them with the tuning-fork they are certainly much louder than Swiss pine), prevent the sound parts from "paulking" out on either side, which they do at present, and consequently the wood is rarefied sideways. And then not a cut must be done without strictly observing the law of vibration, which includes specific gravity, inertia, tension, leverage, and in this respect the form also. I think this a fitting place to say a few words on "The Harmonious Blacksmith's" ingenious invention (let. and diagram 4201, p. 254). Whatever merits that instrument may have when finished after the diagram, it cannot produce the tone of a violin, because the strings pulling on the soundboards and frame tend to rarefy instead of compressing the soundboards.

J. H. SCHUCHT.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[9440.]—**Mathematical Question (U.Q.)**.—This is answered in No. 370, with diagram. To find K, the simplest construction is to sweep a circle from E as centre with ED radius, making the chord EK equal to ED (the versed sine of arc AE). The demonstration makes a good exercise in geometry.—CORRESPONDENT.

[10478.] — **Pork Diet.** — While admitting the advisability of being extremely careful in the selection of pork, owing to the ease with which parasitic insects, trichinæ, ascarides, &c., may be introduced into the human system by the use of diseased animals, I am by no means prepared to go the "whole hog" with a "Mother" and "Sarah" in the universal condemnation of Piggy, Esq. Pork is really extremely well adapted to the nourishment of those inhabiting cold countries, as the large amount of carbon it supplies is a great aid in maintaining animal heat. Poor bunny has been very harshly treated, and I am confident from experience without any just cause. As to oysters, &c., they are certainly highly nutritive, and it is greatly to be regretted that our supply is so limited. The annexed table of the amount per cent. of water, starch, fat, gluten, and fibrine, present in beef, pork, rabbit, and oysters, may perhaps interest Sarah and Co.:—

	Water.	Starch & fat.	Gelatine, gluten, and fibrine.
Lean beef	78·0	8·0	19·0
Lean pork	76·0	5·0	19·0
Fat beef	63·0	27·0	10·0
Fat pork	60·0	30·0	10·0
Rabbit	88·0	2·0	10·0
Oyster	79·0	0·0	21·0

—S. BOTTONE.

[10664.] — **Angle of Reflection and Incidence.**—Many thanks for "F. N.'s" suggestion, but with a true stroke the ball will not rotate on a vertical axis at the moment of contact, nor during any portion of its course. If, however, the ball be struck a little to the right or left of the centre, this will take place, and the ball will form a parabolic curve after impact. With regard to the ball taking a direction parallel to the top cushion, this is at variance to the notions I have hitherto imbibed of motion and forces. "F. N.'s" diagram leads me to suppose he is under the impression that in each case the red is struck so that it returns from the top cushion at right angles. If so played, "strength" would not be required; both strokes should be played a half ball, and if the harder stroke be played from the left-hand side of the table, the red returning from the bottom cushion will come to rest near the left top corner pocket. If the ball from the first position be played with strength, the ball will strike the side cushion instead of going into the pocket, and if from the second position, with a gentle stroke the ball will strike the top cushion.—BILLIARDIST.

[11196.]—**Turning Perpendicular Shaft.**—The various replies to this query have all omitted the fundamental rule to be observed strictly, that is, that one shaft may be driven by a belt from another lying at all angles with each other from 0° to 90°, provided that their centres are in parallel planes, without which the belt will not keep on.—SEPARATOR.

[11386.]—**Crystals in Gas Tar.**—Let "Ethyl" refer to his Schützenberger, and he will find that naphthazarine is the artificial alizarine, in contradistinction to the real alizarine, however obtained.—S. BOTTONE.

[11423.]—**Surgery.**—Some years since a servant girl in my family ran a needle into her foot, just below the ankle. The doctor could do nothing, especially at a venture so close upon a joint. In this dilemma the girl was ordered to bed, and a large linseed poultice applied. Removing this in a few hours, a careful search discovered one-third of the needle. In twelve hours a second poultice was applied, the result being the recovery of the middle portion. A third application, and the remaining third, the point, was, after a most patient search, found. Fitted together, the needle was entire. Four heaped tablespoonfuls of meal put into a saucepan with a small quantity of heated lard, and mixed well when on the fire with cold water, rapidly, and well stirred till quite hot all through, makes the best form of poultice for the purpose, stiff and firm. Months of suffering may be spared by remembering the saying, "A stitch in time saves nine."—H. B.

[11564.]—**Blackberry and Strawberry (U. Q.)**.—I have read and re-read this query without being able to make out which of the fruits the first two sentences relate to, or what M. Paris wishes to ask about the blackberry, which he does not name after the above heading. I never heard of its cultivation, though it is brought to market both in England and France. It requires to be very fully ripe before developing its peculiar flavour, and seems to be nearly always, when gathered at all, gathered too soon. This flavour exceeds in richness that of its two cognate varieties, the red and white raspberry, as much as the black currant exceeds the red or white. I know not whether botanists have in these cases made the black fruit another species from the red and white, but its flavour would seem to entitle it to that distinction; and there are other differences, as the black currant, having a much larger "snuff" (or remains of the flower), and the blackberry, growing in greater bunches than either of the cultivated rubi, and having stouter thorns. I once read in a newspaper of some seeds found in the stomach of a skeleton in a Wiltshire barrow being sown, and producing the red raspberry! This was supposed to show that the red, as well as the black fruit, had been indigenous in ancient Britain, and had since become extinct. Some botanical reader may perhaps tell us where the raspberry is now indigenous, and how we obtained it.—E. L. G.

[11572.]—**Compressing Water.**—May I venture to point out to "Saul Rymea" that in replying to this question (p. 284) a detail has escaped his memory, which, although, of little importance, probably, so far as concerns Mr. Westwood's query, may as well be mentioned here. The compression produced by each additional pressure of one atmosphere in one million parts of water *freed from air* was found by Colladon and Sturm to be 51·3 millionths. This result is almost identical with "Saul Rymea's," as given at p. 284, save that the italicised words are omitted in his reply. I hope "Saul Rymea" will not deem me guilty of needless and carping criticism in directing attention to the *lapsus*. I merely do so, because in compressing water containing air, the result obtained by Colladon and Sturm was 49·5 millionths. The latter result approximates more nearly to Regnault's 47 millionths. In fact, Regnault's result may be taken, I think, as the mean compression of water, if we call Colladon and Sturm's 49·5 millionths the maximum, and Oersted's 46·1 millionths the minimum result.—A. J. V. G.

[11589.]—**Dry Steam.**—I am afraid "A., Liverpool," is still rather at fault in his attempt to explain what dry steam really is. Every one knows that each increment of heat increases the pressure of steam, but action and reaction must be reciprocal, and therefore the pressure of the superheated steam must be as great towards the boiler as towards the other end of the pipe; and, indeed, if the resistance was not greater at the boiler end than at the other, the steam would evidently rush as readily back into the boiler as into the atmosphere; the pressure of the steam, therefore, after all the additional heat it has required by passing through the furnace coil, cannot possibly exceed the 3lb. pressure in the boiler. Still, this is a long way from accounting for what dry steam really is; and, I suspect, if chemistry — which "A." seems to ignore — cannot give a satisfactory explanation, still less can pneumatics.—CALORIC.

[11589.]—**Dry Steam.**—In my reply, p. 284, for 250° C. read 2500° C.—F. T.

[11589.]—**Dry Steam.**—This very easy query has been singularly ill-treated; not one reply without some ludicrous error! First, "A., Liverpool" (p. 157), says "You may place your hand in high pressure steam," which is absurdly impossible. The only way to *touch* high pressure steam would be to have your hand bound to an aperture in a boiler, so as to form a valve confining the steam. That which has once left the boiler, be it only a barleycorn from the outlet, is no longer high, but "low pressure" steam, and the reason it will not scald you like the lower pressure steam of a tea-kettle is its cooling by sudden expansion. I cannot see (with deference to "Caloric," p. 232) how the term "dry" steam can be otherwise applied than as a synonym with "overheated" or "subsaturated steam" that which will dry bodies, or take up additional water. Atmospheric steam is dry, except in a rain-cloud; dry even in falling rain, and may have its dryness expressed by the number of degrees it has to be cooled to reach its "dew point," or become "steam of saturation." The comet of the Deluge, however low in temperature, was, I have no doubt, dry steam; and need not during its whole fall render the air anywhere a wetting air, though a mile of water should fall through it as rain in a day or two—of course, the steam that "Caloric" says (p. 106) was incondensable by cold, was no longer steam at all, but decomposed, as all steam is when passed over iron, zinc, coal, or other combustibles at a temperature "to kindle timber,"—but not decomposed "into oxygen and hydrogen," after "J. L." (p. 181). The oxygen remains with the iron or zinc, or carbon, and in the latter case forming carbonic acid, will, by its mixture with the hydrogen, make it uninflammable. This would even be the result of passing through tubes of red-hot cast iron, but with wrought iron the steam may be made inflammable hydrogen, and balloons have been thus filled. Of course, a certain remnant of undecomposed steam would also mark its inflammability.—E. L. G.

[11630.]—**Compendious Perpetual Calendar (U.Q.).**—The querist should refer to "The Perpetual Cross Calendar," by C. J. Recordon, B.A. London: Trubner and Co. This little work was noticed not long ago in the ENGLISH MECHANIC, and in the introduction to it, the querist will see how he could construct such a calendar as he desires, say in metal, by rendering the position of certain pieces of the apparatus there described yearly interchangeable.—B. A.

[11632.]—**Debility.**—I may, perhaps, be permitted to make a few remarks with reference to the discussion between "Amateur" and "Saul Rymea." The latter thinks there is no occasion to defend either allopaths or homœopaths against the charges of the former. Now, as one desirous to learn, I should be very glad if "Saul Rymea" would state what the principles of allopathy really are, and what is their rationale. Till lately the sheet anchor of the medical profession was the lancet, which was used indiscriminately in diseases of every class. Take the instance of typhoid fever. Here, as far as modern science has been able to ascertain, the blood is poisoned. As a remedy allopathy dictated the withdrawal of a part of the blood in the hope of purifying the remainder. Is not this just as logical as if we, in order to disinfect a river suffering from the influx of sewage, should pump out and throw away a few gallons of the water, hoping that such a step would in some "occult" manner render the residue limpid and wholesome? If "Saul Rymea" is acquainted with the history of medicine, he must be perfectly aware that what are called "feverish symptoms" were deemed especially to indicate copious blood-letting. Yet, he ought also to know that those very symptoms are brought on by loss of blood, as every army surgeon who has had experience on the battlefield can testify. It may be said that blood-letting has now fallen into comparative disuse. Granted: thanks to the pressure from without, which the *Anti-Lancet* has contributed to create. But has the irrationality of the practice ever been formally admitted? And what shall we say of a system which can thus repudiate its grand procedure, and yet claim the adhesion—I will not say of scientific men—but of a community not void of common sense? Equally prevalent with blood-letting, and almost equally ruinous, was the sweeping use of drastic purgatives. But a short time ago, if an allopathic practitioner was called in, one of his first steps was, quite irrespective of circumstances, to administer a brisk dose of what is still popularly and inclusively called "medicine." This error, though on the wane, as the diminished consumption of Epsom salts can prove, survives still in the "theories of quacks," who appear to treasure up what the allopaths have gradually and quietly repudiated. But I cannot help reminding "Saul Rymea" that the allopaths have by their practice created that very faith in "Solidway's pills" which he now deplores and wonders at. "Saul Rymea" may, again, urge that random purgation is now less frequently employed than it was half a century ago. True, allopathy is gradually changing its nature, though not its name; its practice, though not its principles, and is approaching the altera-tonic system. Your correspondent thinks that nervous debility is certainly not the cause of cholera. Will he kindly explain how it is that, of three men, living in the same house, and exposed to the same influences during the epidemic of cholera, one shall entirely escape the disease, another shall take it, but recover, whilst the third shall die? Heart-disease seems also to your correspondent something inconceivable as a result of nervous debility. Is he not aware that it increases almost *pari passu* with disease of the brain, and that it is found most widely prevalent among the very class who are most subject to the latter? The fact is that allopathy, at least in the days when it was young and bold, conceived of disease as a positive entity—as a something which could be drawn out by blood-letting; driven out by purgatives and sudorifics, or poisoned by "drugs and counter drugs." The only difficulty was that sometimes the patient was poisoned instead of the disease. There is deep truth in the story of the French physician who undertook the treatment of a desperate case of cutaneous disease. The eruption gradually vanished under his treatment, but just as the last trace had disappeared the man died. The physician, carefully examining the corpse of his patient, remarked with an air of self-complacency, "Il est pourtant guerri." This is scarcely a caricature of allopathy. I will only add that I shall be very glad to answer, through the ENGLISH MECHANIC, any questions which may be put to me on this important subject.—CHARLES ROOKE.

[11650.]—**Annealing Steel.**—It is what are called pins—viz., fine hard places—in the steel that spoil your cutters. They will sometimes defy a file to touch them; you can make your steel beautifully soft by putting it into a box made for the purpose, filled with dust charcoal, closed air-tight, heated thoroughly through to a red heat, and then allowed to get cold. A piece of stout gas-pipe, with one end welded and the other plugged, makes a very good box for a small quantity of steel. For large quantities make a charcoal fire, heat the steel to a red heat, and let the whole get cold together.—KYRLE.

[11656.]—**Boiler for Small Steamboat.**—In reference to the above query would "P. W. H. J." please inform me if the boiler and engine, as shown on p. 259, would be powerful enough to drive a boat 21ft. long by 7ft. beam? And would there be a governor required, as I think it would not work without one or a fly-wheel? The engine is stated to be 7in. by 3½in. stroke: am I to understand that 3½in. is the diameter of the cylinder and 7in. the length of stroke? Are the double eccentrics for reversing gear? If so, how are they joined where the two ends meet? An answer to the above will much oblige.—W. H. SHEPHERD.

[11674.]—**Stretched Indiarubber.**—I do not suppose that any of your readers can give "Philanthropist" the information he requires. It appears to me that the power required to stretch the rubber would be more than that given out by the rubber in returning to its normal state.—E. M.

[11687.]—**Speeding Machinery.**—ERRATUM.—The last two lines or so of my reply belong to reply 11869, Zinc *v.* Coal.—PHILANTHROPIST.

[11711.]—**Time at our Antipodes.**—Is "Kelby" quite sure that every particle of fog has cleared away from his own mind with regard to this question? He tells us that the announcement of the destruction of a building in Paris by fire at 12 o'clock can be made in New York the same evening, a similar case to the publication in London of the eclipse telegrams from India on the afternoon of the day on which the event occurred. He also tells us that telegraphic messages from New York are found on our breakfast tables. Surely he does not mean the news of the previous evening, in which there would be nothing extraordinary. At the time we were acquainted with a message flashed the same morning we should have finished our breakfasts long ago. I may still be enveloped in a fog, but to me the two statements do not seem to be accordant. I may have been in error in assuming the diagram No. 1, on p. 234, to represent the simultaneous existence of Tuesday all over the world, and even if this be so the principle will nevertheless remain, as is manifest from the following statement:—A day of twenty-four hours — Tuesday, for example — can only exist simultaneously over the world for a single moment; previous to this moment some portion of Monday remains to some of the inhabitants of the earth. At and after this moment a portion of Wednesday comes into existence. The Monday is separated from the Wednesday by its being Tuesday in every part of the world. After Monday is gathered to its predecessors Tuesday is separated from Wednesday by a single meridian on the hemisphere turned away from the sun. As this meridian approaches the sun, more and more of Wednesday comes into existence, and less and less of Tuesday remains. When this meridian has passed over an arc of 15° one hour of Wednesday exists, leaving twenty-three hours of Tuesday. The time east of this particular meridian is reckoned as of Tuesday, the time west of it as of Wednesday. Will "Kelby" have the kindness to determine which of the 360 meridians it is? Perhaps it may assist "Kelby" if he can really devote sufficient thought to the subject, to call attention to the increase, fall establishment, and decrease of the absolute, as distinguished from the local day on the earth. Diagram No. 1, on p. 234, assuming it to be Tuesday over the whole world, gives the commencement of the absolute Wednesday on the meridian 270°. Twelve hours afterwards the meridian 270° comes up to the sun, diagram 3. During these twelve hours Wednesday has been increasing, but as yet its noon has not occurred. Bearing in mind that twenty-four meridians mark the successive hours, twenty-four noons of Wednesday must transpire before the departure of Wednesday from the earth, and when the twenty-fourth has passed the decreasing portion of Wednesday has still to run out. We have consequently four periods of twelve hours each. When the meridian 270° is turned away from the sun it is Tuesday everywhere. During the first period the twelve morning hours of Wednesday occur to places west of the upper solar meridian, diagram 3. During the second period twelve noons occur, and Wednesday is established over the whole globe, diagram 5. During the third period the remaining twelve noons transpire, and one half of Wednesday has departed, one half of Thursday having taken its place, and during the last period the afternoon hours of Wednesday leave the globe at places east of the upper solar meridian, and Thursday is fully established. As, according to "Kelby," I am in a state of fog it is not unlikely that I have imagined the above described diurnal progression, if so, I beg my readers to regard it as an instance of the use of the imagination in scientific inquiry.—W. R. BIRT.

[11711.]—**Time at our Antipodes.**—Some of your correspondents appear to have got into a maze on this subject, and by diagrams have only made confusion worse confounded. I shall endeavour to answer the very sensible question put by "T. S." Fortunately, there is no great amount of inhabited or inhabitable land at our antipodes, or as "T. S." justly remarks, there would be great confusion, because immediately to the east of the meridian of 180° it is Sunday and to the west it is Monday, and any of the small groups of islands situated in the Pacific on either side of this meridian may have Sunday on one island and Saturday on an adjoining one. The only parties at present affected by it are travellers by sea, and it is usual for all navigators on passing the meridian of 180°, if going eastward, say, on a Saturday, to call the next day also Saturday, thus having two Saturdays in the week; but if going to the westward they would skip over the Sunday, and have only six days in that week. I hope these remarks may throw some light on the subject to "T. S."—F. N.

[11711.]—**Time at our Antipodes.**—Replying to "Kelby" on what he considers a very interesting question, I think I can satisfy him, and set the question at rest, having travelled much over the Australian Continent, and also most of the islands in the South Pacific, and spent some considerable time at the Fiji Island named by him, with whose man-eating king, Thackambau, I am personally acquainted. I beg to state that in every island I thus visited they reckon their time in advance of ours, and in no case did I find it, or hear of its being reckoned, otherwise—the reason being, I presume, that by far the greater majority of Europeans have arrived in those islands from the westward, and, therefore, have shortened each day in proportion to the distance travelled due east, until, arriving on the 180° longitude at any given day at twelve noon in England, it will be twelve the previous night, and so in proportion for any shorter distance.—SEPARATOR.

[11711.]—**Time at our Antipodes.**—I have to thank Mr. W. R. Birt for the trouble he has taken in answering my question, and only regret that the knotty point is to my mind still unsolved. In his letter (p. 259) he states that I am wrong in supposing that a message dispatched from London at noon on Tuesday, May 7, would be dropped at New Orleans at 6 a.m. on the same day; and, further on, explains that the difference in time reckoned according to the earth's rotation being 18 hours, the message would really be dropped at New Orleans 18 hours in time later than its despatch, or at 6 a.m. "Wednesday" morning, not on "Tuesday" morning. This, reckoning New Orleans to be 270° East instead of 90° West, seems right enough, but unfortunately totally at variance with daily experience. We have no direct communication with New Orleans by telegraph, but we have with New York, and as the longitudinal difference between these two cities only accounts for about one hour difference in time, either place would answer my purpose quite as well. But to be correct, if the time at New Orleans be 18 hours later than our own, the time at New York should be 19 hours later, but this is not the case. Every afternoon about 4 p.m. we receive in London the opening prices of the New York markets of that very day, the markets opening there at about 11 a.m. Now, applying the argument of Mr. Birt, that the time at New Orleans is 18 hours later than our own, and therefore at New York 19 hours later, Tuesday 4 p.m. in London, ought to be synchronous with Wednesday 11 a.m. in New York, not Tuesday. Referring to his diagram No. 2 in his former letter, p. 234, he says: "If now we take the times for diagram No. 2, we have

90° civil time, Tuesday, May 7, 6 p.m.
270° " " Wednesday, May 8, 6 a.m."

Clear enough as regards the difference of 12 hours, the one being the antipodes of the other, but he also shows

0° civil time, Tuesday, May 7, 12 noon;

and as I have just shown that by our telegraphic despatches that the time at 270° (or 90° West) is 6 a.m. Tuesday, and not Wednesday, I only find myself landed at my original starting point—viz., that the message from London, Tuesday, May 7, 12 noon, by the east, if dropped at Calcutta, would find the time there to be Tuesday 6 p.m. (this is admitted), and that the one by the west, if dropped at New Orleans, would find the time to be Tuesday 6 a.m., and thus meet at the antipodes the first at Tuesday midnight, the second at Tuesday break of day. That every day must have an absolute commencement somewhere on the earth's surface, I do not doubt, and I can only imagine that every country fixes its own time, or adopts that already fixed by some other; but if the two cables could drop a message every 15° equivalent to one hour in time, there must be some point at which they would find themselves entirely out in their reckoning. I would add, that though the Americans reckon their time by the Observatory at Washington instead of Greenwich, their day from San Francisco to New York is precisely the same as ours, therefore we could not have Tuesday 12 noon at London and Wednesday 6 a.m. at New Orleans at the same moment.—T. S.

[11718.]—**Cheap Water Filter.**—The zinc and lead would not improve the water; but would not do more harm than the usual zinc-lined cisterns and lead pipes.—AQUARIUS.

[11721.]—**Assayer's Duties.** — Thanks to J. Roskell for his kindness in bringing under my notice the fact that the method given by me in reply to "G. T. H." is not correct. The rules given would, indeed, be right enough if such a thing existed as a copper ore standard, but there is no such thing, the so-called "standard" being a "sublime humbug." Now, unfortunately, when "G. T. H.'s" query first appeared, I was busily engaged, and could not find time to reply, and when I had the time, I found that I had misplaced the number containing the query, so that it was out of my power to apply myself to the solution of the example given. Had I done so, I would have advised "G. T. H." to see from the last sales the average standard of such low produce ores, and then to apply the rules given, when he would have a fair approximation to the value of his ore; or he might take the price per unit, and from the produce of his ore deduct its value. Indeed, I could show "G. T. H." one other mode of valuation, and explain at length the valuation of the silver and auriferous ores, were it not for the same reason given by J. Roskell—namely, that it would be a betrayal of professional confidence. My rule, without this explanation, would be certainly ridiculous, as even at the present high rate of copper, "G. T. H.'s" ore is only worth about, at the outside, £1 12s. a ton. I need hardly remark how much obliged I am, therefore, to J. Roskell for his kindness in pointing out my error, and I deeply regret that one so capable of contributing to our metallurgical department does not oftener figure among our correspondents.—UN IRLANDAIS.

[11725.] — **Reversing Gear for Oscillating Cylinders**—"Erin" will find the usual plan employed in the steamboats on the Thames described by "Jack of All Trades" on page 91, Vol. XIV. No better system has yet been devised.—E. M.

[11727.] — **Cork-cutting Machine.**—"Balmarino" will find a description of a machine of this kind in Spon's "Dictionary of Engineering," page 1082, but whether that is the best, or what is its price, I cannot inform him.—E. M.

[11741.]—**Boot and Shoemaking.**—First you must get patterns. Some leather-sellers will cut you the shoe or boot out if you take your last; but the surest way is to take an old shoe or boot to pieces. Get one the pattern and size you want it, put the pieces in water to soften them, open them out, and lay them on thick paper, and cut pieces of paper the size of the leather, tack these pieces of leather together with small steel tacks, or paste them with paste (paste made with rye flour is best); then close or stitch them together, holding them between your knees with clamps. Next get the last the size you want your shoe. Procure some insole leather, soak in water, place the last on the smooth side, mark the leather round the size of the last; then cut the pieces off exactly by the mark, place the smooth side on the last, tack on with three or four tacks, press it close to the last, and while wet trim your insole close to the last all round. The shape of your shoe depends on this. Trim the rough off the bottom of your insole. Some shoemakers make two slight nicks round the insole, one about a quarter of an inch from the edge, the other about half an inch. Putting the awl in at one and out at the other of these nicks you sew more level, and the stitches are not so liable to break their hold of the leather. Next place the top level and straight on the last, get the pliers, and pull tight over the toe; drive a tack in the centre of the toe, and one in the heel. Shoemakers generally push some bits of leather betwixt the last and the top leather on the instep, according to the size of the foot round the instep. Next, tack the top all round, then get a piece of top leather about an inch broad that will reach round the heel. You then place the heel of the shoe towards you, holding it on your knee with a strap, which goes under your foot and over the shoe. Sew round the heel first, put your awl in at the insole, but not too deep; sew the narrow piece round the heel, leaving enough to turn over; this done, take a bit off the edge of your welt, and sew round your shoe, putting from four to five stitches to the inch; keep your welt level while sewing. Get a stick, make it flat at one end, work it round your shoe, between the top and the welt; trim your welt round level, cut your leather level round the heel, turn the narrow piece of top leather (some call it a ran) over, and stitch down with a few stitches. Place your shoe on the rough side of your bottom leather, mark round, and cut off. You might save a little leather by putting your sole about half-way along the heel. Then put a bit of inferior leather to finish up the heel, hammer your bottom soles, fill up the middle with small bits, put on your sole, and tack down. Next stitch the sole on; place the awl through the welt, holding the shoe so that you will stitch towards you; place the heel on, put the awl between the top and the narrow piece that is turned over and through the heel pieces; these being sewn on, get the sharp end of your hammer, and hammer round the edge of the sole and welt while they are wet, this will make the edge better to finish. Trim the edges round when dry, being careful not to cut the top leather; scrape round and put ink on, let the ink dry, put your heel-ball on, and heat your iron hot enough to melt the ball, but not to burn the leather; rub up with a bit of old cloth. If Mr. Lonsdale wants to make the bottom smooth, and put a polish on, he must cut a nick in the bottom sole to let the stitches in; then scrape the bottom, and file it and rub with sand-paper (he must do this with the edges, if he wants a first-class polish). He can colour the bottom if he thinks proper. He can buy the tools at the leather-seller's—a shoemaker's kit contains but few. I will answer any questions that he asks for information on shoemaking to the best of my ability, either on sewing, riveting, or pegging.—S. H. L.

[11756.]—**Power of Water-wheel.**—It is a pity the pipe is so long, as the water loses "head" from fluid friction. I cannot say exactly how much, as I have not access to tables. 6ft. fall in pipes, 14ft. 9in. fall at wheel. Suppose the effective fall to be 19ft., and the buckets three parts full; if filled too full the water runs out too soon; 48 × 5 = 240 gallons, or 2400lb. of water delivered to wheel, 2400 × ¾ = 1800lb. contained with the buckets three parts full; 1800 by 6 = 10,800lb. of water delivered to wheel per minute, 10,800 × 19 = 205,200 units of work; take the *modulus* as ·6 or 3-5ths, we get 123,120 units of work per minute, or about 3¾ horse-power. The overshot water-wheel utilises the velocity of the water as well as its fall, but the weight of water on the wheel increasing the pressure on the axis augments the friction.—PHILANTHROPIST.

[11799.]—**Botany of Cornwall.**—The Christian Knowledge Society publish "The Flowering Plants of Great Britain," by Anne Pratt, in three vols., which are ten shillings each. There is a plain practical account of every flower, and a coloured picture of each also. I have used the book for years, and have seldom failed to identify a flower with its aid. There are companion volumes of mosses and ferns.—E. M. P.

[11801.]—**Question in Trignometry.**—Finding that the answers by "H. H." and "Theodolite" to this query did not exactly correspond, I worked it out myself, and found A P = 700·033, B P = 600·028, and C P = 499·927. I also worked it backwards, using "Theodolite's" 500, 600, and 700, and "Numa's" three angles of 120° each, and found the side A B = 1126·95, the side A C = 1044·03, and the side B C = 954·47; instead of 1127, 1044, and 953·9, as given by "Numa." As no two of us agree, will "Numa" kindly say, in the ENGLISH MECHANIC, which calculation he considers nearest the truth? And I shall also be obliged to "H. H." to say whether his method of constructing the diagram is applicable to any triangle. Would it do, supposing the angles from the station P within the triangle A B C had been 100°, 130°, and 130°?—TRIANGLE.

[11801.]—**Question in Trigonometry.** — The following is one solution of this question, without calculating any angles: Let A = area of the triangle, and S = sum of lines drawn from angle to point, P = $u + v + w$

$$S = u + v + w = \left\{ \tfrac{1}{2}(a^2 + b^2 + c^2) + 2 \cdot 3^{\frac{1}{2}} A \right\}^{\frac{1}{2}} = 1799 \cdot 9884$$

$$u = \frac{S}{3} + \frac{b^2 + c^2 - 2a}{3\,S} = 700 \cdot 0364$$

$$v = \frac{S}{3} + \frac{a^2 + c^2 - 2b}{3\,S} = 600 \cdot 0301$$

$$w = \frac{S}{3} + \frac{a^2 + b^2 - 2c}{3\,S} = 499 \cdot 9219$$

—F. M. 1799·9884

[11801.]—**Question in Trigonometry.** — Your correspondent "H. H." has embellished his reply to this query with a more elaborate diagram than is usually employed to illustrate the problem which is the subject of it, and I wish to be informed, through the ENGLISH MECHANIC, whether "H. H.'s" directions and diagram will apply to all triangles having the station P within them, or whether they will serve for one description of triangle only? Suppose, for instance, the station P had been at D, half-way between A and P in "H. H.'s" diagram, how would the intersection of the circles described from the centres of the equilateral triangles have fixed the position of this point? I shall be glad to be corrected if I am wrong, but it appears to me that "H. H.'s" method of finding P will serve for such triangles only as have the angles subtended by their sides from P = 120° each.—THEODOLITE.

[11811.]—**Lime-juice and Glycerine.**—Thanks to "Auld Reekie," and will he kindly inform me how to prepare the lime-water, and the tincture of cantharides?—COUNTRY BARBER.

[11818.]—**Aerated Water.**—Gazogene too expensive for my private use; is there anything cheaper that would answer same purpose.—COUNTRY BARBER.

[11825.]—**Testing Bleaching Powder.**—The mode proposed by "Aughrim" and "Ethyl" is certainly much more accurate in skilful hands than the one I gave. Will "Ethyl" kindly inform me where he obtained samples of chloride of lime containing 35 per cent. of available chlorine? This exceeds the theoretic amount of available chlorine contained in the compound $Ca\begin{cases}Cl\\ O\,Cl\end{cases}$, while in the commercial product I have never found it to pass 20 per cent.—S. BOTTONE.

[11826.]—**Tinning and Soldering.**—"W.T.M.D.," if he refers to my communication, will find that I state distinctly that resin is only to be used in soldering lead or zinc, that being the flux suitable for those metals, or candle grease will do for lead. If he ever spent a day in soldering with spirits of salts, he would not clean his hands either with "clear water," or even with soap without a deal of trouble. I have to call in the aid of washing-powder.—A., Liverpool.

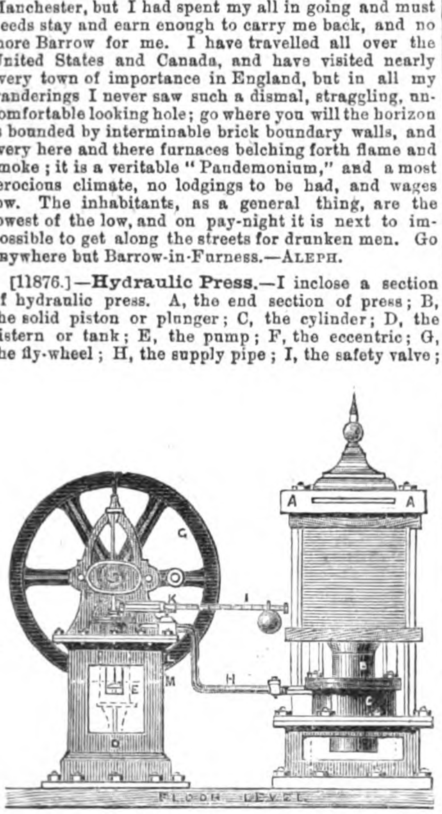
[11835.]—**Arsenic in Wall Papers.**—The plans for detecting arsenic, described at p. 262, by F. Greenway, and "E. B. H.," are very good, and unless the quantity be extremely small, will answer. There is, however, the possibility of a very small quantity of arsenic being carried away in the gas allowed to escape to avoid risk of explosion, and, if the whole quantity be very small, it may thus escape detection. This is not probable, but possible, and may be avoided by a slight modification of the apparatus proposed. Instead of using a common bottle or test tube, if one be used with a little hole at the bottom, and the bottle quite immersed in water contained in a larger vessel, the bottle may be completely filled with acidulated water, containing also the zinc and the substance suspected to contain arsenic in some form. The hydrogen generated will displace the water, and being unmixed with air, may be burnt without exploding. It is convenient to confine the gas as generated by a small stop-cock. If there be arsenic in the hydrogen, the flame will be more visible than if there be none; it will produce a little smoke, which will condense on glass (or on copper wire gauze, which is better) in the form of metallic arsenic or of white arsenic, most probably some of both. To make certain that this is arsenic, it should be converted into white arsenic, by heating it in a test tube by a small flame of a spirit lamp, dissolving it in a few drops of water, acidulated with hydrochloric acid, and testing with sulphuretted hydrogen, which gives an intense yellow slightly orange precipitate; also with nitrate of silver and bisulphate of copper, adding with each a very small quantity of ammonia. The first will give a bright lemon yellow, the last an intense green precipitate, both soluble in excess of ammonia, precipitated again by acid. Some prefer to the first process precipitating metallic arsenic from an acidulated solution by immersing a slip of bright sheet copper, which becomes leaden coloured if arsenic be present. The slip of copper is then placed in a test tube, and the arsenic driven off, oxidised, and tested as before. I prefer the reduction by nascent hydrogen as first proposed by Mr. Marsh, but some think the other as good and less troublesome. —PHILO.

[11839.]—**Plates Chemically Clean.**—I have for many years taken a deep interest in its chemical bearing in photography, and after very many experiments—Carey Lea's bichromate bath included—have found nothing so effective as the well-known "Diamond Polish," and the later, but, if possible, more praise-deserving, "Tunicare," both to be obtained of most dealers.—CIREB.

[11853.]—**Pedal Harmonium.**—I thank "Pneumatic Lever" for his kind answer to my query, and shall be glad to have his plan for pedals, actions, and soundboard. Should like the pedals to slide under instrument; depth of my case 2ft., length (inside) 38in. The tubes I require are such as are advertised as being in the "Canterbury Model," by Rudd and Co., in which the vibrators are said to be ranged on vertical tubes instead of the horizontal arrangement, thereby giving a more organ-like tone.—G. J. C.

[11863.]—**Barrow-in-Furness.**—I am a joiner, and having heard of the place, and being out of collar, I packed myself away there. It was all that I had heard as to business—plenty of work on hand and in prospect; in fact I got a job before I had been there half an hour. But didn't I wish myself back to Manchester, but I had spent my all in going and must needs stay and earn enough to carry me back, and no more Barrow for me. I have travelled all over the United States and Canada, and have visited nearly every town of importance in England, but in all my wanderings I never saw such a dismal, straggling, uncomfortable looking hole; go where you will the horizon is bounded by interminable brick boundary walls, and every here and there furnaces belching forth flame and smoke; it is a veritable "Pandemonium," and a most ferocious climate, no lodgings to be had, and wages low. The inhabitants, as a general thing, are the lowest of the low, and on pay-night it is next to impossible to get along the streets for drunken men. Go anywhere but Barrow-in-Furness.—ALEPH.

[11876.]—**Hydraulic Press.**—I inclose a section of hydraulic press. A, the end section of press; B, the solid piston or plunger; C, the cylinder; D, the cistern or tank; E, the pump; F, the eccentric; G, the fly-wheel; H, the supply pipe; I, the safety valve;



K, the turning handle; L and M, high and low water marks. As there should be double actions, I need not go into details. Two pumps, two eccentrics, two supply pipes, two safety valves. I cannot show them, both being the end sections. — JOSEPH WILLIAM FENNELL.

[11877.]—**Slide Valve Question.**—Will "Rook" give detail of the action of the slide? also state use of small lever seen on top of slide box, where steam enters, where exhausts, and what size steam and water cylinders would require to be for a fire-engine? boiler being 3ft. high, 18in. diameter, 36 field tubes.—PUMP.

[11878.]—**Photography.**—To retouch negatives, the best plan is to spot the parts requiring attention with asphalte varnish or Bates's black varnish, and after printing, spot the white places in the usual way with water-colour and gum, to match the tone of your print. In reply to your second query, I should say you over-expose your outdoor pictures, which would fully account for the symptoms which you describe. Try half the exposure by way of experiment.—R. M. HATCH.

[11885.]—**Power of Boiler.**—I don't know of any existing rule for the solution of this question, so I have invented the following, which I extract from my notebook. Let N be the number of cubic feet contained in the boiler (plain horizontal cylinder), and z = number of square feet of surface exposed to the action of the air, and x = the number of square feet contained in the sides and bottom (area of bottom to be divided by 2). Then N $\left(z + \frac{x}{10}\right) \div 45$ for small boilers and by 50 for large ones. Applying it to the case stated, let $z = 15 \times 6$, and $\frac{x}{10} = \frac{\frac{90}{2} + 2\ (4 \times 15)}{10} = \frac{165}{10}$

$\therefore$ N = $\left(90 + \frac{165}{10}\right) \div 50$ = say $2\frac{1}{8}$ cubic feet; $\therefore$ a boiler of 12in. diameter, and about 26in. long, will be sufficient; but, as it would require constant attendance, for fear of being short of water, I think that it would be better 15in. diameter, and 3ft. long. I think that it would be advisable to have a float, to let on the water supply besides the ordinary hand-tap, and a fusible plug. With these, the smaller boiler could be worked with as much safety as the larger one. The calculation is made for an uncovered sheet-iron tank, and if made of stone, slate, &c., the equivalent of x will have to be much diminished.—P. W. H. J.

[11887.]—**Hair Dye.**—The best hair dye that can be made is made with a solution of nitrate of silver and gallic acid (separately). If "Gray Beard" will advertise his address he shall have the benefit of an analysis I made some four years since of one of the best hair dyes extant, and much advertised, as well as sold at a high price.—R. M. HATCH.

[11891.]—**Contents of Cistern.**—I think "J. K." must mean the cistern to be like the letter D, placed in this way, ᗜ, if so, the following rule may do:—To three times the square of the cistern's radius, add the square of its height, then multiply the sum by the height (or depth), and the product by ·5236 for solid content, which sum, divided by 277·278, will give the number of imperial gallons.—C. B.

[11898.]—**Tempering Cast-Steel Chisels.**—If "U. V. U." adopts R. Welbank's plan to harden his chisels, he will have nine out of ten of them break off just about where the surface of the water came. The best way to harden chisels of this kind is to get the cutting part only to a red heat, plunge in water slightly chilled till cold, brighten on stone, and bring down to dark purple by putting head into the fire.—KYRLE.

[11903.]—**Quinine.**—(1.) Quinine is rarely adulterated at all, especially the well-known makes. When it is, its adulterants are chiefly quinidia and cinchonia, (2) which may be detected in the following manner:—Take 10 grains, add 10 minims of dilute sulphuric acid, and half an ounce of water, which dissolves the suspected sample perfectly; add ammonia, which throws down a white precipitate. This re-dissolves on agitating the whole with half an ounce of pure ether, and if pure, without producing any crystalline matter floating on the lower of the two strata into which the agitated fluid separates on rest. If either of the two other salts be present, they become very visible there. The upper stratum of fluid, if entirely removed and evaporated in the air without heat, must weigh 8·6 grains, and is pure quinia. Salicine has been known to be used to adulterate quinine, but on account of its property of turning red on the addition of strong sulphuric acid, is, I should say, extremely improbable now a days. If soluble organic impurities are suspected, the salt will blacken with strong sulphuric acid, and when the quinia has been separated by ammonia as described above, these will be found by evaporation of the solution. (3.) I do not think it has ever been known to salivate; such is not its supposed therapeutical action. (4.) Amorphous quinine may be prepared by dissolving purified quinoidine in pure sulphuric ether, decanting the etherial solution, and evaporating it with a very gentle heat. Amorphous quinine remains.—R. M. HATCH.

[11903.]—**Quinine.**—I suppose that the question put by William Hamilton Hey refers to sulphate of quinine, and that what he calls amorphous quinine is the alkaloid itself derived from the bark. Sulphate of quinine is commonly adulterated by one or more of the following substances: Calcium sulphate, boracic acid, mannite, sugar, starch, salicin, stearic acid, and cinchona sulphate, or quinidine sulphate. Pure quinine sulphate, when incinerated, does not produce any ashes. When it does, it is a clear indication that it it has been adulterated with mineral matters. If quinine sulphate is pure, two grammes of this compound will dissolve in 120 grammes of alcohol without leaving any residue. The residue, if there is any, consists chiefly of starch, or magnesia, or mineral salts. Salicin is easily detected by the deep red colouration imparted to the suspected compound by the addition of pure concentrated sulphuric acid. Stearic acid is easily detected by dissolving quinine sulphate in water acidulated with some sulphuric acid, as stearic acid does not dissolve. In order to detect mannite or sugar, dissolve quinine sulphate in water acidulated with sulphuric acid, then precipitate by a slight excess of the solution of baric hydrate. Filter carefully the liquor, and pass through it a stream of carbonic anhydride, and boil for a few minutes, and filter again. The solution, when evaporated, will leave no residue if the suspected salt was free of sugar or mannite. As concerns the cinchonine sulphate, the purest quinine sulphate contains always two or three parts per cent. of it; a larger proportion may be detected in the following manner: Put in a test-tube 1 gramme of the salt, and 12 grammes of ether, and then 2 grammes of liquor ammoniæ. If there is any cinchonine it will form a precipitate at the surface of the water, as the quinine will be entirely dissolved in the ether which occupies the upper part of the test-tube. Quinidine may be detected, as it does not precipitate by ammonium oxalate, whilst quinine does. Oxalate of quinidine is afterwards removed from the solution by adding some liquor ammoniæ. Does quinine cause salivation? This question will be better answered by a physician. How is amorphous quinine prepared? Consult any manual on organic chemistry.—F. T.

[11904.]—**Suitable Spectacles.**—"A." has apparently arrived at that time of life that he must do as the writer does, use the weakest power that answers his purpose by day, and if such power is too weak at night use spectacles of greater power.—S. J.

[11906.]—**Spectroscope.**—It is difficult to say which is the better, to have a micro-spectroscope or a simple one, because they are both useful in different ways. A very simple one can be adapted to the microscope or used as a pocket spectroscope for a cost of £2 2s.; but a really good instrument that will separate the D lines cannot be had under £5 5s. to £6 6s.—R. M. HATCH.

[11912.]—**Chemical.**—I should say you will get all the information you need from the last edition of Fowne's "Chemistry" (Churchill).—R. M. HATCH.

[11912.]—**Chemical.**—One fundamental alteration has been in regarding the atomic weight or combining proportion of oxygen as 16 instead of 8; thus, hydrogen being 1, water was formerly considered as $\frac{H}{1} + \frac{O}{8}$, or HO in symbolical language. It is now indicated by symbol H_2O, which expresses two parts of hydrogen by weight (not atoms) to 16 of oxygen. Many of our other formulæ are changed in consequence. Roscoe's is a very good elementary chemistry, but I do not know if it gives much information on the atomic theory.—PHILANTHROPIST.

[11914.]—**Expansion Joints in Steam Pipes.**—I prefer the old fashioned stuffing-box and gland properly fitted up, and packed with good indiarubber rings lapped with spun yarn. I also cast four brackets, two on each pipe, a convenient distance from joint, to receive a couple of tie rods for preventing pipes from being forced out. If pipes are already cast, fix a couple of clasps, they will answer the same purpose.—CLEAN FINGERS.

[11914.]—**Expansion Joints in Steam Pipes.**—The joint used is a stuffing-box packed with indiarubber core, surrounded with hemp strands. To save expense, it would be as well to have an ordinary stuffing-box with packing wedged very tightly in it; but instead of having the ordinary stuffing-box gland, to have just a round plate with a hole cut in it. This would be a consideration when there are many required.—P. W. H. J.

[11915.]—**Corn Screen.**—Dell's Complete Wheat-cleaner is the best I have ever met with.—H. M. S.

[11915.]—**Corn Screen.**—If "A Young Tyke" has a barley mill on his establishment he will find it answer his purpose admirably.—S. J.

[11920.]—**"Jack of All Trades."**—This gentleman would seem to be in a queer way, though I have no doubt but that the symptoms are mainly the result of debility following his recent illness, and will eventually wear away. But should he wish to physic himself, let him take bromide of potassium, 5 grains; tincture of nux vomica, 8 drops in 1oz. of water, three times a day; live as well as he can; have one glass of port wine daily; no malt liquors, and relax his studies, especially at night, for a time.—T. I. PRESTON.

[11921.]—**Curing Sprats.**—I hope this article is not to be prepared for general consumption. Having chosen some fine large fish, decapitate, and wash them. To one pint of pure olive oil add six bay leaves and six cloves, place the vessel containing the mixture on the fire and raise to boiling point. Pack the fish in tin cases, pour in sufficient hot oil to cover them, and solder down immediately. Keep for one month before using.—T. I. PRESTON.

[11923.]—**Potatoes.**—Cutting off the tops necessarily injures the potatoes to a certain extent, but as far as my experience goes the remedy, in this case, is preferable to the disease. As to the size of potatoes, that is a matter of taste, and on my table I always like to see fine specimens of everything. The saving of labour in digging the crop, in sorting, storing, and cooking, as well as the fine sample for the market, are my reasons for preferring size. I have never found any hollows in mine, and I cannot say I have as yet discovered that the smallest potatoes are the best.—INQUIRING MIND.

[11924.]—**To Millers.**—I should advise "M. C." not to have a 4ft. 6in. French stone for grinding wheat upon any consideration; 4ft. stones are the best size he can possibly have, they take less driving, are quicker dressed, and not so liable to "kill" the flour. All the millers that ever I came in contact with like the 4ft. stone the best of any.—H. M. S.

[11924.]—**To Millers.**—Where a number of stones are employed the 4ft. size is generally preferred, as it is more manageable, and does not heat the flour so much in grinding as the other. However, in small mills where two or three pairs of stones are at the most employed, a little time can be devoted to grinding; the larger size is mostly employed, as more work can be performed by it. The speed at which each is driven ought to be about the same, the chief difference between the two sizes being that the larger requires less "face" than the other.—TEVIOTDALE.

[11924.]—**To Millers.**—A 4ft. millstone has the greatest power, and is much easier driven than a 4ft. 6in. one. Dressing has a good deal to do with the power and speed of a stone. I would recommend "M. C." to have 7in. of face upon the stones, and keep the eye slack, as it not only allows the stone to run easier, but also makes the flour much sharper and better. This is on the supposition that "M. C." is a flour miller.—BED OF STONE.

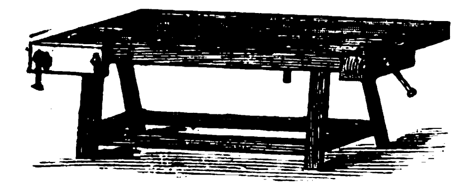
[11927.]—**Ants.**—In Spain, I cleared my bedroom, sitting-room, and verandah by dropping a few drops of tincture of iodine down a hole in the bedroom, where, amongst other places, they used to come up. I tried nearly every other photographic chemical previously. I never saw another ant after this application. I think it would be worth trying for white ants, or preserving timber from them.—R. Y. T.

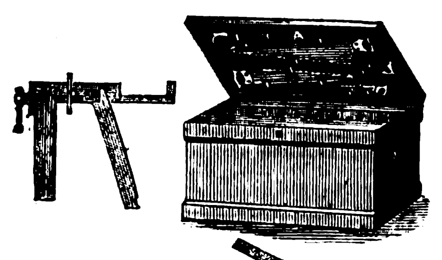
[11927.]—**Ants.**—Has "A. N. T." tried squirting solution of carbolic acid into the tube occupied by his namesakes? I think it will either drive them out or keep them in for good. Boiling water is bad for them if it reaches them before it gets cool, which is not always easy to manage.—PHILO.

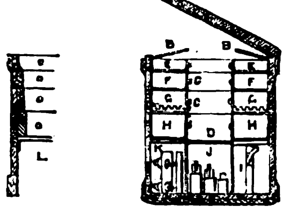
[11928.]—**Microscopes.**—These instruments are often advertised according to magnifying power; this is by no means the sole criterion; two microscopes of the same power may differ greatly in excellence in other respects, such as field of view, brightness of image, achromatism, and clearness of definition, also in the steadiness of the mounting and apparatus. The old fashioned sort, having a vertical sliding tube, has the defect of requiring a somewhat constrained position for observation, and the eye, in such a position, is not so evenly lubricated with its secretion.—PHILANTHROPIST.

[11937.]—**Filtering Water.**—Ordinary filtration has little useful effect in eliminating the impalpable sedimentary matter in waters derived from clay lands; whilst natural subsidence requires several weeks to secure clarification. The flood waters of the Nile I have filtered through charcoal repeatedly with no effect. I bottled flood water from a local stream weeks ago, nevertheless, complete subsidence is not even yet attained. "Jannifred" will find that with potable water the most useful remedy is precipitation by calcic hydrate, being the late Dr. Clark's process, already described in these columns under several heads of queries, amongst others, I believe, the Prevention of Boiler Incrustation, for which see indices to last two or three vols. Cost: a penny or so per thousand gallons of water, and time a few hours.—W. R.

[11938.]—**Carpenter's Bench and Tool Chest.**—The saws are buttoned to the top as A; the hinged lid of the upper till B is polished mahogany, as also the fronts of the tills C, and divided in length to represent drawers; D is a mahogany slide to run from front to back, and acts as a cover to plane box; E E, partitioned off for files and gimblets, &c.; F F, for plough bits and brace bits, to fit in racks; G G, for chisels and gouges in racks; H H, spokeshaves, levels,

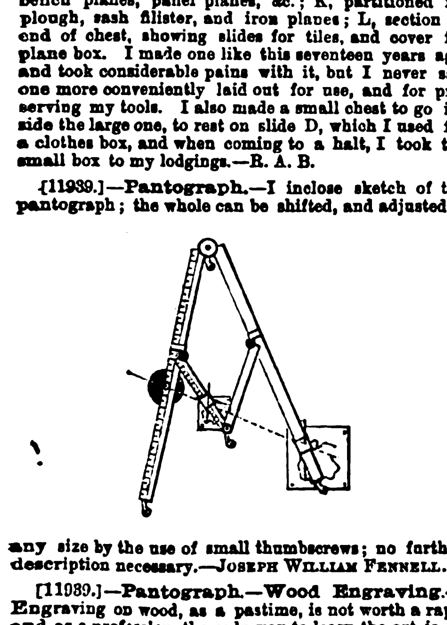






squares, &c.; I, hollows and rounds, for heads; J, bench planes, panel planes, &c.; K, partitioned for plough, sash filister, and iron planes; L, section of end of chest, showing slides for tiles, and cover for plane box. I made one like this seventeen years ago, and took considerable pains with it, but I never saw one more conveniently laid out for use, and for preserving my tools. I also made a small chest to go inside the large one, to rest on slide D, which I used for a clothes box, and when coming to a halt, I took the small box to my lodgings.—R. A. B.

[11939.]—**Pantograph.**—I inclose sketch of the pantograph; the whole can be shifted, and adjusted to



any size by the use of small thumbscrews; no further description necessary.—JOSEPH WILLIAM FENNELL.

[11939.]—**Pantograph.—Wood Engraving.**—Engraving on wood, as a pastime, is not worth a rap; and as a profession, the only way to learn the art is to be with an engraver for five or six years (to some people even six years is not time enough). Engraving cannot be learnt from a book, because there are hundreds of little things that refine the work that are not mentioned, but which you learn by experience. To draw on wood, it is best to know something about engraving, or at least what sort of drawings are the best to cut. When you are about to draw on the block, you must prepare it by spreading a wash of flake white on the surface. When this is dry, sketch in the outline, and then put on what are technically called the washes or tints (which are composed of Indian ink and water in different shades) with a brush. This requires care, to avoid rubbing off the ground of white. To do this, you must put it on at once, and not go over it again till it is perfectly dry. When the washes are on, you touch it up with pencil, ink, and white, if requisite. In what is called a *fac simile* drawing, no washes are used, and it is all done with pencil or ink.—XYLOGRAPHER.

[11943.] — **Worms for Fishing.**—Having only lately become a subscriber to the ENGLISH MECHANIC, I cannot tell you where to find the way given to prepare worms for baiting, but I think I can give you a few hints on the subject which may prove useful to you and others. Your expression "preparing worms for baiting" may have a twofold sense: it may mean either preparing them for the hook, or for ground bait, and to prevent any mistake, I will answer both. Isaac Walton, in his "Complete Angler," says that "camphor put in your bag with your moss and worms gives them a strong and so tempting a smell that the fish fare the worse, and you the better for it," but I don't believe that. The means I use are simple, and, from experience, I can recommend them. Procure a large earthen mug (say) 1ft. 6in. deep, and 1ft. 6in. across; fill it half full of moss, well washed, dried in the sun, and damped before use; put your worms (maiden-dew worms are the best for all fish) on the top of the moss, and let them work their way down to the bottom; turn them over every day; thus treated, they will scour in about a week. To give them a red, healthy, appearance, I mix bole Armenian (a red earth procurable at any chemist's shop) amongst the moss. This is, certainly, the best and simplest method for preparing worms for the hook. To prepare them for ground bait, I make use of three different ways, according to the water I fish in, and the fish I want to catch. If the stream be rapid and rather deep, I procure a ball of clay, about the size of a large turnip; I beat it out until it is a quarter of an inch thick, and then roll up the worms in it, not chopped up, but whole. The stream wears away the clay in the course of a few hours, and the worms crawl out. If the water be deep, but the stream not rapid, I chop up the worms in a basin with a pair of scissors, and put them into a large paper bag, in which I have already placed a stone, heavy enough to sink it to the bottom. I tie the mouth of the bag up, and attach a string to it long enough to reach to the bottom. I then lower the bag, and, after allowing it to remain in the water long enough to make the paper soft, I give the string a sudden jerk, which breaks the top off the bag, and the worms are washed out. If the water be dead, or sluggish, I simply chop them up, and throw them in with my hand.—PISCATOR.

[11945.]—**Leaky Tap.**—When a tap becomes leaky in a short time it may be due to dirty water, or to its having been ground with emery, which should never be used upon anything which is to move afterwards, as it is impossible to get rid of it again as it imbeds itself in the work, and continues to cut when its action should cease. The plug ought always to be re-turned. I find the dust scratched off a good setstone the best to use.—A., Liverpool.

[11947.]—**Power of Water-wheel.**—It will be necessary to know the head and velocity of the water before the first part of your query can be answered. As regards the second part, two pipes of the diameter of 6·77in. will discharge the same quantity of water as your weir, the velocities being the same.—EXCELSIOR.

[11948.]—**A Bad Sleeper.**—"N. K. R." no doubt is troubled with a sluggish action of the liver. I would recommend a very light diet, with a medicine I adopt myself. Senna leaves, powdered rhubarb, jalap; of each a pennyworth. Ground ginger and cream of tartar one teaspoonful. Boil the senna in a pint and a half of water; add the other ingredients, and sweeten with syrup of orange or sugar; shake it up before taking; three doses for adult.—JOSEPH WILLIAM FENNELL.

[11949.]—**Doctors' Commons.**—It is certainly not necessary to employ a professional man. Any person can procure a copy on payment according to the length of it. If "Auspicious" will advertise his address in the MECHANIC, I will procure it and send it to him.—G. C.

[11949.]—**Doctors' Commons.**—Any person (male or female) may search for a will, and if found, obtain a copy. The applicant should know the Christian as well as the surname of the deceased, and the year of death from whence to begin the search. A shilling search stamp must be obtained from one of the stationers opposite the Probate Office, and applicant, having passed into the office, will, on inquiry, be directed how to proceed. The cost of copy will be stated to applicant, who will be required to pay an amount on account, and the balance when the copy is ready. No money is taken in the office, all payments being in stamps, to be obtained at the stationers.—S. J. M.

[11950.] — **Sewing Machine Difficulty.** — "Lovatt" must first set the needle in the bar to its proper height, making the set-screw fast; then lower the needle to its lowest position, by turning the handle in the direction the machine is worked. He will have noticed that in the formation of the stitch, the needle after leaving its lowest point, rises from an eighth to three-sixteenths of an inch to form the loop; let him so raise the needle, still by turning the wheel or handle as before, and when the loop is well formed, the shuttle point must be just entered in the loop, and about the eighth of an inch above the eye of the needle. I forgot to mention that he must thread the needle first. In adjusting the feed he must notice that the teeth rise as the needle rises, but do not move horizontally till the needle is quite clear of the cloth, and that as the needle descends the teeth descend also. Should the above shuttle adjustment not work quite satisfactorily, it may be in consequence of the shuttle being a little too late. "Lovatt" will easily ascertain by trying it a little sooner if necessary.—HONE KO JO.

[11950.]—**Sewing Machine Difficulty.**—If it has a rest motion, let the needle descend below the shuttle-race and return upon a level with it just before the shuttle start; if it has no rest in the needle-bar, to allow the shuttle to enter the loop set it that the shuttle just enters the loop as it comes up.—JACK OF ALL TRADES.

[11950.] — **Sewing Machine Difficulty.** — "Lovatt" should adjust his "Defiance" sewing-machine as follows:—Replace the large wheel, leaving the small wheels loose on their shafts. Place a bit of stuff under the presser and make one stroke (with the hand) of the threaded needle. When the needle just begins to rise, and a small loop is made in the thread, clamp the small wheel on the needle-bar tight with its screw. Then, holding the large wheel tight, move round the shaft, actuating the shuttle in its loose pinion until the point of the shuttle enters a little way into the loop, and pinch the small wheel tight. If a finer adjustment should be necessary it may be effected by the needle itself; anyhow, it is necessary that the point of the shuttle should just enter the loop as the needle is beginning to rise. The same adjustment holds good in all shuttle machines.—GEO. FOX.

[11951.]—**Photography.**—If "Camera" gets a tub and puts a false bottom about 3in. from the real bottom, and conducts a siphon from underneath the false bottom, he will be able to work as follows:—Fill the tub with water, put the prints in for ten minutes; then draw the water off with the siphon. Repeat the operation several times; let them remain in water for twenty-four hours. The false bottom must be perforated.—W. BRIGHT.

[11951.]—**Photography.**—I was once in the same fix as "Camera," and this is the way I got out of it. I got a piece of 9in. by 1in. board and planed smooth, and down each side I screwed a number of wood buttons (such as used for fastening cupboards), then laying on the prints in the same manner as you would lay slates on to a house, fastening them at the joints by turning the buttons. Then I got an old pail, and knocking a small hole in the bottom close to the edge, I hung it on to the spout of the pump, then pumped until full, and fixed the board with the prints at an angle, so that the water fell an inch or so above the top print; it then ran down, and I thus had a running stream, which books on photography so strongly recommend. Of course you require to pump your pail full again, say three or four times. If I wanted to get them washed quickly I used a little warm water at first.—LICTOR.

[11953.]—**Chemistry.**—It would far exceed the limits of a reasonable reply to give even a short explanation of the recent changes in this science; and I do not at all wonder that "Paterfamilias" fails to recognise his old friends in the complex notation now in vogue. If he wishes to go in for what is termed the rational notation, he cannot do better than read the "Introduction to the Study of Inorganic Chemistry" (price 3s. 6d.), by W. A. Miller, a short review of which work he will find at p. 341, Vol. XII.; or he would find Roscoe's "Lessons on Chemistry" very useful (price 4s. 6d.). If, however, he wishes to study the theory of atomicity, and the constitutional formulæ advocated by Dr. Frankland, he may get the first volume of the "Lecture Notes for Chemical Students" (published by J. Van Voorst, Paternoster-row, price 4s.), and he can follow this up with the "Textbook of Practical Chemistry," by W. G. Valentin (price 10s. 6d.). I may add that I recommend him to obtain the last-named works, for they present by far the most satisfactory view of chemical science. — BEACON LOUGH.

[11954.]—**Harmonium Stops.**—"B Sharp" will find the information he requires in ENGLISH MECHANIC, Nos. 109 and 116. All the stops might be added, but the result was compared some time ago in our paper to "powdered footmen behind a one-horse chaise."—G. J. C.

[11954.]—**Harmonium Stops.**—"B Sharp" can introduce the expression stop into his instrument by making a small slide or shutter for the opening on the top of the reservoir bellows, below the soundboard. It can be opened and shut by means of a wire attached to it, and working through a small hole in the side of the soundboard, the hole being stuffed round about with chamois leather to prevent escape of wind. The expression stop consists simply in shutting off the reservoir bellows; but as it is very troublesome to wind the harmonium when using it, I would advise "B Sharp" to try another plan which I tried, and found it to work well. Remove the spiral springs below the reservoir bellows at the back of the instrument, and see what height they rise to when at their freedom. They will, perhaps, rise to twelve or fifteen inches. In that case there is too little variation in their pressure upon the bellows, and you will require to get two sofa springs that will only rise till about nine inches, and put them in the place of the ones you took out. With them there will be little pressure when the bellows is nearly shut, but a great deal when it is open the length of the safety-valve; consequently, with any rate of pressure, you can get any strength of tone. You could not introduce a tremulo stop without constructing a separate wind-chest between the soundboard and bellows, which is a good deal of trouble.—J. SMITH.

[11958.]—**Level of Railway Curve.**—Where W = width of gauge in feet, V = velocity in miles per hour, and R = radius of curve in feet, the following formula will suffice:— $W \frac{V^2}{1 \cdot 25\ R}$. Substituting the values W, V, and R in the above formula, we have $4\frac{3}{4} \times \frac{40^2}{1 \cdot 25 \times 1680} = 3\frac{13}{21}$ inches, the difference of level or cant of the rails. Half of the cant should be given by raising the outer rail above the level of the centre line, and half by depressing the inner rail. It is not necessary to take into consideration the weight of the engine.—W. AIREY.

[11958.] — **Level of Railway Curve.** — Let "Pupil" strain a line, 22 yards long, holding each end against the top flange of the rail, inside of curve, then measure in centre from rail to line, and whatever curve he has in the chain, put one-third of the same in "cant"—as we term it—on the curve. Let "Pupil" remember that too much "cant" is worse than too little. "Pupil" should be very careful in running his "cant" into the straight line, and run it far enough, so that the engine may enter upon and leave the curve as easy as possible, for if the engine has a tendency to leave the rails on a curve, she will almost certainly do so on entering upon it, if not properly "run out." If "Pupil" should require more information, I shall be glad to oblige him.—POINTS AND CROSSINGS.

[11958.]—**Level of Railway Curve.**—According to the formula $W \frac{V^2}{1 \cdot 25\ R}$ = elevation of outer rail in inches, the letters in the formula expressing as follows: W = width of gauge in feet, V = velocity in miles per hour, R = radius of curve in feet. I find in your case the required elevation of outer rail to be 3·6190in.—EXCELSIOR.

[11963.]—**Brass Springs.**—You are using soft brass, which is unsuitable for springs, but can be hardened only by hammering. In making some tongues for concertinas I fell into this mistake, and they did not retain their elasticity. I then procured hard-rolled brass; but found eventually that there is a sort of gray steel coloured brass, of which English concertina notes are manufactured, and which would make admirable springs if strong enough.—A., Liverpool.

[11964.]—**To Prevent Paper Sticking to Silk after being Printed with Metal Leaf.**—Rub your paper with a piece of hard curd soap, and you will have what you require.—JACK OF ALL TRADES.

[11965.]—**To Blacken Brass.**—Warm it over clean gas flame or spirit lamp, and plunge it while hot into nitric acid for two or three seconds. Then return it to the flame, and heat it till it blackens, brush off blisters, and lacquer.—J. F. E.

[11965.]—**To Blacken Brass.**—Brass may be stained black by means of a liquid containing two parts of arsenious acid, four parts of hydrochloric acid, and one part of sulphuric acid in eighty parts of water. Zinc may also be given a fine black colour by cleaning the surface with sand and sulphuric acid, and immersing for an instant in a solution composed of four parts of sulphate of nickel and ammonia in forty of water, acidulated with one part of sulphuric acid, washing and drying. The black coating adheres firmly, and takes a bronze colour under the burnisher.—HONI KO IO.

[11966.]—**Dandelion Roots.**—The best time to get the dandelion is from March till September; its best properties are in the root.—JOHN.

[11967.]—**Emigration to San Francisco.**—In answer to the inquiries made I can reply as follows:—(1) Yes! if he lets mining stocks alone. (2) Living is nearly as cheap in San Francisco as in London, and about 50 per cent. cheaper than in New York. (3) Take only what is necessary. Thin summer clothing is never wanted. Clothing is dearer in San Francisco than in London, but not over 15 per cent. dearer. (4) Nearly 3,000 miles. Seven days trip by rail from New York, or twenty-two to twenty-five days by steamer, *via* Panama. (5) Can stop three times each day, long enough to get meals at the stations. Some trains have dining-room cars attached. Breakfasts cost from 60 cents. to 75 cents., and dinners from one dollar to one dollar fifty cents; that is, 4s. to 6s. (6) Trübner and Co., Paternoster-row, or information can be had of Bowles Bros. and Co., 449, Strand. (7) Very! for persons who have not weak lungs. (8) As a large commercial town, no! As an agricultural or mining centre, yes! (9 and 10) The American bankers, Bowles Bros. and Co., 449, Strand, can probably give you the desired information.—A RETURNED CALIFORNIAN.

[11968.]—**Dog with Weak Sight.**—If the dog never closes its eyelids to protect its eyes from a sudden light, or a cold blast of wind, and if "Libra" is in the habit of striking it on the head, the dog is suffering from gutta serena. Let the dog have a new bed, wholesome food, but no flesh, a cold bath or swim daily, good running exercise, and brush the dog's body well with a hair-brush that will reach the skin. Do not meddle with its eyes, or give it any opening medicine.—MONTE CRISTO.

[11972.]—**Hot Soldering Iron.**—An 8-jet cassene lamp, or an ordinary triple burner benzoline lamp, would, I think, keep a small iron hot enough for light jobs.—W. T. M. D.

[11981.]—**Science Examination.**—A candidate informed me to-day that the result was expected towards the end of June.—EXCELSIOR.

[11982.]—**Thrush.**—I refer "A. C. L." to page 645, No. 863; the proper food is there stated. Feed the birds regularly with moist food, fresh made every day, in the shape of elongated pills. Leave some stuck on edge of cage, and feed over that, to teach them to peck for themselves. Keep them clean, dry, and free from all draught; nestlings should be covered at night with a cloth over the cage. A good cage is easily made out of an old tea box with wickers or osiers. As they grow up and begin to be able to perch, separate them. And when the cocks begin to chirrup, kindly let the hens regain their liberty, and oblige—JOE.

[11988.]—**Dyeing and Fixing.**—I have used Judson's dyes for many years, and find that a very little starch in the dye-bath fixes the colour. With the exception of blue, green, and black, all of the colours will dye wool, silk, and feathers, without any other preparation than their being first cleansed from dirt and grease in soap and water.—OLD HAND.

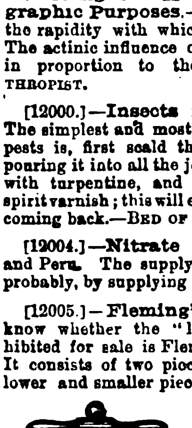
[11993.]—**Photographic Process.** — The following, perfected by Major Russell, is extremely good and reliable:—(1) *Bromised Collodion:*—Pyroxyline, 5 grains; cadmium bromide, 8 grains; alcohol (specific gravity: ·805), 4 drachms; ether (specific gravity ·725), 4 drachms. (2) *Nitrate Bath:*—Distilled water, 1 oz.; nitrate of silver, 60 grains; acetic acid, 1 minim. (3) *Preservative Fluid:*—Tannin, 12 grains; distilled water, 1 oz.; alcohol, 1 drachm. (4) *Alkaline Developer:*—Aqueous concentrated solution of bicarbonate of soda, 30 minims; water, 4 drachms; pyrogallic acid, 1-5th grain; alcohol (absolute), 10 minims. To be mixed just before using. Having thoroughly cleaned the glass or mica plate, coat it with a solution of guttapercha in chloroform, two grains to the ounce. Dry the plate before the fire. When quite cold coat with collodion. Let it "set" well. Immerse in nitrate bath, where it must remain fifteen minutes. Remove from bath, and wash in several waters, until every trace of free nitrate is eliminated. Now coat with the preservative solution by immersing in a bath containing the tannin solution. The plate is to be drained and reared upon end to dry. When dry it will keep good several months (away from light and dust, &c.) Expose as for an ordinary wet collodion. To develop.—Wet the film thoroughly by immersion in a bath of pure distilled water. Then pour on the developer and develop until all details are well out, but of a faint red colour. Now wash away thoroughly the developant, and having flooded the plate with an extremely dilute solution of acetic acid, the image may be intensified by using the usual wet collodion developer. The picture is to be fixed and varnished as usual.—S. BOTTONE.

[11994.] — **Instrument for Measuring and Recording the Amount of Light for Photographic Purposes.**—I think there is. It depends on the rapidity with which sensitive paper is darkened. The actinic influence of different days is not always in proportion to the amount of light.—PHILANTHROPIST.

[12000.]—**Insects in Tables and Chairs.**—The simplest and most effectual way to get rid of these pests is, first scald the furniture with boiling water, pouring it into all the joints and cracks, then rub over with turpentine, and when it is dry, give a coat of spirit varnish; this will effectually cure and prevent them coming back.—BED OF STONE.

[12004.]—**Nitrate of Soda.**—Comes from Chili and Peru. The supply appears inexhaustible. Acts, probably, by supplying nitrogen.—S. BOTTONE.

[12005.]—**Fleming's Locking Corks.**—I do not know whether the "lock" cork now extensively exhibited for sale is Fleming's, but this is a description. It consists of two pieces of box wood preferably, the lower and smaller piece being firmly secured to a pin having a screw thread on its upper part. Three small india-rubber rings are placed between the junction of the two parts of the "cork," and a key being applied to the square portion of the pin or to a square nut at the top, the two pieces of box-wood are brought forcibly together, consequently expanding the rubber rings till they fit the bottle neck tightly. The key is, of course, removable; the square nut on the head of the screw is protected from the action of all but a suitable sized key by being sunk into the top of the "cork." The annexed figure will, I think, make all plain. A non-locking "cork" on a similar principle has been in the market for some time. It consists of two pieces of wood, with a pin carrying a screw-thread projecting at the top. Indiarubber rings are placed between the two portions of the "cork," and a wing nut turned by the finger and thumb causes them to expand till they tightly fit the neck of the bottle.—SAUL RYMEA.



[12009.]—**Photographic Lens.**—It is possible to take a picture (?) with a single bi-convex lens, but the result is not at all satisfactory, in consequence of the indistinctness arising from the spherical and chromatic aberrations inseparable from such a lens. To cover a plate $3\frac{1}{4}$in. by $4\frac{1}{4}$in. the length of focus must be about 6in., the diameter $1\frac{1}{2}$in. to 2in., stopped down to $\frac{1}{2}$in. But "A Beginner" can get a very decent unmounted achromatic lens, of the above focus, for about 5s. Should he not be inclined to speculate that sum, let him invest 2s. in a deep meniscus (single lens) of the same focus. This will give a picture free from distortion, and by a few trials to find the exact difference between the visual and actinic foci, will prove far superior to the bi-convex.—S. BOTTONE.

[12012.]—**Water Power.**—Area of pipe, $3^2 = 9$, $9 \times \cdot 7854 = 7$ square inches. Substituting in the formula $v^2 = 2\,g\,h$, we get $v^2 = 2 \times 32 \times 6 = 384$, extracting the square root $v = 19\frac{1}{2}$ nearly; but from the effects of fluid friction and the well-known phenomenon of the contracted vein, the practical velocity will not be so much (I have no books of reference on this subject here), say 10ft. per second, and, besides, I do not know the length of the pipe. $10 \times \frac{7}{12} = 6$ cubic feet nearly per second = 360lb. of water about per second = 21,600lb. of water per minute falling 6ft. = 129,600 units of work per minute, or about 4 horse-power. I may remark here that in calculations there is little use in aiming at greater accuracy than we have in the data presented to us, as the latter circumstances preclude a very accurate solution being obtained, and we experience this difficulty in most physical problems.—PHILANTHROPIST.

[12012.]—**Water Power.**—"Ignoramus" follows in the same course of other of your correspondents requiring information on "Water Power," but in the absence of specific details of velocity of water and length of pipe, I may give him some idea of the power he can obtain by adopting either a water wheel or turbine. By adopting an open conduit instead of a 3in. pipe, the flow of water per minute would be about 85 cubic feet.

Consequently, $85 \times 62 \cdot 5 = 5312 \cdot 5$lb.

Hence $\frac{5312 \cdot 5 \times 6\text{ft.} = 31875 \cdot 0}{33 \cdot 000} = 0 \cdot 9659$ H.-P.

$0 \cdot 9659 + \cdot 60 = \cdot 579540$ H.-P. water wheel.

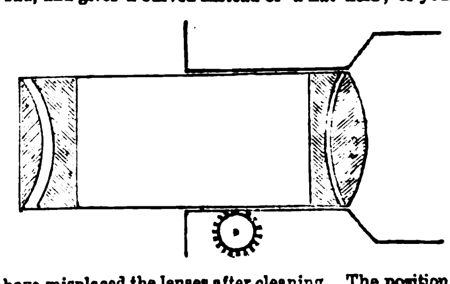
$0 \cdot 9659 + \cdot 75 = \cdot 726425$ H.-P. turbine.

So that, to adopt the best form of water wheel (overshot) would give out a little over half horse-power, and using a turbine would only slightly increase the power; but in either case the machine or motor would be of such a size as to render it practically useless.—J. GILLARD.

[12014.]—**Organ.**—"E. C." will find every information already supplied by "Adept" and "J. D.," and fully shown in section of organ supplied by me in the last number of Vol. XIV. (Consult indices.)—JOSEPH WILLIAM FENNELL.

[12019.]—**Damp Walls.**—The process is similar to one used for waterproofing cloth, as in the "shower-proof overcoats." I have not tested the matter, but have no doubt that the result of the action of the alum on the soap, &c., is the production of an insoluble soap of alumina, which is deposited within the pores, and (from the non-adherence of water to it) exerts a sort of repellant action upon the water. A similar effect may be observed in a wash-hand basin with hard water, when a film of lime soap forms on the surfaces.—SIGMA.

[12024.]—**Photographic.** — Your "fix" depends on one of two causes. Either your lens is radically bad, and gives a curved instead of a flat field; or you



have misplaced the lenses after cleaning. The position they ought to occupy is represented in the adjoining sketch.—S. BOTTONE.

[12024.]—**Photographic.**—The objective may be faulty, and not capable of covering the proper size plate; in that case try a smaller stop. It is possible the lenses may be out of place. The front lens of a portrait combination is generally composed of a double convex lens and a plano-concave lens cemented together, the convex side towards the object. The back lens is also double, but although held in the same brass cell, the two glasses are not cemented together. The one nearest the front is a meniscus, or concavo-convex, the convex side towards the object to be photographed; the lens next the camera being a double convex. I would make a sketch of the position, but it is not fair to ask the editor to have such a thing engraved.—A BARRISTER.

[12025.]—**Chiding Stone.** — There is one in Squire Streatfield's Park, close behind the village of Chiddingstone, Kent.—W. A. G.

[12026.]—**Greenheart Timber.**—The fact that "Khoda Bux" bought a considerable quantity of this valuable timber at a surplus sale of Government stores would seem to indicate that the majority of the buyers at the sale could have had but little knowledge of its qualities, for I presume he got it cheap, or he would scarcely use it for flooring even a granary. As some slight instalment of the information he requires, I send the following particulars:—Greenheart is one of the "first-class" woods acknowledged by Lloyd's surveyors as excellent for shipbuilding—no indifferent character to begin with, but besides this it is one of the very best woods of which to make fishing-rods. In many of the celebrated Irish fishing-rods, such as the "Castle Connell" for salmon, it is the one material used. It is, however, peculiarly suited to the manufacture of "tops," being, in fact, the only wood which is sufficiently stiff and at the same time elastic to admit of being used in single pieces of small bulk. It may often be seen in light fly-rods, in pieces about 8ft. long, tapering off to the thickness of a knitting needle. But it is chiefly from its power of resisting the attacks of sea-worms that it is so valuable to a maritime nation; for in its natural state it is proof against both the *Teredo navalis* and the *Limnoria terebrans*, while it is only second to teak in resisting the attacks of the white ant. There are, I believe, two kinds of greenheart, one being considerably darker than the other; the more abundant variety having the sap-wood of a pale yellow and the heart-wood a deep brown. Greenheart comes from British Guiana, is the wood of a tree known as the Sipiru in that country, but called *Nectandra rodiœi* by Tredgold, and *Laurus chlorozylon* by Ure in his Dictionary. It is a difficult wood to work, as "Khoda Bux" has found; according to Tredgold, the log requires tightly binding while being sawn to prevent it splitting up into splinters. The timber is admirably adapted for shipbuilding, for bridge piles, and for facing wharfs. My attention was first drawn to it some years ago by noticing the high character awarded in Lloyd's Register to vessels built of greenheart, and I have but little doubt that "Khoda Bux" has got a bargain, as the wood has probably been thoroughly seasoned. I do not know, but I should think it would be a very serviceable material for the purposes he mentions. He will be able to supply his friends with the very best material for making fishing rods, for although rather heavy for butts its extraordinary strength enables a sharp taper to be taken from the lower end of the rod. The Santa Maria timber, mentioned by "Khoda Bux," I do not know—by that name at least.—SAUL RYMEA.

[12028.] — **Dimensions of Balloon.** — W = weight to be raised, including the weight of the balloon itself; A = weight of cubic foot of air—G = weight of cubic foot of the gas; D = diameter of the balloon.

$$D = \sqrt[3]{\frac{W}{\cdot 5236\ (A - G)}}$$

$$W = \cdot 5236\ D^3\ (A - G)$$

Approximately with hydrogen gas, but varying with the state of the atmosphere—

$$D = \sqrt[3]{25\cdot 5\ W}$$

$$W = \cdot 0392\ D^3.$$

The buoyancy of hydrogen is about 13·3 feet to 1lb. From Molesworth's "Pocket-book."—WILLIAM C.

[12031.]—**Hot Peas.**—Parched peas, lentils, and paddy, are articles of general consumption throughout India. The mode in which they are prepared is as follows:—A flat thin iron pan, filled with sharp gritty clean sand, is put on the fire, forming a sand bath; with this the grain to be parched is put; when sufficiently done, the grain is whisked out by a broom made of split bamboo, the sand falling to the bottom. "Poor Teeth," I have no doubt, can do the same in a large frying-pan three parts filled with sand. If he wants his peas or Indian corn soft, he had better soak them in water for six or seven hours previous to cooking. I am surprised that parched grain is not more used than it is. It is portable and clean, and with a little salt, very tasty. On one occasion parched rice and peas, washed down with a little brandy and water, formed my breakfast, dinner, and supper, for nearly a fortnight. I was never in better condition in my life at the end of my tether.—KHODA BUX.

[12034.]—**Ordnance Map of London and Environs.**—At a given spot in the Regent's Park, London, the altitudes are these:—Above mean level of the sea at Liverpool, 126ft.; above Thames high water, 117ft.; thus the difference 9ft.—LEVEL.

[12035.]—**The University of Turin.**—I will obtain all information for "Silex" that I possibly can, with regard to the Turin University, and send it in next week.—S. BOTTONE.

[12038.]—**Atmospheric Electricity and Magnetism.**—It would require a treatise to answer this question to advantage. Peltier's electrometer is commonly used for observing atmospheric electricity, but requires special fittings for the purpose. There are also apparatus made for measuring the intensity of the earth's magnetism. Ordinary scientific instrument dealers would be unlikely to have the instruments in stock, but Negretti and Zambra, of Holborn Viaduct, give special attention to this department, and a visit there would, probably, give "R. C." more information than I could put in a column or two, particularly as I have not given any great attention to this department of electricity.—SIGMA.

[12040.]—**Navigation.**—Procure Norie's "Epitome of Navigation."—A., Liverpool.

[12040.]—**Navigation.**—As an ex-mate of ships, and, once upon a time, reckoned a good navigator, I should recommend "A.B C." to study Norie's "Epitome" (many of the examples for one edition of which were calculated by myself); but as this is an expensive book, I may say that I believe there is a small but useful work on the subject in Weale's Series, which could be obtained through any bookseller.—SIGMA.

[12041.]—**Burnishers for Brass-work.**—Either good silver steel or agate. Never used after lacquering. —JACK OF ALL TRADES.

[12046.]—**Endorsing Ink.**—If "F. V. H." will see indices he will there find it given by—JACK OF ALL TRADES.

[12047.]—**Radius of Sector.**—I am free to confess I do not understand "T. E. G.'s" question. What does he mean by the measurement being given "as chords" or "as curves"? If he will kindly word his question a little more definitely, I shall be glad to help him if able.—V. B.

[12051.]—**Fire Engines.**—This appears to be self-evident, as fire-engines generally are used with flexible hose pipes, unless an air chamber were used to exhaust from, the hose pipe would be exhausted for part of its length and would flatten up, thereby preventing the water from flowing along it.—A., Liverpool.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "Correspondent" has answered 9440; "E. L. G.," 11564; "B. A.," 11630.

11668 Astronomical, p. 158
11670 Electrical, 158
11672 Birth and Death Rates, 158
11678 Photographic, 158
11679 Fork and Wedge Valve Motion, 158
11683 Wheatstone's Bridge, 158
11689 Reel for Rotary Sewing Machine, 158
11690 Anchovy and Bloater Paste, 158
11693 Ice Chest and Refrigerator, 158
11700 Ginger Beer Making, p. 159
11705 Small Yachts, 159
11707 Para, 159
11709 Smoking Cap, 159
11717 Removing Gold from Plated Articles, 159
11720 Extracting Zinc from Plumber's Solder, 159
11726 Toughening Cast Metal, 159
11727 Cork-cutting Machine, 159

QUERIES.

[12056.]—**Echo.**—Can any of your readers suggest a remedy for stopping the echo caused by speaking in a large chapel with a high vaulted roof, without any galleries?—J. T. OAKLEY.

[12057.]—**Defective Sewing Machine.**—I have constructed a sewing-machine, the exact counterpart of a Newton Wilson, but, although apparently perfect in every detail, I often find, when working it, I cannot make a single stitch, owing to the needle thread winding itself round the rotating hook, although at other times it works satisfactorily. Could any of your able correspondents inform me of the cause, and remedy for the same?—PLUMBAGO.

[12058.]—**Bees—Swarm or Brood.**—A box hive (15in. square) filled with old black comb, out of which woodlice, a blackbeetle, a slug, and old dead bees were shaken six weeks ago, was replaced in its outer case, and was left on the supposition that it was empty. To-day it is occupied by bees in considerable numbers, who have proceeded to clear the hive of dead bees, broken bits of comb, &c. Room has been added at the top for fresh comb, and food given. Has a swarm taken up its abode in the hive, or has the warm weather hatched brood from the old comb? Information and advice will be gratefully received by—C. R. H.

[12059.]—**Watch Conversion.**—Some information respecting the conversion of vertical watches into levers would be useful to many. I have never seen the subject mentioned in the MECHANIC yet. What new wheels and parts are required, and their probable price? —A. A. A.

[12060.]—**Glass Blowing.**—Would some one kindly give particulars of bending glass tubes to any angle? Also how to blow a bulb on a thin glass tube of ¼in. bore, with the use of a spirit-lamp and mouth blow-pipe?—EMILY JANE.

[12061.]—**Chemical.**—How may chlorate of potash and chloride of potassium be distinguished in testing?—EMILY JANE.

[12062.] — **Induction Coil.** — Would any brother reader give me the following information:—1. Should the secondary wire be coiled the contrary way to the primary? 2. Should the secondary wire be separated by a layer of guttapercha tissue between every coil of wire?—J. B. P.

[12063.]—**Tambour Frame.**—How can I make a common tambour frame?—T. GREENHALGH.

[12064.]—**Diameter of Screw.**—What must be the diameter of a vertical screw about 22ft. long, to act upon the rim of a cast-iron ird x cog-wheel, not exceeding 4cwt., and divided into 22ft.? Also the size of a float to work the screw? The float will be encased in a rectangular cast-iron pipe, perforated and placed against a breakwater. I am designing a simple tidal harbour signal, intended to show the water in harbour at each foot of depth, at flow and ebb.—J. A. ADAMS.

[12065.]—**Paint and Varnish for Portable Engine Boilers.**—Will some subscriber tell me the best kind of paint and varnish for engine boilers? Colour green.—ENGINE DRIVER.

[12066.]—**Washing Baliste.**—Can any of your numerous readers inform me if there is any compound with which a blue material (baliste) may be washed which will cause it to retain its colour? Plain hot water and soap brings it out.—GWASTAD.

[12067.] — **Portable Force Pump.** — Could any fellow reader of our ENGLISH MECHANIC give me any information how I could construct a portable force pump suitable for watering a garden, one that could be fixed in any place required?—W. M.

[12068.]—**Surgical Dentistry.**—Will any fellow reader kindly give me names and publishers of standard works upon above, and profession generally? A really thorough good compendium might suit me best for reference; with plates preferred.—JOE.

[12069.]—**Trip to Australia.**—Would any of your many readers of experienced knowledge be good enough to say if they think a trip to Australia and back would be beneficial to a person who has suffered from congestion of the left lung, but who is now enjoying pretty good health, with the exception of a little weakness if he exerts himself? Also, could they recommend any commission that would help to defray expenses, in the hardware line or agricultural line?—WESTERN.

[12070.]—**Electric Kite.**—Will any one kindly give me particulars as to the materials and construction of an electric kite?—AEDTANNES.

[12071.]—**American Drill Chucks.**—What is the best method for fixing these to a lathe spindle? I have one with only a plain socket, and am at a loss how to fix it. Would heating it a little, and shrinking it on a carefully turned spindle do, without risk? Mine carries only a ⅜in. bit.—JOE.

[12072.]—**Magnetic Moment.**—"The moment of a magnet is the force lodged in one of its poles multiplied by the distance between them." Will "Sigma" give me a little explanation of the above sentence, which is taken from Ferguson, p. 8. For instance, I want to know what units of force and distance have to be employed.—BEACON LOUGH.

[12073.] — **Scarlet Runners.**—Can any of your numerous readers inform me what is the proper treatment of the roots of scarlet runners, to make them grow after the first year?—T. A. SALTER.

[12074.]—**Hollis Observing Seat.**—I am informed its range is from 5in. to 20in. high, and I should feel obliged to hear from any correspondent who may have used the seat how it suits in this respect, as I cannot see how any ordinary tripod or equatorial stand can be of any use on objects below 45° from the horizon with the seat even at its greatest elevation, which is only the height of an ordinary room chair. I understand if the maker is required to construct it higher an extra price is charged.—CROOKED NECK.

[12075.]—**Fruit Syrups.**—How are these, which are sold at one shilling per bottle, manufactured?—COUNTRY BARBER.

[12076.]—**Polishing Slate Clocks, &c.**—I have several slate and marble clocks, which, when new, had a very black and bright appearance, which time has sadly altered. Will some kind reader inform me by what means they can be restored to their original polish?—ALFRED HEALD.

[12077.]—**Pyrethrum Parthenium: the Common Feverfew.**—This plant, which is usually considered as a weed, is said to have occasionally double flowers. I shall be glad if some of "our" readers can inform me of the characteristics of these double flowers, in what respects they differ from the ordinary discs and rays, and how they may be obtained.—W. R. BIRT.

[12078.] — **Cabbage Planting.—Rhubarb.**—Will some one tell me what is the best kind of early cabbage seed? Also which is the best time for planting out, so as to obtain early cabbages? Is it best to manure the ground in the end of the year where they have to grow, or is it best to defer manuring and planting till the spring, and to have good plants for that purpose then? Also, in planting rhubarb roots, when is the time for planting them? Is the end of the year the best time for procuring the plants, or not till the spring? Also which is the largest and best in cultivation? — GEORGE RICHARDSON.

[12079.]—**Detonating Crackers.**—Will some one tell me what the crackers are composed of, which, when dropped on the ground, detonate with a loud noise?—G. E. L.

[12080.]—**Analysis of Manures and Assaying for Certain Metals.**—Would any reader be good enough to give me the names and addresses of some of the most reliable chemists by whom analyses and assays are made at moderate charges?—X. Y. Z.

[12081.]—**Chemistry.**—Can any kind reader inform me of any simple method of detecting arsenic and phosphoric acids, in acid liquors containing various metals in solution?—MOLECULE.

[12082.]—**Turning Tools used for Metals.**—Will S. Smither or any other of "our" readers, inform me the names of the various kind of turning tools used for metals?—BLACKSMITH.

[12083.]—**Polishing the Edges of Glass.**—Will some brother reader kindly give me directions for polishing the edges of glasses for lockets? I generally grind them in with an emery wheel.—TURQUOISE.

[12084.]—**Tools with Swiss Mandril.**—Will some one kindly give me a little idea of the uses of the various tools supplied with a Swiss mandril?—TURQUOISE.

[12085.]—**Cricket Bats.**—Would any reader say what the cricket bat makers use in staining and polishing bats, and what kind of string they use for binding. Small watercord does well, but it comes too expensive.—B. C.

[12086.]—**Velocipedes.**—Can any reader tell me how to put rubber tires on velocipedes when the wheels are iron tired, and which is best, the half round or the flat rubber?—BOB C.

[12087.]—**Violin.**—How are the sides of the violin bent, and set in their proper form? Can any one tell an ancient fiddler?—BOB C.

[12088.] — **Cleaning Jewellery.** — Which is the best and quickest way of cleaning gold. What is it that I have seen shop assistants dip the article in, let dry and polish with a brush, when it looks equal to new?—W. C. B.

[12089.]—**Felt Hats.**—Some of my felt hats got quite white round the band, just where the brim joins. Can any one inform me what causes this whiteness, and what will remove it without damaging the felt?—Bed of Stone.

[12090.]—**Strawberries.**—M. Paris states, in some interesting "Garden Stuff" contributed by him, that the ground about strawberries can hardly be trampled too hard. Does he know this from experience or experiment, or does he report it on hearsay? I should like to know. Also if he is a strawberry fancier. Does he know anything of the kinds, Dr. Hogg, Keen's Seedling, and Myatt's Hautbois? Is Myatt's Hautbois a second cropper?—as I got some plants in the spring of 1871, some few plants of which bore fruit, well tasted but slow ripening very late in the autumn, but the plants seem to have been quite exhausted, in fact, almost killed by the exertion. I gave them a dose of liquid manure (mixture from watercloset and cow byre) about once a week while fruiting, and this may have stimulated them too much.—Derf Errac.

[12091.]—**Plums.**—Why do plums and cherries which have set or formed well now begin to fall off, turning yellow or getting a red pip on the point before they fall off? If it were frost (of which we have had a severe touch here), where the trees were in blossom would it not have altogether prevented the formation of fruit and caused the blossom to fall off or wither up? I know it has had this effect on some of my trees in flower at same time, therefore, I cannot think this is the cause of what I mention. The trees were covered with blossoms, and are covered with half formed fruit, which will all fall off. I should mention that there is, at the same time, on the tree a fair crop of fruit, which will, I trust, ripen; but this part (distinguished by size, now as large as filberts, while the rest, though still green, do not seem to be increasing in size, or only very slowly, and are only as large as barleycorns) is not a third of the fruit which set properly. The tree is about 25 years old and looks quite healthy, but in past years it did not get fair play, suckers having been allowed to grow from its roots, which, however, I have had carefully pruned off. It is well dunged, and in fruit time watered with liquid manure.—Derf Errac.

[12092.]—**Curl in Peach.**—Will some kind horticultural friend prescribe remedy for curl in peach trees? I have heard it is caused by a fly. Some information on its appearance, habits, and mode of life, would be very interesting; the best mode of destroying, or preventing its injurious effects. Mine is a young healthy looking (in other respects) Barrington peach, planted in good ground, on a carefully prepared station on a south wall, in the open air, and carefully attended to, yet I shall have only one peach on it. Do "slaters," the only name I know for them, eat into the stalks of peach blossoms, as many of mine were so destroyed, but by what insect or bird I could never find out?—Derf Errac.

[12093.]—**Budding or Grafting.**—Will some practical man tell me why peaches, plums, and cherries, are generally budded and not grafted (or have I been rightly informed that they are so)? I have got some plum stocks on which I intended to graft scions in March next, but though I have been very successful in grafting apples and pears, I have only succeeded in grafting one plum, though most of those that I budded last year have done well. Is there more difficulty in grafting plums and stone fruit than other kinds, and is this the cause of the adoption of the practice of budding? If budding in the case of stone fruit is more certain than grafting, what should I do with my stocks now? They are good strong ones, but, unfortunately, I did not get them till rather late, and they have gone back a little. They are about 4ft. high, and about ¾in. diameter at bole. If budding is to be adopted, should I cut them down so as to get young shoots for budding on in August? Is there any good book of practical instructions, on the grafting, budding, pruning, and training of hardy fruit trees, and not very costly? The name of such would greatly oblige—Derf Errac.

[12094.]—**Preserving Caterpillars.**—Will some of "our" entomologists kindly tell me how to preserve caterpillars to mount in case, with their respective moths and butterflies?—Chrysalis.

[12095.]—**Hardening Steel Shafts.**—We have an order for a number of steel shafts from 4ft. to 6ft. long, 2in. to 8½in. diameter, with neck or bearings about a foot from the end, 4in. long, 1¼in. diameter. Now, the difficulty is to harden these in the necks, and there only. If I should not be asking too much I should like a rough design of furnace most suitable for heating a number at once, and the best material for hardening.—J. Jones.

[12096.]—**Copying Music.**—A schoolmaster of my acquaintance is in the habit of lithographing the parts of music, and giving them to his boys. Will some one tell me to what extent the practice is illegal?—F. J. Thomas.

[12097.]—**Venetian Blinds.**—Being about to make some for my windows, I should be thankful for a hint as to painting the laths. I am told there is some peculiarity in mixing the paint for this purpose. Any other information on the subject would be acceptable.—F. A. R.

[12098.]—**Dandelion Roots.**—I am greatly obliged to our friend, S. Bottone, for his information (11966). I should esteem it a great favour if he will kindly inform me the simplest and best way to obtain the extracts for medicinal purposes, as I am troubled very much with a sluggish liver. Is it possible to obtain the virtues out of the root so as to keep it by you in case of need? and which is best—a decoction, tonic or aperient, for one troubled as I am? His advice will be thankfully received.—Leicester.

[12099.]—**To Advanced Chemists.**—I have an important question to ask of chemists. I have consulted numbers of doctors—and some of them of European reputation—in vain, and I cannot help thinking that chemistry will assist me; and I trust that none but those well qualified will venture to give advice, as the answer is little less than life or death to me. The query is this: Is there any liquid or solid, or combination of both, capable of being taken internally, that will produce the dissolution—*i. e.*, be a solvent for a stone or calculus, and of which the following is a chemical analysis: Calculus essentially of magnesian character with no trace of uric acid?—Cirer, Brussels.

[12100.]—**Venomous Serpents.**—To Saul Rymea.—How does he (4092, p. 198) account for the well-known "snake stone" of India, and "snake bean" of Africa, acting as an antidote, or at least, preventing all dangerous consequences, as I believe is well authenticated, at any rate, I have seen it used and with full effect on an unknown snake bite, and on a cobra bite?—Cirer, Brussels.

[12101.]—**The Watch.**—I should like to see in the Mechanic a lesson on the watch, how to clean and how to repair it, with the name of the tools used, so that any of the amateurs could refer to it. Could "Yorkshire Pivot," or "West Cornwall," not do this?—S. H. L.

[12102.]—**Lightning.**—Will some one be kind enough to inform me at what rate lightning is supposed to travel? Also, whether lightning is or is not the quickest traveller?—Fred. Moore.

[12103.]—**Staining Glass.**—Could you kindly get me informed, through your columns, how or with what colours or acids glass is stained in the brilliant colours of deep red, pale red, amber, green, &c., and how, or with what, are letters taken out so clearly from the same stained glass?—Geo. Parker.

[12104.]—**Spring Curves.**—Will Mr. Proctor or any of our mathematical friends kindly inform me on the nature of spring (steel) curves when the pressure is at the centre? Does the curve vary in its nature as the pressure is increased? Is it different for different thicknesses? My reason for asking is that I have had some intentions of trying to grind a speculum, and knowing that a spring curve is very near a parabola, I thought it might be very valuable for roughing out.—T. Thorp.

[12105.]—**Equation.** — Will some mathematician kindly solve me the following simultaneous equation, involving a quadratic? It is taken from Todhunter's "Algebra for Beginners." 19th equation—

$$x^2 + xy = 28 \ . \ xy - y^2 = 8.$$

There are two equations—the dot divides them.—C. J. B.

[12106.]—**Organ Building.**—Can any of your numerous correspondents on this subject give me any information, through your columns, on the following? Considering the value of space in constructing chamber organs, and the room pedal (Bourdon) pipes take up, is there any practical difficulty in making one of such pipes do the work of several by means of valves at different intervals along the pipes on the principle of those on flutes, &c.? Seeing that two pedal notes would seldom, if ever, be required to sound at once, no difficulty on that score would arise. I think I have said enough to explain to any one conversant with these matters what I mean; if not, I shall be glad to give further particulars and drawings, but as I am only an amateur, and have never tried the experiment, I ask for information. I believe it is not an original idea; but I have never seen it carried out, so I rather fear it cannot be.—O. V.

[12107.]—**Recipe for Greasy Strapping.**—I am in want of a good recipe for piecing the above kind of strapping, so that I shall be able to work up all spare ends. Can any of the readers of the English Mechanic furnish me with one?—T. W. J.

[12108.]—**Confusion in the Head.**—What does this indicate? I seem always to have noises in my head, ears, &c., and am anxious and desponding. It is not a moral or philosophical defect, but must be a physical one. I wake up in the morning very heavy, and have a disinclination to get up. If I stoop the blood seems to rush to my head; age forty-seven. Bitter taste in mouth frequently. The best remedy I can find is to put myself on half rations. If any correspondent has been similarly afflicted, and knows of a remedy, I should be glad of a hint. Is it possible that it can arise from locality, occupation, &c.? I always fancy I feel more "all there" when I go from home.—Agent.

[12109.]—**Old Locomotive Tubes.**—Having to use old tubes for various purposes, would "Jack of All Trades" or some one else inform me the best method for "bending" them without causing a collapse in the bend?—Young Engineer.

[12110.]—**Silver-Plating.**—Will some one of our correspondents inform me of a simple way of recovering the silver from twelve gallons of cyanide of silver plating solution, or to improve the same, as it deposits the silver of a dark colour inclined to brown? The silver plates or anodes turn of the same colour, and I cannot keep them clean. The solution evolves gas with a very weak battery. What is the cause? Also, what is the best way to remove gold from brass plates, without acting much on the plates, and to recover the gold? I do not want to save the plates, but to remove the gold so as to be able to use it again.—Electro.

[12111.]—**Hothouse Boiler.**—My vineries are heated by a saddle-back boiler, the furnace pit of which fills with water from a spring unless pumped twice a day for about ten minutes each time. I shall be glad if any of your many ingenious correspondents will inform me if there be any other kind of boiler that admits of being placed higher? The present saddle-back cannot be altered in this respect to work efficaciously. A foot and a half would be a great gain to me.—W. F.

[12112.] — **Silvering Mirror for Telescope.**—I should feel much obliged if the Rev. C. Key would answer the following query:—I have just completed a glass speculum 10¼in. aperture, and 65in. focal length, out of a disc of glass an inch and a half thick. On trying it upon a first magnitude star—for example, Arcturus—with the plane mirror silvered, but with the large mirror unsilvered, in order to test its figure, I see the star quite round and small, with two interferences round the disc of the star, but without any rays or appendages. Of course, as the larger mirror was unsilvered, I could not, from want of light, use a high power, the power I used being about sixty linear. Might I consider my mirror sufficiently good so that I might proceed to silver it? To silver so large a mirror is rather an arduous affair, and I should not care to do so, before I was quite satisfied as to its figure. Would Mr. Key also kindly inform me how to make the silver film sufficiently hard to bear a good polish? I am tolerably successful in the process, but my films are always too soft.—T. Godfrey.

[12113.]—**Gold Quartz.**—A specimen of gold quartz weighs 806 grains; and its specific gravity is 3·25. Will some one kindly say what quantity of gold there should be in it, in grains, and also give the rule for estimating?—Augustus.

[12114.]—**Dye for Cricket-Cap.**—I have got a blue velvet cricket-cap with white lines down it and lined with gold braid, and a silk tassel: and after wearing it a little it gets quite worn, and loses its colour. Can any one tell me how to get it into a clean state without spoiling it.—T. T. G.

[12115.]—**To "Sigma."**—About twelve months ago this valued correspondent mentioned that he had a new form of battery in view, and that when he had tried it he would communicate the result. I think many of us would be glad to hear how he is progressing. I, for one, am delaying a long-desired change in my form of battery, awaiting the result of "Sigma's" experiments.—H. H. G.

[12116.]—**Hydrogen Lamp.**—Can any one tell me why it is that frequently a smart explosion ensues when the platinum has been glowing intensely without igniting the jet? It is evidently confined to the outside of the apparatus.—H. H. G.

[12117.]—**Restoring Colour of Watch-Plate.**—Will some friend give me a hint as to restoring the colour of a watch-plate? I want to bring the gilding back to a rich gold colour: it is now too white, though the gilding has not worn off.—F. E.

[12118.]—**Organ Construction.**—Can any reader tell me if I can use a set of harmonium reeds on an organ soundboard? I have made a small organ to have two stops, but having only one at present, I want to use the reeds to carry down the bass octave. Can this be done without cutting the soundboard, and so spoiling it for the other stop? Any information would oblige—Hautboy.

[12119.]—**Pump for Colliery.**—Would any of your scientific readers inform me what would be the cheapest and the most economical kind of pump for a colliery to fetch along the galleries of the mine about 500 gallons of water per day a distance of about 200 yards? I want one to work with the least possible motive power, as the quantity of water is small, and my means small.—One in Need.

[12120.]—**Light.**—I have often thought that light on issuing from the sun may be non-luminous electricity, flowing through empty space (ether being an imaginary substance invented to support the undulatory theory) until it comes in contact with gases such as surround our earth; and in its passage through these gases being converted into light and heat; the deeper the strata of gases, the greater the heat and illumination. For, on ascending a high mountain, the higher you ascend (the depth of the strata of air decreasing), the heat and light decreases. The heat certainly does, and I have heard that the light also does; the sky being of a dull leaden colour. The electricity might become vibratory through contact with different sized atoms of the different gases. Such a theory might lead to the discovery of the size of these atoms by the number of vibrations. Such a theory would satisfactorily account for the tails of comets. If the comets are in a fluid state, and rotated on their axis, they would be greatly flattened at their poles. Electricity in passing through in a polar direction, when illuminated by passing through the gas or gases, would meet in a point giving the conical tail. If the poles were still more flattened, approaching each other until the comet assumed a double concave form, the rays would diverge, giving the fantail. Would Mr. Proctor, or "F. R. A. S.," say if there is a shadow of probability in my theory? Query: Has light been ever seen through only a vacuum?—W. H. S.

[12121.] — **Chemical Preparation of Fruit Essences.**—Could any readers inform me of the method of preparing fruit essences from fusel oil or potato spirit?—H. Billings.

[12122.]—**Driving Bands.**—Will some person of experience say if indiarubber or leather driving bands are the best and most durable for driving steam threshing machines?—J. J. V.

[12123.]—**Worn Waterproof Bands.**—Will some one tell me the best composition to lay on waterproof sheets that are much worn, to make them more durable and waterproof?—J. J. V.

[12124.]—**Voice Weakness.**—I shall feel thankful if any brother reader can kindly inform of the best remedy for weakness of voice. Sometimes my speaking subsides almost to a whisper, which is very detrimental to my business duties.—Jacques Erick.

[12125.] — **Cover Plates.**—Can any correspondent give a practical rule for the length and thickness of cover plates in wrought iron riveted girders?—Excelsior.

Regelation.—The curious phenomenon of regelation can be exhibited by placing a block of ice on a netting of fine wire. The ice will be melted by the wire, and passing down through it will become frozen into a mass again below the wire. A single wire can, in a similar manner, be drawn slowly through a block of ice, the ice uniting again behind the wire and finally showing no sign of having been cut at all.

Nitrogen in Plants.—It has long been known that the quantity of nitrogen contained in cereal crops frequently very far surpasses the amount contained in the manured earth from which they are grown; and the manner in which the additional nitrogen has been acquired is one of the many puzzles of agricultural chemistry. (See p. 400, Vol. XIII.) That it is derived from the air there is no question, but in what manner? Has it been absorbed by the plants directly from the air, or has it been first withdrawn from the atmosphere by some of the constituents of the soil, with which it could form compounds capable of being assimilated by vegetable structures? According to *Les Mondes*, M. Deherian seems to have succeeded in demonstrating that in the presence of organic matter oxygen combines directly with nitrogen, forming a compound analogous to the ulmic or humic acid, produced by neutralising an acid with the potassic solution of garden mould. Into a perfectly dry tube he introduced oxygen, nitrogen, ammonia, and glucose, and on heating the mixture found that a black nitrogenous matter was formed, while at the same time a portion of the nitrogen disappeared from the atmosphere of the tube.

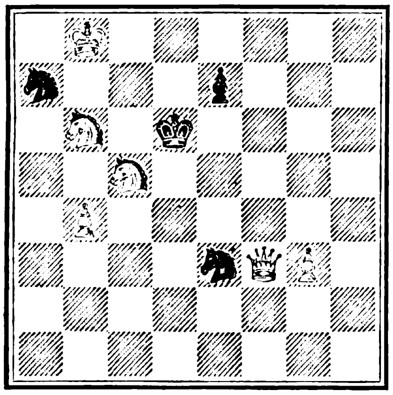
CHESS.

[*Edited by J. W. Abbott.*]

IN compliance with the desire of many of our subscribers, we propose to devote a corner of our publication to the game of chess. The superiority of this game over all others, as an intellectual recreation, has been for centuries acknowledged by philosophers and statesmen, who have praised it not alone for the inexhaustible source of amusement which it affords, but for the educational advantages to be derived from its practice. The popularity which the game of chess has attained in recent times is proved by the number of publications upon the subject; but no student of the chess literature of the last twenty years can fail to perceive that it is in the problem branch of the game rather than in play that modern progress in chess is most clearly demonstrated. He would be a bold man who would, on a comparison of their published games, pronounce Steinitz a better player than Philidor, whilst few people acquainted with the subject require to be argued into a conviction of the superiority of Healey, Bayer, and Loyd over the problem composers of Philidor's time. In fact, the case of Problems *v.* Games may be summed up in the statement that in the present day the genius of the composer has elevated the art of problem construction far above practical play, and that it is in the former that the highest manifestations of contemporary skill and subtlety in chess are to be found. It is unnecessary to enlarge upon the attractions which puzzles and problems have always had for the human mind. With most intellectual people the mere statement that a thing can be done is sufficient to imbue them with a desire to do it, and without taking higher grounds, it is just possible that the interest which the chess fraternity now evince in the construction and solution of problems may be attributed to some such feeling, but whatever the cause the popularity of the chess problem is beyond cavil. We therefore intend to direct attention to problems alone, and we introduce the reader to the latest production of Frank Healey:—

PROBLEM I.—BY FRANK HEALEY.

Black.



White.

White to play and mate in three moves.

All communications intended for this department to be addressed to J. W. ABBOTT, 7, Claremont-place, Loughborough-road, Brixton, S.W.

"JACK OF ALL TRADES."

"JACK OF ALL TRADES," whose health has been fearfully shattered, is about to follow the advice offered by Mr. Hayward, as indicated at foot-note of let. 4266, last week. He also accepts, with thanks, the present of £10 10s. which has been transmitted to him. The following correspondents immediately responded to the appeal made:—

	£	s.	d.
J. H. Hayward, Tonnage House, Carrow, Norwich	1	0	0
"Philo"	1	0	0
"J. K. P."	1	0	0
"Sigma"	1	0	0
"Khoda Bux"	2	0	0
"Cireb"	2	0	0
The Editor	2	0	0
"J. C."	0	10	0
	£10	10	0

A "Well-Wisher and Friend," has sent 2s., and B. Marsh, Rochdale, has sent 6d. The two last sums have been added to the Life-boat Fund.

It will be seen that the contributions of other correspondents rendered it unnecessary for the Editor to subscribe more than £2, and that the contemplated amount is made up. Let us hope that "Jack" will soon be himself again, and when he is he will doubtless let us know it.

USEFUL AND SCIENTIFIC NOTES.

Hydraulic Plate-bending Machine. — The largest armour-plate bending machine ever manufactured has just been completed by Messrs. Westwood, Baillie, and Co., and erected by them at her Majesty's Dockyard, Pembroke. The machine has been tested to the enormous pressure of 4,000 tons. The large cylinder and ram are capable of being moved on the bed, so as to apply the pressure at any part between the columns to suit the difference in shape of the plates required to be bent. This movement is effected by means of a small hydraulic cylinder fixed on one end of the main bed casting. By an arrangement of screw valves the water can be applied at either end of the small hydraulic cylinder, or it can be connected with the large cylinder, and the ram made to lift instantaneously. The machine consists of a massive cast-iron block, top and bottom, each weighing upwards of 24 tons. These blocks are connected by four large columns forged from the best scrap iron. The large ram is 40½in. in diameter, and is worked by a set of four pumps contained in one cistern, two being of large and two of small diameter; all four work in concert to lift the ram up to the plate to be bent, and when about 600 tons pressure has been attained, the large pumps, by their own self-action, throw out of gear, and the small pumps continue to work and produce the power necessary for bending the armour-plate. The whole weight of the machine complete is about 83 tons.

Royal Cornwall Polytechnic Society, Falmouth.—The fortieth annual exhibition of this society (instituted 1833) will open on Wednesday, 21st of August, 1872. Medals and prizes in money will be awarded in the following departments:—*Mechanics:* Machinery and models; mechanical and other scientific inventions and improvements; specimens of naval architecture; essays and scientific papers, &c. *Fine Arts:* Pictures and drawings by professional artists and amateurs, sculpture, architectural drawings and models, and specimens of ornamental art. *Photography:* Photographs by professionals and amateurs. *Natural History:* Essays, local observations, collections of specimens, &c. *School Productions:* Mechanical and freehand drawings, specimens of penmanship, &c. *Plain Needlework, &c., British Lace,* and all objects of interest connected with science and the fine and industrial arts, which may be considered deserving by the judges. This exhibition has been established thirty-nine years, and affords an excellent opportunity for making known the merits of inventions, &c., throughout the West of England. The exhibition is held in a spacious hall, and continues open for eight days. No charge is made for space. The society will defray the expense of carriage, to and from the exhibition, of pictures and drawings by professional artists; and photographs by professional photographers. The carriage of all other articles must be paid by the exhibitor; except in special cases, when an exceptional arrangement may be made. Exhibits should be forwarded so as to reach the Polytechnic Hall, Falmouth, not later than Tuesday, August 13th, after which no space can be guaranteed. Lists of prizes and premiums, and all further information, may be obtained from the Secretary.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, June 4, and unacknowledged elsewhere:—

H. Spink.—V. Buckley.—H. Burridge.—H. Greenwood.—Screw-cutter.—G. A. Adams.—E. H. B.—Wanderer.—G. J. Lough.—J. W. Hood.—Henry Frances.—James Verity.—C. Dening and Co.—W. and H. M. Goulding.—Gillett and Bland.—Payne and Son.—H. A. Rawson.—Frances Blake.—J. D. B.—Evan Davis.—Richard Lloyd.—R. L. Jones.—Soul and Co.—Western.—J. B.—Young Natural Philosopher.—James Beal.—R. A. Proctor.—Fire Engine.—J. G. Parry.—Microscopist.—John Goundry.—E. Sharp.—Jos. Lambart.—J. M. Gorham.—Gilford Mills Reading Society.—Cervus.—F. J. T.—Philo.—Sigma.—F. R. A. S.—Art Student.—M. Reynonds.—J. P. Drake.—F. Paget.—E. M. Peacock.—J. N. Newton.—Chemical.—Saul Rymea.—Jack of All Trades.—Trovatore.—E. L.—Spotsman.—H. C. L.—H. G. W.—Needy.—J. W. Rodwell.—Bee.—Pneumatic Lever.—Lictor.—T. A.—A., Liverpool.—A. B. A.—Thos. Robinson.—C. H. P.—Alfred Waters.—Tourist.—Landsend.—B. N.—E. Anderson.—J. T. Burgess.—Comrade.—E. L. G.—W. S. G.—American Subscriber.—G. P. Coffin.—Thos. Gulliver.—P. W. D.—Robert Johnson.—North-West Yorkshire.—Robert J.—H. W.—A Sufferer.—Constant Subscriber.—Shafto Douglas.—A Would-be Baker.—J. Foster.—Jas. Cunliffe.—J. David Smith.—Xylographer.—Lanca.—J. Barwick.—Great Walker.—H. A. S.—Tripod.—M. J. Dodworth.—W. A.—Philanthropist.—Proven.—Zellus.—Mangle.—T. Perry.—Optical Bricklayer.—F. E. D.—Try Again.—W. Allan.—Experimenter.—Chignen.—J. H. T.—Ben Marsh.—Henry Clarke.—W. C. Hughes.—N. G. Robson.—Cireb.—G. Waterton, Jun.—Stewart Spires.—Ovo.—Assistant Manager.—Try It.—C. S.—Henry Blake.—E. W. James.—F. E.—D. N. E.—Un Irlandais.—Rev. E. L. Berthon.—W. T. Whitaker.—H. B. B.—Old Sub.—Cape Colony.—John Hopkins.—J. X. T.—York.—J. L.—E. W. S.—Leicester.—Monte Cristo.—Before Noon.—Letter Writer.—Horos.

THE DELUGE.—Old King Coal, M. Paris, Derf Errac, J. W. Rodwell, E. L. B., Un Irlandais, and Hill and Vale have sent us letters on this subject.

HOROS.—Why not, instead of finding fault, have assisted to supply deficiencies. Ask for what you want, and no doubt, some one will assist you. You can do no good by growling at what is done. Let us, at all events, part friends.

TOM DAWS.—You want us to repeat much of what many correspondents have from time to time said about photography in our pages, which we cannot do. If you refer to them you will get the information you require.

T. W. J.—"S. W. J." has asked a similar question.

AMATEUR ELECTRICIAN is referred to indices and back numbers. We cannot repeat our information on the construction of galvanic batteries, and you ought not to expect us to do so.

CIREB.—Please answer "Canada" through our pages, so that others may have the benefit as well.

WELL-TO-DO.—Thanks for offer to answer inquirers, but judging from the two answers inclosed, you might do better by *asking* for information on "Fire Engines."

G. E. L.—You may insure insertion by sending something worth inserting, either in the form of query, answer, or letter.

C. H. W.—The fault rests with the Post-office.

A SUBSCRIBER (Lymington).—The Planchette was illustrated and described in Vol. X., p. 280.

J. H. JONES.—Not inserted because not of use to others. You appear to think that the ENGLISH MECHANIC exists exclusively for you, and that, if it does not insert an essentially trade question, it acts unfairly. If we inserted it we should have acted unfairly to other readers, by appropriating space that belongs to them for scientific purposes.

HENRY JOHNSON.—Inform querists through our columns.

KING COAL.—One letter inserted. The other, "A Universal Deluge," contains no specific information not given before.

HONE KO JO.—You can call on employers who want such skilled labour as you have to sell, or you may advertise.

S. SMITHER.—On "Ornamental Turning, &c." next week.

J. T. SPRAGUE.—Your first articles on "Electro-metallurgy" will appear next week.

J. T.—The first *chess problem* appears this week.

UN IRLANDAIS.—Your wish shall be complied with.

B. H. L., Saturn, W. G. S., Australia, J. Barnard, and Steeplehouse.—Your queries and replies are to all intents and purposes advertisements.

WESTWARD HO!—One part of your query is an advertisement, and the other part cannot interest any one but yourself.

J. H. G.—Read the last four volumes of the ENGLISH MECHANIC. Why not ask for "the whole body of physicks" as Montaigne has it?

E. W.—Consult the series of articles on "Plumbing," now appearing in the *Building News.*

E. WHITWELL.—See "Astronomical Notes for June," in last week's ENGLISH MECHANIC, by "F. R. A. S."

E. L., W. M. Edwards, and Peter Piper.—Consult indices.

W. H. SKELTON.—The times given in the *Nautical Almanac* are calculated for Greenwich.

R. B.—Is not your caution somewhat superfluous? When *have* we allowed the insertion of "Infidel attacks on the Truth of Holy Scripture"? We are sorry to notice a half-threat in the latter portion of your letter. We think the ENGLISH MECHANIC would survive your interdict—we are sure all that was good and worth preservation in it would, and we are not at all concerned for the fate of anything else. A general and vague accusation against some of our most able contributors should have been supported by something more than two initials—two initials, moreover, which we do not remember to have seen at the end of any attempt to help us or our readers.

ASTRONOMER.—You need not have wasted our time by writing eight pages to tell us that you possess the knowledge of the true theory of the deluge, and that you mean to publish it somewhere, some time or other.

E. N. PEARS.—Your reply is an advertisement.

T. SMITH.—Consult a medical man.

T. A. (Birmingham.)—Cannot understand your query; write again.

M. A. SIMMONDS.—You had better bind him apprentice to some large shipping firm.

M. CARTER, Mahogany Table, A Subscriber, R. Galloway, G. A., Old Tar, and W. M., are referred to indices to back volumes.

LOUISE.—Never mind your hands, but pay more attention to your spelling.

J. H.—Apply to your local postmaster.

A SUBSCRIBER (Liverpool).—You are apparently suffering from sycosis, and should consult a physician.

Communications which can only appear as advertisements to hand from Cymro Glân, X. Y. Z.

JNO. PARSONS.—If you wish to protect yourself you had better not publish the drawings at all till the invention is patented.

R. O. BERRY.—For soldering without fire, see p. 546, Vol. XII. We gave this reference only last week to another correspondent, who, like yourself, was too lazy to consult his indices to back volumes.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING MAY 28, 1872.

1538 F. R. Gaspary, Berlin, for a self-working threading machine for acting sewing machines.

1539 W. Weldon, The Cedars, Putney, for improvements in the manufacture of soda, potash, hydrochloric acid, and chlorine.

1540 H. Kenyon, H. Kenyon, and I. Swindells, Warrington, Lancashire, for improvements in the manufacture of chlorine and sulphuric acid.

1541 W. H. Dupre, Jersey, for improvements in the construction of wind guards and other ventilators.

1542 G. R. Wood, Wishaw, Lanarkshire, for improvements in steam boilers and furnaces.

1543 R. A. Browne, Richmond-hill, for an improved utensil to be adapted to saucepans, fish kettles, and such like cooking utensils.

1544 J. Holmes, Lincoln's Inn-fields, for improvements applicable to coats and waistcoats.

1545 T. G. Messenger, Loughborough, Leicester, for improvements in the coupling of pipes and in the fittings thereof, and in valves to use in connection therewith and other similar purposes.

1546 E. G. Brewer, Chancery-lane, for a new or improved stocking or hose. A communication.

1547 C. A. C. Eckhold, Green-street, Charing-cross, for improved means of and apparatus for producing and applying motive power.

1548 E. Poulson, Martin-street, Bermondsey, for improvements in apparatus for securing the safety of sailing and other boats.

1549 J. A. Moe, Manchester, for improvements in machinery or apparatus for drawing wire.

1550 J. Worrall, Manchester, for an improved mode of and apparatus for dyeing cloth.

1551 J L. Baker and T. N. Cox, Hargrave, Northamptonshire, for an improvement in ploughs.

1552 H. A. Bonneville, Piccadilly, for improvements in machinery for treating cotton seeds. A communication.

1553 W. R. Lake, Southampton-buildings, for improvements in rolling bearings for plummer-blocks, axle-boxes, and other journal supports. A communication.

1554 G. Havcraft, Faversham, for improvements in the manufacture of pebble gunpowder, and in machinery for the same.

1555 W. Lockwood, Sheffield, for improvements in safety valves for steam boilers.

1556 J. Ricketts, Liverpool, for improvements in stationary and other cases constructed with two or more lids or covers.

1557 S. Cates and W. Swindlehurst, Bedminster, Bristol, for improvements in printing upon metallic or other surfaces by transfer.

1558 M. A. Soul, Southampton-buildings, for a new or improved system of pumping apparatus for compressing atmospheric air or other gases. A communication.

1559 T. Cocks, Gosberton, Lincolnshire, for improved machinery or apparatus for digging and gathering or collecting potatoes, turnips, and other agricultural roots.

1560 T. Cocks, Gosberton, Lincolnshire, for improved machinery or apparatus for planting potatoes.

1561 F. Holloway, New Cross, for improvements in presses for cutting and embossing various substances.

1562 J. Fielding, Liverpool, and W. Duckworth, Manchester, for improvements applicable to breaks for railway trains.

1563 W. B. Woodbury, Greenhithe, for improvements in magic lanterns. A communication.

1564 T. B. De Forest, Southampton-buildings, for an improved machine for making pins.

1565 T. B. De Forest, Southampton-buildings, for an improved machine for sticking pins in paper.

1566 P. Michaelis, Great Winchester-street-buildings, City, for an improved means or apparatus for stoppering bottles. A communication.

1567 P. Michaelis, Great Winchester-street-buildings, City, for an internal capsule for bottles. A communication.

1568 M. M. Harris, Cockspur-street, Westminster, for improvements in hubs or naves for the wheels of vehicles. A communication.

1569 S. Sanderson, Huddersfield, for improved fire-indicating apparatus.

1570 R. Thomas, Shepherd's Bush, for an improvement in tinting or colouring spectacle and other lenses.

1571 T. Brooks, Minerva, U.S., for improvements in the manufacture of steel.

1572 G. Westinghouse, jun., Southampton-buildings, for improvements in slide valves for steam and other engines.

1573 J. E. Rogers, Smethwick, Staffordshire, for an improved differential screw motion applicable to presses, punches, rail benders, shaft straighteners, and other mechanical contrivances of a similar character.

1574 W. R. Lake, Southampton-buildings, for an improved process of manufacturing sheet iron. A communication.

1575 W. R. Lake, Southampton-buildings, for an improved apparatus for removing seeds from raisins and similar fruit. A communication.

1576 W. R. Lake, Southampton-buildings, for improvements in couplings for railway carriages. A communication.

1577 A. J. Murray, Albany-road, Camberwell, for improvements in the treatment of sewage deposits.

1578 R. Rowat, Glasgow, for improvements in and connected with flexible metallic webs, applicable for carrying materials, or as window shutters or otherwise.

1579 J. Knowles, Wolverhampton, J. C. Mayell, Woolwich, for an improved portable cooking apparatus for field or camp use, and an improved formation of trench in connection therewith.

1580 W. Begg, Preston, for an improved feed water heater for steam boilers.

1581 P. F. Connelly, Florence, Italy, for improvements in screw propellers.

1582 J. Maver, Great Portland-street, for improvements in scissors, shears, and forceps.

1583 I. C. Johnson, Newcastle-upon-Tyne, for improvements in the manufacture of Portland and other cements.

1584 W. R. Lake, Southampton-buildings, for improvement in apparatus for propelling ships and other vessels. A communication.

1585 W. R. Lake, Southampton-buildings, for improvements in the manufacture of blocks for paving and other like purposes, and in apparatus employed therefor. A communication.

1586 W. R. Lake, Southampton-buildings, for improved processes and apparatus for the extraction of oil and the production of flour from maize. A communication.

1587 L. V. Simon, Bordeaux, for an improved system of gun, called the "elementary fictitious Chassepot," to be used in the colleges and lyceums.

1588 C. Muratori, Bessborough-gardens, Pimlico, for an improved substitute for iron and steel, chiefly designed to be used in the construction of defensive armour for soldiers, and in the building, lining, and covering of ships.

1589 J. Imray, Southampton-buildings, for improvements in the manufacture of iron and steel, and apparatus therefor. A communication.

1590 J. L. Boone and R. Herman, San Francisco, U.S., for improvements in the construction of the permanent beds of railroads, which improvements also embrace an artificial railroad tie or ...er of a semi-elastic or woody nature, and which block can be ...ted to various similar uses.

1591 G. T. Bousfield, Loughborough-park, Brixton, for a new and improved combination tool for use in mending machinery belts, and for other purposes. A communication.

1592 J. Farquharson, Blairgowrie, Perthshire, for improvements in breech-loading fire-arms.

1593 L. A. da Costa, King-street, Cheapside, and T. Lawrie, jun., Shepherd's Bush, for an improvements in the construction of traps, waste-plugs, or gullies, for baths, sinks, drains, and other conduits of water or other fluids.

1594 W. E. Newton, Chancery-lane, for improvements in caloric engines for obtaining motive power. A communication.

1595 F. Le B. Bedwell, Croydon, for an improved construction of life buoy.

1596 H. Figatner, Finsbury-square, for improvements in voltaic or galvanic batteries.

1597 A. B. Houghton, Birmingham, for an improved apparatus for locking up or securing type or other printing surfaces in frames or "chases," and for locking chases on the beds of presses or machines.

1598 E. T. Hughes, Chancery-lane, for improvements in furnaces for puddling, melting, re-heating, cementing, and for heating boilers. A communication.

1599 J. Shackleton and J. P. Binns, Halifax, for a machine or apparatus for "ticing-in" warps.

1600 F. J. Cheesbrough, Liverpool, for improvements in machinery and apparatus to be used in the process of manufacturing oil from seeds. A communication.

1601 R. Jackson and J. B. Jackson, Sheffield, for improvements in machinery or apparatus for cutting files.

1602 S. Smith, Halesworth, Suffolk, for improvements in the mode of opening and shutting doors of vehicles and in apparatus therefor, which improvements are more particularly applicable to common road carriages.

1603 R. Mather, Fountainbridge, Edinburgh, for improvements in splitting, separating, cleaning, and dressing fibrous materials, more especially rhea or china grass, and in machinery for these purposes.

1604 R. Irvine, Leith, N.B., and J. Mackintosh, Buenos Ayres, for improvements in the manufacture of paper stock.

1605 C. E. Wallis, Albert-street, Peckham, for improvements in repeating or revolving fire-arms.

1606 W. Easterbrook, Finsbury-place South, for improvements in the mechanical contrivances and apparatus employed for locking, and more especially for actuating or setting in motion the locking and interlocking gear for governing railway points and signals.

1607 F. Walton and J. Jones, Staines, for an improved machine or manufacturing nuts for screw bolts.

1608 J. H. Selwyn, Gloucester-crescent, Hyde Park, for a new method of treating refractory ores of silver.

1609 I. B. Harris, Edinburgh, for improvements in and connected with moulds for the production of indiarubber valves and such like articles.

1610 W. H. Davey, Islington, for an improved machine for ironing, calendering, or smoothing linen and other fabrics.

PATENTS SEALED.

3168 R. Wattson, for improvements in stuffing-boxes with metallic packing.
3173 W. E. Gedge, for a novel fabric, being elastic velvet, and improved machinery or apparatus to be used in its manufacture.
3182 J. Johnson, for improvements in the construction of bedsteads, adapted more particularly for invalids.
3198 J. McCool, for improvements in the means or apparatus for stopping holes in ships or other vessels.
3287 A. Gilbertson, for improvements in the manufacture of tin and terne plates, and in machinery therefor.
3290 D. Greig and J. Greig, for an improved rotary lithographic and type-printing machine.
3320 A. Pritchard, for improvements in corks for bottles and other vessels, and in apparatus connected therewith.
3321 A. V. Newton, for an improved mode of preparing for spinning flax, hemp, china grass, and other vegetable fibres.
3336 J. R. Wigham, for improvements in fog and other signals.
3368 J. H. Harrison, for improvements in hydraulic apparatus for raising, hauling, and lowering weights, applicable also for other winding apparatus.
3377 P. Schutzenberger and F. de Lalande, for improvements in employing certain preparations of indigo in printing and dyeing.
3437 J. A. Jaques and L. Sterne, for improvements in the manufacture of bags and pouches.
3455 W. Anderson, for improvements in domestic apparatus for rendering sewage gases innocuous.
83 B. Hunt, for improvements in meters for measuring water or other fluids.
291 E. Barthelmes, for improvements in shuttle sewing machines.
301 C. Wood, for improvements in apparatus for cooling blast furnace or smelting furnace slag or scoria as it runs from the furnace, and loading the same into waggons or trucks in a solid state.
348 E. Jones, for improvements in the manufacture of cartridge cases and in the apparatus to be used in the said manufacture.
466 G. Printz, for improvements in machinery for stamping needles.
511 J. C. Mewburn, for improvements in hackling machines.
582 S. Whitham, for improvements in the manufacturing of pile for bloom for weldless tires made of either iron or steel.
600 J. W. Wood, for a new or improved apparatus or appliance for stopping holes in ships, boilers, and other vessels or objects.
670 F. G. Underhay, for improvements in apparatus for controlling the supply of water to dwelling-houses and other buildings.
761 S. Doards, for an improved apparatus for heating water for warming conservatories and other buildings.
949 H. Y. D. Scott, for improvements in the treatment of sewage water.
63 W. Benson, for improvements in machinery or apparatus for cutting coal.
867 W. A. Lyttle, for improvements in poles for telegraphic and other purposes.
878 P. M. Parsons, for improvements in ordnance and in carriages and projectiles for the same.
879 J. Milroy and J. W. Butler, for improvements in the construction of coffer-dams.
887 E. A. Cowper, for improvements in regenerative hot-blast stoves for heating air, steam, and other gases.
948 J. H. Johnson, for improvements in laying the permanent way of railways and in apparatus employed therein.
974 J. Ashbury, for improvements in apparatus for propelling and steering vessels for inland navigation.
984 J. L. Casartelli, for improvements in pyrometers.
992 W. R. Lake, for an improved subsoil implement chiefly designed for making trenches or ditches for drainage and other purposes.
3192 J. Hargreaves, for improvements in treating dilute chlorine to separate impurities therefrom.
3194 J. W. Harding, for improvements in the method of registering the number of passengers and distance travelled by them in tram cars, "busses," cabs, and other vehicles, and in the apparatus or machinery employed therefor.
3200 E. Gregory, for a new or improved instrument or apparatus to be used in "fining" or improving the condition of ales.
3201 R. B. Starr, for improvements in omnibuses, and improved apparatus in connection therewith, which apparatus is also applicable to other purposes.
3210 M. A. Wier, for improvements in the means of and appliances for fixing buttons, studs, hooks and eyes, and other fastenings in or upon garments, furniture, and other articles.
3214 E. T. Hughes, for improvements in the manufacture of pegged boots and shoes, and in machinery or apparatus connected therewith.
3227 C. Galland, for improvements in the manufacture of leather cloth.
3229 J. D. Gauldie, for an improved apparatus for regulating the speed of steam-engines.
3231 J. Dunbar, for improvements in screwed bushes for the bungholes of casks and in apparatus employed for fixing or withdrawing the same.
3234 J. Wood, for improvements in machinery for polishing yarn or thread.
3243 W. G. Lankester, for improvements in heating and ventilating houses and other buildings.
3248 D. Macfarlane, for improvements in discharging or scattering powdered substances on plants or trees in order to destroy insects or parasites thereon, and in machinery or apparatus employed therefor.
3257 C. Nightingale, for an improved mouthpiece for protecting the wearer against atmospheric influences.
3264 W. R. Lake, for an improved tie or fastening for securing bales of cotton and other merchandise.
3277 A. M. Clark, for improvements in steam-engines for obtaining an efficient steam distribution therein.
3299 T. G. F. Dolby, for an improved means for attaching to the person those watch chains known as "Alberts" and "Victorias."
3392 H. W. Hammond, for a new moveable stamp.
105 R. Brown, for an improved ventilating stove.
339 A. Bauman, for improvements in steam-engines.
525 W. R. Lake, for improvements in cases or vessels for packing caustic alkalies, acids, salts, and other like materials, and in apparatus for forming the same.
571 E. Konigs, for improvements in obtaining sulphate of soda or of potash, and hydrochloric acid or chlorine.
777 E. Edwards, for improvements in dial plates for calendar clocks and watches.
988 G. Westinghouse, jun., for improvements in pneumatic apparatus for working brakes and communicating signals in railway trains.
969 B. Platt, for improvements in purifying turpentine and resin or resinous substances and obtaining the spirit therefrom, and in apparatus employed therein.
1019 W. R. Lake, for improvements in theodolites.
1031 S. Norris, for an improved pavement.
1035 T. Nutting, for improvements in machinery for spinning wool or various other fibrous matters.
3253 F. J. Fahlman, for improved apparatus for disinfecting and collecting fœcal matters, sewage, and manufacturing refuse.
3236 S. Rogers, for improved self-acting couplings for railway carriages, waggons, and other rolling stock.
3249 L. Fortoul, for improvements in treating fatty bodies.
3250 J. Taylor, for improvements in stoves or fire-places.
3261 J. J. Knight, for improvements in the manufacture of caustic soda and potash, carbonates and bicarbonates of soda and potash, phosphates of soda and potash, muriatic acid, and chlorine.
3268 W. Mann, for improvements in the method of purifying gas and in the apparatus employed for that purpose.
3346 L. S. Chichester and C. F. Chichester, for improvements in the preparation of grain for grinding into flour and in apparatus therefor.
3371 E. C. Vickers, for improvements in the preparation of cotton pulp to be used as a substitute for leather.
3490 W. Pawson, for improvements in water-closets.
48 Earl of Caithness, for improvements in cleaning railway rolling stock, and in the machinery or apparatus employed therein.
120 W. R. Lake, for an improved reflector for facilitating the threading of needles.
220 A. M. Clark, for improvements in railway carriage axles and wheels.
319 M. Bayly, for a new or improved combined machine for printing with or without self-inking apparatus, perforating, stamping, copying, and embossing.
450 B. Hunt, for improvements in postal cards and in covers therefor.
586 A. Moore and A. C. Moore, for improvements in roll caps for sheet-metal roofing.
632 E. Kenward, for improvements in ploughs.
649 H. R. Marsden, for improvements in stone-breaking machines.
698 H. Glover, for improvements in local magnetic attraction indicators.
702 A. M. Clark, for improvements in covering top rolls of carding, spinning, and twisting machines.
780 R. H. Patterson, for improvements in the purification of coal gas.
837 R. Monteith, for an improved process for preserving animal and vegetable substances.
851 J. A. Jaques and J. T. Oakley, for improvements applicable to machinery for grinding, surfacing, drilling, or otherwise working articles made of iron or steel.
904 G. Little and T. C. Eastwood, for improvements in machinery for preparing and combing wool, cotton, and other fibrous materials.
910 S. Moorhouse and W. J. Kendall, for improvements in the construction of umbrellas and parasols.
931 T. R. Crampton, for improvements in furnaces.
935 E. Meldrum, for improvements in the purification of paraffin oils and paraffin.
1071 J. Heberlein, for improvements in apparatus for working brakes in railway trains.

Terms of Subscription,

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post Free.

Volumes V., VI., VII., VIII., IX., X., XI., XII., XIII., and XIV. bound in cloth, 7s. each.

Indexes for each half-yearly volume, up to Vol. X (except Vols. II., V., and X.) inclusive, 2d.; Post Free, 2½d. Cases for Binding, 1s. 6d. each.

*** Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The new regulations of the Post-office prevent their transmission through the Post.

To American and Belgian Subscribers.

☞ American and Belgian Subscribers, *especially when renewing their subscriptions*, are *particularly requested* to advise the Publisher of the transmission of the Post-office Order, and the exact amount for which it is made payable.

Subscribers in the United States and Belgium can be supplied with the ENGLISH MECHANIC post free from this Office, for the sum of 18s. (3 dols. 25 c. gold, or 15fr. 60c.) per annum, payable in advance.

The remittance should be made by International Post-office Order. Back numbers cannot be sent by the ordinary newspaper post, but must be remitted for at the rate of 5d. each to cover extra postage.

Notice to Subscribers.

Subscribers receiving their copies direct from the office, are requested to observe that the last number of the term for which their Subscription is paid, will be forwarded to them in a *coloured wrapper*, as an intimation that a fresh remittance is necessary, if it be desired to continue the Subscription.

Charges for Advertising.

ARTICLES.

NATIONAL OBSERVATORIES FOR THE STUDY OF THE PHYSICS OF ASTRONOMY.

BY RICHARD A. PROCTOR, B.A.
Honorary Secretary of the Royal Astronomical Society.
AUTHOR OF "THE SUN," "OTHER WORLDS," "ESSAYS ON ASTRONOMY," &c.

IT will be known to the readers of the ENGLISH MECHANIC that Colonel Strange, who has long been earnest in urging that science should receive extensive Government aid, has recently pointed out the insufficiency of existing national observatories. He urges that new observatories should be erected for the special purpose of studying the physics of astronomy. In other words, whereas the national observatories at present in existence are devoted almost entirely to the determination of the position and motions (real, or apparent) of the celestial bodies, Colonel Strange deems it desirable that other observatories should be erected for the study of the aspect and changes of aspect of the sun, moon, and planets; as also, doubtless—though Colonel Strange makes no distinct mention of these objects—for the study of comets, stars, star-clusters, and nebulæ.

It appears to me that no real lover of science can entertain the slightest question, either as to the importance of the general subject which Colonel Strange has been forward, if not foremost, in discussing, or as to the desirability of the establishment of such observatories as he has described. It cannot be too frequently pointed out that the progress of science must be slow, so long as the students of science are compelled, as at present, to make considerable sacrifices, either of money, time, or work. That zeal, indeed, which causes them to be willing to make such sacrifices, is of the utmost value to the cause of science. But it is to be remembered that there are hundreds, as eager to serve that cause as those who are now so engaged, who are absolutely prevented from so doing because unable to make the sacrifices required of them. Those who possess the requisite wealth, or leisure, or both, may sacrifice of that which they possess, and so advance the good cause. But what must happen with those not equally favoured by fortune, who yet are equally anxious to advance the interests of science? What must the man do whose possessions are but barely equal to his own requirements, or who is compelled to employ his whole time and his whole energy in professional avocations? In the present condition of things, he must simply abstain from science. He must refuse himself the luxury of advancing knowledge. At the utmost he must give only his leisure moments to original researches.

Now, it will scarcely be denied that there are hundreds who are thus circumstanced, and that among these hundreds are men as well fitted to carry out important processes of research as those who, being more fortunately placed, have done noble work in interpreting the secrets of nature. It cannot but be admitted that a system which compels hundreds who might advance science, to abstain wholly, or almost wholly, from the study of science, must seriously retard the progress of scientific discovery. Only in one way can the services of these lovers of science be secured—viz., by making of the study of science a profession—in plain words, by paying those who work in the cause of science for their time and labour, and by providing them with suitable means for carrying out their researches. At present there is no suitable provision for this purpose. A few students of astronomy may find a place in our Government observatories, though even in their case the class of work required is such as few students of astronomy can greatly care for. A few students of other branches of science, again, may find in professorships (*pace* Mr. Lowe) and other like positions, such remunerative employment as may in part free them for original research. And a few others may find in scientific bookwriting, at least the means of obtaining a livelihood without *wholly* abandoning science. But these cases are altogether exceptional, nor even in these cases is the want in question supplied. We cannot suppose for a moment that a professorship at one of our universities is the position which a Herschel or a Huggins would desire to occupy, if the want of means or of leisure prevented him from devoting his powers to original research. Nor is the writing of books on science the employment which would be selected—except as a *pis aller*—by one who was anxious to investigate the secrets of nature. And for the most part it is only the fortunate few who can even thus to any degree devote themselves to the advancement of science. The salaried stations in our observatories are eagerly filled; our professorial chairs are not for the many; and ninety-nine out of a hundred who take to scientific writing with the hope of profitable returns, find the expenses of publication greater than the support they receive from the public.*

It is obvious that science must suffer seriously when so many, who might do yeoman's service, are debarred from taking part in scientific work. Let it be remembered that there is here no question of disinterestedness, or the reverse. There is, probably, not one student of science in a hundred who would not be perfectly willing to do scientific work for its own sake and without hope of reward *if free to do so*. But it is one thing to look solely to the profits to be derived from scientific research, and quite another to require before entering on such research that the degree of support commonly called "a livelihood" shall be insured to the worker. I speak plainly, because plain speaking is required. If science is to be the pursuit of the many, it must be followed as a profession, providing, like other professions for, those who enter it and are capable and industrious. At present, science holds no such position. It is only by making important sacrifices, and by running the risk of others much more important, that any person not possessing considerable means can occupy himself with scientific work.

There can be no question, then, that all who desire to see science progress as it should (and as it *can* progress), should give their earnest support to any scheme whereby room may be found for scientific workers at present lost to the good cause. Not in astronomy alone, but in every department of science, the great want is systematic work and an increase in the number of regular workers; and there is only one way in which this desideratum can be supplied. We *must* have national observatories, national laboratories, national scientific salaried offices of many kinds,—and I do not entertain much doubt that before long we *shall* have them.

It is important, however, to notice, that in this matter not merely is it *le premier pas qui coûte*, but that everything will depend on the nature of that first step. Science is strong enough, probably, to secure a first move from Government. But if the consequences of such first move be unfortunate, science will lose much more than she will gain. Now, it cannot be denied that the first move advocated by Colonel Strange is not free from a considerable degree of risk. In the first place, Colonel Strange has associated with it a promise or *quasi* promise of certain practically useful results. This is in itself, I conceive, unfortunate. It cannot be too often insisted upon that science is not bound to answer the question *Cui bono?* so repeatedly asked of her. She is, on the contrary, bound to assert her true dignity by promising nothing. She is high enough—she has done enough—to claim to be served for her own sake. The good will come; of this we need have no fear; but it may not come in the particular way anticipated. In any given case it may be direct, but it may also be indirect; it may come quickly, but it may also be deferred for many years. All that can be predicated with confidence is that it will reward more than amply the efforts through which it has been obtained.

But the particular good suggested by Col. Strange and by Dr. De La Rue, who supported him at the recent meeting of the Royal Astronomical Society, is scarcely such as can be safely promised by astronomers. I venture, for my own part, to express my utter want of confidence in the probability that the systematic study of the sun will throw useful light on meteorological relations. That all weather-changes may be traced to the sun's influence I admit, or rather, the fact is too obvious to require mention. But that man will ever be able by studying the spots, the faculæ, the prominences, or the chromatosphere of the sun, to interpret the phenomena of the weather, appears to me to be an opinion all but demonstrably incorrect. We know that the sun's varying diurnal course accounts for seasonal changes; yet we know, also, that the seasons are not similar in different years, even as respects their general features, while the weather of any single day is almost wholly independent of the general character due to the season. In one region of the earth, again, a season will be exceptionally cold or hot or mild, while in another region precisely opposite characteristics will prevail. And again, whereas one part of a year may be (like last winter in the British Isles) exceptionally warm, another part may be (like the late spring) exceptionally cold, though the sun, "the dominating source of all weather changes," presents throughout the year the same general characteristics. The great eleven-yearly solar spot cycle may be supposed, without improbability, to be accompanied by some corresponding peculiarities of weather or by variations in the total quantity of heat received by the earth. Indeed, Mr. Baxendell has found evidence in favour of the former view, and Professor Piazzi Smyth (followed by Mr. Stone) has found evidence in favour of the latter. But these peculiarities are all but imperceptible, they vary in different places, they are not such as to throw light on the wider features of meteorological change. Now, the circumstances here considered—the sun's varying diurnal path and the great oscillatory change producing the spot-period—are altogether the most striking features of the sun's relation towards the earth. If *they* do not throw useful light on meteorological habitudes, surely none of the minor features which we may hope to detect by prolonged and systematic study of the sun can be expected to do so. And even if the direct action of the sun were more obviously recognisable in its general effects, yet, inasmuch as even in the length and breadth of England—a speck on the earth's globe—the greatest variety of weather is commonly experienced, it is surely hopeless to attempt to predict the conditions which will prevail in any one country when the solar relations exhibit such and such a character. Yet, short of this, what sort of prediction would be of the least use to men? Even if we admit that is the slightest prospect of our being able to do so much as this, of what earthly use would it be to predict that a storm will rage, for instance, on such and such a day, if the storm is as likely to rage in Russia as in England, or in India as in China?

It seems to me, then, unfortunate that Col. Strange's proposal has been accompanied by anticipations so chimerical. It is still more unfortunate that some who have supported it have not hesitated to sneer at the work done by meteorologists with the Government grant of £10,000 per annum. It is certain, in the first place, that whencesoever the means of interpreting meteorological relations are to come (if they ever come), we *must* know what those relations actually are. In other words, we *must* have these long arrays of tabulated figures—thermometric, barometric, wind-recording, cloud-recording, and the rest—if we are to understand the cause or causes of changes in the direction of the wind, in the prevalence of cloud, in temperature, barometric pressure, and so on. Hitherto very little has come of these records, it must be admitted—and, for my own part, I entertain a particularly strong impression that very little ever will come of them—*but if ever the great mysteries of meteorology are solved those tabulations will have fulfilled their purpose. To cease to make them is to admit that these mysteries are inscrutable.*

Moreover, it will scarcely do to approach Government with a request for Government assistance, on the plea that the Government assistance granted to meteorologists has been completely thrown away.

But the chief point to which I would invite attention in Col. Strange's proposal* is this, that he has not indicated with sufficient clearness what he would wish Government to do. If a

* It is, doubtless, due to the present unsatisfactory position of scientific teaching in this country, that what the *general* reading public would take is not that which the student of science would prefer to supply. A volume containing the results of a long process of original research would scarcely have a chance of success as a literary venture. No publisher would accept the risk of such a volume. It should be remembered, in fact, that the scientific author is not free to select his own line or style of writing, unless he can publish at his own expense. He is bound to consider the opinion of the publisher as to what the public is likely to find attractive.

* I refer throughout to the paper read by Col. Stran[illegible] before the Royal Astronomical Society. If there [illegible] been less public utterances on his part, I either ignorant of them or ignore them.

vague resolution, such as his paper seems to promise, were submitted to Governmental consideration, Government might, with the best intentions, proceed to action which would by no means accord with the wishes of true lovers of science. The Royal Astronomical Society, the acknowledged representative of the astronomy of England, knows what sort of man should be placed at the head of a great national observatory; but Government, not knowing, might place there some person without any real regard for science, and with none but borrowed scientific knowledge. If Col. Strange would so bring his proposal before the Astronomical Society, and thus before Government, that none but those who were at once zealous astronomers, trained observers, sound mathematicians, and skilful theorisers, were placed in authority in the proposed observatories, no true lover of science could refuse the proposal his most earnest support. Nothing but good could follow from such a course. But if there were the slightest risk that an appointment of the sort should fall into unworthy hands—and such risk would assuredly be involved if vague resolutions were submitted to Government—it would be the duty of all who wished well to science to oppose the resolution to the utmost of their power.

A point to be most carefully insisted upon is that the head of any national observatory such as has been proposed should be one who would behave in a generous, considerate, and courteous way to all who worked under him.

In conclusion, I must remark, to prevent the possibility of misapprehensions which might mar the effect of what I have been saying, that *personally* I have *no interest whatever* in Col. Strange's proposal. I wish to see science advance as rapidly as possible, and in particular that astronomy may so advance; and I speak out of the interest I thus take in the progress of science. In so far as I advocate the proposal for new national observatories, it is because I believe such observatories to be very much wanted, and that their erection would be followed by important advances in astronomy; in so far as I oppose the proposal for their erection, it is because I fear lest if the project be improperly carried out, it would lead to retrogression instead of advance. I cannot recall any instance, for years past, where it behoved the true lover of science to be so careful as to his action as in the present case.

AIR AND RAIN.*

WE have already (p. 239) examined a few of the facts brought forward by Dr. Angus Smith on the subject which forms the first moiety of the title of this article, and have endeavoured to point out the conclusions to which they lead. We have seen that a very small deficiency in the proportion of oxygen in the air we breathe, when compared with that which is known to exist in notoriously healthy spots is sufficient to call for a rigid sanitary investigation into the causes which produce it, not merely because a deficiency of oxygen is in itself sure evidence of the insalubrious character of the atmosphere in which it occurs, but because there is ample ground for believing that this deficiency of the life-giving gas, found to be the normal condition of the air, is made up by a greater or lesser number of other gases, many of which are known to possess noxious properties, and which are also believed to be the media that afford sustenance to, and assist in the propagation of, the as yet undefined poison-germs of disease. Granting this premise a very little consideration will show us that the rain must exercise a great influence on the number of these germs floating in the air which it traverses, and that it is, therefore, as essential to make a rigid scientific investigation into the peculiarities of the rain of different localities, and the numerous foreign substances brought down by it, as into the air through which it has fallen. We know that after rain the atmosphere contains a larger percentage of oxygen than it did previously, and there is at the same time a diminution of carbonic acid; but although we have not been able to discover the cause of this increase of oxygen in the facts which chemical climatology has as yet presented to view, there can be but little doubt that it is mainly brought about by the removal of "atmospheric dust" and carbonic acid and other gases by the mechanical and chemical actions of the falling water. The analytical examination of the collected rain, indeed, enables us to form a very good idea of the character of the air of the locality in which it has been gathered, and, taken in connection with an examination of the air itself on a fine day, affords a reliable criterion of what may be termed the external salubrity of the place under investigation.

The principal substances found in the rain-waters experimented on by Dr. Angus Smith are chlorides, sulphates, and ammonia. Amongst the most important, as far as quantity is concerned, is undoubtedly common salt, the base of which, sodium, spectrum analysis has shown to be universally present. Common salt is found in abundance in the rain of the sea-coast, to the extent of 1 part in 10,000 parts of rain-water; but it cannot be supposed that any noxious property exists in this compound. In making analyses of the substances found in rain, therefore, allowance must be made for the proportion of hydrochloric acid due to the salt found near the sea and in the neighbourhood of towns, where it is one of the products of coal-burning; but a distinction is easily drawn between the two, from the fact that rain-water near the sea is not acid, while that taken in towns is invariably so, from the fact of its containing sulphur compounds. The compounds of sulphur, too, are found where there is no coal-burning to account for them, and these invariably proceed from decaying animal and vegetable matters, which give off sulphuretted hydrogen and sulphide of ammonium, which, happily for us, are speedily oxidised, and split up. Ammonia, however, is the compound which affords a fair test of the amount of impurity in the atmosphere. When organic substances undergo decomposition, says Dr. Smith, the nitrogen goes off with hydrogen, forming ammonia, unless strong oxidising influences are present. But ammonia itself is not an infection — a small amount, even when constant, may not be hurtful; but the probability is that this small amount is better absent, because its presence indicates objectionable or decaying matter, which may send out worse substances than ammonia. The results obtained by the investigations of Dr. Smith into the constituents of the rain taken in various parts of Great Britain give the amount of chlorides found in London rain-water as 2·6, when compared with Valentia as 100; while for sulphuric acid, taking Valentia as 100, London has 750, and Glasgow 2,571, a fact which Dr. Smith regards as explaining in some degree the great mortality of the last-mentioned place, because sulphuric acid is not merely a measurer of manufacturing industry, but also of decomposition, being a part of the oxidised sewage of the air. The "acidity" of the rain-water is another measure of the impurity of the atmosphere, and in this respect, taking the inland country parts of England as exhibiting 0, Glasgow figures with the high comparative amount of 109, and Manchester and Liverpool with 83, while London has 28. The comparative amounts of combined ammonia are shown by Valentia 1, Glasgow 50, with Liverpool and Manchester following closely with 30 and 36. In the most important table of all, that giving the comparative amounts of albuminoid ammonia —*i.e.*, the measure of unpurified air-sewage—which includes the "germs," Valentia being taken as 1, Glasgow gives nearly 9, while Liverpool (3) is less than London (6), and St. Helen's and Manchester press closely on Glasgow.

The tables containing the averages of the experiments made on the different rain-waters are full of interesting and valuable information, but they must be read in their entirety, with a clear appreciation of the effect of the prevailing wind and other circumstances, before correct notions can be gained; for we find that on one occasion the amount of hydrochloric acid found in rain collected at North Uist was no less than $3\frac{1}{4}$ grains per gallon, while a specimen taken at Kelly, Wemyss Bay, yielded only ·0852 per gallon, a difference which of course can only be accounted for by the elevation of the place, the direction of the wind, and the time of the year. We have said sufficient here to show that an analysis of the rain may be made to determine approximately the healthiness of a given locality, or at least point out the direction which further inquiries should take. For the results of the investigations made at the various places we must refer our readers, as before, to the book itself: so many different localities have furnished the materials for the experiments that a tolerably accurate prevision of the result of analysis can now be made for any spot in the British Isles. Dr. Smith supplies several lithographs of characteristic specimens of the crystals found after evaporating rain-water—those obtained from Newcastle-on-Tyne rain exhibiting beautifully-defined crystals of Glauber's salts (sulphate of soda). These specimens were obtained by boiling down 200 cubic centimetres to the bulk of about one, and allowing one drop of this to evaporate spontaneously on a microscope slide, affording in many cases interesting, and in all, valuable, objects for the study of the sanitarian chemist and microscopist. It is not necessary for the would-be investigator into this subject to wait for a shower of rain in order to obtain an idea of the matters held suspended in, or the gases mixed with the air, for it is quite possible to obtain exactly similar results by taking the air in a bottle containing a little pure water and washing it by agitation. This method has been followed by Dr. Smith in analysing the air of houses and close places; still, he says, that although air-washings enable us to examine air where rain cannot come, and to a great extent must supersede the examination of rain, the latter must not be neglected, since we obtain from it a knowledge of the contents of the atmosphere at a time when we cannot watch it, and we obtain also the mean of a long period. With these air-washings of specimens of metropolitan air, Dr. Smith obtained some curious results, which show how necessary it is to take into account the state of the weather at the time, for in an air-washing from Westminster Abbey Yard, taken on a fine day, he found albuminoid ammonia in the proportion of 37 grains per million cubic feet; in one taken on the embankment in front of the Houses of Parliament 71·8; and in one taken in a field two miles beyond Clapham Junction, no fewer than 118·4; but the second specimen was obtained on a windy day, and the latter during a very strong wind. It is, therefore, necessary to take the mean of a number of experiments before deciding on the amount of impurity in the air of any particular spot; but those at present made by Dr. Smith, though comparatively few in number, are of the first importance in showing the difference between the air of some of our health-resorts, and the vitiated stuff which a large portion of the community are condemned to breathe daily and hourly. Thus, putting the amount of hydrochloric acid found at Blackpool (Lancashire coast) as 100; the comparative amount for London is 320, and on the Underground Railway, 974. The amounts of sulphuric acid (anhydrous) for the same places are Blackpool, 100; London, 352; Underground Railway, 1,554. The quantities of ammonia and albuminoid ammonia are compared with those found at Innellan on the Firth of Clyde, which, being taken at 100, shows London with 117 and 108, Glasgow 150 and 221, and the Underground Railway 138 and 271; so that on these results London has but little more albuminoid ammonia than Innellan—100: 109; while Glasgow and the Underground Railway have atmospheres little better as regards their freedom from what Dr. Smith calls "potential ammonia" than the air obtained over a midden! It is true that while our author points out that the albuminoid ammonia is the most important of the chemical constituents, he cautions us against drawing too many conclusions from its presence. "The organic matter," he says, "is sometimes quite sound, and so far from producing disease it may help to drive it away. All that we can say is that organic nitrogenous matter shows that some organisms of a hurtful kind may be present. If there is no excess of albuminoid ammonia, the hurtful organisms or other matter may be presumed to be absent. If there is an excess, it is well to avoid such air until we know that it is from a source which produces not only that which is wholesome but that which continues to be so."

With regard to the lowest percentage of carbonic acid deemed positively hurtful, scientific men have failed to agree, and even Dr. Smith can give but a hesitating opinion, although he thinks that the "smallest diminution of the oxygen in the air breathed affects animal life, if its place is supplied by carbonic acid." But the question, How can the blood be influenced by a diminution of oxygen in the atmosphere to the extent of ·1 per cent. has met with contradictory answers. Liebig says, "In a closed space 8ft. long, 9ft. high, and 8ft. wide, a man cannot breathe twenty-four hours without uneasiness." The danger to life is not immediate, however, according to Dr. Smith, when the percentage of carbonic acid is less than 4 per cent., provided the person breathing the air so adulterated is healthy; but "the constant lowering of the pulse, even in much less impure air, must have a gradual effect on the

* Air and Rain. By R. Angus Smith, Ph.D., F.R.S., &c. London: Longmans.

vitality." Dr. Smith considers that a certain quantity of oxygen is required to drive out the carbonic acid from the blood, and that this quantity being deficient less carbonic acid is given out, and it is certain that no danger to life and no difficulty of breathing is experienced in situations where the air contains less than the normal amount of oxygen, if carbonic acid is also almost entirely absent. Dr. Smith gives a good rule for ascertaining the amount of carbonic acid in the air of houses:—"Let us keep our rooms so that the air does not give a precipitate when a 10½oz. bottleful is shaken with half an ounce of clear lime-water," a sanitary regulation which can easily be carried out.

This book also contains valuable information on the constituents of smoke, looked at both from the sanitarian's point of view and from the point of view of the consumer of large quantities of coal for heating purposes. We may at some future time call attention to this aspect of the smoke question, which is still imperfectly understood, and in connection with which the teachings of science are strangely neglected. The influence of acids derived from chemical and other works upon vegetation also finds a place in this volume, which, as we intimated before, is a record of work, the full value of which will be recognised at a future time. One of our contemporaries regards the book as useless because ozone finds no place in it; but as Dr. Smith has not yet been able to make the contemplated experiments on the subject we cannot well complain because his "*beginnings* of a chemical climatology" are not so complete as we could wish.

ON A NEW SYSTEM OF CHEMICAL NOMENCLATURE.

BY SELIMO BOTTONI.

MUCH interest has been evinced by several of "our" correspondents with regard to the nomenclature employed in modern chemistry. Though at first sight it might appear that the name applied to any substance would have little to do with the comprehension of its possible properties, and its theoretical relations with other bodies, yet in practice it is found that nothing is so conducive to a clear apprehension of the relation which things hold to one another as a systematic and natural nomenclature. The grouping of plants into natural orders has had a marked influence in the facilitation of the study and the acquirement of a correct knowledge of the science of botany. Thus, for instance, to the botanist, the knowledge that a plant belongs to the order named *Leguminosæ*, immediately gives him an insight into the probable properties, mode of growth, of flowering, &c., possessed by that plant. Again, the nomenclature proposed by Lavoisier, and others, towards the beginning of the present century, has done much towards placing chemistry on the solid basis on which it at present stands. In fact, fresh and more accurate knowledge of the constitution of bodies necessitated novel and more accurate nomenclature; and, as a natural consequence, this more accurate nomenclature pointed to new and hitherto unexpected relations. Let us for a moment turn back 100 years. What possible relation does the mind become cognisant of on hearing the words "water" and "muriatic acid"? How different is the case when we use the modern scientific names "hydrogen oxide" and "hydrogen chloride." We are immediately aware of the similarities and dissimilarities of these two bodies, and are able, within certain limits, to predict the behaviour of the one from a knowledge of that of the other.

But chemistry has taken such vast strides within the last forty years that the present Lavoisierian nomenclature, superior though it be to the old Stahlian, is totally inadequate to furnish us with distinct ideas of the numerous and complex bodies which organic chemistry is daily bringing to light. Let not the student, nor even the professed chemist, for a moment suppose that this inadequacy is imaginary. Let him call to mind the annexed moderately long name, and try whether he can, without reference to some chemical work, give an idea of the composition, properties, &c., of the body named, TETRETHYLPROPYLBUTYLAMYLAMMONIUM HYDRATE. In the hope of awakening an interest in this very necessary branch of chemical science, I propose giving a few extracts from a work published in 1871, at Bologna, by Professor Filopanti, of the Bolognese University, entitled "Alcuni Misteri di Chimica popolarmente spiegati, e nuova Nomenclatura." The system proposed has received favourable notice from the following professors:—P. Piazza, F. Selmi, D. Santagata, G. Fabbi, and G. Carini, and, though novel and strange to the eye, contains, undoubtedly, the germs of a very perfect system of nomenclature. Having thus broached the subject, I shall leave Professor Filopanti to speak for himself.

Atomic Nomenclature.

"The new system of nomenclature, which I propose, is based on a principle, as easy of conception as it is of execution; and yet able to explain all the discoveries of modern chemistry, with even greater perspicacity than the French nomenclature was capable of explaining those which were made at the conclusion of last century. The principle consists in giving in certain determinate cases, an entire ideographic signification to *each* letter of the alphabet; the execution consists in the expression by such letters, of the exact chemical formula of the body to be named. Four elements are present in organic compounds, with such great frequency as to almost exclude the others; and these four are also among the most abundant in minerals. These four elements are at present known under the names of *hydrogen*, *oxygen*, *nitrogen*, and *carbon*. In organic chemistry these occur with greater frequency than all the rest put together. Hence, we will represent them in the simplest and most convenient manner, which (humanly speaking) it is possible to find—that is to say, by means of one vowel for each of the four. But it is by no means indifferent which vowel we choose to assign to each of these very important elements; we wish that our names should aid the student, not only to remember the composition of the bodies named, but also the *reasons* for their having such a composition; we wish that such names should also enable him to foresee the reactions and transformations of which the bodies named are capable. For this reason, a*, the *first* vowel, will be the most appropriate name for *hydrogen*, as hydrogen is *monovalent*—that is to say, has only *one* combining power. e, the *second* vowel, will, for a like reason, be the most adapted to *oxygen*, oxygen being *bivalent*—*id est*, possessed of *two* combining powers. For similar reasons, i will stand for *nitrogen*, as nitrogen acts generally as *trivalent* with *three* combining powers; while o is the best vowel for carbon, as by its *fourth* place in the alphabet of vowels, it reveals the *four* combining powers, or *quadrivalence* of carbon.

All the other elements are to be represented by a combination of four letters; the first of which is invariably to be u, followed by the two most conspicuous consonants in the common name of the element; the ending to be a vowel indicative of the valency of the element. Thus, for example, we shall have *ucra* for *chlorine*; *upsa* for *potassium*; *urga* for *argentum*; as these are all monovalent elements: *ucle*, *calcium*; *upre*, *cuprum*, being bivalent; *uphri*, *phosphorus*; *umri*, *aurum*, which are trivalent; *uslo*, *silicon*; *upto*, *platinum*; these being tetravalent, &c.

We must also agree to assign a numerical value to ten consonants, which, with the new names of the four biogens,† are tabulated below:—

a	*e*	*i*	*o*
Hydrogen.	Oxygen.	Nitrogen.	Carbon.

b	*c*	*d*	*f*	*g*	*l*	*m*	*n*	*p*	*r*
1	2	3	4	5	6	7	8	9	0

The names of compounds are then to be derived from an examination of their chemical composition; placing the new name of the element first, followed by the consonant indicative of the quantity of atoms which exist. Should the number exceed *ten*, it is to be formed by binary combinations of the numerical consonants. The repetition of the same vowel (which may be allowable, for the purpose of facilitating pronunciation) does not alter the value of the other letters. *t* is used to express an indefinite number: *s* to mark the hypothetical nature of the body named. For instance, *splandrafnacti*‡ would be the name of a hypothetical body, composed of 96,830,482 atoms of hydrogen, united to an imaginary number of atoms of nitrogen.

I have coined this fantastic word solely with the object of rendering more palpable the wonderful fecundity of this system as well as its remarkable brevity. In fact, this word can be pronounced five times more rapidly than the corresponding Arabic number, which denotes the number of atoms of hydrogen—viz., ninety-six million, eight hundred thousand, four hundred and eighty-two, contained in the compound.

I must here note, however, that in the names of the non-biogenous elements, such as *upsa*, *ucle*, &c., the two consonants retain their ordinary alphabetic signification, and do not acquire the conventional numeric value. There is no danger of confusion, as these names *invariably* begin with *u*.

Let us now come to the application of this new system, beginning at the commonest and most important of binary compounds, water. Water is composed, as we know, of two atoms of hydrogen, united to one atom of oxygen; therefore, in our atomic nomenclature its name will be:—

B	è	c	a
Two	Hydrogen	one	Oxygen.

I must explain here the use of the accent, which before giving an example, I could not well do. When the accent is placed on the last syllable the body is a *solid*, when placed on the penult it exists as a *liquid*, and, finally, when placed on the antepenult the accent denotes that the body exists as a *gas*. Consequently, we may express the four states of water by the four following words, the position of the syllables being quite immaterial:—

Bèca = Water.
Bèaca = Steam.
Becà = Snow.
Cabè = Ice.

Let us now stop to consider for a moment what the short word bèca teaches us, and what it calls to mind:—(1) it shows that the body contains oxygen, *e*; (2) that it contains hydrogen, *a*; (3) that in every molecule there is only one atom of the former, $b = 1$; (4) and two of the latter, $c = 2$; (5) that it contains no other element, there being no other vowel; (6) multiplying the exponents $b = 1$ and $c = 2$ by the relative atomic weights of oxygen = 16, and hydrogen = 1, we learn that oxygen forms exactly eight-ninths, and hydrogen one-ninth of the total weight of water; (7) that it is a liquid, for the accent is placed on the penult; (8) that the first element is bivalent, being represented by the *second* vowel in the alphabet, that the other element is monovalent, as it is represented by the *first* vowel of the alphabet; (10) that water = bèca must be one of the simplest and most perfectly saturate (chemically) bodies, for we see that the valencies of the two monad atoms of hydrogen = *c a* completely satisfy the two valencies of the dyad atom of oxygen *b e*; (11) that water must, therefore, be one of the most stable and consequently one of the most abundant bodies in all the three kingdoms of nature. Now compare this with the usual nomenclature, and see whether *that* is able to denote so many things, not with four letters only, but even with four of its longest words."

Having given this simple example I can proceed to enlarge upon certain modes of spelling these atomic words, which will enable us to indicate whether the body in question be acid or basic, and whether we view the acidity as dependent on the hydrogen or the oxygen, we can easily point out, not only the *fact* of its being an acid, but also the view we take of the cause of its acidity. Let us agree to place the vowel which stands for the hypothetical acidifier (be it *oxygen* e, or *hydrogen* a) at the *beginning* of the atomic name. After this let us place the numerical consonant, indicating the number of atoms of this element which the compound contains. Lastly, let us repeat the vowel. This repetition does not influence the numeric value of the element, as we have already explained. It is only used to give a distinctive character to the name. We can, therefore, write the following names in two distinct modes, each perfectly intelligible, and each illustrative of different theoretic views.

1. As hydracids:—

H_2SO_4	Sulphuric acid	=	Acabuspèfe.
HNO_3	Nitric acid	=	Ababide.
H_2CO_3	Carbonic acid	=	Acabode.
HCl	Chlorhydric acid	=	Abàbucra.

* In order that the ear may not confound certain names, it is absolutely necessary that these vowels be pronounced as in Italian: viz., A = Ah, E = Eh, I = He, O = awe, U = who.

† Our author calls these four *biogens*, owing to their occurrence in animal and vegetable *life*.

‡ The numerical consonants refer always to the vowels with which they form syllables. Thus: splan-draf nac-ti.

2. As oxyacids:—

Sulphuric acid = Efebuspèca.
Nitric acid = Edebìba.
Carbonic acid = Edebòca.

In a like manner we can express the basicity of a compound by doubling the last vowel, *without* interposing the numeric consonant, thus:—

NH_3 Ammonia = Bìdaa.
KHO Potassium hydroxide = Upsababeè.

I shall now run through a few of these atomic names, leaving my readers to make observations similar to those which I have already made with regard to *water*. Ammonia is an *ai** of the commonest kind, as water is the commonest *ae*†. Each molecule of ammonia is composed of one atom of nitrogen, united to three atoms of hydrogen, hence its simplest atomic name will be *bida*. But, as at ordinary pressure it is a gas, and possesses an alkaline reaction, we will apply the preceding rules, and write and pronounce its name as *bidaa*.

The simplest and commonest of the *ao* (hydrocarbons) is marsh gas, each molecule of which contains one atom of carbon united to four of hydrogen; its name will, therefore, be *bòafa*. We immediately perceive this to be a saturate body, for the four monad atoms of hydrogen, *fa*, satisfy the quadruple affinity of the single atom of carbon *bo*, which is tetravalent, as the vowel *o* (the fourth in the alphabet) indicates."

Professor Filopanti then goes on to give numerous other examples, of which I will only reproduce a few. The first I shall choose is an example of the exactitude with which these atomic names indicate the substitutions which take place during chemical reactions:—" Nitric acid being ababìde, potassium nitrate is bupsabidè; in other words, one atom of hydrogen, *aba*, has been replaced by one atom of potassium, *bupsa*. The accent at the end of the word denotes that the resulting compound is solid; while the absence of doubled vowels, either at the beginning or end of the word, shows that it is neither acid nor alkaline. To illustrate the facility with which this system lends itself to cases in which isomeric bodies are to be named, I give the annexed examples of the essential oil series or terebenes:—

Oil of Turpentine = Bàlbor.
,, Lemons = Balàbor.
,, Bergamot = Boròbal.
,, Neroli = Bòrbal.
,, Lavender = Balàbro.
,, Pepper = Blàbro.
,, Chamomile = Blàbor.
,, Carraway = Ablàbor.
,, Cloves = Ablàbro, &c.

That phenomenon of fifteen syllables which formed the opening of our subject — viz., tetrethylpropylbutylamylammonium hydrate, is in our new language bofbibedàd; and as four of the names composing the fifteen syllables refer to the "monatomic alcohol radical" series, I propose giving the four first terms of six of these series, first with their ordinary names, and again with their atomic names:—

1. Methyl, ethyl, propyl, butyl.
2. Methylene, ethylene, propylene, butylene.
3. Methyl hydride, ethyl hydride, propyl hydride, butyl hydride.
4. Methylic alcohol, ethylic alcohol, propylic alcohol, butylic alcohol.
5. Formic aldehyde, acetic aldehyde, propylic aldehyde, butyric aldehyde.
6. Formic acid, acetic acid, propionic acid, butyric acid.

Now I believe I shall not be doing any injustice to my friends, the chemists, when I say that nine-tenths of them would be very much puzzled to give the exact composition (not to speak of their physical state) of these twenty-four bodies, now so celebrated and important in modern chemistry.

Let the reader now refer to the little explanation I have given of the rules for building up the atomic names, and by so doing he will be able (be he a chemist or not) to give the exact chemical composition, basicity, neutrality, or acidity, liquid, solid, or gaseous state, whether hypothetical or otherwise, by simply reading the names of these bodies, as expressed in the new nomenclature:—

1. Bodas, gacos, domas, pafos.
2. Bòsaca, fàoco, dòala, nàofo.
3. Bòafa, làoco, dòana, bàrafo.
4. Bobèfa, becòla, benàdo, ofbèbar.
5. Bobesca, becofa, belàdo, ofbèna.
6. Acabòce, afacocè, aladocè, anafocè, &c.

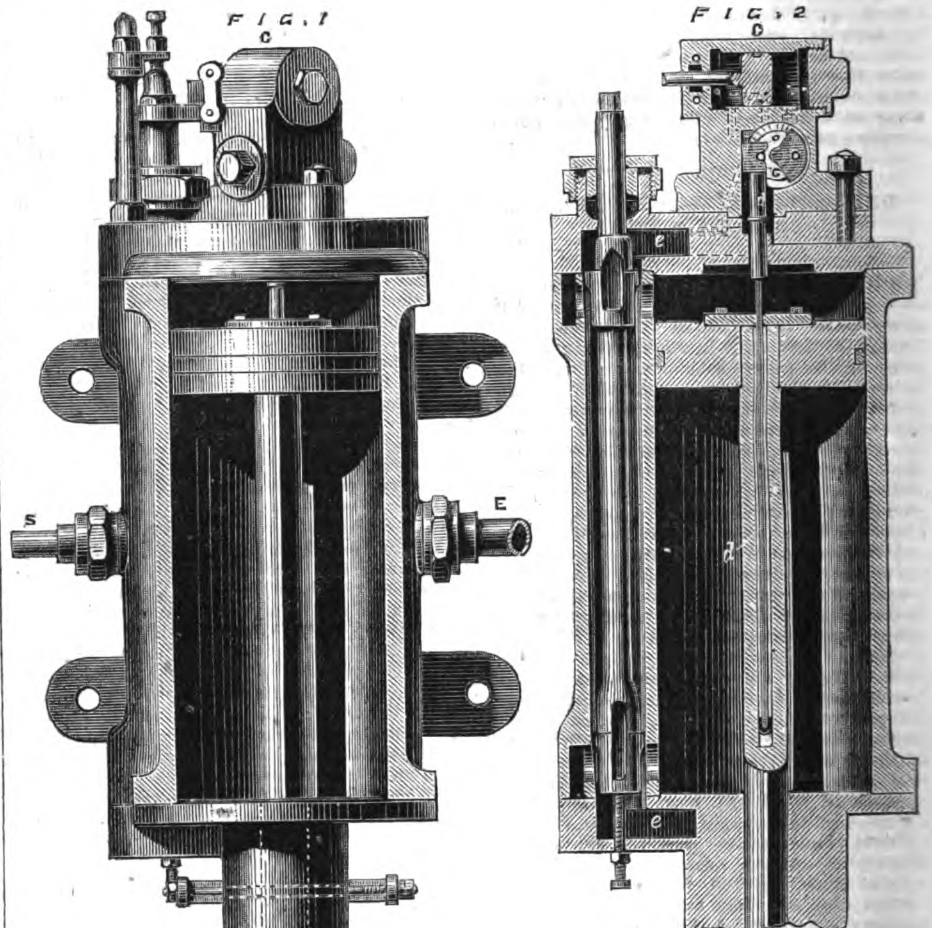
* Compound of hydrogen and nitrogen.
† Compound of hydrogen and oxygen.

'Strike me, but hear me,' said Themistocles. 'Laugh, but reflect,' say I."

Those of my readers who would like to follow Professor Filopanti, in his new ideas will find a fund of information in the pamphlet which I have quoted at the beginning of this paper.

ROTATING VALVE FOR STEAM-ENGINE.

According to a promise made in our article on the Westinghouse air-brake last week, we now illustrate the small engine employed for compressing the air, as the plan may be found useful for other purposes and under different circumstances. One advantage is that the eccentric and its rod are dispensed with, as are also the fly-wheel and the guides—one rod connecting the two pistons in the machine to which it is applied at present. It will be seen from the engravings—Fig. 1 being an elevation with part of the cylinder removed, and Fig. 2 a vertical section taken through the valve-chest—that the valves governing the admission and eduction of the steam are of a conical form, and are cast in one piece with the stem, which passes out through a stuffing-box. The valve-chamber is cylindrical, and is cast on one side of what must be termed the main cylinder to distinguish it from the small cylinder at the top, which is employed to give motion to the valves. This is accomplished by means of a short arm attached to the upper end of the valve-stem, the short arm carrying a pin which works in a transverse slot cut in the head of the piston-rod of the supplementary cylinder C. The latter is supplied with steam from the main valve-chest, the admission and eduction being regulated by a rotating conical valve *c*, actuated by the rod *d*, working in a boring made in the main piston-rod. The diameter of this rod, *d*, is reduced for the greater portion of its length, and collars are formed at each end which strike against a clip-plate secured to the top of the main piston, so that as the latter completes its stroke the clip-plate strikes the upper collar on the rod *d*, driving it up and rotating the conical valve *c*, which then admits steam to one end of the little cylinder C, and by the subsequent movement of the small piston the main valve is rotated so as to admit steam to the top of the main cylinder, and of course simultaneously placing the bottom valve in the position for exhausting. To prevent any noise from the smaller piston the ports are so placed that a small quantity of steam is shut in at the end of each stroke, thus forming a cushion. The main valves can be adjusted by means of set-screws, seen in the figures, so that while steam-tight they may be considered in practice to work without friction. The steam is conveyed to the valve-chest by the pipe S, and the exhaust goes through the passages marked *e* to the pipe E, which conveys it to the chimney of the locomotive. The illustrations will make the arrangement clear, and we need only say here that the engine and the pump in connection with it work very smoothly, even when driven at the rate of 100 double strokes per minute.



PROGRESS OF METEOROLOGY.

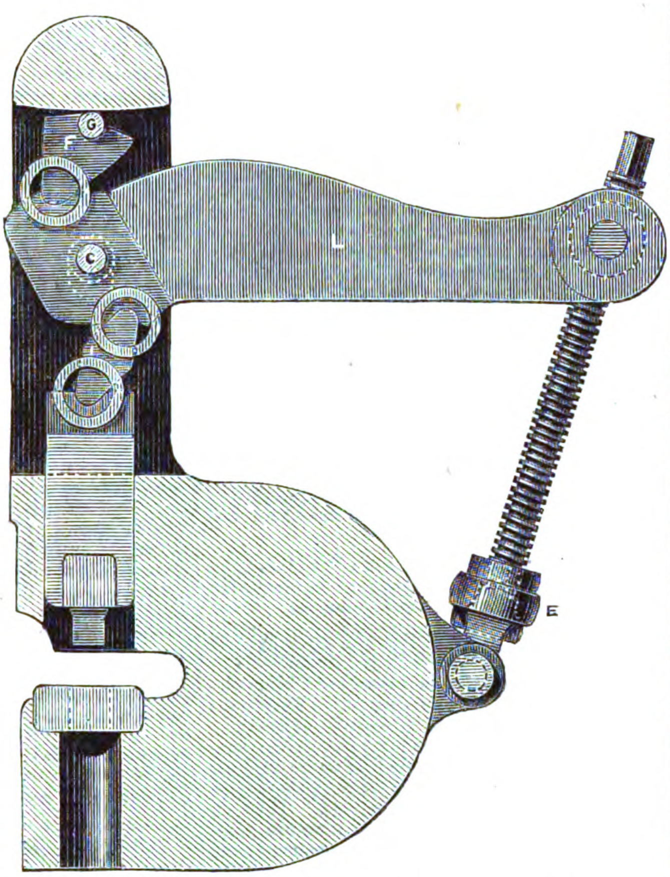
The "Quarterly Journal of the Meteorological Society," just issued, contains two or three important papers. One "On Large and Small Anemometers," by the Rev. Fenwick Stow, is well worthy the attention of meteorologists. In this paper the author gives the results of a series of experiments made at Hawsker with eight cup anemometers of different sizes, ranging from cups of 3in. to 9in. diameter, the arms varying from 4in. to 24in. in length from the cup centres. He finds that in the case of every instrument tried the results are utterly irreconcileable with Dr. Robinson's dictum, that the centre of each cup travels at one-third of the rate at which the wind moves, and that *this law is irrespective of the size of the cups or the length of the arms*. The standard anemometer used in these experiments was an electrical anemometer, with cups and arms similar in size, shape, and construction to those of the anemometers recently erected by the Meteorological Committee of the Royal Society, and so arranged as to make one contact for every mile of wind. The readings were taken by one of Breguets's "Compteurs Electriques." Assuming the indications of the standard to be correct, the cups of most of the small instruments were found to move through a space scarcely more than one *fourth* of that passed over by the wind. Under these circumstances it is important to ascertain the mode in which Dr. Robinson determined the relation of the motion of the cups to that of the wind. It appears that the Doctor's original paper is now very scarce in which he relates the experiment made for the purpose, viz., a small anemometer placed with its axis in a horizontal position at the end of a long arm was caused to revolve by a weight at velocities reading up to, but not exceeding, eleven miles an hour, and which when afterwards fixed in a vertical position was found, by counting its revolutions at a velocity of the wind of eleven miles an hour only, to agree approximately with the large instrument. It is somewhat remarkable that the relation of the instrumental motion to the motion of the wind should for so many years rest upon a *single* experiment, and now that the law obtained by this experiment has been proved not to be applicable to anemometers of *all* sizes, the author considers that the Meteorological Committee of the Royal Society and managers of observatories should investigate the subject for themselves. At first the Rev. F. Stow was disposed to come to the conclusion that small anemometers are not more valuable for the purposes of meteorological science than children's windmills, but on looking at the matter more closely he proposes two sizes—viz., 4in. cups on 9in. or 9¼in. arms, and 5in. cups on 12in. arms, and recommends that experiments be made to ascertain the true relation existing between small and standard instruments. The concluding remarks of the paper appear to be so valuable that we quote them entire. "I cannot avoid," says the author, "expressing the wish that opticians would consult durability more and polish less in the construction of instruments peculiarly exposed to the weather. The weakness of the arms and the want of solidity in the box are sources of mishaps even in a moderate gale. Let the cups be light, the arms both light and strong, the axle strong, and turning on a point, the bearings smooth, and contrived so as to retain the oil for a long time, the wheel work simple, the box large, and the graduations capable of being read to the nearest mile of wind from ten yards distance. A very simple electric contact-marker would be an invaluable addition to most instruments. The great essential is proportion, the next strength, and by attention to other details also, very valuable instruments (I do not mean high-priced) would be turned out."

In a paper by R. H. Scott, Esq., "On a New Form of Cloud," described in *Nature* by Professor Poëy, we are informed that Dr. Clouston and Mr. W. S. Jevons had previously observed similar clouds. Dr. Clouston made a sketch of the cloud on March 5, 1822, the cloud on this occasion being immediately followed by a storm, the barometer falling 1·2in. or from 29·5in. to 28·3in. within 9 hours. The principal characteristic of the cloud consists of a series of dark cumulus-looking clouds hanging like festoons of dark drapery over a considerable portion of the sky, with the lower edges well-defined, as if each festoon or "pock" was filled with something heavy. From this circumstance the cloud has been termed the "pocky cloud."

Speculating on the cause of its formation, Dr. Clouston says, "this cloud may be caused by masses of moist air descending and forcing their way through drier and colder air, for its form suggests air diffusing itself downwards, just as the form of the cumulus, or the steam from the steam-engine, suggests diffusion upwards. If this be so, it shows the moist equatorial currents in greater strength than usual, and an uncommonly quick mingling of air currents, differing in temperature and moisture—the very conditions of a storm. *This cloud is well known and much dreaded by Orkney sailors.*" Mr. Scott introduces a letter from Dr. Moore, of Dublin, who considers that two elements are required for the production of the phenomena characterising the clouds—viz., a rapid condensation of vapour and high *electrical* tension. Mr. Scott adds that the contact of two masses of air at very different temperatures and in very different hygrometrical states is precisely the condition that gives rise to the development of electrical action in the atmosphere, and to thunderstorms, so that a high state of electrical tension would accompany the forcible intermixture of a damp with a dry stratum of air.

IMPROVED PUNCHING MACHINE.

THE improvements in punches recently patented by Mr. du Vallon, of Birmingham, consist in the combination of two knuckles with a single lever, in such a manner that the angle which the lever makes in working is diminished, and the ordinary strain upon it is avoided, while the side strains to which the parts are exposed in ordinary punches are obviated. This is accomplished by connecting the two knuckles to the upper and under side of the lever in such a manner that they are inclined obliquely to the pin of the lever when at the beginning of its stroke, but are brought into a vertical



line with it as the end of the stroke is reached, so that the thrust is exerted in a direct vertical line through the centre of motion. The principal features of this punch will be readily understood from the annexed figure, in which L is the lever, having its fulcrum at C, slotted so as to give the requisite play to accommodate the movements of the lever, the other end of which is connected with a screw carried by the small frame E pivoted to the lower part of the body. F is the upper knuckle turning on a pin G, having its bearing in the upper solid part of the frame, and connected to the upper side of the lever L by means of the ring as shown. I is the lower knuckle, connected to the under side of the lever by a similar ring, and to the body or carrier of the punch also by a ring. The action of the punch is as follows:—On the lever being brought into an inclined position by turning the screw, the two inclined knuckles F and I are moved, until at the end of the stroke they are brought into a vertical line with the pin or fulcrum C of the lever, thereby carrying down the punch with the force applied in a direct vertical line through the centre of motion of the lever. Instead of the two rings, one elongated ring or link may be used for connecting the knuckles together and with the lever. The knuckles also may be varied in form and size, and if required for certain purposes, either of the two could be lengthened or shortened, or in extreme cases reduced to a simple roller, as will be apparent to our mechanical readers.

ELECTRO-METALLURGY.—I.

By J. T. SPRAGUE ("Sigma").

Introduction.

IN the series of articles headed "Electricity: its Theory, Sources, and Applications," I have examined closely the general principles of the science, and described fully all the more important instruments for the generation and measurement of the electric current. These articles, however, are scattered through Volumes X. to XIV., and, therefore, are not in possession of many readers; for their convenience, therefore, and also for the purpose of treating the general subject now, in the point of view of the special application of the current to the depositing of metals, I will, as required, touch afresh upon such matters as are requisite. As many readers will probably be mere beginners, I shall arrange these papers also upon the system of leading on from step to step, which in this application of electricity is possible, though quite impossible in the study of the science itself, where advanced knowledge is necessary to comprehend the simplest fundamental facts.

Although electro-metallurgy is a purely practical art, and its successful practice may be accomplished with a very small modicum of science, this is true only of the factory; to learn it from books and solitary practice, and in any case to learn it intelligently and to pass beyond the range of mere "rule of thumb," it is necessary to clearly understand the principles in operation, and the terms necessarily employed in explaining those principles. Therefore, to avoid the misconceptions so commonly due to imperfect acquaintance with the meaning of terms, I will here give a concise explanation of each of those likely to be used by myself, or to be met with and misunderstood in other books. That this is necessary will be evidenced by the following extract from one of the best of existing books on the subject—viz., Watt's "Electro-Metallurgy:"—"Smee's battery, although far from economical, and somewhat uncertain in its action, is still employed by some, owing to the great *intensity* of the current which it produces, a quality of but little service to the electro-plater when the *quantity* is deficient." Now, *intensity of current* is a term in common use for "quantity;" the special feature of the Smee is its production of large quantity against small resistance at a minimum cost; its fault is that it has a very low intensity, if this term is used (as it appears to be here) as meaning *tension* or electro-motive force.

The following definitions are only intended for outlines; references are given for full information to the former series of papers, and, where requisite for the present purpose, further information will be given at the proper portion of the papers themselves.

AMALGAMATION.—Zinc is protected from waste by having its surface coated with mercury. Information as to use and economy of zinc will follow.

ANION.—The electro-negative or chlorous radical of the salt or acid decomposed. Oxygen, acid radicals as chlorine are anions; see ions.

ANODE.—The positive electrode or pole of a battery; the wire or plate connected to the copper or other negative element of the battery; the plate which leads the + current into a solution to be decomposed, and at which are set free the oxygen, acid radicals, and all — ions (anions). In electro-metallurgy it is usually formed of the metal to be deposited, in which case it is called the soluble anode or pole.

ATOM.—The supposed ultimate particle of the elements; there are constant discussions as to the actual existence of atoms, but chemical reactions can only be satisfactorily explained by means of the atomic theory. The old idea was that atoms were ultimate particles of matter and indivisible; this is by no means necessary; all we need to assume is that matter, as we know it, is arranged in the form of these atoms, and that if divided the separated parts would no longer have the same nature; and, further, that whatever mathematical teaching may prove as to the *possibility* of subdivision, no such division does or can occur under the existing conditions of nature.

There is still much confusion as to the terms atom and equivalent, which were formerly used for the same purpose, but modern chemistry attaches a distinct idea to the atom, which correlates it, not only to chemical affinity, but to heat and other forces.

ATOMIC WEIGHT.—The relative weights of the atoms as compared with that of hydrogen taken as 1. In No. 342, Vol. XIV., p. 55, I gave a table of the atomic weights and other particulars of the elements most important in electricity.

Battery.—A combination of voltaic cells. The word is commonly—but erroneously—used for a single cell (*e.g.*, Smee's battery), but it strictly means two or more cells coupled together in series. For the laws regulating the combination, see Electro-motive Force, Resistance, Current, Cell. For full description of the different forms see Vol. XI., No. 264, General Classification; No. 267, Smee and other Single Liquid Cells; No. 269, Daniell's; No. 270, Minotto's and other Modifications of Daniell's; No. 272, Grove's and Bunsen's; Nos. 275 and 277, Bichromate of Potash; No. 281, Manganese, Leclanché, Sulphate of Lead, and of Mercury. In these papers the relative cost of working, &c., was given, and further information as to those cells, useful in electro-metallurgy, will be given hereafter.

Base.—See Radical.

Break.—See Commutator.

Bridge. — Wheatstone's. An apparatus for measuring resistances by balancing the unknown R against one known and capable of regulation. Description, No. 299, Vol. XII., p. 290.

Cathode.—The negative pole of a battery; the wire or plate connected to the zinc; the plate at which, in any decomposition cell, the cations or − ions are set free. In electro-metallurgy, the object upon which the deposit is to be formed is the cathode.

Cation.—Electro-positive elements and radicals, which are set free in electrolysis at the cathode. Hydrogen and metals in the order of the electro series are cations; see ions.

Cell.—Each separate vessel in which a chemical action occurs, forming part of the electric circuit. Thus there are the active or generating cells—*i.e.*, those which form the battery, and the decomposition cells, and these last may be of two classes: (1) Passive, or mere resistances, such are those employed in electro-metallurgy where the metal is dissolved from the anode, and simply transferred to the cathode; (2) where chemical force is exerted and absorbed in effecting true decomposition, as in the voltameter.

Chemie.—See Units of Current.

Chlorous.—Pole, a term sometimes used for the negative pole or cathode. Chlorous radical is that radical of a salt or acid which answers to chlorine in HCl—that is, it is the acid radical or electro-negative element or anion.

Circuit.—The path along which the current travels. It may be divided at any part into two or more paths. If this happens in the external circuit the proportion of the current which passes in each "derived circuit" will be in the inverse ratio of the several resistances. When in the battery the cells are arranged side by side (or "for quantity"—*i.e.*, for small resistance), instead of in series, they are such derived circuits, and their internal resistances and consequent contribution to the general current will be governed by the same law. See No. 330, Vol. XIII., p. 423. It is of importance in electro-metallurgy to bear this law in mind, because when several objects are suspended in one depositing vessel, each of them forms a "derived circuit," and the amount of deposit on each will depend upon its position and distance from the anodes. The same applies even to the different parts of the same surface when not flat, and these laws explain the causes of uneven deposits.

Commutator.—Break, contact breaker, and circuit changer. They are of many forms, according to the purpose required; a simple spring pressing on a point serves for a mere break or interrupter of the current, but the arrangement is often complicated when it is necessary to provide several different circuits for the current.

Conductivity.—The degree of power to permit current to pass; it is the opposite of "Resistance," which see.

Conductors.—Substances which permit electricity to pass. It used to be thought that substances were of two distinct classes, conductors and insulators; but it is now known that it is only a question of degree of resistance. Silver is the best conductor, then other pure metals, then alloys; solutions of electrolytes follow, but at a long interval. Current passes through conductors in the ratio of their sectional area, and the inverse ratio of their length; see wires.

Connections.—Wires, &c., completing the circuit between different apparatus; they should be sufficiently large, and of copper, so as to give little resistance. There is often much trouble caused by the stiffness of stout wires, it is, therefore, well to form a spiral upon each connection, so as to give a little elasticity. The best connections, however, are made of wire cord, such as is made for window sash-line, or by twisting up fine copper wire into a cord; lengths suited to various purposes should be cut, and to the ends pieces of No. 12 copper wire, of a couple of inches long, soldered, for insertion in binding screws. If these ends are well silvered or gilt much trouble in cleaning will be saved. Annoyance from accidental contacts, &c., is also avoided by covering these conductors with narrow tape plaited on, and soaking with boiled oil.

Current.—This word is used in many ways. The electric current means the supposed flow or passage of electricity or electrical force in the direction from + to − or positive to negative. It, therefore, originates at the zinc surface in contact with the solution, and passes from the zinc to the copper or other negative metal *in the liquid* of the battery, but *from* the negative metal *to* the zinc in the external circuit (see Positive and Negative). *Current* also means, scientifically, the measured work done chemically, or what was formerly called "quantity" (which see, also Intensity of Current). For the laws governing this, see Ohm's Laws and Units.

In electro-metallurgy an important consideration is the *density* of the current—that is, the relation of the actual or total current passing, to the surface or area of the anode and cathode. This will be fully explained hereafter. It is the *current* or quantity alone, and entirely irrespective of the force developing the current (*i.e.*, intensity in the older books) which affects the amount of work done chemically, or which is measured either by the galvanometer or the voltameter. The electromotive force or tension (or intensity) is concerned only in producing the current against the special resistance in each case (see Tension). Current was explained, No. 331, Vol. XIII., p. 450.

Density.—See Current.

Elements. — The ultimate substances into which all the bodies we know can be resolved, and which, themselves, have not been resolved into any simpler bodies. There are 63 elements known, and two or three more suspected. They are assumed to exist in the form of *atoms*, and further information will be found under that head and under *equivalents*.

Electrodes.—Faraday's term for the poles or plates leading the current into and out of a cell. (See Poles, Anode, and Cathode.)

Electrolysis.—The act of decomposition by an electric current. (See example in Equivalents.)

Electrolytes.—Bodies capable of being decomposed by an electric current. They must be composed of (or rather be capable of breaking up into) two radicals (see ions); therefore, substances which contain three or more radicals are not electrolytes; they may, however, be decomposed by secondary actions. Thus all acids are electrolytes, because they are composed of an acid radical (simple or compound) and basic hydrogen, as HCl hydrochloric and H_2SO_4 sulphuric acids. Water appears not to be an electrolyte (H_2O), indicating that the two hydrogen atoms are separately combined, and do not form a radical; it is, therefore, not decomposed when absolutely pure, but when it contains an acid or salt it is decomposed by the "secondary" action of the acid radical; thus, $H_2\underbrace{SO_4H+{}_2O}$ sets free the elements of water, the hydrogen coming, not from the water but from the acid, the chlorous radical of which decomposes water, reforming the acid and setting oxygen free.

Electrometer. — Instrument for measuring electro-static charge, but which is inapplicable to current electricity.

Electromotive Force.—The tendency to develop electric tension; in ordinary galvanic batteries the electromotive force is set up by the attraction of zinc for an acid radical; its degree depends upon the force and number of such chemical affinities in the circuit, and inasmuch as there are also opposing affinities tending to develop electromotive force in the opposite direction, the actual force depends upon the excess of the total affinities in the direction of the current, over those in the opposite direction. For full discussion of this subject see No. 333, Vol. XIII., p. 504 and 342, 344, and 346; Vol. XIV., p. 54, 136, and 187. *Electromotive force* of batteries, see Table E, No. 346, Vol. XIV., p. 187. The unit of electromotive force is the Volt.

Endosmose.—The power possessed by liquids and gases of diffusing into each other when separated by a partition or septum of animal membrane or unglazed earthenware. Electric endosmose is this action, greatly heightened by the passage of an electric current, which will frequently raise the liquid on one side of the partition several inches above the other. The laws ascertained by Weidemann are (1) the quantity of liquid which flows out in equal times is directly proportional to the strength of the current; (2) the quantities flowing out are (all other conditions being equal) independent of the size of the porous substance; (3) the height to which a galvanic current causes a liquid to rise is directly proportional to the extent of the porous surface; (4) the force with which an electric tension present on both sides of a porous division, or in a liquid, urges the liquid from the positive to the negative side of the partition, is equivalent to a pressure proportional to that tension.

The action is very troublesome in batteries, in which the liquid in the zinc or positive cell is transferred to the negative cell. Ordinary endosmose at the same time transfers the liquid of the negative cell to the zinc, causing local action, as when the copper solution of the Daniell cell enters the porous vessel.

Equivalents.—All chemical actions take place in a definite ratio, which is explained by the atomic theory as due to the combination of 1, 2, or more atoms of one substance or element, with 1, 2, or more atoms of others. Each element has its own equivalent weight, as compared with hydrogen, as 1. There is much confusion of ideas, due to the change of modern chemistry from the old system of stating reactions in *equivalents* to the modern system of stating them in *atoms*. For general purposes the latter is the best; for ordinary purposes of electro-metallurgy the equivalent system is most convenient, and will be used here. The Table A, No. 342, Vol. XIV., p. 54, gives the equivalents and other information, but, for convenience, I will here give a list of the symbols and equivalents of the substances likely to be mentioned. The relation of electricity to these equivalents is such that in a chain or circuit composed of any variety of compounds of two of these bodies (which are, in fact, elements, radicals, and ions) the same current would release from combination the relative weight set against each substance. The weights themselves are relative or abstract, but throughout these papers they will be taken as "grains," for the purpose of getting a definite electric measure of current and work. As example, a current from a Smee cell may be taken as passing through water (dilute acid, see Electrolyte), sulphate of copper, and cyanide of silver; in each cell it would release an equivalent for an equivalent of zinc dissolved, which is commonly expressed by saying that in every cell in a circuit (battery or decomposition) there is equal, *i.e.*, equivalent action.

$$\underset{32\ 6\ 48\cdot\ 1}{+\ ZnSO_4H\ -}\qquad \underset{8\ 1}{+\ OH\ -}\qquad \underset{31\cdot75\ 48\ 31\cdot75}{+\ CuSO_4Cu\ -}\qquad \underset{108\cdot\ 26\cdot\ 108}{+\ AgCyAg\ -}$$

The upper brackets show the substances as arranged before action, the lower ones those formed or set free, + marks the anodes or dissolving plates, − the cathodes in each cell.

SEA SICKNESS.

THE following extracts from a paper by Dr. F. Pollard, in the *British Medical Journal*, will be of more than usual interest at the present time. Two opposite theories have been suggested as explaining the cause of mal-de-mer—one that it arises from a depressing effect on the brain produced by the motion of the vessel, for which the remedy would be lying so as to obtain an increased supply of blood to the brain; the other, supported by Sir J. Alderson, that increase of blood in the brain is the real cause, an analogy being drawn between the blood in its vessels and the mercury of a barometer.

The theory is that, as the ship sinks in the water, the barometric tube falls more quickly than the mercury that it contains, so that the latter tends to impinge on the upper part of the tube; and it is argued that, in like manner, as the body descends, the blood falls less quickly than its containing vessels, and so tends to produce pressure on the brain, these successive impulses causing the vomiting. "When the rigid tube falls," says Sir J. Alderson, "the mercury having its own inertia, and not being attached to, or a part of, the tube, remains stationary, at least for a time; thus the tube is pushed down upon or over the mercury." Now this might, perhaps, happen if the barometer were actually pushed down suddenly, because in that case the pressure would be applied to the tube, and not to the mercury, which would simply fall by its own weight. But in the case of a barometer merely allowed to fall, the glass and the mercury begin to move under the action of gravity at precisely the same moment; and so far from the mercury having a tendency to lag behind, its greater specific gravity tends to make it fall more quickly than the tube, the result being that it carries the tube down at a greater rate than that at which the latter would fall if it were empty. At sea, the falling of the ship is due to the action of gravity. There would be no tendency, therefore, for the mercury in the barometer or the blood in the body to commence falling later than the tubes which contain them. They would all begin to move at the same instant.

It is, nevertheless, a fact that the action of the waves does cause the mercury in an ordinary barometer to oscillate when the sea is rough. As already shown, the mere falling and rising of the ship would not account for this. It is the sudden striking of the ship by the waves which in rough weather jerks the mercury up in the tube; and in order to reduce this to a minimum, certain ingenious modifications have been introduced in the construction of marine barometers; moreover, they are suspended from a ball and socket joint, so as always to maintain a vertical direction; otherwise, the mercury would become tilted with the various movements of the ship, and an erroneous impression that it rose and fell might be acquired.

Now, theoretically, we might imagine the blood as being jerked upward against the brain by successive blows of the sea on the ship. But it is obvious that merely assuming the recumbent posture would not prevent this. There would be more probability in supposing that the brain itself might be jerked against the interior of the skull when the ship was violently struck; thus causing a series of small concussions, and adding something to the mental and bodily distress. But this will not explain the occurrence of sea-sickness in ordinary cases, when the ship rises and falls without violent concussions. For this an explanation other than a merely mechanical one must be found.

The most probable theory of sea-sickness is that held by Dr. Carpenter, Mr. Bain, and other writers, who consider that the mental and bodily prostration and the other symptoms arise from the continued action on the brain of a certain set of sensations, more particularly the sensation of want of support. This feeling, arising from the sudden loss of support, as when the footing or any prop that we lean upon suddenly gives way, is one of a most disagreeable kind. Should the accident have been perilous to life, as when the foot slips close to the edge of a precipice, or a rope cracks in Alpine climbing, a sickening feeling seizes the brain, the whole frame is agitated, and cold perspiration is felt all over.

The phenomena of sea-sickness appear to be due to the constant repetition of this feeling of loss of support, consequent on the pitching and rolling of the ship, more particularly the former. This explains the fact that the distress is most acute at the moment of the descent of the ship; whereas, when the part of the vessel in which the sufferer is placed rises beneath him, a comfortable sense of support is felt. It is well known also that the distressing sensations may be to some extent warded off if a downward motion of the body be made at the time of the ship's descent, and an upward motion when the vessel rises. In this way a kind of voluntary character is given to the sinking of the body, the nervous system is not taken so much unawares, so to speak, and thus the sensation of loss of support is less acutely felt. The feeling of want of support resides essentially in the muscular system; but the sensations of other senses contribute towards it. The sight of continually shifting lines and surfaces is an important factor; and on board steamer the constant vibration, the noise of the machinery, and evil smells of various kinds, are other items in the elements of causation.

That vision has something to do with the production of sea-sickness is shown by the fact that closing the eyes will often keep off the sickness for a time; and in illustration of this point, we may refer to the general depression, faintness, and even nausea, which may be produced in susceptible persons by "doing" too many picture galleries in rapid succession, and this not dependent on the quality of the pictures themselves. That the vibration and noise may add to the general depression is shown by the painful effect produced on a person not used to it, by going into a large room of a cotton-factory, full of steam-looms at work. As regards smell, I can testify that going down into a hot cabin and sitting close to a reeking joint of boiled mutton, has nearly brought on sea-sickness, only warded off by a timely retreat into the upper air.

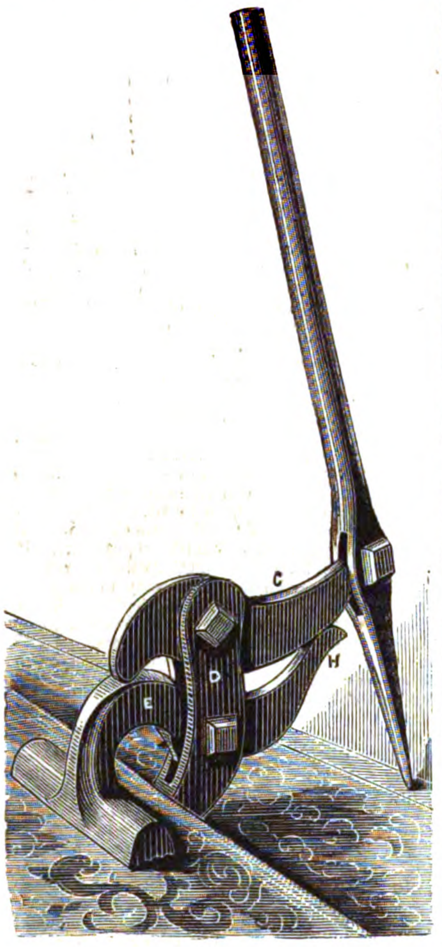
As regards treatment, since sea-sickness arises from certain impressions on the senses, the obvious indication is to render these sensations as feeble as possible. Application of the mind to an engrossing book will keep it off for a short period; and Dr. Chambers relates that his having to bind up a broken finger of one of the seamen relieved his own distress for the time. But the mind will speedily become alive to the sensations which force themselves on its attention. In order to lessen them as much as possibly, the patient should preserve the recumbent posture, as near the centre of the ship as possible; he should lie on a thickly padded couch, so as to diminish the vibration. Fresh air should be admitted in order to remove bad smells. The eyes should be shaded, and as much noise as possible shut out. As regards drugs, the most rational suggestion is that of Dr. Döring, of Vienna, that a full dose of hydrate of chloral should be taken shortly before the vessel starts; and even in long voyages the repeated use of this medicine will insure comfortable nights without the disagreeable after-effects of opium and chloroform.

A BONE CAVE IN YORKSHIRE.

THE scientific exploration of caves in various parts of Europe is daily becoming more important from the light which it throws on ancient races of men, and on the animals which are no longer to be found in the districts which they once occupied. Each fresh discovery offers fresh proof of the continuity which exists between geology and history. A cave seems, indeed, the last place to find anything bearing on history; but, nevertheless, the results of the labours of the Settle Cave Exploration Committee, carried on for the last two years, are most valuable both geologically and historically. The Victoria Cave is situated about half-way up a line of gray limestone cliffs, overlooking the gray limestone "pavements" and broken precipices which extend northwards to Ingleborough, and consists of large chambers filled very nearly to the roof with accumulations of earth, clay, and stones. The committee began their work by cutting a trench from the outside of one of the entrances through a layer 2ft. thick of angular fragments of stone broken away from the cliff above by the action of frost, which rested on a dark stratum composed of fragments of bone more or less burnt, burnt stones which had formed fireplaces, very many fragments of pottery, and a few Roman coins. It was evident that the cave had been inhabited in ancient times, and that the broken bones of the animals strewn about were the relics of the food of the inhabitants. As the trench passed into the entrance the talus of stones disappeared, and the black or Roman-Celtic layer, as it may be called, covered the floor, passing over its inequalities, and lying sometimes underneath enormous masses of rock which had fallen from the roof since it was accumulated. Besides spindleworts, beads, and curious articles of bone, it yielded bronze fibulæ of Roman workmanship, spiral bronze gilt armlets, and a portion of the ivory hilt of a Roman sword. Some of the ornaments present a style of art which is certainly not Roman, being composed of two plates of bronze soldered together, and bearing flamboyant and spiral patterns of admirable design and execution. They certainly belong to the same school as that which produced the illuminations of one of the Anglo-Saxon gospels at Stockholm, and the gospels of St. Columba preserved in Trinity College, Dublin. The bronze gilt brooches and finger-rings, ornamented with enamel in red, blue and yellow, and green, were also of non-Roman workmanship, although some of the designs bore traces of Roman art. Most probably they are the work of the Roman Celts; and there is nothing at all strange that the Irish art of the sixth or seventh centuries should have had some points in common with that of the neighbouring kingdom of Strathclyde, which at that time embraced the whole of Lancashire and a considerable portion of Yorkshire, since there is clear historical evidence that Ireland in the seventh and eighth centuries exerted important influence on the neighbouring countries. The broken bones of the animals show that the Celtic shorthorn, the goat, horse, and pig, were the principal domestic animals which supplied the food of the dwellers in the cave. Bones of fowl implied that they kept poultry, while the roebuck, red-deer, and grouse, contributed but little to their feasts. There can be no doubt that this strange collection of objects was formed during the abode of a family for some time in the cave, and we have to account for the presence of so many articles of luxury in so lonely, strange, and uncomfortable a place. The personal ornaments, and the delicate Samian ware are worthy of the villa of a wealthy Roman, rather than of the dwelling of men who lived by choice in caves. The few coins which were found explain this difficulty—some belonging to Trajan, Constans, and Constantine, and others being barbarous' imitations of Roman coins, which are assigned by numismatists to the time when Britain was being evacuated by the Roman legions. To say the least, there are two extremes between which the date of this occupation of the cave must lie—the fifth century, as shown by the barbaric coins, and the first quarter of the seventh century, when the kingdom of Strathclyde was conquered by the Northumbrian Angles. It cannot be later, because of the presence of Roman, and the absence of all English cultus. So long as the Celts of Strathclyde, cut off from the Roman Empire, held their ground against the Angles, they would certainly follow as nearly as they could the manner of life handed down to them by their forefathers, the Roman provincials, and they would use Roman coins and rude imitations of them for their currency. We can hardly doubt that this cave was used by unfortunate dwellers in Ribblesdale, who were compelled to fly from their homes with some of their cattle and other property, and to exchange the luxuries of civilisation for a hard struggle for common necessaries. In no other way can the association of works of art of so high an order be accounted for side by side with the rude instruments of savage life; for it cannot be allowed that they were introduced into the cave by robbers, because many other caves in the neighbourhood contain articles of the same order. These remains, therefore, afford as true and vivid a picture of the troublous times of the sixth or seventh centuries as the ruins of the Roman villas and cities, which, for the most part, have been burnt. In the latter case we see the homes of the Romano Celts ravaged by the invading English, and in the other the holes in the rocks to which the Romano Celts fled for refuge. But there were evidences of a very much older Roman occupation than this. At the entrance below the Romano-Celtic layer there was a talus of angular stones 6ft. thick, which rested on a layer of stiff clay. At this level the committee discovered a few rude bone awls and a bone fish spear or harpoon, along with chipped pieces of flint and broken bones of ox and bear, which proved that men in a rude state of civilisation inhabited the cave before the accumulation of the talus. And if it be admitted that the débris has fallen from the cliff in equal quantities at equal times, the fact that it is 2ft. thick above the Romano-Celtic layer, and 6ft. thick between that and this earlier one, would prove that the interval between the two is three times as great as that which separates the former from our own time; the 2ft. being accumulated in about 1,200 years, and the 6ft. in 3,600. If this rude estimate be accepted, the date of the earlier occupation would be about 5,000 years ago. The gray clay on which these more ancient traces of men rested offered a serious obstacle to further examination, since it was more than 25ft. in thickness within the cave, and contained no remains of men or of animals. Fortunately, however, the enterprising gentlemen who form the committee have lately sunk another shaft, and have obtained evidence of a still older occupation of the cave, not by men, but by hyænas. The broken bones, coprolites, and teeth of those animals show that in ancient times they lived there in considerable numbers, and the gnawed bones and teeth of the mammoth, bison, reindeer, red-deer, the great woolly rhinoceros, and the cave-bear belong to the creatures which formed their prey. The time when these animals were living in Yorkshire is that which geologists know as "Pleistocene" or "Quaternary," and corresponds with that during which Kent's Hole and Kirkdale caves were being filled with similar remains. The shaft at present has been sunk to a depth of 30ft. from the original surface, and the accumulation of earth and bones extends to an unknown depth below. We very much hope that the committee will be encouraged by these results to continue the exploration, and we should certainly advise any one who cares for beautiful scenery and feels any interest in such investigations as these, to visit the district which lies round Settle, and to see the wonderful contents left behind by the hyænas, which are being discovered every day.—*Pall Mall Gazette.*

CARPET STRETCHER.

A USEFUL form of carpet stretcher has been patented in the United States, which, while holding the carpet firmly, does not tend to injure it. It is very strong, being constructed of iron throughout, and is capable of stretching the thickest and most unyielding carpet. It will be seen, on referring to the figure, that it consists of four levers pivoted together; the longer, which forms the operating handle, being provided with a point at the bottom to take a firm hold of the floor. The two levers marked respectively D, E, are furnished with serrated jaws, which are made to grasp the carpet at a sufficient distance from the edge to secure a firm hold without straining the fabric. The jaws being properly placed, and the point of the long lever pressed into the floor, the handle is pressed in the direction in which it is desired to stretch the carpet, when by the action of the levers C and D the jaws are brought together with a force regulated by the amount of pressure applied to the handle. On reversing the motion of the long lever, the lever C presses on that portion of the lever E signalised by the letter H, thus opening the jaws, so that they can be readily



placed in a position to take a new hold. With this implement a very little exertion will enable any person to lay the most refractory carpet perfectly smooth.

ANCIENT MUSICAL INSTRUMENTS.*

ON the 1st of June the South Kensington Museum opened a special exhibition of ancient musical instruments. They have been obtained on loan from all quarters; money, powerful as it is, could not buy the greater part; and every man and woman, who loves music, or possesses a mind, should study them before the unique opportunity runs away, and this multitude of gems is dispersed for ever.

Talk of the treasures of the deep! Give me the treasures of the country house; for there curiosities can always find a corner to live: in London, novelties jostle them into their graves through mere want of space. In a word, private contributors, English and foreign, have peopled one of the halls of this museum with the spoils of time. Here are Egyptian and Indian instruments, Turkish and Chinese, very curious; oriental banjos, &c.; and above all a most amazing specimen of roundabout resonance—a long black wooden tube, over which the strings are stretched, and the tube rests on two hollow everlasting pumpkins. But the main feature is a number of mediæval instruments, exquisite in form and workmanship, and sometimes encrusted with gems, and inlaid with oriental lavishness and the skill of a Genoese jeweller. Here in stringed instruments alone are full a score of obsolete varieties, and many specimens of each kind, especially of the lute, the archlute, the mandolin, the sweet viola d'amore, with its sympathetic wires that lay and trembled in unison beneath the gut strings, and prolonged the vibration; the viola di Bardone, a larger and more complicated instrument, whose sympathetic wires, twenty-two in number, were placed so that they could be struck with the thumb, while the fingers played the gut strings; the viola da gamba, called by Sir Andrew Aguecheek the "viol de gamboys," and all the tribe of citterns and ghitterns that used to hang in every barber's shop for gentlemen to play, when England was famous as a musical nation, and that was before the monstrous idea of confining musical education to the less musical sex had entered the national head. Here, too, are all the instruments the translators of our Bible have bravely transplanted to Assyria and the night of ages—the sackbut, psaltery, dulcimer, &c.; and here are the children and grandchildren of the dulcimer—viz. the keyed dulcimer, the virginal, the clavichord, the spinet, harpsichord, pianoforte. There are nearly two hundred specimens of the old Cremonese and other Italian violins, violas, violons, and basses, and amongst them I see a violin that a friend of mine once gave £450 for, and a bass that was bought for £800 in Paris. But as this is the one branch I am well versed in, I postpone it for the time, my present object being merely to indicate the various character of the treasures, and the profit that may be reaped. The Marquis of Kildare lends an Irish harp with its one row of metal strings, the wooden frame black with age, exposure, and, methinks, a little peat-smoke. To such a harp Carolan, the last great improvising Irish harper, sang his traditionary melodies that lived by ear and now are dead, alas! One comfort: as the devil escaped being put in a pie by shunning Cornwall, so those divine melodies—some gay, some sad—have died and gone to heaven, and so escaped the defilement and degradation of being hashed and smashed into quadrilles by Jullien and his followers, and played in false time and utter defiance of their dominant sentiment. There is an older harp, lent by Mr. Dalway, on which is inscribed "Ego sum Rex cithararum." "Pride goeth before destruction;" so this self-trumpeting harp is in pieces. The epithet of "King of Harps" is better merited by the noble instrument of Lady Llanover—a triple-stringed Welsh harp, made by the famous John Richards about 140 years ago. On such a harp, made by the same maker (Richards), blind Parry of Ruabon harped his "ravishing tunes a thousand years old" to the poet Gray, and so fired him with brave thoughts that he wrote "The Bard" while the music was fresh in his soul. Woe is me! who can play this harp nowadays? This one looks bursting with music. "I would give a few pounds to hear 'Sweet Richard' played on it." But I ransacked Wales five years ago, and not one public harper did I find could play the triple harp. Yet their greatest airs were all composed for it, and are half lost without it.

Then there are Italian spinets, one of which ought to interest the ladies; for it has nineteen hundred and twenty eight precious stones outside it, and very little music inside. There is Handel's harpsichord. He had more harpsichords than Cromwell skulls. But this time there really is a tidy pedigree made out. There are two much finer double harpsichords with stops and swell, one of them made by Joseph Kirkman and lent by his descendants. I heard this harpsichord played by Mr. Sullivan and the learned Mr. Engel; and it is a great and beautiful instrument, full of sweetness and tenderness, yet not deficient in grandeur: and sings to the heart. It ought never to have been allowed to die. There was room in the world for the pianoforte and the harpsichord too; each can do things the other cannot.

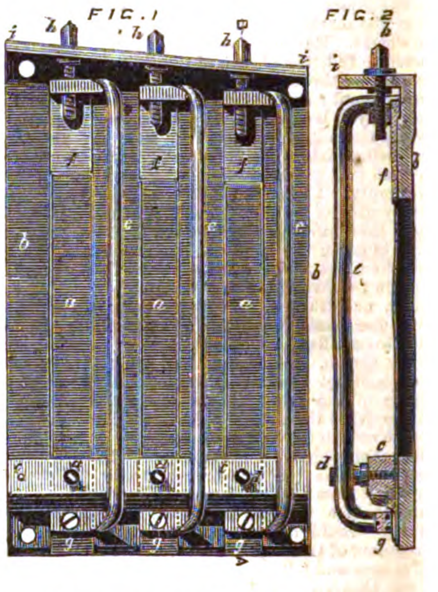
It seems at first sight strange and sad that so many stringed instruments should have been invented in modern Europe, and framed with so much skill and taste, only to die away, when so poor a thing as the guitar survives. They were not killed, as some people fancy, by our four-stringed instruments, for they ran parallel with these for centuries. Some of them no doubt deserved to die; the mandolins, and little citterns, for not making noise enough in such a world as this, and the lute and viola di Bardone for being always out of tune. I read that a contemporary of Handel said, "If a lutenist lives to eighty he must have been sixty years tuning;" and another, writing to lutenists, gave them this warning, "You shall do well ever when you lay it by to put it into a bed that is constantly used." So mankind rose against these invalid instruments and put them to bed once for all.

But I hope that true lovers of music, both male and female, will inspect the harpsichord, the viola d'amore, and the viola da gamba with candid eyes, and give them a trial. Put these two last at their lowest, they must be superior to the guitar, since they have more tone, and arpeggios can be played on them with the hand and suddenly the chords swept with the bow—a rare musical effect for any single instrument to produce. The larger viola of the two could also be fitted with the sympathetic wire strings; the finger-boards of both could be fretted, and I apprehend the bridge of each could be arched a little. Ladies could play the viola d'amore gracefully. Indeed, a Mrs. Ottey played the viola da gamba publicly in 1720, and a Miss Ford in 1761; teste viro doctissimo Carolo Engel. Meyerbeer thought well of the viola d'amore, for he wrote a part for it in "Les Huguenots." The late Prince Consort had music of the sixteenth century performed on various ancient instruments such as are now on show. On that occasion a viola da gamba—that figures in this very exhibition—was played by Mr. Hatton—who, I hope, is alive to play it again—and was much admired. The deceased Prince had many ideas before his age, and I think your readers will appreciate what he did for music in 1845, when in 1872 they have examined this noble collection with the attention it deserves.

* By Charles Reade, in the *Pall Mall Gazette*.

HARMONIUM REEDS.

AN improved form of harmonium reed, which is claimed to afford great facilities in tuning, has been patented by Messrs. Fontainemoreau and Co., as agents for a Miss Procopé, of Stockholm. As most of our readers are aware, the usual practice is to secure the tongues by screws or rivets to the frame, the right pitch being attained by scraping



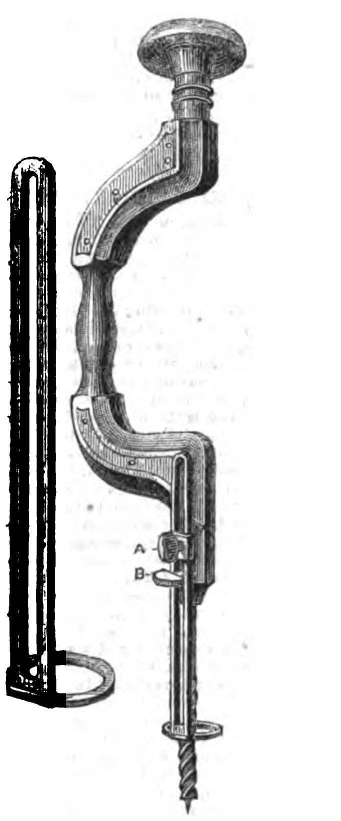
the reed at one or other of its ends. Miss Procopé considers that besides the inconvenience inherent in this system the reeds in time become so worn as to be almost useless, frequently breaking unexpectedly and at awkward times. These unpleasant annoyances and expensive accidents Miss Procopé thinks will be obviated by the use of her improved reed and frame, a plan and section of which is here annexed. Fig. 1 shows three reeds in plan, and Fig. 2 a section on line A B (Fig. 1). The main feature of the invention consists in employing two tongues instead of one, arrangements being made to allow of the tongues being moved in tuning them, so as to increase or diminish the length of the vibrating part of the tongue until the proper pitch is obtained. The metal strips *a*, are ordinary vibrating tongues, held and guided by a bar or ledge *c*, fixed to the frame *b* by screws, and passing through slots on the underside of the bar *c*; they are fixed by the screws *d*, each tongue is connected by a bar *e* to a short tongue *f*, which does not vibrate; and the connecting bars are attached to the tongues *a* by screws *g*, and to the tongues *f* by solder, rivets, or screws; *h h* are set screws passing through holes in a flange *i* on the frame *b*, and through the ends of the connecting bars *e*.

To tune any particular reed it is only necessary to loosen the fixing screw *d* of its tongue, when by turning its set screw *h*, the length of the tongue *a* may be increased or diminished as required until the proper note is obtained, after which the screw *d* is again tightened. In some cases graduated scales are adapted to the frames of the reeds to assist in regulating the position of the tongues *a*.

Such is the inventor's specification, but we have no information whether the effects claimed to be produced have been really obtained in practice.

GAUGE FOR BIT BRACES.

THE gauge for attaching to bit braces, of which the annexed figure is an illustration, has been patented in the United States. It is the invention of Mr. C. Whitus, of Philadelphia, and may possibly be found suggestive, if not useful, to many of our readers. Where a number of holes of uniform depth have to be bored, wooden tubes of the requisite length are frequently used to slip over the bit and prevent it entering too far, or to show the mechanic when the bit has penetrated to the desired depth. It is of course obvious that a number of these wooden tubes are required to suit various descriptions and dimensions of work; these, however, are dispensed with by the employment of this simple contrivance. It consists of a sliding gauge shown detached and in position on the bit-stock. This may be made of brass, steel, or iron nickel-plated, and can be graduated to inches or to any fractions of an inch that may be desired. The sliding gauge is attached to the side of the stock and held in the required position by means of the thumbscrew and plate A; while B is the thumbscrew holding the bit in the stock. The sliding gauge has a ring-shaped foot, through which the boring tool passes as shown, and this meeting the surface of the material being bored prevents the bit penetrating to a greater depth than that to which it is set. The



sliding gauge must, however, be screwed very tightly to the stock, or the action of the tool in boring will force it to slip, and so mislead the workman. Moreover, this attachment seems to us to be a modified "re-invention" of a contrivance we have seen in use in England for boring a number of holes when of a uniform depth.

PLATING WITH NICKEL AND PLATINUM.

PROFESSOR RUDOLPH BOETTGER, the well-known discoverer of gun-cotton, has, according to the German correspondent of *Engineering*, recently vindicated his priority as the inventor of the method of galvanising metals with nickel and platinum, processes which are now attributed to E. Becquerel and Isaac Adams, though they were made public by Professor Böttger, more than thirty years ago, in *Erdmann's Journal für Praktische Chemie*, 1843, Vol. III. He had discovered that a solution of sulphate of nickel-ammonia, even under the action of a not very powerful current, will readily and firmly deposit a bright metallic coating upon copper and brass, which within half an hour becomes so thick and coherent that it will prevent the action of nitric acid upon the underlying metal. Since then, the process has been extended to galvanising iron and steel, and has become highly valuable for the protection of those metals against rust and atmospheric influences when used in the construction of delicate machinery. The coating of metals with platinum is effected by Böttger even without the aid of a galvanic battery, simply by boiling them in a solution of chloride of platinum-ammonium with a small excess of free ammonia, when a bright metallic coating of platinum is firmly united with the metal, which will protect it against oxidation as well as metallic nickel. When a galvanic battery is used, the metal is not generally so well deposited in one coherent mass, but is apt to form minute black crystals; when, however, the above solution is kept sufficiently ammoniacal, and not too hot, it will also deposit on the negative electrode a bright metallic coating. Both processes are now much in use with physical instrument makers for the protection of brass and copper parts, such as wheels in chronometers and other fine instruments, and they were first published at the meeting of German naturalists and physicists at Mayence in 1842.

USEFUL CEMENTS.

A FEW days ago, says the *British Journal of Photography*, we found it necessary to prepare a glass dish from ordinary pieces of window glass, as a vessel of the size and form we wanted could not be obtained to purchase. Cutting the glass was a very easy matter, but a good junction, which would stand a liquid at a temperature of about 80° Fahr., was not satisfactorily effected. We have tried several cements for this purpose, but have found one sold as "coaguline" the best. The glass surfaces are best roughened, so as to give the cement a "bite;" and then, on applying the warmed liquid coaguline, pressing the glass plates together and then allowing the whole to stand for some time, an excellent joint is obtained. In the same way glass and wood, or glass and metal, can be cemented together with facility. All these joints, however, give way to prolonged treatment with water if it be warm; it is, therefore advisable to cover the joint with a layer of mastic or shellac varnish, in order to be secure against mischance. We have not found cold water to affect the cement in ordinary saline liquids, but silver slightly acts upon the unprotected coaguline. We have jotted down the above, as our readers may often wish to prepare large glass dishes for floating paper, &c., economically and conveniently. Our own results have been so satisfactory with the cement in question that we always keep some by us. A cement for glass and earthenware, which is much liked by many who use it, is made by adding half a pint of vinegar to an equal bulk of skimmed milk; the curd thus obtained is mixed with the whites of five eggs (well beaten) and sufficient powdered quicklime to form a paste. When the objects cemented with this "curd cement" are dry, they resist water and a moderate degree of heat.

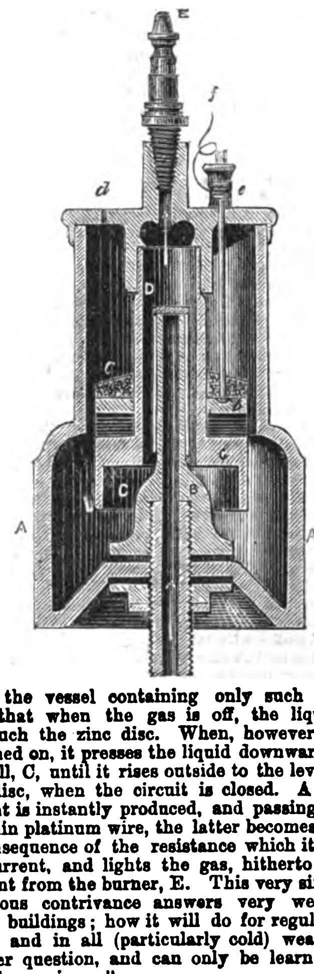
NOVEL BLOWING APPARATUS.

A NOVEL blowing apparatus has, we learn from the *Adelaide Observer*, been erected at a Colonial foundry, constructed on a similar principle to the "trompe" of the Catalan forge, illustrated on p. 73, Vol. XIII. At present it is only used for blowing the ordinary blacksmith's fire, but eventually it will, no doubt, be used for the smelting-furnace. It consists of an empty barrel, or quarter cask, stood on end behind the fire, to the centre of which a blast-pipe, from 2in. to 3in. in diameter, is fixed. On the top of the cask is another pipe, the same size as the blast-pipe, some 6ft. in height, with a funnel-shaped top. Just above this there is a horizontal water-pipe of the ordinary service size, with a nozzle, having an aperture of ⅛in. in diameter, fixed at right angles—that is, pointing down the pipe leading to the barrel, down which there rushes, with considerable force, a tiny jet of water, which causes a rush through the blast-pipe far superior both in power and steadiness, it is said, to any that can be obtained from the common blacksmith's bellows. The waste water, which is very limited in quantity, escapes through a pipe attached for the purpose to the bottom of the barrel.

AUTOMATIC GASLIGHTING.

THE German correspondent of *Engineering* gives an account of the arrangement of automatic gaslighting apparatus designed by Prof. Klinkerfues, the astronomer to the University of Göttingen. It seems that the system has been introduced into the Imperial Parliament House, having first been tried on some of the street lamps of Göttingen. The great feature of these burners is that they are completely self-regulating; the tap at the meter or the one which gives entrance to the building from the street main has merely to be turned on, and immediately all the lamps fitted with these burners assist in the illumination. The following is the description given by the correspondent of our contemporary:—

"A cylindrical glass vessel, A, with perforated bottom, is screwed upon a brass gaspipe, which is prolonged by a lead cylinder, B, the latter being closed at the top and covered by an inverted glass cylinder, D, with which it communicates through small holes. The glass vessel bears a cover of brass ending in a gaspipe and the burner, E, which communicates with the interior of the vessel by means of the bell-shaped lead cylinder C, which incloses the lead pipe, B, and glass cylinder, D, reaching considerably below the latter. If now the vessel is filled with any liquid, so that the bell-shaped part of C is perfectly covered, this liquid will stand equally high outside and inside of the glass cylinder, D, and interrupt the communication between the inlet gaspipe and the burner. If, however, the main cock be opened, and the pressure of the gas allowed freely to play, the gas will enter the glass cylinder, D, through the small holes, and press upon the liquid inside the latter so much that it escapes from under that cylinder, and now, outside of it, communicates with the burner. When the gas is turned off, and the pressure ceases, the liquid will immediately rise again by the action of the atmosphere which, through the opening, *d*, in the cover, presses upon the surface of the liquid outside the lead cylinder, C. It will be seen that by this arrangement it is easy to admit the gas to as many burners as may be desired (?), and to shut it off simultaneously by only turning the main cock, and by regulating the pressure. The next thing is to light all flames simultaneously, and this is done by electricity, each apparatus acting as its own battery. For this purpose a disc of carbon, *b*, is fixed upon the bell-shaped part of C, and at some distance apart, and isolated by glass, the disc, *c*, made of zinc, which by the insulated conductor, *e*, and a wire, *f*, communicates with the top of the burner though a thin piece of platinum wire. The liquid with which the vessel is filled consists of a mixture of 18 parts of water, 4 of sulphuric acid, and 3 of bichromate of potas-



sium, the vessel containing only such a quantity, that when the gas is off, the liquid does not touch the zinc disc. When, however, the gas is turned on, it presses the liquid downwards inside the bell, C, until it rises outside to the level of the zinc disc, when the circuit is closed. A galvanic current is instantly produced, and passing through the thin platinum wire, the latter becomes red hot, in consequence of the resistance which it offers to the current, and lights the gas, hitherto escaping unburnt from the burner, E. This very simple and ingenious contrivance answers very well in all closed buildings; how it will do for regular street lights, and in all (particularly cold) weathers, is another question, and can only be learnt by prolonged experience."

It is to be regretted that the writer does not inform us of the cost of this ingenious apparatus when compared with other and more simple methods of effecting the same object. The contrivance is only applicable where a number of burners are required alight at the same time; for, so far as we can discern, there is no means of cutting off the gas from a single burner without putting out all the lights supplied from the same pipe or tap. This being the case, it seems as if the ordinary arrangement, with the simple addition of a piece of platinum wire to each burner, and a galvanic battery and a few hundred yards or so of copper wire, would answer the purpose equally as well, with the further advantage that, the taps being retained as usual, and kept open as a rule, it would be possible to stop the supply to any single burner or any twenty. No information is offered as to the frequency with which the solution requires replenishing, nor as to the consumption of zinc. Nevertheless there may be circumstances under which the use of this invention of Prof. Klinkerfues might be found advantageous, and it is certainly ingenious.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

*** *In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

PROCTOR'S "ESSAYS ON ASTRONOMY."

[4809.]—As a general rule an author acts unwisely in commenting on remarks made in reviews of his work. But there are exceptions to this rule; and I think an exception can reasonably be made where, in the first place, as in the ENGLISH MECHANIC, correspondence is encouraged, and where, in the second, it must be obvious, as in the case of your review of my "Essays on Astronomy," that the author must be greatly gratified by the general tone of the critique. Your readers will understand, then, that if I defend certain points to which objection has been taken by your reviewer, it is because I think them worthy of discussion on their own merits, and not because I simply wish to prove myself in the right.

I may note, but this only in passing, that my objection to Herschel's "familiarising" of science is based on the *way* in which he familiarised, not on the *fact* that he did so. I objected, not because he "gambolled," but because "his gambolling was that of Behemoth." He was not used to gambolling, and (*me judice*) did not do it well. After all, the fault is but a spot on the sun, and a small spot (a penumbral one, as it were). But the points I care to discuss are the following three:—

First, as to the probable colour of the earth seen from Venus. Here I would point out that it is only because the moon's disc in eclipse, chiefly illuminated as it *must* be by earthshine, does actually appear sometimes green and sometimes brown, that I infer that earthshine, taken as a whole, is sometimes greenish and sometimes brownish. Now, I must demur altogether to your reviewer's objection based on the assumption that "a very large proportion of the visible hemisphere" (that is, the half of the earth turned towards the moon) "was covered with cloud on the occasion of the eclipse of 1870." Your reviewer does not sufficiently take into account the fact that the part of the earth's disc traversed by the moon's shadow was close by the extreme northern rim of the disc, and that inferences from *its* cloudy condition cannot apply to the great extent of the disc occupied by the Atlantic, South America, equatorial and Southern Africa, and the Indian Ocean. Moreover, *that* part which (as your reviewer justly remarks) was much covered with clouds was precisely the part which, being in the moon's shadow, supplied least light to our satellite. I may add that I had before me, when I wrote, a projection of the disc, constructed by myself (see *Quarterly Journal of Science* for October, 1870), with a picture of the moon's shadow upon it, and that my opinion was formed from a study of that projection, and with a full consideration of the points mentioned by your reviewer. A similar remark applies to the eclipse of 1860. I constructed a projection of that eclipse before venturing to express an opinion as to the probable colour of the earth as seen from the moon on that occasion. I do not think the existence of extensive cloud masses in the least affects the argument. The clouds would shine with a white light, and would not neutralise, but simply *dilute* the green, blue, or brown light proceeding from unclouded regions. I by no means suppose (nor have I ever asserted) that the earth would be of a strong green, blue, or brown colour, as seen from Venus, at *any* time, even if wholly unclouded. But I think that as Mars shines with a recognisable ruddy colour, notwithstanding extensive tracts of indigo or bluish green on his surface, besides large whitish tracts, and as the strength of this ruddy colour is variable independently of the condition of our own atmosphere, the case may be somewhat similar with the earth as seen from Venus. The oceans being relatively much larger on the earth, her colour would vary, I conceive, from the brownish hues (much diluted with white glare) due to continents to the bluish green hues due to oceans. I fancy the "blue black" of the oceans, if diluted with the slightly yellowish white of clouds, would give bluish green glare. As for the forests of America, I demur to the theory that *they* would be green, nor would the *heathy* prairies so appear; though at certain seasons the "rolling prairies" and the "Llanos" of South America would be greenish if separately discernible from Venus. But the "Gran Chaco" in South America, and the extensive deserts by the Rocky Mountains in North America, would be brownish, and I conceive the general resulting colour for the whole American continent (diluted with yellowish white light from clouds) would be dun or fawn colour. The supposed greenness of forests is altogether mythical. My old drawing-master used to say, "Trees, as a whole, may be red, yellow, black, or brown; almost *any* colour, in fact, *except* green"—and, "with allowance for friction," this is not far from the truth. I should add that the Americas were not the *only* land regions turned towards the sun and moon during the eclipse of 1860. The whole of Africa and large parts of Europe and Asia were so turned. In any case, my views were not put forward without careful study of the subject.

Secondly, as to Mädler's theory of the orbital motion of our system round Alcyone, it is not quite the case that this theory "only had its warrant in that astronomer's imagination." Mädler based the theory on arguments of considerable weight in themselves. However, it will scarcely be thought that *I* adopt Mädler's theory, since I have been at great pains to show that it is erroneous. I presented his reasoning, and the objections against it (overwhelming, as I conceive) in my lecture at the Royal Institution in May, 1870, and I touched on them in a paper read before the Royal Society in January of the same year. I quote from this paper the following passage:—"It is worthy of notice that Mädler, having been led by certain considerations to examine the neighbourhood of the Pleiades for traces of a community of proper motion, founded on the drift he actually found in Taurus his well-known theory that Alcyone (the *lucida* of the Pleiades) is the common centre around which the sidereal system is moving. But in reality the community of motion in Taurus is only a single instance, and not the most striking that might be pointed out, of a characteristic which may be recognised in many regions of the heavens. In Gemini and Cancer there is a much more striking drift towards the south-east, the drift in Taurus being towards the south-west. In the constellation Leo there is also a well-marked drift, in this case towards Cancer."

Thirdly, as to the nomenclature of star-magnitudes. This is a matter which ought to be attended to by writers on astronomy, in order that a definite rule may be adopted. I must say it seems to me that my method is the most natural. Let your reviewer ask any ten persons at random whether they would understand "a star of a very high magnitude," to mean a very faint or a very bright star. I think he will find, as I have done, that great brightness is usually inferred. I admit that "twenty" is a higher number than "one," but I submit that the "first" is a higher order than the "twentieth." When we speak of any person or thing standing high in a list, we imply that the *ordinal* number expressing his or its place is small. The highest place is the first, in ordinary parlance; and we only associate "highness" with "largeness" of number, when we use the number cardinally. The only exception I know of (and that a doubtful one), is where a mathematician speaks of equations of a high order, but even here *number* is in question, the high order being arrived at by so many "multiplyings," so to speak, of the involved quantity in that term which determines the order.

Of the errata, your reviewer's "'Handibook' for 'Handbook,'" should have been "Handibook" for "Handy Book." The printers governed this matter. Buchan calls his book "Handy Book of Meteorology," and I so wrote it, but the printers would not have it, and I left them to their own devices.

The other errata are indefensible (I observe that one of them is repeated in the essay you have reprinted, where "southern" horizon, line 16 of the essay, should be "northern horizon") except in so far as the law of averages teaches us that in a given number of pages, a certain number of errata will always occur. If the odds are a hundred to one that no glaring error in a given page will escape detection, the probability is, that in a work of over 400 pages, there will be four glaring errors. RICHARD A. PROCTOR.

SPINNING TOPS AND GYROSCOPES.

[4310.]—I AM somewhat surprised at "A Barrister's" statement (let. 4303, p. 306), that "amidst all the plausible theories and speculations to account for the movements of tops and gyroscopes, none as yet appear to afford any satisfactory solution of the problem." The movements in question are strictly in accordance with the results deducible from the mathematical analysis of the subject. The difficulty is in popularly expounding the subject; and this difficulty is almost insuperable.

As to the general features of spinning motion, I would remark that for a spinning top to fall in a given direction, all the moving particles in the top, except those in a certain vertical plane through the axis of the top, must have their direction of motion changed. But the weight of the top is insufficient to change the direction of the particles' motion in a brief interval, so long as this motion is sufficiently rapid; precisely as this weight would be insufficient to change the direction of the top's motion appreciably in a brief interval, if the top were simply flung through the air at a high velocity. The principle is the same in both cases. But in the case of a top flung through the air, the top's weight has time to act, and does eventually so act as to change the direction of flight. It is otherwise with the particles of the rotating top. For a particle which, moving horizontally in rotation, should move somewhat downwards if the top is to fall in a particular direction, will a moment after be so placed that for the top to fall in that direction, this particle should move somewhat upwards. Hence the steadiness of the top's motion while the rotation is rapid. RICHARD A. PROCTOR.

ATMOSPHERIC ELASTIC FORCE, &c.

[4811.]—MR. J. M. TAYLOR (letter 4250, p. 279) intimates that he would be surprised to hear that a top has "stood erect in vacuo." He means, I presume, while spinning. If Mr. Taylor will refer to No. 47., p. 352., of the *Philosophical Transactions*, I think he will find an account of one that spun for two hours and sixteen minutes. Has Mr. Taylor tried the experiment himself? If not, would it not be better for him to do so before attempting further to maintain so very novel a theory?

The centrifugal force, or, as it is now the fashion to call it, the centrifugal tendency, causes all rotating bodies to resist, to a greater or less extent, any force acting in such a manner as to shift the direction of the plane of rotation. When a paddle-wheel steamboat is lying at anchor in a seaway she rolls to an extent that she never does when the paddles are at work; and the top wobbles when its rotation is ceasing for the same reason—it is succumbing to the forces of gravitation and of friction, which are trying to pull it down. Mr. Taylor doubts whether I ever spun a top in a vacuum. I own I never have; but I doubt whether he ever spun a top at all, or, at all events, many tops, or he would know that a top will spin with perfect steadiness, gyrating certainly, but not rising nor falling, at an angle to the horizon of considerable amount, its inability to raise itself depending upon the fineness of the point of the peg. When a top "sleeps," gravity acts equally upon it, and its fall is occasioned solely by the friction of the ground and air. When the top is inclined, a composition of forces takes place, and the effect of gravity is to cause gyration. The reason why a top with a blunt point can raise itself is owing to part of the force of friction acting at right angles to the axis of rotation. With a fine point, this resolution does not take place, and the top is incapable of getting up to go to "sleep;" but instead, gyrates in an "orrerific" manner, to the delight of that very disagreeable young person, the too scientific schoolboy. M. PARIS.

THE COMETARY DELUGE.

[4312.]—I SAID, p. 303, "These are my last words upon it," but "Derf Errac's" let. 4290, p. 303, being mainly addressed to me, compels a reply, beyond which I will not go, because I prefer to expend my time and labour upon subjects of some use, and to write about things I know something of. To discuss the progress of a hypothetical and impossible event, appears to me waste of time; and as is evident from some remarks in the "Replies to Correspondents" the "odium theologicum" is unavoidable: let one debate ever so reasonably, one is sure to be charged with "infidel attacks on the truth of Holy Scripture," exactly as Galileo was when he argued for the Copernican system. Now, will "Derf Errac," who asks me if I think I am arguing honestly for the truth, tell me if he thinks he does so when he attributes to others that which they never said? Will he have the goodness to say where either "F.R.A.S." or myself say that we "consider all who differ from our dicta, as regards a flood 5,000 years ago, to be playing deliberately into the hands of the infidel and scoffer"? This is just an illustration of the unfair way in which men of science are treated, and which generates the much talked of antagonism between religion and science. We said that to link together religious dogmas and statements of very questionable facts; that to say that any one who doubts whether the world was made in six days, or whether a flood covered the entire globe, or whether the sun and moon stood still to give one set of men a little longer time in which to murder another set of men; that to venture the credit of religious faith in contact with these statements, and to compel every man to choose between being an "Infidel," or swallowing bodily all these statements—that *all this folly* is "playing into the hands of the infidel and scoffer." In fact, is it possible to conceive any better process for compelling reasoning men to reject altogether principles so discredited? This is a very very different thing from what "Derf Errac" asserts of us.

I cannot help "Derf Errac's" understanding "E. L. G." in a different sense; to me it appears that he used the illustration of the action of falling water upon a heap of sand or clay as describing the action of the flood; and, if so, it was a fair reply that the conditions being different altogether, the illustration fails; that illustration was that in a heap of sand or clay, causes now in operation—that is, rain—would produce only deep furrows and steep walls, while a flood, as the tide flowing over, would convert them into sweep vales; ergo, it was deduced, sweep vales on the earth were formed by a flood, not by ordinary causes.

I may incidentally remark that we may see the early history of the earth in the moon; instead of the moon being, as the author I quoted (p. 196), and others suppose, a dead planet merely, it very plainly shows that planetary bodies were at one time in a state of fusion, that a crust first formed on them, that that crust was pierced by openings through which the fused contents poured out as the crust contracted, and that, ultimately, as the mass solidified, its surface would be rent by vast chasms. All this we actually see in the innumerable craters and clefts on the moon, all this we see when any body of lava pours from a volcano, and can watch in progress any day in the slag pouring from a blast furnace. In the moon, the result remains because there is no water and atmosphere to disintegrate the first formations. (Probably the greater mass of the earth retained all the lighter materials, gases, and vapours, around it.) In the earth, when this stage was reached, the vitrified crust was exposed to the action of heated gases and vapours which, as the temperature lowered, were enabled to react upon it, to change its nature chemically, and to break it down mechanically, and when at last liquids could be formed, the débris thus produced would drift into the hollows of what was then truly a mere film covering a mass freely mobile, because in a highly heated state of fusion. In this stage small changes of pressure would be really capable of disturbing the equilibrium of the shell and its contents. In this way we can easily conceive how through gradual very slow changes, through many a myriad of ages, the world assumed its present state.

Returning to "Derf Errac's" remarks, it is very difficult to argue and analyse exactly as to the pressures the supposed falling torrents would produce—there is too much of the "might be" about it. According to the originator of the notion, few of the now elevated lands then existed: it appears that the Andes and Himalayas did not (at least so "E. L. G." says), and therefore what can we know as to the supposed spaces on which an extra pressure *might* accumulate? I see no sort of reason to imagine that under the supposed conditions the fall would be even a second earlier on the land than on the sea, as the whole atmosphere would be densely charged with vapour first; but it is a pure assumption, without a particle of evidence to support it, that such a pressure (if real) could produce any distorting effect whatever. I referred to the assertions of some distinguished mathematicians that the crust of the earth must be, from astronomical considerations, 800 miles thick; I did not say I believed it; on the contrary, as a mere matter of present opinion, claiming no great weight, even in my own mind, I consider it probable the thickness lies between 20 and 40 miles of solid matter, resting upon an exceedingly dense and agglutinated fused mass; but I see no sort of reason to conclude that any possible accumulation of water upon any portion of this could appreciably distort it—taking into account the balancing effect of the water fallen on the sea, the hypothesis appears monstrous and improbable.

The key to the discussion lies in the point I have already stated. One single fact inconsistent with the occurrence of a universal deluge disproves it. Ten thousand circumstances consistent with such an occurrence *do not prove* it, because there may be other explanations. Now, we need no comet to show that all the earth has been under water—that is, that every portion of its existing surface was formed under water except a few protruding eminences—in fact, all its surface has been so under water many times, and for prolonged periods, one part at one time and another part at another; *there* is the explanation of all those facts which appear to support the universal flood, and which also fits in with those other facts which incontestibly disprove it.

Before turning from the subject, however, I may as well add that when "E. L. G." has explained what became of the water of his comet, he has a still more difficult problem behind—viz., what became of the *heat*, and how did anything survive it. Comets would seem to be incandescent, and it is very doubtful if water could possibly exist undissociated into its elements in cometary conditions; but as we must assume against all evidence (as "E. L. G." admits) that there was *one* water comet, we need not stick at assuming it to have been cold; give it the temperature of absolute zero; it must have been in a highly diffused state, filling a vast space; it *may* have been moving in the same direction as the earth, so we may disregard the loss of its motion and consequent transfer into heat. But the earth's attraction drawing the water to it from space in quantity sufficient to generate a fall of 10ft. per minute, would also generate enormous heat, as we see when any substance actually comes under these conditions, as with meteors; so that it is probable that not only would the water itself be uncomfortably hot, but the air would be filled with heated vapour. Cold vapour would not form cool water after falling (say) 200,000 miles, and having that motion suddenly arrested.

And all this is devised to support the idea of the mere universality of a flood, while its deviser is going to prove one of the worst foes of the theological dogmas attached to that idea, which alone give substance to it; if we are to take the account as literally true, Noah's Ark was provided for the purpose of perpetuating life; to suppose that any land-living creatures were saved except those in the Ark is equally subversive of the account as to deny the universality of the flood, for if the greater part of the world was replenished by creatures saved upon "E. L. G.'s" "rafts" (fancy anything living on a raft under a fall of 10ft. per minute) the Ark was an entirely unnecessary provision, except for the comfort of Noah and his family. I move (and carry for myself) "the previous question."

SIGMA.

P.S.—If any one feels inclined to smile at the number of "may be's," and "it is probable," will he kindly remember this is "'rote ironical"?

THE DELUGE.

[4313.]—I PERCEIVE that there are those among your readers who consider the case of "E. L. G.'s" "steam comet *versus* Lyell and Scrope" as the case of "religion *versus* the infidel." This being so—"*E.L.G.* *having started so dangerous a notion*—I conceive that it has become his duty to tell us something more about his comet. Of course, no one can expect him to tell us exactly the nature of the actual comet; but he should be able to describe the nature, size, motion, and condition of a hypothetical comet which *might* have accomplished what he requires from his steam comet. Thus, it rained upon the earth forty days and forty nights (Gen. vii., 4 and 12). In this time the earth travelled (roughly) some sixty millions of miles on her orbit, rotating forty times on her axis. This should be considered. Then, again, the waters of the earth had returned to their normal condition one year and ten days after the commencement of the flood (Gen. viii., 14). This allows 335 days for the subsidence or drying of the water—subsidence, I suppose, according to "E. L. G.'s" theory. Then, by the way, what was the action of the wind which "passed over the earth" after the flood? It would be well, also, to describe the condition of a suitable comet, as to total quantity of steam, maximum pressure at or near nucleus, actual quantity of aqueous vapour (per cubic mile, say) in the part traversed by the earth; because, if a creed is to be formed containing the words, "I believe in 'E. L. G.'s' steam comet," it is as well that we should be able to give reasons for the faith that is (or that, I suppose, *will be*) in us.

I would submit, further, that while there may be excellent reasons for believing Darwin, Lyell, Scrope, Huxley, Tyndall, and others, who do not take certain Scriptural assertions *au pied de la lettre*, to be *mistaken*, it is certain that these gentlemen are fully persuaded of the truth of what they assert; that they have spoken with the object of advancing truth, not of injuring any man's faith; and that even by comparison with "E. L. G." they are not, strictly speaking, idiotic. It can serve no good purpose, then, to sneer and be scurrilous. Correction, not castigation, is called for if Lyell or Scrope (for instance) be mistaken. We may sympathise with that courage arising from conviction which leads a man to oppose argument to authority; but I have never yet heard that abuse or ridicule strengthened any cause against those who, right or wrong, are certainly in earnest. I conceive, therefore, that "E. L. G.'s" steam comet would not suffer if he could eliminate "oh" and "ah" and "assuredly" and "just observe" and "now mark" from his paragraphs, and trust rather to "semicolons" and "points" than to "notes of admiration and (startled) interrogation." Sydney Smith has told us that "nothing does, for ten pages together, but the indicative mood," with whom, also, I would remark that I should "not wish to deprive 'E. L. G.' of these indulgences altogether, but merely to put him upon an allowance, and upon such an allowance as will give to these figures of speech the advantage of surprise and relief."

As a change from the Deluge, "E. L. G." might exercise his talents in showing us (for example) how the destruction of Sodom and Gomorrah was brought about by a downfall of the November meteors. I commend this in a special manner to his ingenuity. He will see that the time of day and other circumstances of the catastrophe agree well with the theory; and as these meteors contain much sodium, the transmutation of Lot's wife into a pillar of salt (chloride of sodium) becomes pleasingly explicable. It is true Leverrier has set the introduction of the November meteors into our system at the year 126 A.D.; but that is a detail,—like "Sigma's" question as to what may have become of the water received from "E. L. G.'s" steam comet.

RICHARD A. PROCTOR.

[4314.]—I AM sure many other readers of the ENGLISH MECHANIC agree with me in hoping that the forty days of this flood are nearly over. With a view of pouring oil upon the troubled waters, I cannot refrain from expressing a very decided opinion that there was no occasion at all for any such disputation. I presume that it is only a laudable zeal for the authority of inspiration which has led "E. L. G." and a few others to believe in the universality of the Deluge; because they concluded the Scripture expressions to be quite unmistakeable, consequently, in defiance of the overwhelming evidences afforded by both geology and astronomy, they have taken up the wildest notions and most impossible theories. With the deepest conviction that their difficulties are imaginary, I put forth the two following statements:—(1) That the inspired record does not declare the Deluge to have been universal; (2) that the description of it given in Genesis vi. is inconsistent with such a belief.

The former was the clearly expressed opinion of Bishop Stillingfleet before the days of Lyellian geology, of Dr. Pye Smith, and many other good men who had the profoundest reverence for inspiration. Such men pointed out that the right way of reading those statements which seemed to declare the universality of the Deluge was to compare the expressions used with others of a similar kind in Scripture, of which the contexts or other passages gave an explanation—*e.g.*, in Matt. xii., we read that "the Queen of the South came from the uttermost parts of the earth," when the actual distance was a few hundred miles, but not to multiply examples, I would ask whether the expression "all the high hills under the whole heaven were covered," proves that the Alps, and Andes, and Himalaya ranges were submerged any more than the expression "there were dwelling in Jerusalem Jews, devout men out of every nation under heaven," asserts that some came from China, others from Great Britain, and others from America. I dare say it will be replied that, of course the writer of the Acts meant only all the nations where Jews were then established. Precisely; and so the writer of Genesis meant only the lands where the human race then existed. The tract of land between the Caspian and Black Seas appears to have been the cradle of the human race, and a deluge extending no further than that—the then known world—would fulfil both the divine intention of punishment and the language in which it is narrated.

2. I maintain that the account given in Genesis is inconsistent with the idea of a universal deluge, and especially with an extraneous source of the water such as the cometic sac d'eau invented by "E. L. G." The record does not say that the chief part of the water descended from the skies, though it did rain during forty days, and we must remember that such a downpour as would produce a layer of water six miles thick in so short a time would cease to be rain, and become a furious cataract that would leave no olive leaf for the dove to pluck off. But what do the Scriptures assign as the sources of the water? They are twofold, mentioned twice in the same order; (1) the fountains of the great deep; (2) the windows of heaven, of which last the equivalent is certainly rain, nor can there be any doubt that the former is the sea or ocean to which the priority of causation is ascribed. Thus we find Scripture and geology in harmony, when we regard the Noachian Deluge as the result of a local subsidence by which the barriers of the sea were removed, and the "fountains of the great deep broken up."

E. L. B.

[4315.]—IF "E. L. G." (letter 4239, p. 276) has not explored the Upper and Lower Eifel, I strongly recommend him to take his wallet and walk about this wonderful district. In the neighbourhood of Gerolstein alone he will find enough to upset, in my humble opinion, his Whartonlike theory. The Auberg here, a limestone rock, so exactly resembles a castle that every one who has seen my sketch of it has taken it for a ruined feudal stronghold, and when I took the sketch I actually thought it a castle. Now, "E. L. G." would maintain that this shape was produced by a deluge of water which rounded the slopes, out of which the rocky mass protrudes; yet within a mile we find a large crater with beautifully rounded sides. If this crater existed before the Deluge, why was it not filled up with the débris of the adjacent hills and rocks? If it was subsequently formed, why are its sides and its lava stream so rounded, except by the same agency that has rounded Cæsar's camp at Wimbledon, the moats and earthwork all over the country—namely, the never-ceasing action of gravitation upon the surface? The sand-dunes but of yesterday are again a case in point. Loose sand may at first be piled up and form ridges with sides more or less steep and not undulating, but sand-dunes formed a century ago will be rounded. Old chalk quarries show just the same thing.

M. PARIS.

[4316.]—WITH every respect for "E. L. G.'s" intellectual and polemical powers, I am at a loss to understand how he has, as he says (letter 4292, p. 304), "demolished any connection between their facts and their dogma about the Deluge." (Who has propounded any dogma but "E. L. G." himself?) Now I maintain that the facts mentioned by myself (let. 4240) and others are pertinent to the question, and any one who undertakes to give a theory of a universal flood is bound to take them into account. In the letter in question, "E. L. G." appears to have got himself on to the horns of a dilemma in this way; fresh-water plants and animals die in salt water, salt-water plants and animals do the same in fresh water; if the flood covered the whole earth either one or the other must have succumbed. Supposing the sea to have been made sufficiently fresh to have transported pond life, then the corals must have died; if it retained sufficient saline material to keep the latter alive, then the former could not have been transported in this way. This deluge is certainly most accomodating, for it occasions not only the wide distribution of fresh water life, but also "the fewness" and "separateness" of species "on islands even within sight of each other," *i.e.*, the same cause gives origin to two diametrically opposite effects. The quotations in the latter part of the letter neither militate against Darwin's theory, nor support that of "E. L. G.," but as we are discussing the Deluge and not Darwinism I will not go into them. In conclusion, I would point out that "E. L. G." has as yet given no evidence fixing the date of this deluge at 5,000 years ago, and it seems to me that if he does not make haste we shall be overtaken by another comet before he has finished.

P. SANTALINUS.

"E. L. G." AND HIS COMET.

[4317.]—I HAVE read through the column and a half of words with which "E. L. G." attempts to dispose of "F.R.A.S.," M. Paris, "Sigma," and myself, if not with instruction, certainly with amusement, being strongly reminded of the old lawyer's advice to his son reduced to practice, "Bad case, abuse plaintiff's attorney." As an example of "special pleading," I would commend to the attention of the bar the way in which "Sigma's" reply to the remark of "E. L. G." that a deluge would obey "the laws of yesterday's shower" has been answered. "Sigma" is, however, well able to fight his own battle, and those who read his letters can take the real meaning out of them, though, I very much doubt if they are able to do the same out of the parenthetical periods of "E. L. G." In entering into the Deluge controversy, my only object was to obtain the premises from which "E. L. G." draws the conclusion that a deluge did occur about 5,000 years ago, and that that deluge was caused by a comet; but this information he appears determined not to afford me, for the very good reason that indeed I must be ignorant of all concerning "comets, the earth, and properties of fluids," or I would have never asked for it. And this ignorance of mine he infers, *mirabile dictu*, because a letter of twenty odd lines contains no proof of my knowledge of such subjects! If any reader will come forward, however, who believes it proved from his acquaintance with science that a comet could cause the Deluge, "E. L. G." will kindly prove it for him! Considerate "E. L. G."! As in my defective knowledge, I am placed on a par with such a writer as "Sigma." "E. L. G." has done me honour over much; for if "Sigma" and "F.R.A.S." are ignorant men, what a light of science he must be, and how well suited to be our instructor in "steam comets," *ad hoc genus omne*. For my part, I shall never aspire to stand on the eminence occupied by men of science (?) who have adopted for their motto *nul n'aura de l'esprit que nous*.

In conclusion, I will once again ask "E. L. G." to prove that a comet could cause the Deluge, and then that one did cause it, when, no doubt, the readers of the MECHANIC will join with him in the belief that we all must have been "profoundly ignorant" to have doubted even for a moment its steam comet origin. I hope "E. L. G." will believe me when I declare that if his theory be true (which I do not believe), I hope he may be able to prove it for the sake of the cause of science; but, I trust, that he will at once apply himself to the task, and waste no more space in what savours only too much of struggles for victory, not for truth, otherwise the Editor had better put his veto on the discussion, which is fast becoming like Hamlet's reading, "Words, words, words!" UN IRLANDAIS.

P.S.—If "E. L. G." is not acquainted with the weight of a comet, nor cannot even form an approximate idea on the subject, why does he quarrel with Roscoe's ideas as to the magnitude of one? If Roscoe's assertion is to be put against "E. L. G.'s," may we not take our choice; for if both parties are ignorant on the matter, and Roscoe a "buffoon," for saying a comet might fit in a room, may not "E. L. G." be a still greater "buffoon," for saying that one did deluge the earth?

WHERE IS THE WATER GONE TO?

[4318.]—THIS question of "E. L. G.'s" possesses very great interest for me, and I shall be very glad if some of our learned friends will tell us where the water does go to. I have a theory, but will instantly abandon it if it can be shown that it will not hold water, my object being to discover either what does hold it, or what becomes of it.

While cruising in the Mediterranean with the British fleet, in 1862, we had occasion to touch at Cephalonia, and, coming to anchor off Port Argostoli, the Admiral gave leave to the watches to go on shore; and, availing myself of this privilege, I landed, and proceeded to inquire whether there was anything to be seen, and upon hearing of a wonderful well, within half an hour's walk to the northward of Argostoli, I provided myself with a guide, and upon arriving at the so-called well I found what greatly excited my surprise, for the water was rushing through a break in the sea-barrier, and along a rocky channel, until it finally disappeared in a large cavity in a rock, which crossed the channel at right angles, and at about 40 yards from the sea, and my guide informed me that so it has gone on for ages, and without interruption, the tide not disturbing the almost uniform level of the sea in this region. He told me also that scientific men from various countries have visited this well, many of whom have cut inscriptions on floating substances, which they have sent into it; but, although the waters in the bay and surrounding the island have been anxiously watched, and the island itself explored, nothing ever sent into the well has been known to reappear.

If there were any geysers in that part of the country, it might be concluded that they ejected the water received by the so-called well, but there being none, the matter is not so easily settled. Is it probable that the water may be conveyed into a huge cavern somewhere near the crater-passage of one of the volcanoes of the Mediterranean, and, there being converted into steam, is carried off by the passage? J. W. RODWELL.

DOUBLE STARS.—CORRECTION.

[4319.]—There is an error in the place of the new double star, f δ Corvi, mentioned in my last letter. This star is Lalande 23536 (not 23488), and its right ascension is 2m. 50s. greater, and declination 10′ in excess of the latter. The magnitude in Lalande is 6½, but it seems nearer 7 now. It is brighter, however, than L. 23488, which is noted in the same catalogue as 8 mag. As stated, the double is the most northerly of two stars of the same right ascension, and is easily found from δ, which precedes, 5m. 50s.

Chicago. S. W. BURNHAM.

DR. CARPENTER AND PERSPECTIVE.

[4320.]—I HAVE been surprised that none who have taken part in this controversy have mentioned Cruikshank's attempt to picture a *converging giant*. Falling into the same mistake as Dr. Carpenter, Cruikshank reasoned that a *very* tall giant should be pictured with his "upper works" somewhat reduced, since his head (for example) must be further away than his feet from an observer of ordinary size. The effect, of course, was a complete failure. The picture of the giant represented him monstrous in more respects than mere size.

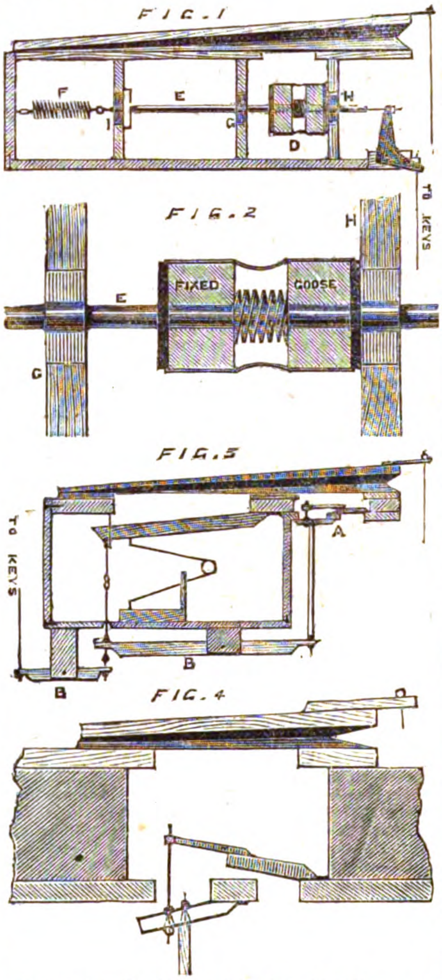
I must demur to M. Paris's remark about pictures being compromises, understanding that remark to apply to perspective. As to colour, shading, and so on, there must always be some degree of compromise, but the perspective of a picture ought to be mathematically exact. There is only one point which is conventional, and that is, that the plane of projection shall be regarded as vertical. (This holds, of course, even when a picture lies on a table or desk; it is *understood* to be vertical.) This rule renders it mathematically necessary that all vertical lines shall be drawn parallel, no matter where the point of sight may be. More generally, all lines parallel to each other, and also to the plane of projection, must be parallel in the picture. Thus, if an artist is drawing a long horizontal row of equal houses, placed in a direction square to the line of sight, he must draw the roof-lines and basement lines parallel and horizontal. Dr. Carpenter's reasoning would indicate that these lines should converge, *as well to the right hand as to the left*, which is, of course, out of the question.

The fundamental rule in perspective—strictly in accordance with the mathematics of the subject—is that scale depends on the relative distance of objects from the plane of projection. Under ordinary circumstances this amounts very nearly to saying that scale depends on the relative distance of objects from the eye; but in cases such as that considered by Dr. Carpenter there is a difference.

RICHARD A. PROCTOR.

PNEUMATIC LEVERS FOR ORGANS.

[4321.]—As there are many of the subscribers to the ENGLISH MECHANIC who take great interest in organs, I venture to send you sections of two pneumatic levers, thinking that they will be acceptable to many readers. The construction of them presents as great a contrast as, I think, can be found in similar contrivances. Drawings of these were shown to me by a person who had been employed for many years by a celebrated German organ builder.



The most noticeable, and in fact chief feature, of Fig. 1 is the great simplicity and ingenious application of the valve D. This valve is composed of two round pieces of wood, each of which is faced with soft leather; one of these pieces (nearest the hinge of the bellows) is fixed to the sticker E, the other is loose, so as to work easily to and fro on the sticker. These pieces are connected at a distance ½in. apart by a strip of leather (split skin) glued round the circumference of each of the pieces; and a light spiral spring is placed between them on the sticker. The object of this is that the valve may accommodate itself to any little variation in the working of the key action. This contrivance forms both the supply and escape valve. When the key is not pressed down the spring F draws the fixed surface of the valve to the hole at G and prevents the wind from entering the bellows, while the hole at H allows the wind to escape out of the bellows, when the key is not held down. The sticker E is pursed at the hole I. Fig. 2 is an enlarged section of double valve at D. Fig. 3 is a very complicated piece of mechanism; its absence of simplicity is its chief feature. The double escape valves A are particularly objectionable, as are also the two backfalls, the latter take up so much space, and are very liable to make the key action noisy. Fig. 4 shows escape valves; enlarged section at A, Fig. 3, the valves in contrary position. Both the sections show the levers with the key pressed down.

PNEUMATIC LEVER.

SOLAR EYEPIECES.

[4322.]—I HAVE been much interested in reading the letters of the Rev. Mr. Berthon and other correspondents on solar eyepieces; and as the subject is by no means yet exhausted, perhaps a few remarks on my own experience may not be altogether uninteresting to your readers. Your valued correspondent "A Fellow of the Royal Astronomical Society" will, I think, forgive me for pointing out a remark in his letter (4223, p. 273) which surely must be a mistake. In comparing smoked field lenses with silvered ones he remarks, "Absorbing light and heat by minute solid particles. In the one case they are of carbon, in the other of silver; but the principle is the same." With smoked lenses the light and heat are undoubtedly absorbed, but with silvered ones the greater part of the light and heat must certainly be reflected—a most important difference of principle. I formerly used smoked field lenses for several years. They defined beautifully; indeed, I doubt if it is possible to surpass, or even to equal, the definition of a Huyghenian eyepiece which has the front surface of its field lens smoked. But there are the following serious objections to this form of eyepiece:—

1. It is by no means easy to obtain a perfectly level surface of smoke on the lens, especially if the eyepiece is of low power, and the lens consequently large. There is also great risk of fracturing the lens in the process of smoking. 2. If the most minute particle of smoked surface comes off the lens, bright dazzling rays diverge from the point in question over the field of view, and the eyepiece is practically useless till a new surface of smoke is deposited. This happens incessantly, for the intense heat of the solar rays in the focus of the telescope usually causes fragments of the smoke to fall from the lens within the first half-hour of using. 3. The smoked surface being black, nearly the whole of the light and heat is *absorbed* by the field lens, which consequently becomes intensely hot, and very often splits.

The continual expenditure of field lenses, and consequent trouble of grinding new ones, and the lenses so often requiring to be smoked just when a favourable moment for observation occurred, caused me to abandon these eyepieces, in spite of their fine definition. I now use Huyghenian eyepieces with coloured lenses—the colours of the two lenses so combined as to produce a white image. By this arrangement I obtain a clear white image of the sun upon a very deep blue sky, and the definition is quite satisfactory. This form of eyepiece, however, has its objections. In my lowest power, the field of which is exactly the size of the sun's image in the telescope I use, I have had no less than three field lenses split, owing to the absorption of the solar light and heat; but no accident of the kind has happened to the two higher powers. When a white image is produced, the chromatic dispersion of our atmosphere produces coloured fringes round the solar spots when the sun's altitude is less than about 35 or 40 degrees. When the sun is in this position, a reddish orange fringe is seen along the upper limb of the sun (with inverted image), and a bluish violet one along the lower limb, the right and left limbs being free from colour. As the spots are black (or bluish black) on a white ground, the position of these fringes is, of course, reversed—the orange fringe being produced on the lower portion of the spot, and the violet fringe on the upper portion. I am convinced that these fringes are much more strongly developed in rainy weather, when our atmosphere is charged with moisture. In such weather, when the sun's altitude is not more than 15 degrees, the colours are sometimes so violent as nearly to destroy all definition. At first I tried to get rid of the colour by tilting the eye-lens in the manner adopted by our Astronomer Royal in his correcting eyepiece; and although this improved the definition very much, I could not *totally* get rid of the colour; but I found another way of doing it as follows, without altering the eyepiece: If, when the sun's altitude is low, the upper or lower limb be brought into the centre of the field, the characteristic fringe will be seen. If the eye be now gradually lowered, the fringe will be seen to become narrower until a point is at length reached where the fringe completely disappears, and the limb is quite free from colour and sharply defined. By carrying the eye lower than the achromatic point, the fringe reappears of the complementary colour; where the orange was at first it now appears violet, and *vice versâ*. In the same manner, all the colouring round the solar spots may be quite got rid of. Numerous printed observations might be quoted where observers have noticed colour round the spots, or round Mercury in transit, without apparently knowing what produced it; but had they looked through the telescope a little below the centre of the eye-lens, the colours would probably have vanished at once.

I have not yet tried the silvered lenses recommended by the Rev. Mr. Berthon, but from the correspondence which has appeared I infer that nearly the whole of the light and heat is reflected. As but little is absorbed, the lens cannot become unduly heated, and consequently cannot split; but I think it probable that silvered lenses will ultimately be found to fail, from the same cause as the smoked ones—viz., minute particles of silver coming from the lens.

In No. 390 of the ENGLISH MECHANIC is an article on "Solar Microscopes," in which the writer explains a method of separating the rays of heat from the rays of light by taking advantage of the smaller refrangibility of the heat rays. Could not something be done in this direction with solar eyepieces? If the rays of heat could be got rid of, the rays of light could be easily managed.

W. A.

THE HOWE SEWING MACHINE.

[4328.]—The Howe Machine Company, established by Elias Howe, jun., original inventor of the sewing-machine, make three varieties; one kind, the A, B, and C, being table machines nearly alike, but differing in size; the D, arm cylinder machine; and the E, a large cylinder arm machine, all specially adapted for boot work; the latter making the nearest approach to the hand and boot closing stitch, the holes made by the needle being filled well up with the silk or thread. This is accomplished by drawing out the needle, the thread is then pulled through the leather, instead of allowing the needle to remain in while the thread is passing through, which, of course, must make the hole larger; although the best work from the E machine is seldom to be met with even in high-priced boots. It is, however, deserving the attention of all who like the very best work. The machine called the "Howe" has been imitated by many makers, with more or less success; the newest form is represented in Fig. B, and one of Elias Howe's earliest machines, the A size in detail in Fig. A. The figures indicate the corresponding parts. 1 is the bed, 2 the arm, 15 the outside face plate. Fig. A shows the top side of bed 1, shuttle race, and holes, with the four screws for fixing the arm 2 to bed. Fig. B shows the under side of bed 1, and the position of the working parts, 179 the main shaft supported by brackets cast in the bed. In the early machines, no allowance was made for the wear of the shaft holes; in the new, caps are placed on the bearings so as to allow for refacing when worn; two screws to each cap keep them tight. On the right hand outside the bracket is the driving pulley 13, the right hand cam 52 works the needle lever 48, and 49 its stud being the centre from which motion is communicated to the needle bar 40. The left hand cam 74 is the shuttle cam, which gives motion to the short arm of the shuttle lever 78, which is pivoted on its bolt 79, riveted in the bed, it has a washer and pin to keep the shuttle lever in place. Outside the left-hand bracket is a collar, 180, set up to prevent lateral play of the shaft.

Howe Wheel Feed.—This feed mechanism consists of 24 separate parts, besides the presser 8 parts; when the machine is made to lift the presser at each stitch so as work patterns, 12 pieces additional are added, making a total of 44 pieces for the complete feed mechanism. Instead of 12 pieces for the *vibrating presser* 5 pieces will serve, as shown in Fig. A, 300. The face plate 15 is shown with its top screw hole enlarged on the inside, and a slot cut to the top; in this is placed the standard 300, the face-plate screw 24 passing through its hole, keeping all firm together. On the top of the standard is pivoted a lever; its curved end is driven downward on the descent of the needle bar, by the thread-guide 43 striking on the curved end of the lever, its other end then raises the presser-foot 186 placed on the presser bar 56. The top end of the presser bar is fitted with either a bracket and adjusting screw; or the top end formed into a screw to receive thereon, a nut with a flange which the end of the vibrating lever strikes and raises. The nut serves the purpose of regulating the height of the lifting of the presser-foot at each stitch; a set-screw in the top of the nut prevents unscrewing. Any Howe machine may be cheaply and simply improved this way; it makes more noise, but acts effectively, and can, by unscrewing the nut, be disconnected so that the foot is continually on the work. This improvement of a *vibrating-presser* to the Howe Machine was first made in London, and made it more popular in the Exhibition of 1862. The Howe feed must be kept clean, and have the patient study of any one determined to master the machine, and to prevent the delay and expense of going to a mechanic to regulate it. The feed-wheel stud 163 has on it a collar between the feed-wheel and bracket; the bracket has a vertical slot, and the stud made flat to fit it; on its inner end is a washer and nut, which by means of a spanner can be set fast, when the feed-wheel is placed in the best position for stitching, or just above the needle plate. When this is done, then the feed-clutch lever 169 may be put in its place (when all is taken to pieces to clean, it is advisable to put all the parts together, and test

FIG. B

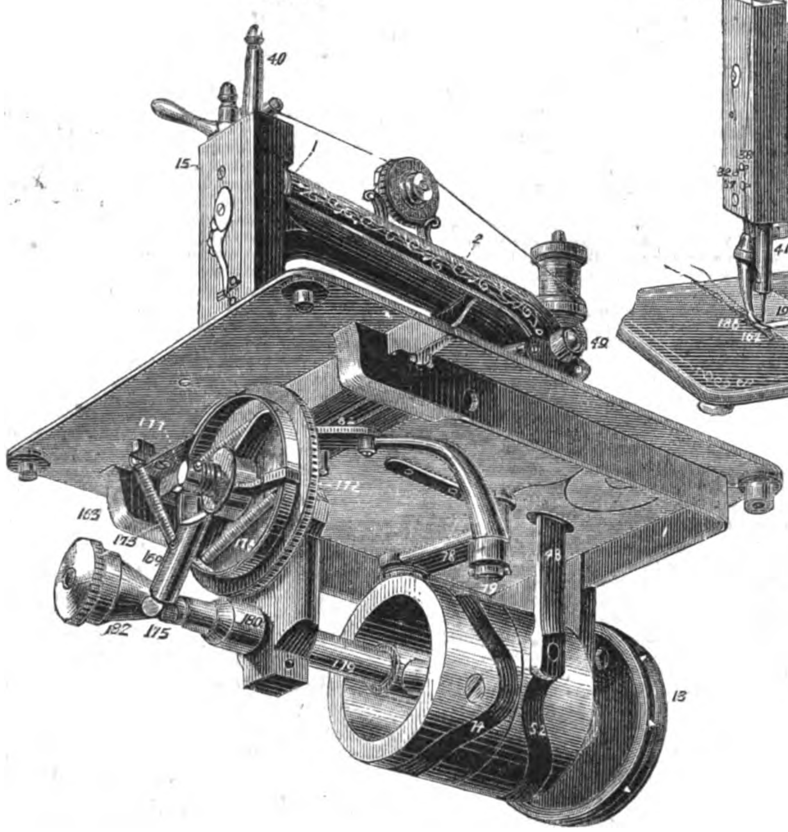


FIG. D

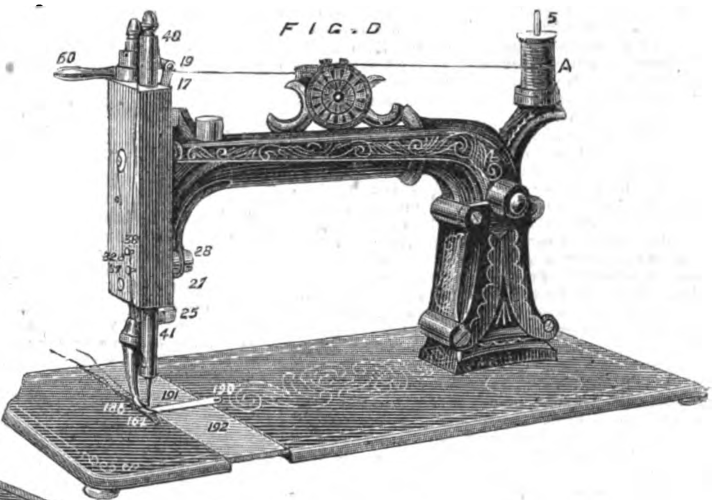

FIG. C

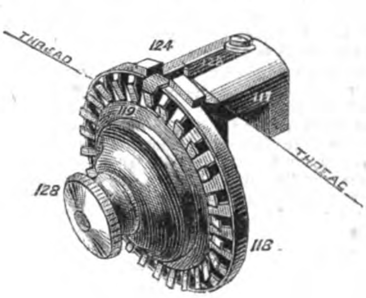

FIG. A

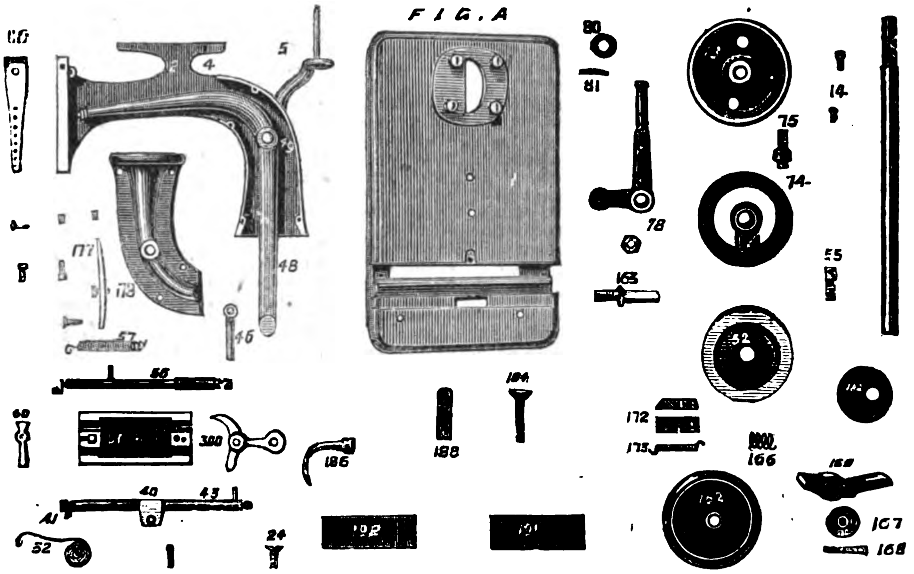

FIG. E

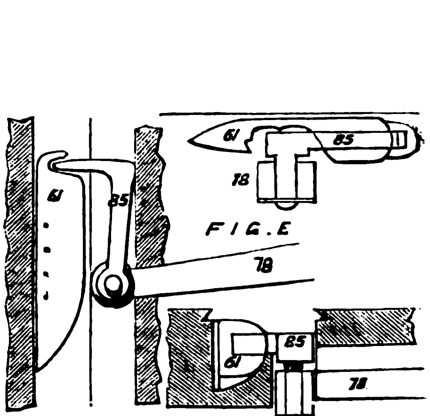


them, before fixing in the machine). Now put in the two feed clutches 172, and connect their springs 173, to the feed clutch lever; holes or hooks are arranged for the eyes on the ends of spring to connect to. Now put on the feed clutch lever washer, its spring, and press in while putting the pin through the hole in the end of feed wheel stud. Now try if all moves very evenly, and easy, no jerks; test by moving a little at a time for a short stitch, and if the feed clutches are drawn back by the springs, lively and with certainty, if not try one at a time. This part of the machine—the feed clutch—wears sooner than other parts, and it requires a mechanic to repair it, or to get a new one from the maker. The slotted part in the feed clutch must be hard, or it will not grip on the band on the side of the wheel. This band must be kept very clean. If oiled in parts only it will make short and long stitches. On making certain all is right set up the screw of the feed brake 177, until the wheel cannot be pulled backwards by the feed motion. Get the hand to judge by practice the strain required; for want of this knowledge many workers strain and wear out the machine.

All being right, set the feed cam 182, Fig. B, towards the feed wheel, and the feed rider 175 will be made to operate the wheel. Connect the feed clutch lever spring, 173, to its hook under the bed, and test it. Now advance the feed cone cam 182, by turning its nut, 184, and all is ready for work. The feed cone cam is kept in its place from turning on the main shaft by a slot, in which slides a screw along with the cam to prevent its twisting. This description applies to the new feed. The old feed differs only in the cone cam part, 182. Instead of this silent motion the action in the old is by an eccentric, 182, in Fig. A, fixed on the end of the shaft, so as to act on the lower end of the feed clutch lever, 169 (on a solid part instead of a hole and its rider 175). The upper or short end has a projection which can only move the length of the stitch as regulated by a screw 184 A, placed under the bed in front of the lever. The parts are shown detached in Fig. A. The durability of this feed lever is very good, if the eccentric is oiled in the old machine. As it works well, boot machinists care little about the noise of the feed. Indeed, all well constructed machines, however noisy, maintain their place in trade use, over others recommended as silent. Noise with plenty of good work done is cheerful, but silence with much trouble in working, or slow speed and poor earnings, is condemned by employers and employed.

The Howe Shuttle Mechanism consists of 13 parts in the new, Fig. B, and 11 parts in the old, Fig. A and E. In the latter the parts are shown detached, the shuttle 61 has on its butt end a hook or tail piece; between this hook and the butt end the shuttle driver is fitted, leaving room for the thickest thread to pass easily between the shuttle, 61, and the hook driver link, 85, Fig. E, which, instead of sliding, is simply carried direct by the shuttle lever 78; it has on its longest end the hole to take the stud of the shuttle driver, so that it will swivel slightly, and is thus kept guided by the shuttle race in a straight direction, while the end of the lever 78 makes a curved motion. To prevent the driver lifting out, a washer and pin below the lever keeps it in place. The shuttle lever works on a stud, 79, as a centre, and is kept up to its place by a washer and pin. The stud is riveted into the bed of machine. On the short end of shuttle lever is a hole into which is riveted a steel stud, on which revolves the roller, actuated by the groove of the shuttle cam 74, adjusted on the main shaft by a screw. An inspection of Fig. B will show the parts in working position, having the same reference numbers as Fig. A pieces. This new shuttle driver is more steady and durable at its work. It will be seen the hook shuttle driver 85, is here replaced by a slide. It has a stud riveted in it to connect to the hole of the shuttle driver link 82, which has its stud working in the hole on the end of shuttle lever 78. The shuttle driver slide is fitted into a groove on each side of the shuttle race, which makes it travel truly. On its upper side is fixed the shuttle driver, and adjusted by two screws so as to work and clear the shuttle. Instead of this plan to work the hook shuttle, sometimes a shuttle without hook is used, and then the shuttle driver is formed to embrace the shuttle so as to drive it from both point and butt end, as in the Singer or Thomas's machines.

The Howe Needle Mechanism consists of 16 parts in the new, B, and 9 in the old, including some of the thread guides. The detached parts are shown in Fig. A, old machine, and all in place in new machine Fig. B. The needle-bar 40 is drilled at the lower end to hold the needle, which is set fast by its screw 41. On the opposite side of the screw a hole is drilled in the bar to guide the thread, but in the new machines separate pieces are attached for guiding the thread and keeping the oil away from it. On the top of the bar there is a hole or short tube to guide the thread, and carry it up and down with the bar. About the middle of the bar a projection holds a pin and forms a joint for the needle-bar piston 46. The piston end fits into the hole in the end of the needle-lever 48. This is a very durable joint, but it is badly applied, the centre pin and strain not being in the centre of the needle-bar; it is not only harder to work, but throws the wear to the sides of the bar. The needle-bar works on a centre stud 49, and is bent downward, passing through the hole in the bed, to the needle cam 52. In the cam groove fits a roller revolving on a stud riveted in the needle arm.

The Howe Presser Mechanism consists on 9 parts in the old, and 10 in the new machine, Fig. B; but to lift the presser so as to stitch patterns, or work figures or designs, about twelve pieces more are added. For toe-cap flowering this is needed. Without this lifting the presser or feeder at every stitch made, there is a great stiffness in handling the work, yet the bulk of modern machines, especially for family use, are so made, to avoid expense sometimes, but mostly because of the impossibility of attaching mechanism that will keep in order. For general work there is a decided advantage in the presser lifting off the work, or better still, as in Thomas's machine, and its class, the feeder itself lifting. In this machine the feeder mechanism is certainly complicated, but has only a total of 18 parts, compared with 44 in the Howe. If the same work could be done with 4 instead of 44 pieces, every mechanic would pronounce in favour of simplicity, and every machine-worker would find far less trouble. In practice the repairing of Thomas's machines often require no work to the feed, but the Howe seldom escapes without it. The fact is here noted in its place, and will in due time be compared with other facts to be brought forward respecting other machines, some of them cobbled with leather or wood when new to prevent noise, but such that a few days good work would show the makeshift nature of such contrivances.

The Howe Tension consists of two pieces in the old plan machine. A plate of steel Fig. A 116 with a large hole at the wide end, through which the thumb stitch screw is passed to its hole. At the top, on the right hand side of the arm, or nearest the arm spool pin 5. The spool of thread placed on this pin is passed to the tension-plate, entering a hole in the end, at the right hand of the thumb-nut, then passing its side enters a series of holes, to make friction according to the tension required, the final adjustment being regulated by the thumb-screw pressing the tension-plate 116, acting as a spring upon the top of the arm, Fig. A., the thread laying between the plate and arm is thus pressed with delicacy. It is a good tension, but troublesome to thread through so many holes; to avoid this, the new thread is tied to the used up, and so drawn through all the holes quickly, but it is a waste, especially felt when silk is used. The new tension, Fig. C, avoids this; it consists of 12 pieces. The stand 117, back plate 118, tension-wheel 119, its edges are formed somewhat like saw-teeth being bent alternately on opposite sides, which leaves a V space for the thread to lay in. The thumb-nut, 123, regulates the tension when screwed by pressing on a washer, which acting on pad or cloth washers, one each side of the tension-wheel presses thereon to check its turning, and is thus graduated to the nature of the work.

Ready for Work.—Fig. D represents the upper side of the new machine, with the manner of threading it ready for work. 190 shows the throat-plate screw in one end of a narrow steel-plate, in the other end is the needle hole, covering the needle-slot in the shuttle-race. To suit different sized needles or work, there are two throat-plates, and easily changed. By sliding out the shuttle-case cover, 192, the shuttle can be removed or replaced. The needle bar set-screw secures the needles, the bar slides up and down between a front and a back cap-plate, the back cap-plate being adjusted to the arm, so that by turning, and adjusting cam 27, and its screw 28, the needle-bar and needle can be moved nearer to or from the shuttle.

Thread "Take-up."—At 32 is a coiled spring wire, at its upper end screwed against the cap-plate, its lower end having an eyelet. 37 and 38 are guide pins. From the spool, the thread is passed to the tension, Fig. C; draw it under its check spring 123, that rests on the top of the tension stud 117, carrying the thread back until it rests against the check spring 124, then pass the thread around the outside of the tension wheel 119, once, or if fine twice, then through the thread controller 19, Fig. D, and thence into the slot at the top of the needle-bar 40, thence downward under the thread guide pin 33, and through the take-up eyelet 32, and back again to the right of the lever pin 37, and thence through the guide at the end of needle-bar, and, lastly, the eye of the needle. The shuttle placed in position, one turn of the machine will cause the shuttle cotton to be brought up through the needle hole, and lay in the position shown ready for working.

[*The formation of the lock-stitch will be explained hereafter, when describing a more simple machine, to avoid perplexing the reader needlessly.*]

Before leaving the Howe take-up, it is well to notice that it is copied in many machines, but for domestic use it is certainly much too liable to derangement by bending, and it will cause "slip-stitch" and other troubles. The strain on the thread is regulated by setting the screw when the take-up eyelet 32 is placed away from the pins 37 and 38, about 1in. to 2in. to the left. On pulling into place the spring must be tested by the fingers, until experience enables it to be done properly, otherwise to meddle with it will cause very great trouble indeed. The eyelet should be set for the medium thickness of fabric; the travel varies for thick and thin. One of the newest improvements is to make a self-acting compensation for this by causing a pin in the presser bar to act upon the side of the take-up, so as to press it forward when the presser bar is lifted by the extra thickness of fabric. This is a welcome improvement, as it prevents slip-stitch or breaking thread.

A review of the foregoing description cannot fail to show the contrast between one of the earliest and one of the most modern Howe machines. While Figs. A and E illustrate the principal parts in detail, it is necessary to observe that all the items, such as screws, pins, &c., are not shown, nor the holes in the parts, so as to enable any one to make the machine from this description. It is not a convenient machine to make, too many special tools being required for the purpose, and to be of any service the Howe machine must have good workmanship, especially the modern machine, and the extra number of parts in it would make the task a severe trial to put so much work in a machine for family sewing. Figs. B, C, and D, if shown in detail, in all its parts, would convey an idea of immense labour. It is usually supposed that Americans aim at simplicity in construction, and economical production, but here, as in the Singer machine, we have examples to the contrary. Having spent thousands of pounds in factory and special tools, any change would involve a great outlay, and no doubt it has been considered better to continue to make the old plan, and add costly improvements, rather than make an entire change on a new system.

Without counting shuttle and winder, in the old machine, Fig. A and E, there are 80 separate parts, and in the modern machine B, C, D, with vibrating presser, 130 parts. If the parts were merely castings containing but little work, then this complication would be an objection, but as nearly every part is machined, and some passed through several machines, the amount of labour far exceeds what is necessary for a sewing-machine; and on consideration it really is astonishing to find such extravagant samples from the Americans, who are usually allowed to be above all other makers throughout the world in devising and making the most simple and economical articles, especially in light domestic machinery. The Wheeler-Wilson machine is an exception to this complication, but its power is so limited that it cannot be fairly compared with the Howe and large Singer machines, which are so well known for doing heavy work. The Howe class machine, no doubt, is doing nine-tenths of all the boots made, besides other work; the Singer class is also doing heavy work in various manufactories. The fact of this extensive and constant employment will be sure, in no distant time, to cause manufacturers to consider the advisability of adopting machines simple in construction, cheaply made, less liable to expensive wear, and equally effective.

Some manufacturers consider three years as the duration of a machine, and then replace the old with new, to keep up the quality of the work, and save the enormous cost of repairs such complication entails. When they are able to discover machines may last four times longer, and be equally, or more effective, because of simplicity and scientific construction, then a great change will occur in factory management. By means of the English Mechanic conveying throughout the world valuable information on this subject, and reliable, because open to correction if error be advanced or misstatements made, the truth may be simply arrived at, while the information obtained by the perusal of conflicting trade circulars is comparatively useless, seeing nearly all claim to vend the best machine, and such statements have influenced many to buy machines that are remarkable chiefly for the trouble they give the worker, and their money-wasting properties. When sewing-machines become as common as clocks, and as commonly understood, better things for the users will appear; then puffing circulars and big column advertisements will diminish, merit will stand secure, the best and cheapest will be sought and obtained, while the useless disappear. A Practical Man.

"P. SANTALINUS" AND HIS CORALS.

[4324.]—"P. Santalinus" may depend on it that it takes not much "care" (letter 4240, p. 277) to avoid mentioning these "reef-building corals." Why should I mention them? If there be evidences at what rate any reef is growing, then at what rate it formally grew, at what rate the growth has been accelerated or retarded at each period for the last 80,000 years (or whatever age he is going to argue about)—evidences as to what kind of interruption a fall of fresh water would cause (they must have rather heavy falls from tropical rains twice every year)—evidence of the pressure it would take to arrest them, of how long their growth has been unbroken, and a few other points, it may throw some light on the Deluge, possibly on its amount. But whatever evidence is *known* must be somewhere producible or recorded. Why does he not tell us where? That would surely be a less waste of your paper than asking me if I expect him "to believe" this or that. I have no doubt he will believe with a very capaciously "digesting faith" whatever he likes; but what on earth can it matter to any one else what a man "believes," who is capable of believing hills and vales rounded off, with their convex and concave sweeps of half a mile to a mile radius, by frost cracking the strata (p. 220, letter 4108)? His last letter (p. 277) seems to imply we have somebody who has lived upon and watched certain coral reefs long enough to "report from personal knowledge," how many "thousand years" they have grown without a break. Of course Agassiz never said anything so absurd. He has, probably, discussed evidences about the said length of growth, and these would be matter of scientific interest, and proper to explain in a "*Mirror of Science*." But if he used the language of "Santalinus" above, that is in no sense "*Science*," but *Dogma*; and the acceptance thereof is *Religion*. Whatever is taken thus, on what some one "reports from personal knowledge," whether the "personal knowledge" be that of Agassiz or of Brigham Young, or of Elder Harry, pastor of the Peculiar People, is *Religion*, a totally distinct thing from science.

In the beginning of his letter "Santalinus" appears to know this difference, because in the matter of the Alpine and Arctic plants, he imitates scientific method. Before any such Alpine facts, however, become "subversive" of anything of mine, he has missing links to supply. First it has to be shown that a new Alp, now upheaved among lowlands, would remain some time (indeed 50 centuries) without those same peculiar plants. In the absence of opportunity for experimental proof of this, I can only suggest the nearest analogy at hand. Many plants, he probably knows, are peculiar to the sea-side fields, except that they also grow around salt springs, natural or pumped up for salt-works. In the heart of Germany are many salt-mines and works, always with these plants abundant; and when a new mine is opened, be it hundreds of miles from such plants, no sooner has the brine been at the surface one season, than the sea-side plants appear. They are as incapable of growing in other inland fields as the Alpine and Arctic plants in a rich lowland, or rather more so. For Alpine ones could probably thrive in far warmer climates if not *crowded out* by the competition of the many fitter to those climates. Well, you see, most plants have their seeds nearly microscopic, to be conveyed everywhere. Arctic and Alpine ones especially have them minute, abundant, and transportable; and their non-growth in a given place no more implies the non-arrival of their seed there than the absence of sea-side plants in Oxfordshire implies absence of their seed; or than the (reported) existence of but one plant on London Bridge, a cherry stock, proves that no more cherry-stones than one have been thrown there.

What Mr. Wallace means by "a perfectly distinct fauna" in two islands, I cannot tell. In the only accurate sense I can give the words, namely, that no animal should be common to them, I doubt if any two countries on earth have been proved to have a "*perfectly* distinct fauna." Perhaps, the most striking fact of this kind is that stated in Johnston's Atlas about Borneo and Java, that on the former (the largest equatorial island, largest but one or two on earth, and absolutely largest *wholly intertropical* piece of land) no snake has yet been found; while Java, its next neighbour, has the *most* ophidian species (both harmless and venomous) of any island known! But I fail to see the bearing of such facts on the Deluge questions.

E. L. G.

ROSCOE'S "HATFUL" OF COMET.

[4325.]—ON referring to Roscoe's "Spectrum Analysis," second edition, I find, as I suspected (p. 277), that the playful (or rather buffoonish) expression quoted by "Sigma" (let. 4193, par. 11) is modified by something that would have opened any reader's eyes to its absurdity. Copying one line further would have done so, and accordingly the "verbatim extract" carefully stopped short without this line. "We do not know," wrote Roscoe (p. 292), "whether there is as much matter in this comet [Brorsen's] as would fill this room, or as much as would fill one's hat; and *this* amount of matter [*what* amount?] is spread over an enormous space. The diameter of this comet has been determined for me by Mr. Baxendell, who tells me that it is about 60,700 miles—an immense space over which to spread so small an amount of substance." The rich Hibernicism of this whole extract, when one comes actually to write it down, is really too much for me, and leads me to apologise for the insinuation that he was only "playing the buffoon *as much* as" our "Sigma." I must frankly acquit "Sigma" of rivalling, or as yet approaching, this bit of professional logic. The cream of the fun is that instead of a measure of mass,—instead of saying "we know not whether there is" a ton or a hundred-weight, Roscoe pitches upon that sole kind of measure, for the cometary matter, which *was* known. The only thing popularly known about it was, not indeed how much matter, but what space it filled,—not how much more than a ton, or a billion or a trillion tons (each equally probable), but simply and directly, how much more than a hat or a room it "would fill"!—namely, according to his computing assistant, 60,700^3 spherical miles. All that he can say of the matter, dense or rare, is that it *does* fill these 60,700^3 × ·5236 cubic miles. "And this amount of matter" (namely, whatever occupies these billions of cubic miles,—we know not whether much or little for them)—"is spread over an enormous space"! "Mr. Baxendell tells me,"—60,700^3 spheric miles,—"an *immense* space over which to spread *so small* an amount of substance"! He had just as much ground to say, "a *very little* space wherein to compress *so great* an amount of air or vaporous substance"!

For aught that any astronomer knows, that very comet's "*inappreciable*" mass exceeds an equal bulk of the very air the Professor was then breathing. In Herschel's "Familiar Lectures" (p. 132) it will be found that only two comets hitherto, Lexell's and Encke's (this is neither of them), have approached near enough to planets to have made their masses appreciable had they exceeded (according to Mrs. Somerville and Humboldt in "Cosmos") a 5,000th of the earth's mass, which latter I find in Chambers's "Descriptive Astronomy" set down as 6,069 trillion tons. Either of *the se two* comets then, for aught yet known, may contain *one* trillion tons, and *any other*, as Brorsen's, several trillions! and still have their mass *inappreciable*.

But I need not have said (p. 277) that possibly the buffoonery about the room or hat might be logically allowable, that possibly the comet is not *known* to contain more. A heavenly body, though of mass "inappreciable," must, to continue in its orbit, even the few days it is observed—much more to make, like Brorsen's comet, whole observed revolutions—have very many times the mass of the same volume of cosmic fluid or ether. Now, Sir William Thomson showed in a paper in the *Edinburgh Philosophical Transactions*, 1854 (p. 57), "On the Possible Density of the Luminiferous Medium," that its density cannot be below a limit he there computes; and he says "it is also worth observing that the luminiferous medium is enormously denser than the continuation of the terrestrial atmosphere would be in interplanetary space, if rarefied according to Boyle's law always." His conclusion is, "A pound of the medium, in the space traversed by the earth, cannot occupy more than the bulk of a cube 1,000 miles in side. The earth itself, in moving through it, cannot displace less than 250 pounds of matter." That is not weighing the ether by its *gravity*, observe (since it must be non-gravitant) but its *inertia* density. Well, then, the comet, occupying 60,700^3 × ·5236 cubic miles, or ·5236 × 60·7^3 of the above cubes, you see the very cosmic fluid or ether occupying that space must not be under 60·7^3 × ·5236 pounds—that is, close on 224,000 pounds, or 100 tons; and the comet's own mass, constantly overcoming this inertia, and being not mere inertia, but also visibly gravitation downward, could not be under a very great many such hundreds of tons, without being rapidly retarded and brought to a stand-still. These, *at least*, Professor Roscoe has to get into his room or hat.

E. L. G.

[It is really a pity that so able and so industrious a writer as "E. L. G." should so freely utter provocative words. Why call "Sigma" a "buffoon" or "buffoonish"? We believe "Sigma" to be an earnest and sincere searcher after truth, as much so as "E. L. G." It is the easiest thing in the world to call names and use exasperating language; and the lowest porter in Covent-garden, as we can testify to our sorrow, can beat "E. L. G." in that line any day. But it is not so easy to speak with propriety and precision. Wisdom, as a rule, is moderate, and strength, as a rule, is calm. "E. L. G." has launched a theory as to the cause of the Deluge as recorded in the Old Testament, which naturally evokes spirited criticism, and he must not expect that every one who opposes him is necessarily a fool, or hostile to him personally. As he gives hard blows to others he might fairly expect hard blows in return. He seems always ready "to strike out from the shoulder," but unprepared for reciprocal action. More than once "E. L. G." has wisely deprecated wasting our space. Might he not economise fragments of it, and fragments of correspondents' temper as well, by a less generous use of inevitably irritating epithets? If he did so his wealth of learning, his courage, his enthusiasm, and his "devouring activity," would command the admiration of a still larger circle of readers.
—ED.]

ON THE RIFLING OF GREAT GUNS.

[4326.]—NOT being a scientific artillerist, I shall be greatly obliged if "Artillery Captain," or "any other man" who knows, will correct any errors I may inadvertently have put forth on this subject, the practical importance of which—until all men become Christians—seems to justify its ventilation.

I believe most of our great guns are rifled on the American plan, otherwise known as the French or Woolwich system of increasing twist, the advantages (?) of which seem to be very problematical, for it is open to the objection that the rotation of the projectile depends on the employment of soft metal studs, usually inserted in holes bored in the shell, which must necessarily weaken its walls, unless the casting be reinforced where those holes are drilled. Increasing twist is also objectionable; because if the projectile be guided by two series of studs, one of which is necessarily in practice some distance behind the other, they cannot both be made to fit the grooves of the rifling, simply because the cast-iron shell is a trifle too rigid to enable the gunner to twist it while it is being rammed home. To enable shells thus guided to be introduced and thrust down the chase, the front series of studs is usually made considerably smaller than the other, so that nearly the whole work of rotating the projectile is thrown on the hinder series. This prevents the twist from being increased sufficiently to insure the rotation of shells whose length much exceeds two and a half diameters—in other words, it limits the weight of the projectile which can be employed for a given calibre. I think this a fatal objection—not to mention that drilling holes in shells and fixing studs therein must be more costly than casting them on the shell itself, which might be done were it not that soft metal is a necessity for guiding shells in guns with increasing twist. It is not a necessity when the twist of the rifling is uniform.

I have taken some trouble to learn what the advantages of the increasing twist are; but I fear, like the Spanish fleet which could not be seen because it was out of sight, those advantages are quite hidden from both intellectual and corporeal vision. "Out of sight, out of mind" was the good old practical rule, especially in the case of our friends; but the advantages of increasing twist, although to me quite out of sight, seem by no means out of the minds of those who direct the construction of our great guns (probably because their minds are characterised by a considerable, not to say an "increasing" twist), but however that may be, the twist they employ, although increasing, certainly is not enough for modern long ranges with greatly elongated projectiles.

Probably the original "Yankee notion" we imported was that if the grooves had little or no spiral inclination near the chamber, putting the shot into motion would be less resisted, which is quite true. It is also quite true that this is not (when proper powder is used) of the slightest practical importance. Were the greatest pressure of the gases, into which burnt gunpowder is converted, developed before the shot commenced to move along the chase, it would be no more than reasonable to employ some means (not necessarily this means) of diminishing the resistance to its motion, or what is far preferable, preventing so rapid development of pressure, which is the very thing we do when we employ prismatic or pebble powder. Practically, nothing of the kind happens; the maximum of pressure does not obtain until the projectile has travelled some distance, usually from half to two-thirds its own length, so that the very slight increase to its forward motion, which results from making the twist of the rifling as great at the chamber as it is now made at the muzzle, would not dangerously increase the strain on the gun, in fact, it would enable us in practice somewhat to diminish that strain, for a smaller weight of powder would expel the projectile with the same velocity it now obtains, because a uniform twist does not resist its expulsion nearly so much as an increasing twist does. N. B.—This fact was proved by many experimental trials.

Increasing twist is a common cause of the gun's destruction. Several of the American "Parrott" guns thus rifled had their muzzles blown off at the siege of Charleston, and one 8in. cast-iron gun employed at Sebastopol suffered the same rather rapid method of shortening its chase, but it is some comfort to benevolent Christians (who invariably do good to those who despitefully use them) that this "Whistling Dick," as our men designated it, afterwards did very good service as a howitzer.

I have already mentioned that among the evils of increasing twist, diminution of range is one, and not the least. Burning the same weight, 25lb., of the same powder, Mr. Scott's 7in. gun expelled its 110lb. shell with a velocity of 59ft. per second, greater than the Woolwich gun of the same calibre did; it would consequently have struck a blow 133 foot tons heavier—or what comes to much the same thing, it would have sent its shot considerably farther, for *cæteris paribus* range depends on the velocity with which the projectile leaves the muzzle of the gun.

We are told Sir J. Whitworth has succeeded in casting shells which fit his new gun with sufficient accuracy just as they leave the mould, or rather, I opine, as they leave the trimming shop. "What man has done man—*i.e.*, another man—can do," so as soft studs are not a necessity for guns rifled with uniform twist, I presume Woolwich can rival Manchester, and cast shells with continuous spiral ribs on their outer surfaces. Such ribs, being part of the casting, rather strengthen than weaken the walls of the shell, and add nothing to its cost except the trifling additional weight. Probably, however, as the shell, if cast in sand and moulded vertically, would have to be withdrawn spirally, machine moulding would, as usual, be preferable to hand labour, especially for lifting the pattern or model out of the sand; but I suspect in practice metal moulds would be generally employed, and they may be formed in any number of parts required to enable them to be taken away from the casting, even if the latter could not be withdrawn from them by having spiral motion communicated to it; however, I see no practical difficulty in doing this.

I suspect it would be difficult in practice to cast continuous spiral ribs, even in metal moulds, which would fit the grooves of the rifling like planed ribs do, and, as planing is costly, and we can do without it, I think it would be well to cast the ribs with these surfaces, which bear against the grooves somewhat hollow. It may be objected that doing this would convert the continuous ribs into two series of studs; doubtless it would, but they might in practice be very long studs, indeed, so long that there would be no danger of their becoming crushed like soft metal studs are whose bearing surfaces are usually too small to endure the pressure they are subjected to. In conclusion, I beg to inquire if there would be any insuperable practical difficulty in converting Woolwich guns into guns with uniform twist, provided the twist be not increased. Of course, it could be done if they were bored out about the depth of the grooves larger. If this be done, the new bores might have any amount of twist required even for projectiles five or six diameters long; but I fear our guns are hardly strong enough to bear this treatment. They might, however, have new steel tubes forced into the old ones after boring them, and their calibres thus diminished.

THE HARMONIOUS BLACKSMITH.

BILLIARDS.

[4327.]—I BEG respectfully to suggest that a few articles on the science of billiards (if not written *too* scientifically) would be acceptable to many of your readers. I have recently been trying to purchase a book on the subject, but can get nothing between a worthless handbook, price 3d. and a thick tome, price 80s.

H. J. C.

AURORA.

[4328.]—ON June 3, 1872, at 11 p.m., a fine aurora, exhibiting a pale, delicate, silvery-gray light, was observed at Walthamstow. A perfectly vertical rectilineal, but not very broad, streamer nearly coincided with the magnetic meridian. Should any of the numerous readers of the ENGLISH MECHANIC have observed this aurora spectroscopically and will kindly communicate a notice of the lines seen, with a measurement of wave length, the observations may be of service.

While announcing this aurora, I may just note that, from the researches of Loomis, it appears that the number of auroræ has a maximum and minimum about every ten years, and this is confirmed by Donati. It is a singular circumstance that in the period of ten years there are two or three consecutive years during which fine auroræ are seen in places which are not very near to either of the poles of the earth. The heights of auroræ vary from 60 to 160 miles. "What," asks Donati, "exists at these heights?"

W. R. BIRT.

TIME MEASURERS.

[4329.]—LAST month's *Argosy* contains an excellent article on the above subject, and believing that the article is one that will be of interest to many, if not all, of your readers, I give a condensation of it. It states that the probable mode for the men living in the earliest ages to find the time would no doubt be by noticing the movement of a shadow from a rock, &c.; but as the world grew, a more minute division was essential. Pliny said that twelve years before the war with Pyrrhus, a sundial was said to have been erected at the Temple of Quirinus, and this dial served for ninety-nine years, after which one more minutely defined was placed near it. As this would only serve when the sun shone, a water-clock was invented by the Greeks, and introduced into Rome about 195 B.C. The water clock consisted of an earthenware or metal vessel perforated with a hole, and filled with water, and the water dropped into another vessel marked with lines denoting the hours, as the water rose to the level of the mark. In the Athenian and Roman Courts of Justice the water clock was used, the water being in three portions, one each for defendant, prosecutor, and judge. The next mention of a sundial was that erected by the Emperor Augustus in the Campus Martius. In the middle of the third century an Alexandrian invented the hour or sand-glass. King Alfred the Great measured time by wax tapers, marked off and denoting the hour as they burnt from mark to mark. The first clock showing the hour on the dial, was supposed to be one sent by Pope Paul as a present to Pepin, King of France. Then one is mentioned as invented by Pacificus, Archdeacon of Genoa, in the ninth century, that indicated date, day, and phases of the moon as well as the hours. But the most splendid amongst the early specimens of horology was the clock presented to Charlemagne by the Caliph Haroun-al-Raschid. Its case was of brass, damascened with gold, and it showed the hours on a dial, and at the end of each hour an equal number of iron balls fell on the bell, which sounded, and immediately twelve windows opened, out of which proceeded the same number of horsemen, armed *cap-à-pie*. After performing various evolutions the figures withdrew, and the windows closed. The motive power was water. After remarking that it has never been clearly ascertained where or by whom weights were first substituted as motive power, the article adds, the invention must have remained imperfect, as little use was made of clocks in the 11th and 12th centuries. The first allusion to a striking clock is found in the "Usages de l'Ordre des Citeaux," compiled about A.D., 1120. In the eleventh year of Edward I., A.D., 1228, the clock-house, near Westminster Hall, was furnished with a striking clock. In 1286, the first clock was erected in St. Paul's, and in 1292, one in Canterbury Cathedral. In the reign of Edward III. protection was granted to three "orlogiers." An impulse was given to clockmakers in the fourteenth century, and the art from then made steady progress; about this time weights and a fly-wheel began to be made for private use. About the end of the fourteenth century, the spiral spring (a band of fine steel rolled in a drum or barrel) was invented. Watches would now begin to be made. One watch is mentioned in the sixteenth century set in a ring, and in 1572, Parker, Archbishop of Canterbury, bequeathed to his brother a walking-stick with a watch in its head. Henry VIII. had a watch that only required winding up every eight days. Watches were mostly oval in shape and of exquisite exterior, and coffins and death's-heads were also the forms used. A death's-head watch, belonging originally to Mary Queen of Scots, is still extant. In 1540, the fuse was invented. But even in Shakespeare's day pocket dials were much used. In the reign of Charles I., a charter of incorporation was granted to English watchmakers, forbidding any clocks, watches, or alarums, to be imported from any other country. In 1639, Galileo Galilei published his discovery of pendulums, and the pendulum was then applied to clocks. If Huyghens was not the inventor of the pendulum clock, he applied the regulator in the most scientific manner. In 1641, Richard Harris invented a long pendulum clock, and this, or a similar one, was put in St. Paul's Church, Covent-garden. In 1676, Barlow, a London clock-maker, invented the repeating mechanism, by which the hour last struck might be known by pulling a string. The anchor escapement was added by Clement in 1680. In the eighteenth century further improvements were made, and Jno. Harrison constructed a chronometer which determined the longitude within such limits as to procure for himself the Parliamentary reward of £20,000. Other interesting particulars and anecdotes are added, which I have omitted for fear of encroaching too much on your space. I may add that the article is well worth the perusal of all your readers.

Farnworth, near Bolton. FRED. W. BRISCOE.

TIN BOXES TO HOLD COPPERS.

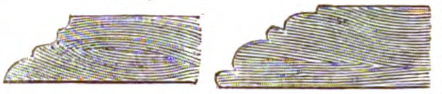
[4330.]—I SEE that in large grocery establishments coppers are counted out in five shilling bundles and tied in brown paper; this system does not give the receiver a sufficient means of checking the amount, as it is awkward to break the paper and count them over again, although the initials of the sender placed on each bundle may be given as a guarantee. I propose that small tin boxes of a cylindrical form, having a hinge at the end or along the side, as most convenient, and stamped with a maker's name should be used, each to have 30 divisions; each division should be large enough to hold one penny loosely.

PHILANTHROPIST.

ORNAMENTAL TURNING.—XII.

[4331.]—HAVING described the mode of turning and ornamenting small table pillars, I may not be out of place if I describe the easiest way to finish off the table by making and turning the top. Procure the wood required for the top, make good joints with best glue, the more joints the better, if good, as that prevents the table top from warping or twisting; when the joints are quite dry (by the way, do not dry the joints too quickly, near a fire is best) plane off the top smooth; then veneer with walnut burrs or ordinary walnut-wood veneer; when dry you may turn the mouldings; if the top be twisted, stand it before the fire a short time, having previously damped the other side, but if the twist cannot be removed by ordinary means, the following process very seldom fails: If the table top is 20in. in diameter, turn a piece of wood 16in. in diameter, as a back board; bore four holes ½in. from the edge, equal distance apart; lay the table top upon the bench, the back board upon the top as near the centre as possible (by the way, a very simple means of so doing is to mark the centre of the top with the compass point, stick in a bradawl minus the handle, carefully lay the back board so that the awl is the centre of the hole in the back board); then fasten the board to the top with stout screws; by that means a table top can be invariably drawn flat, and when the mouldings are turned, kept in a flat position by means of the clamp. I send sketch of two descriptions of mouldings suitable for small fancy as

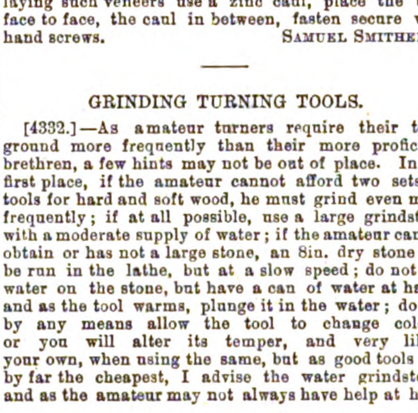
1 2



well as coffee tables. No. 1 is called an ogee and thumb moulding; No. 2 is a double moulding adapted for carving. By the way, a very simple mode of ornamenting such mouldings, where the amateur is not up in carving, is to purchase one or two stamp punches, and stamp the mouldings; if care be taken in the execution of such, a very pretty effect can be had. While upon this subject, I may state for the information of our readers that veneers can be purchased very cheap, and of suitable sizes to suit the amateur; if a fancy top be required, the pattern can be purchased entire, such as draught boards, basket of flowers, and in fact, every variety; the veneers are laid on paper, and in laying such veneers care must be used, not forgetting to lay the veneer the paper side upwards, as when dry can be removed easily. The veneers for such tops vary from 9s. to 10s. each; in laying such veneers use a zinc caul, place the tops face to face, the caul in between, fasten secure with hand screws. SAMUEL SMITHER.

GRINDING TURNING TOOLS.

[4332.]—As amateur turners require their tools ground more frequently than their more proficient brethren, a few hints may not be out of place. In the first place, if the amateur cannot afford two sets of tools for hard and soft wood, he must grind even more frequently; if at all possible, use a large grindstone with a moderate supply of water; if the amateur cannot obtain or has not a large stone, an 8in. dry stone can be run in the lathe, but at a slow speed; do not use water on the stone, but have a can of water at hand, and as the tool warms, plunge it in the water; do not by any means allow the tool to change colour, or you will alter its temper, and very likely your own, when using the same, but as good tools are by far the cheapest, I advise the water grindstone, and as the amateur may not always have help at hand



to turn away at the handle, I send sketch of a simple way of doing without extra help; the sketch will explain the mode to our readers. A grindstone of the above description can be purchased, and the frame made and fixed for 10s., or those who would rather buy than make, can purchase one ready for work for £1. For wet grindstones purchase a bilstone; if required to work dry as described above, state so on purchasing one. SAMUEL SMITHER.

HORSE-POWER.

[4333.]—I AM directed to forward you copies of a letter addressed by the Board of Trade to this Institution on the subject of nominal horse-power, and of the reply thereto, and I am to express a hope that you may be able to find room for these in the columns of the ENGLISH MECHANIC.

ADRIAN VIZETELLY, Assist. Sec.

Institution of Naval Architects, 9, Adelphi-terrace. London, W.C., June 6, 1872.

[*Copy.*]

Board of Trade, Whitehall-gardens, March, 22, 1872.

SIR,—I am directed by the Board of Trade to inclose some copies of a Memorandum on "Horse-Power" of Steam Engines. Representations have been made to the Board that the term "nominal horse-power" conveys no definite meaning. This term occurs in Section 5 of the Merchant Shipping Act, 1862, of which a copy is inclosed. The Board of Trade will be glad to receive any observations on the subject with which the Council of the Naval Architects may be able to favour them. If some understanding can be come to on the point, a definition of the term might be agreed to which will be accepted not only by the manufacturers and users of engines, but by the Legislature in the event of the term "nominal horse-power" being retained when the Statute is revised.—I am sir, your obedient servant, (Signed) THOMAS GRAY.

The Secretary, Naval Architects, Adelphi.

Institution of Naval Architects, 9, Adelphi-terrace, London, W.C., June 4, 1872.

SIR,—In reply to your letter (M) of the 22nd March, in which you ask for certain advice with respect to the term "nominal horse-power," I am directed to inform you that the subject has been carefully considered by a Committee of the Council of this Institution, with the following results:—The committee were unanimously of opinion that the "nominal horse-power," as at present ordinarily used for commercial purposes, conveys no definite meaning. They were also unanimous in considering that the proposals contained in Mr. MacFarlane Gray's pamphlet could not be recommended for adoption. The majority of the committee were of opinion that no formulæ depending upon the dimensions of any parts of the engines, boilers, or furnaces could be relied upon as giving a satisfactory measure of the power of an engine, and that even if the varieties of engines and boilers now in use could be comprised under one general expression for the power, the progress of invention would soon vitiate any such expression or formula. The entire abandonment of an old commercial standard, such as "nominal horse-power," however inaccurate, must be a matter of considerable inconvenience, and accordingly great attention was given by the committee to the question whether that standard could not be amended and retained. Among the many plans considered, not one received unanimous or even general approval. That which met with least objection was that the indicated horse-power, as ascertained on a trial trip, should be taken either as the "nominal horse-power" or as a basis for it, being divided by a suitable divisor. The committee were of opinion that for the purposes of the Act, if any standard at all of horse-power is to be used with reference to the engineers, it would be better to name 400 "indicated horse-power," in place of 100 "nominal horse-power." The committee were also of opinion that all engineers of coasting and sea-going ships should be required to pass some examination, and the council think it desirable that this opinion should be communicated to the Board of Trade.—I have the honour to be, sir, your obedient servant, (Signed) C. W. MERRIFIELD, Hon. Sec.

The Secretary, the Board of Trade, Whitehall-gardens, S.W.

OUR SUMMER VISITORS.—THE NIGHTINGALE.

[4334.]—LIVING in the East Riding, I am told that the nightingale is, though rather rare, yet not unknown, and a clergyman has told me that he has heard two about three miles apart, singing all through the spring of 1870 near here, so that "Avon's" statement (page 197, let. 4088) would appear to require modification. HEDERA.

RECURRENT VISION.

[4335.]—MR. PETRIE (let. 4272, p. 282), in his remarks on Professor Young (see p. 190), overlooks a fact that should be noticed. Continuous sight requires but eight pulsations per second on the eye. The repetitions of light observed were more faint each time, and rarely reached a fourth. Cannot this be accounted for by external causes? The Leyden-jar sparks of the Holtz machine reached 9in. in length, and the intervals between the illuminations were less than ¼ second each. Could recurrence result from reverberation of the cosmic fluid, as echo results from reverberation of air? Was there no spherical concavity in any part of the room, and was not the Professor in its reflecting focus? May not even a *flat* surface, after a very near and *extraordinary* electric-shock, reproduce vision in the way that sound is reflected from the flat surfaces of an empty room?

In Professor Young's experiment, the intervals of darkness were less than a ¼ second each, and light from the ether-pulse is retained ⅛th of a second, so that the real intervals between the recurrent pulsating in *less than* $\frac{1}{4} - \frac{1}{8} = \frac{1}{8}$th of a second. Does not this admit of the supposition of its arising from ether-reverberation? J. BARWICK.

ENTOMOLOGICAL.—(III.)—ON LARVÆ.

[4336.]—I WILL now proceed to speak of the management of Larvæ. Firstly, the cage demands our attention; very cheap and serviceable cages may be made from boxes purchased for almost nothing at the grocer's, and having a piece of perforated zinc substituted for the bottom, and a piece of glass in the top, the case being stood on end when in use. I should never give any larvæ a space less than 4in. cube to five in. Of course the cages can be divided into suitable compartments. The food should be put in a little bottle of water to keep it green, and there should be a small box of damp earth in the cage for such larvæ as like to enter it, to turn to pupæ. Concerning the earth, I think leaf mould is as good as any, though many soils are recommended by many collectors. Concerning food, pieces should be gathered from the plants on which the larvæ were found. However, this is sometimes not easily obtained, and I then recommend allied genera of the plants, which may be found in botanical books, for these are often useful. Next may be mentioned general favourites; by these I mean plants liked by a family of larvæ. Of these I have found sallow and buckthorn generally liked by *Geometræ*; lettuce, birch, plum, and others by *Noctuæ*. The food should be gathered early in the morning, while it is moist with dew, but wet food should not be given to young larvæ.

Many larvæ are very apt to be lost when new food is given them, as they cling to the old food and hide themselves in it, so they are overlooked and thrown away. Hybernating larvæ should be left out of doors all the winter, and hairy ones should be kept dry, or mouldiness will attack them; whilst smooth ones should be kept moist during the winter. I must caution the reader against cannibals, such as *C. Trapesina*, *S. Satellitia*, and others, which should be kept in cages by themselves, or they will devour all others that are with them. Some, as the puss and kittens, nibble off each other's tails when kept in confinement. The larva of *Cossus ligniperda* should have a piece of a branch of ash that is green given him to feed on.

Larvæ have many ailments peculiar to them, of which I will mention some. Stings of Ichneumons are fatal if the eggs are laid in the larva, for it is sure not to come out, though it may go into its pupa state. Next, larvæ have a great liking for committing suicide by drowning, and this should be avoided by filling the mouth of the bottle in which the food is with cork. Thirdly, hairy larvæ have often been attacked by a fungus produced from a damp atmosphere, and when this comes I think no remedy can be applied, and the larvæ must die. Larvæ may be preserved by being killed by immersion in spirits of wine, and then have the contents of their body extracted and the case filled with wool. ENTO.

A CLEAN PIPE.

[4337.]—I HAVE read all the prescriptions for this luxury which have appeared in the MECHANIC, but have seen none so simple, inexpensive, and effectual, as the following:—Cut up with a pair of sugar-nippers common charcoal into bits about the size of a pea; place two or three bits—more if a half pipe only be wanted—into the bowl, and fill up with tobacco. The latter will be found to burn more freely, unaccompanied by any wheezing or bubbling sound; the charcoal, when the pipe is finished, will have absorbed all the oil and saliva, and the tobacco will be wholly consumed. By this process, there will be effected a saving of at least 20 per cent., as there will be no waste in the shape of the sodden mass of unconsumed tobacco usually left at the bottom of an ordinary pipe. TRY IT.

SAFETY LAMP FOR MINERS.

[4338.]—THE objection to Mr. Plimsoll's lamp (let. 4284) that it would be an inconvenience for the light to go out when brought in contact with gas, is not a valid one. Compared with the less liability to an explosion, the inconvenience is but dust in the balance. Davy's lamp may be an excellent one for measuring the strength and quantity of an accumulation of gas; but its unfitness for the working miner is proved by the fact that it is now little used. At the comparative experiments that were made at the Oaks Colliery, shortly after the great explosion, the Davy lamp was declared the least safe of the whole tried, except, I believe, the "Clany." The lamp wanted for the unintelligent miner is one which is self-extinguishing in an accumulation or a current of gas, and also in the act of being opened. ASSISTANT MANAGER.

SILVER FILMS FOR SUN-SCREENS.

[4339.]—THOUGH an able and esteemed Fellow of our society, the R. A. S., generally writes to excellent purpose what he has well considered, I think the question he has addressed to me (letter 4225) is an exception to this rule—*Nemo mortalium, &c.* In reply, I beg to say that I leave to him the experiment of smoking the field-lenses of his eye-pieces, as I have too great a regard for mine. I must add that I do not "advocate" absorbing light and heat by silvered glass sun-screens, and that, on the contrary, I aim at their reflection. The difference between a coating of lampblack and one of the most brilliant silver is about as great as can well be imagined, the first being the best absorber and the worst reflector of light and heat, the latter their worst absorber and best reflector.

Romsey, June 8, 1872. E. L. BERTHON.

BELL PIANETTE.—To "THE HARMONIOUS BLACKSMITH."

[4340.]—I AM now in a position to fulfil the promise made at p. 275 of the present volume. The name of the original patentee of the instrument, of which the above is a modification (?), is Charles Clagget. The specification is No. 1664, date A.D. 1788, at p. 4, eighth improvement. S. BOTTONE.

WIRING GARDEN WALLS.

[4341.]—HAVE any of "our" horticultural or gardening readers ever tried the French plan of wiring walls and erecting trellises for training fruit trees? Some time since I was strongly recommended by a friend to try the plan, which has answered very successfully, and which I now submit to "our" readers. I know of no way whereby one may so highly improve the garden culture of the pear as by paying more attention to it—as an espalier tree. This is the opinion

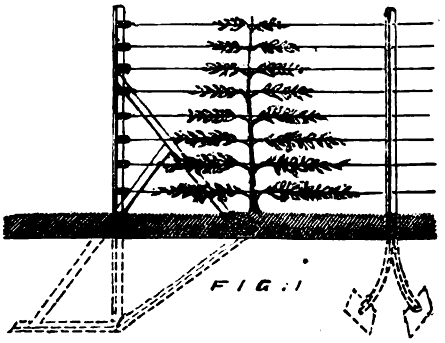


FIG. 1

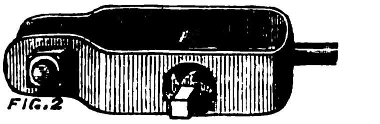

FIG. 2

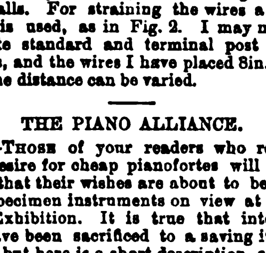
of many of the best fruit growers in Britain, who agree that there is no finer fruit than that gathered from well managed espalier trees. To form the support for their espalier fruit trees, the French have adopted the system, which will at once be apparent to all readers of "ours" as a cheap, neat, and everlasting method. All the fittings are galvanised, No. 14 being the best size wire for walls. For straining the wires a galvanised raidisseur is used, as in Fig. 2. I may mention the intermediate standard and terminal post have self-fixing bases, and the wires I have placed 8in. apart, but of course the distance can be varied. H. B. E.

THE PIANO ALLIANCE.

[4342.]—THOSE of your readers who recently expressed a desire for cheap pianofortes will find some little hope that their wishes are about to be met in a couple of specimen instruments on view at the International Exhibition. It is true that intensity and compass have been sacrificed to a saving in bulk and costliness; but here is a short description, and some of your readers may probably pay them a visit, and give us the benefit of their inspection. There are two instruments, one of five octaves, the other of four, each 3ft. 5in. high, which severally stand in spaces of 2ft. 8in. by 1ft. 8in., and in 3ft. 8in. by 1ft. 8in., and to which are affixed prices that ought to make one or the other admissible to the most modest household and the scantiest study. Instruments are also spoken of as being forthcoming, of the same compass, but of the shape of the spinet. It is claimed for these comparatively diminutive instruments that all the pianoforte music best worth playing is within their compass; but of this I know nothing, and shall feel glad if any of your readers can supply further information. K. T. L.

DUPLICATION OF THE CUBE.

[4343.]—IN 1863, I found that $\sqrt[3]{2}$ is nearly equal the square root of $0{\cdot}93^2 + 0{\cdot}85^2$, or 1·5874—*i.e.*, 1·25992682; the excess being ·00000,526, about 2¼ millionth. Since 1·5874 is 1·26 squared, less ·0002, take this construction. Bisect a line S H successively six times, so as to get its 64th part = H A. Hence, if S H = 1·28, S A = 1·26. Let A V = half diagonal on square of A H = chord A F in circle diameter S A; the supplementary chord $SF = \sqrt{1{\cdot}5874} = \sqrt[3]{2}$ to a 2¼ millionth.



To find the unit of which S A = 1·26, bisect R H in C, C A = A R, chord K A = radius = K E ⊥ on S K. Drop ∠ K ⊥ E S, join E R, and L D parallel to E R. S D = 1·00 to S R = 1·25; for S K : L E : : 4 : 1 : : $SK^2 : KE^2 = KA^2$ chord. S D : S F : : 1 : $\sqrt[3]{2}$ numerically approximate. S. M. DRACH.

THE PALÆOLITHIC AGE AND PRIMITIVE MAN.

[4344.]—THE Palæolithic (or "first stone") age was a period in which, according to Sir J. Lubbock, "man used rude implements of stone, which were never polished," and in which "he was ignorant of pottery, and of metals" (See Lubbock's Introduction to Nillson's "Stone Age of Scandinavia.") Will these definitions stand the test of recent facts? I think not.

First, it is an undoubted fact that pottery has been found in caves which are classed as Palæolithic. In a cave at Pondres in Languedoc, pottery was found in a stratum older than that which contained remains of Palæolithic mammalia: M. Rochebrune lately found pottery in the Rancogne caves mixed with the bones of the cave-bear, and cave-hyæna; at the cave of Frontal M. Dupont found pottery and the bones of the cave-bear together; in Bavaria a cave has just been opened, in which pottery was found mixed with the bones of the lion, cave-bear, and hyæna; and so often did Dupont find pottery in the Palæolithic caves of the Lesse that he devotes a special section of his work to its description. Now, if cave-evidence is worth anything at all, we have proofs that man made pottery in an age when the rhinoceros, cave-lion, mammoth, and cave-bear existed, and as Sir J. Lubbock himself tells us that these animals characterised the Palæolithic age, it follows irresistibly that in the Palæolithic age man did make pottery.

Sir J. Lubbock, it appears, admitted in a recent address to the Anthropological Society that pottery had been found in Palæolithic caves, but he said that these were only "exceptions." This is amusing, for Sir John is taking for granted what he ought to prove; these fragments of pottery in the Palæolithic caves are exceptions only if his hypothesis is true, but not otherwise, and to assume that man made no pottery in the first stone age, and then to call the facts brought against that assumption "merely exceptions" is to beg the whole question in dispute. Secondly, it is also a fact that polished stone weapons have been found in Palæolithic deposits. In a gravel pit in Charente in Western France, a few years back, a fragment of a polished stone hatchet was found below the bones of the elephant, and tichorhine rhinoceros; in the gravels near Monthiers of the same age, a polished stone instrument was also found; a hatchet perfectly polished was found in the diluvial beds of Loire-et-Chère by M. l'Abbé Burgeois; while in the diluvial beds on the shores of the Lake of Soing polished stone weapons were found. Not merely have the gravel beds yielded these polished tools, but M. Rochebrune has found them in the caves at Charente, and he states that the polished hatchet found in the gravel beds of Roffit was just like the ordinary type of polished stone hatchets, and that these polished tools occur in the valley gravels, mixed with the bones of the mammoth and rhinoceros.

Now, Sir J. Lubbock says that polished hatchets "do not occur in the river-drift gravel beds, nor in association with the great extinct mammalia" (Nillson's "Scandinavia," p. 28), but the instances given above show that this statement is now quite incorrect, and as these valley gravels in which the polished hatchets are found are undoubtedly of Palæolithic age, it follows that man made polished weapons at that time.

But now let us go a step further, and ask the question "On what evidence is the opinion founded that Palæolithic man made neither pottery nor polished weapons, and that he was ignorant of the metals?" We find that it rests on negative evidence alone. We have not found these things in the Palæolithic deposits, therefore they did not exist at that time. But every geologist knows that Sir C. Lyell and Sir J. Lubbock regard negative evidence as nearly valueless, and believe in the extreme imperfection of the geological record; how, then, does it happen that when they approach the questions of the antiquity and primitive condition of man, they suddenly change front and say that negative evidence which in palæontology is almost valueless, suddenly in connection with primitive archæology becomes so very valuable that a whole series of classifications can be based on it? The value of negative evidence is thus expressed by one of the best known of modern English geologists:—"The absence of fossils of a certain kind, assumed because such fossils have not yet been determined, is no proof whatever that the animals which would have left them did not exist." Very good; then we ask that in common fairness this principle be also applied to primitive archæology, and we say in the same words, "The absence of pottery and of polished tools, assumed because such relics have not yet been discovered, is no proof whatever that these relics were not made." If Sir C. Lyell's principle is good in the Silurian or Carboniferous period it is also good in the Palæolithic period, and as he hesitates to say that certain races of animals did not exist in the Cambrian age because we have not found traces of them, so he ought also to hesitate to say that pottery and polished axes did not exist in the Palæolithic age because we have not found them.

Curiously enough, Sir C. Lyell, when he comes to answer the question why no bones have been found in the Somme gravel-beds, regards negative evidence of no value, for he immediately puts forward ingenious arguments to account for their absence, and precisely in the same manner, instead of assuming no pottery or polished tools existed in the Palæolithic age, he ought, in accordance with his principles, to try to explain that although we have not found these relics yet they were in use at the time.

We have seen that primitive "Palæolithic" man was neither ignorant of polished tools nor of pottery, and this being the case, we find that geology does not reveal that man originally was in a state of "utter barbarism." The fragments of bones from the caves refute such a notion, for the Engis skull might have belonged to a European of the present day, and the Naulette jaw has affinities with the Sclavonians. These are the oldest human remains in Europe that we can call into court, and they are emphatic witnesses against the theory of "utter barbarism." True it is that that theory has other sciences brought in to support it, but whatever may be said in its favour it is clear that geology does not support it. As for the arguments brought forward in its favour from modern savages, they break down totally under a searching investigation, and only afford another instance of how a ponderous theory can be built upon a foundation of sand, while fresh discoveries only show us how true were the words of a modern philosopher when he described "the slaying of beautiful theories by ugly facts."

D. G. W.

ARE CONVENTIONAL TERMS SCIENTIFIC?

[4345.]—IN "Sigma's" letter (4193) the following argument is used:—As the biblical cosmogony is always in perfect accordance, not with late scientific discovery, but with the ideas of the people to whom the narrative was addressed, therefore, accounts involving scientific facts cannot be relied on; this is only partially true, as the evident exceptions in accordance with "late scientific discovery" (such as the earth being stated to be hung upon nothing) will, of course, be borne in mind. Now, if "Sigma's" above argument be true, I am forced to the conclusion that as modern scientific works contain expressions not in accordance with scientific discovery, they cannot be relied on; Humboldt, for instance, used such terms as "The Celestial Vault," "Fixed Stars," though we all know they have a vast motion of translation, and probably of rotation also; he says that the zodiacal light "rises in a pyramidal form," and he mentions as distinctly as possible that there is a "Milky Way between the Scorpion, the Centaur, and the Southern Cross;" are we to believe in the scientific accuracy of the description of this curious collection? Herschel also writes of the "diurnal motion of the stars," and defines the day as the time between "the departure of the sun from a given meridian, and its next return to the same;" he also implies a top and bottom to space, for he writes of the "ascending and descending nodes."

As we accept all the statements of modern scientific books, unless they are professedly such terms as are conventional, so we must do with that one most ancient book, which stands alone in antiquity by its showing a perfect agreement with modern science, excepting, of course, certain conventional terms which, like the above quoted, were perfectly understood as such. It is news to me that the Mosaic accounts are only concerning "the Jewish family and race, and all the rest of the world and its history is ignored;" if so, what is the tenth chapter of Genesis about, and to whom does it refer? If the Deluge only affected a people dwelling in "a fertile river district," as "Sigma" gratuitously supposes, how is it that those people were landed on the top of a high mountain? One part of the narrative is quite as authoritative as another. I have as great a desire as "Sigma" not to get "into a morass of theological squabbles" in the ENGLISH MECHANIC; but as he has already stated one side of a matter, the other side must also have a hearing.

W. M. FLINDERS PETRIE.

ARTIFICIAL STONE.

[4346.]—"KHODA BUX" (letter 4242, page 277) says "an artificial stone has been produced of surpassing hardness and capable of a beautiful polish by the mixture of caustic magnesia slacked with chloride of magnesium." Will "Khoda Bux" kindly mention whether he has personally tested this assertion, which I know well appeared in many papers a few years ago? I have repeatedly made the mixture, and never obtained anything approaching to stone—at least, nothing more like stone than, say, Keene's or Martin's cement is—not, in fact, much harder than good plaster of Paris. Ransome's artificial stone is more like real stone, because the constituents of stone are induced to combine and form his compound, but Ransome's method produces only surfaces too coarse to take a polish. His siliceous fluid will not sink into sand, &c., in an impalpable state. Mr. Ransome was working at this when I last saw him, and, amongst other experiments, had pumped the air out of masses of plaster, &c., and then, while in the exhausted receiver, had let in his dissolved silica; but the flinty-hearted fluid still refused to enter the pores of fine plaster, or, indeed, practically, of any substance whose pores were not as open as coarseish sand, which is, of course, incapable when it sets of anything like a polish. Being, therefore, unable to find anything so like (say) marble as to be suitable when set, for statuettes, &c., I shall feel greatly obliged by "Khoda Bux," or S. Bottone, or any of our chemists, saying whether caustic magnesia and chloride of magnesium, or any other mixtures, have been proved by themselves to do what M. Sorel claims for his invention.

As "Khoda Bux" is interested in concrete, it is well worth his while to see Mr. Nicoll, the shirt manufacturer in the Regent-circus, not the Regent-street tailor. When working under a Government commission, we examined his method of building thoroughly, and it has some excellent features. Amongst other things he proposed to whitewash his insides with Sorel's mixture, so as to obtain that much desired thing for the poorer classes—washable walls—but being, as I have some reason to still fear it is, only a porous cement, it absorbed water, and he had to give up that feature in his plan for building cottages, &c.

Time seems to be a sine-quâ-non in stone-making. Whenever Nature gets a very hard job to do she takes plenty of time to do it in. Perhaps a sham meerschaum, the constituents of which are the same as a real one, if let alone for a few million years, and pressure, perhaps, added, would get real in the end.

NOT PROVEN.

DEFINITION OF CHEMICAL COMPOUNDS.

[4347.]—I HAVE not had time to analyse the contents of both bottles sent by "S. S." (query 9457, p. 489, Vol. XIV.). "S. S." adverts in one of his communications to his analyst leaving *two* inorganic compounds undefined, as also to organic matter being present of unknown kind or origin. The fluid I have examined must surely be very different from the substance originally quoted, for this is simply crude liquor soda, very possibly prepared as a boiler anti-incrustating fluid. The amount of organic matter present is very small, certainly less than half per cent., and is merely dirt—that is, matter out of place, and is probably derived from the crude materials of which the preparation is made. I cannot understand why two undefined inorganic substances should remain in the former analysis, for the mixture is simple enough, presenting no difficulties to any one engaged in analytical operations. I must, however, mention that all the alkali in the analytical table is calculated as soda. I may explain that this includes some potash present in undetermined quantity. The second bottle which I have not analysed appears to contain a large quantity of carbonated alkali, and is probably somewhat analogous to the other specimen, but of different quality. It should be noticed that my analysis is quantitative, that of Mr. G. E. Davis qualitative. Table of results of chemical analysis of a sample of fluid marked "No. 1 Liquid," received from "S. S.," a correspondent of the ENGLISH MECHANIC, &c.:—

	Percentage.
Water	87·50
Sodic hydrate	7·52
Sodic chloride	3·32
Sodic silicate	0·14
Sodic sulphate	0·76
Iron and alumina	0·10
Carbonic acid, organic matter, and soda combined with alumina	0·66
	100·00

W. R.

GOVERNMENT AND AMATEUR SCIENCE.—II.

[4348.]—THE subject of the cultivation of science by amateurs is of no ordinary dimensions. To arrive at a just conclusion upon the relation of the amateur to the professional astronomer, for example, many circumstances must be taken into account; in both departments there are different grades, dependent on the one hand upon patronage, and on the other upon mental capability. In my first letter I discussed the subject of Government patronage as extended to one of the most important branches of astronomy, and endeavoured to show that to bring that branch to its present state of perfection a high order of mind was necessary. Now, patronage from the highest source extends downwards through every grade of society, and we may recognise two directions in which it has been manifested in the greatest degree short of Government aid. We have, for instance, the establishment of endowed observatories maintained by funds bequeathed by cultivators of astronomy administered by trustees; others have been necessitated by the requirements of commerce and are maintained by municipal or other funds; and there are not a few observatories, which have been founded by private gentlemen, who either themselves cultivate some branch of the science or employ observers to carry out their views, but they make no provision for carrying on their work. The highest class of professional astronomers are those immediately connected with the Government; next to them rank the regularly appointed observers of endowed and similar observatories; and, lastly, in the same class—*i.e.*, professional astronomers—may be reckoned the assistants in private observatories, and those classes may to a certain extent afford a measure of astronomical calibre. Amateurs, who stand on a different footing are, like the various sources of patronage, found in every grade of society. The private gentleman having ample funds at command, and possessing an astronomical taste, erects an observatory, furnishes it according to his means with the best instruments of the day, and employs his leisure in observing, and, probably, prosecuting some special object for the advancement of which he employs an assistant, or it may be that even with the services of an assistant he may not devote the observatory to any special branch of inquiry, but use it in a desultory manner. The artisan, who has but few leisure hours, saves a few pounds of his earnings and purchases a telescope, with which he observes the heavens, comparing his seeings with such records as the astronomical literature that he is able to command affords, and which, perhaps, induces him to bestow his attention on some particular subject in which he supposes there is a deficiency of information. It is to these sources of patronage and developments of mental power that astronomy is indebted for its progress otherwise than from Government aid.

The mention of astronomical literature directs attention to the greatest of all human helps, either to the professional or amateur astronomer. There are two methods by which the results of the labours of astronomers may be preserved, either by manuscript or printed records. There is, doubtless, in one way or another a large quantity of manuscript records in existence; but it is in comparatively few instances that such records are permanently preserved. Even in the case of an office closely connected with astronomy some valuable manuscript calculations were sold for waste paper; it is, therefore, of the last importance that the results of observations should in some way be promptly printed. It is by the publication of astronomical works forming the staple literature of the science that the amateur is helped forward in his inquiries, and the more he is acquainted with the labours of his predecessors and contemporaries the less likely is he to tread on ground already occupied.

It was my intention to glance in this letter at the progress of three departments of astronomy which have been specially cultivated by amateurs—namely, variable stars, binary stars, and solar physics, but the above remarks on the relation of amateur to professional astronomy have left but little space for the purpose. As regards binary stars, I may briefly remark that it is not so much the history of the subject as a notice of its departments which at the present time would, I apprehend, be of the greatest use to amateurs. These departments consist (1) of measurements, (2) of catalogues, and (3) of computations of orbits, and exercise three classes of mind. In his report to the Board of Visitors, the Astronomer Royal, alluding to a possible extension of the objects embraced by the observatory, spoke of the *exclusion* of double star measurements. He had previously said that "observations which can be made at any convenient times, which do not require telescopes of the largest size, and which do not imply constant expense, ought to be left to private observers." It is, therefore, probable that the further progress of our knowledge relative to double stars will be left entirely to the efforts of amateurs. Now, what do we require to insure steady progress? We have existing in our literature numerous notices of double star measures. We have valuable catalogues of double stars at various epochs brought down to a comparatively late date, and we have scattered here and there in works not so readily accessible as our popular literature, the computations of the orbits of certain binary systems. Taking the present moment as our standpoint our literature contains the records of what has been done. For the future we need early publication of measures, the issue of revised catalogues at stated intervals of a certain number of years; a tabular view of the elements of binary orbits, and a synopsis of existing records in the form of a table of references to the various works in which they occur. On the means of meeting these wants, I may probably speak in a future letter; as regards the first there is no difficulty.

W. R. BIRT.

OUR COAL STORES AND THE ATMOSPHERE.

[4349.]—THERE has lately been much inquiry as to the period when our coal-mines will be exhausted, or the time when our carboniferous store will have disappeared. But I have never seen the question asked or answered where is it all going to, and can the atmosphere contain it without being reduced to a poisonous mass.

Now, when three tons of carbon are burned in the atmosphere they unite with eight tons of oxygen and produce eleven tons of carbonic acid, or what is the same, one hundred million tons of carbon will unite with two hundred and sixty-six million tons of oxygen, and form three hundred and sixty-six million tons of carbonic acid, and as England alone is raising to the surface one hundred and twelve million tons of coal annually, it will be seen that she is converting three quarters of a million tons of oxygen into one million tons of carbonic acid every day. Also, when we take it into consideration that carbonic acid gas is more than half as heavy again as common air, consequently its tendency is to float near the surface of the earth, and when we know how small a quantity it takes to render the air unfit for respiration—for Dr. Smith has shown that when there is two and the one-tenth per cent. of carbonic acid gas in the atmosphere candles give indications of going out, and the young lady who was breathing in the same air suddenly became pale, and had to be assisted out of the chamber in which the experiment was made—I think it behoves us to inquire how long this process can be continued without affecting the animal kingdom, especially as other nations are following the footsteps of Great Britain, for had they been producing and consuming coal at the same rate, we would evidently have had to cease working coal before the expiration of a century; and before our mining engineers talk about raising all the coal to the surface—that is, thick seams and thin seams, and seams at a great depth—they must tell us what they are going to do with it. Evidently it will not have to be burned, or the animal kingdom will have to perish.

To illustrate the above remarks, I will take Great Britain and its atmosphere, whose weight is about three and a quarter billion tons. Now we have one hundred and forty million tons of obtainable coal, which, when burned in the atmosphere, will give half a billion tons of carbonic acid, a sufficient quantity to render ten atmospheres like Great Britain unfit for respiration.

I am aware that vegetation is ever active in decomposing this gas, but the carbon extracted from the atmosphere in this way is sent back to it again by the animal kingdom in the form of carbonic acid gas, and as the population of the earth increases, all those large and ancient forests which exist will have to be broken up and cultivated, consequently their large store of carbon will be reduced to carbonic acid gas, and ultimately find its way to the atmosphere. In concluding, I may remark that the time when we shall have to cease working coal for the above reason may be far distant, but it will surely come long before we have consumed such an amazing quantity of coal as is imbedded in the bowels of the earth. WILLIAM THOMPSON.

BOOT AND SHOE MAKING.

[4350.]—AMONG your correspondents, do any understand the philosophy of boot and shoe making? It strikes me forcibly (telegraphed up from my big toe) that the science of fitting is very far behind the age. Some really practical articles on this subject would be of much greater utility (which Lenoir defines as that which has the power of producing pleasure, or preventing pain) to many readers than theories on the Deluge. Unfortunately, I am only Jack of some trades, and these don't include shoemaking, else, wanting "the thing done, I would do it myself," but my poor feet have compelled me to give some thought to the subject, and I fancy I have made the following discoveries:—Boots and shoes are generally made according to a fashionable, but faulty pattern—or in other words, the form of a last, instead of that of the feet on which they are to be worn. Now, I happen to have an extra long big toe, which refuses (without giving great pain) to be twisted over its neighbours, though shoemakers have laboured to produce this distortion, and last-makers have abetted them. The joint has been somewhat swollen by this brutal treatment, and can now stand very little pressure. The instep at one part measures less than at big toe joint, and the hollow of the foot at the inside stands an inch clear above a level surface on which the foot may be placed. I have never been able to find a ready made pair of boots or shoes that I could wear, and when shoemakers make them according to the ordinary system, to measure, I cannot even get my feet into their place. I have had lasts made twice, and even that is no remedy, as the last maker pursues the same course with the shoemaker. Now, I think the form of the foot must be considered as well as the measure. Two persons may have feet of same length and width, and require very differently shaped boots to fit comfortably, yet shoemakers would make them on the same lasts. It is clear that to do the thing perfectly, every one should have his own lasts, but then, where will you get competent lastmakers? My big toe lies straight forward, and has raised the boot at the point on that side, but the lasts I have lately got are pared off to a thin edge on both sides, and have only height for point of big toe in the very centre, where that member cannot possibly utilise it. Can any one advance the science, and help sufferers in the feet, and among the rest,

IRISH MECHANIC?

PIANOFORTE BRACING AND BELLYING.—I.

[4351.]—THE subjoined article was written several weeks ago, but postponed for more interesting matter.

There can be no doubt the method "T. C. L." (let. 3772) proposes for making the backs of cottage pianos stronger, would be effective in preventing them from becoming arched, because almost the same method, and other methods identical in principle with it, have long been successfully employed. Somewhere about sixty years ago the late Mr. J. J. Hawkins effected the very same result by subjecting the backs of his iron braces to compression by means of tension rods which effectually resisted the tendency of the tensile force of the strings to arch them. Yet later, others have done similar things, especially Messrs. W. Rolfe and Sons, in 1851. Mr. Hattersley (1845), produced the same result by trussing the wooden bracings just as other wooden beams are trussed by metal rods, but all these contrivances are more costly than that of Mr. Mott, in which the bracings are tied to the key frame, as shown in Fig. 2, p. 613, Vol. XIV., in which all the tie bolts required for one piano would not cost more than about half-a-crown. I think, however, that excepting this plan, it would puzzle any engineer or pianoforte maker to truss his bracings even on Hattersley's system—one of the least costly—or to increase their power to resist flexure by counter tension rods, *à la* Hawkins, or to back them up with angle or T iron (in the manner the late Thos. Rolfe did about 1854), or with flat iron, as "T. C. L." proposes, for so little cost as that of a few additional wooden bracings which stand the maker in only about eighteenpence each. Such contrivances are perfectly legitimate for strengthening the backs of old pianos, although personally I prefer front iron bracings on Kohlman's plan, when they are found to be either too weak for their present strings, or when it is desired to string them heavier (in most of such instruments, no great improvement can be expected unless both this and increasing the lengths of their strings of given pitch be effected), but they can hardly be termed legitimate methods of making new strong backs, when cheaper and simpler methods are in common use.

The besetting sin of most of these contrivances—and they share this reproach with additional wooden bracing—is that they exaggerate a too common existing defect—viz., excessive weight, for cottage pianos are now, as usually constructed, much too heavy to be handled conveniently. *Cæteris paribus*, the lightest bracing will be that which is in the same plane with the strings—or at least that bracing parts of whose material rises above and descends below that plane just like that employed by Messrs. Erards for upright instruments. Any piano with its bracing entirely above or below its strings, or in two series (one above and the other below them, which is just what the bracings of ordinary grand pianos and of cottage pianos braced *à la* Kohlman are, both of which arrangements require the bracing to be tied or strutted, or both), must be so much heavier than Erard's as the additional material necessitates. Of course, it is theoretically possible to design and construct bracing partly above and partly below the strings whose weight—excepting the weight of the tie-bolts—shall not exceed Erard's, but it would be rather difficult, in practice, to apply it.

When the bracing is only on one side (say, under the strings), the tendency of their tension to arch it increases in proportion as they are placed further from it—unless, indeed, the braces be tied to the key-bottom on Mott's system, when, practically speaking, they cannot become arched, so their distance from the strings becomes of no importance. Hence, it is desirable to place the strings of ordinary cottage pianos as near their bracing as possible. Their strings are too often from 1½in. to 2in. from their bracings; but when the soundboard is not arched more than is needful, and the down bearing of the strings not excessive, by making the bridge only ⅝in. thick the strings may be kept within about 1⅛in. of the bracings; closer they cannot well be, as any one may satisfy himself by making a sectional full-sized drawing of the parts. Of course, when the bracing is disposed above and below the strings, it cannot be of any practical importance how far the one set of bracings is from the other, for their power to resist the tension of the strings will be equally great whatever distance they may be from the latter, and it becomes a mere matter of practical convenience how far they shall be placed apart.

"T. C. L." also asks for my experience in sounding-board making. Alas! it is nearly *nil*, at least, very limited, although I have some rather peculiar notions thereanent. If, however, my practical experience has been but small, I have long been a persevering industrious inquirer and a careful observer of others' doings in this matter; but I may remark that practical pianoforte makers are usually remarkably reticent on bellying, and some other branches of their art. Whether they know much or little, may be a fair question, but certainly they are very unwilling to communicate knowledge.

I have observed the thicknesses of pianoforte soundboards differ considerably, and that really good instruments are constructed in which they vary much, not only in thickness, but also in superficial area, and in the section of and number of their bars. In ordinary cottage pianos the number of belly bars seems often to be subordinated to and determined by the number of bracings in the back and the distance the latter are apart. When few in number, say five, two belly-bars are often found between each, which makes their total number ten or twelve; in my opinion, this is none too many in the treble, but needless for the bass. When the number of wooden bracings became increased to seven, eight, or nine—I have seen nine in some modern backs—the spaces between each became so much diminished that there is not room for more than one belly bar between each. In pianos with seven bracings, I have, however, occasionally seen two belly bars, between each of the bracings nearest the treble end, those bracings being placed somewhat further from the lining and further apart to allow room for two bars between it and them, which I consider an improvement. This enabled ten to be used, which I think quite numerous enough.

If designing a soundboard, I should prefer placing the four shortest belly-bars only 4in. or 4¼in. apart from centre to centre. This would necessitate the introduction of one additional brace into the back figured on p. 613 (No. 302)—in other words, placing five braces in the same space four occupy in that figure at the treble or right-hand side. It is obvious the more numerous the belly-bars the more nearly uniform the rigidity of the soundboard must be. I think this is a matter of some importance, especially in the treble, for avoiding inequalities of loudness in the sounds of adjacent notes; and I am not singular in this opinion, for the late W. T. constructed a back the six treble bracings of which were made of only 2in. stuff, which, when planed, became about 1¾in. thick. These were placed 2½in. apart from centre to centre, leaving spaces ¾in. wide between them, in each of which was a belly-bar made of ⅞in. stuff (tapered sideways so that it could not touch the bracings), the section of which, before its sides were tapered, was 1in. × ⅞in. It was also tapered pretty regularly from its deepest part beneath the bridge to three-sixteenths of an inch in thickness where it entered the rebates. The design was mine, and its executant had not much faith in it until the strings were put on and he was able to "hammer" them, after which he acknowledged it was the most powerful treble he had ever constructed. Certainly it was fine, although the scale was comparatively a short one: pitch C, bichord, being only 12in. long, No. 17; its octave 6⅛in., three unisons, No. 16; and the top A 2in. long, of No. 14 wire. Had the scale been that figured in No. 372, its power would have been increased at least 50 per cent.

Besides its normal function of affording a firm support for the strings, the bridge acts as a transverse bar, not only connecting the strings with the soundboard, but also with all its belly-bars, thus distributing the downward pressure of the strings (technically termed the down bearings) pretty equally over a considerable area. The more massive the bridge be made *cæteris paribus* the better must it do this, which is probably the reason we see the bridges of modern grand pianos so much thicker and wider than those of older instruments. It would seem, however, that every augmentation of the mass of the bridge must, like increasing the stiffness of the belly-bars, obstruct the communication of the impulses of the vibrating strings to the soundboard, and we ought to bear in mind that the latter is only caused to vibrate by the former.

The ordinary practical method of proceeding is to glue the bridge on the soundboard before the belly-bars are attached to it. As it is then quite flat, this greatly facilitates making the joint, and is the least costly way of proceeding, but I am far from believing it to be the best way, because, considering the bridge is a rigid oblique transverse bar, it must resist—in proportion to its rigidity—any force which is applied to the belly to arch it. This is usually effected by making the under faces of each belly-bar a segment of a circular arc—it is much preferable to make it elliptical —and the belly bars, when glued to the soundboard, are forced down on its back by wooden spring bars (technically termed "go bars"), many go bars being sprung on each belly-bar, so that the convex surfaces of the latter are compelled to become parallel to the flat surface of the soundboard. Thus all the arching the latter obtains being caused by the reaction of the curved belly-bars when, after the glue has become dry, they are relieved from the pressure of the "go bars." So long as we are content to have our soundboards segments of circles, this plan would answer admirably if the bridge were not glued to the soundboard, although it won't serve for soundboards whose surfaces are longitudinal segments of ellipses, by far the best form. They require a belly-board hollowed out or blocked up, so as to become a counterpart—allowing for the thickness of the wood of which the belly is made—of the elliptically formed belly-bars, provided always the bridge be not attached before the belly-bars, because the thin soundboard, whose grain is at a right angle with the direction of those bars assumes their form readily, but it don't do this when the bridge has previously been glued on it. On the contrary, instead of becoming a circular or elliptical arc, it becomes distorted; in workshop phraseology, "it winds like roast pork," and we can hardly expect distorted soundboards to vibrate as freely as those do which are either flat or of some regular geometric figure (say) circular or elliptical, which latter has the advantage of enabling the soundboard to be made sufficiently convex in the treble without making it unnecessarily convex beneath middle C, and thereby necessitating the placing of the strings further from the bracing than is desirable in ordinary cottage pianos, all the bracings of which are usually behind their soundboards, and therefore unavoidably more distant from their strings than could be wished.

I think I hear ye practical man exclaim "All very fine, 'Mr. Harmonious Blacksmith,' but if you arch your belly before the bridge is glued on, how are you to make a sound joint between the bridge and the belly." Well, I must acknowledge it is more difficult to do this after than before, and rather more costly, but certainly no impossibility, for it has been done more than once. It was done by the late W. T. in my experimental grand, who made the bridge in four pieces (lengths), connected by long vertical-scarfed joints duly dowelled. He fitted each length separately to the convex surface of the belly, and glued them on it successively, commencing at the treble. To insure the total absence of any possible strain which might distort this sounding-board (the reader will understand that in this sense I prefer being "a total abstainer,") it was fitted into the case of the instrument and fixed by screws, just as it was to be fixed ultimately, before the bridge was fitted to it, and the latter was even glued in its place before the soundboard was taken out. No "go-bars" were used, indeed they were not required, for he inserted several screws through the soundboard into the bridge, which effectually clamped that and the bridge together. Of course, both were made pretty hot before glueing, and the (thin) glue used was not allowed to become cold before the screws where driven home, and a better joint I never saw made. I will conclude this subject next week. THE HARMONIOUS BLACKSMITH.

BEE MANAGEMENT.

[4352.]—"COLNEY HATCH" (let. 12010, p. 288) does not seem to understand my figurative allusions to the almanack and the weather in a late letter on this subject, and I am equally in the dark as to what he is driving at; but considering the strong local associations of both Colney Hatch and Hanwell, it is not at all surprising that one cannot understand the other.

Quibbling at my figure of speech will not alter facts, and it must be patent to every one that "time is out of joint" as regards the experience of men and the instinct of bees. Bees, and men too, have a right to expect more favourable weather in this month of June, and I adhere to the sense of my former letter, that with bees as with men, instinct and experience are both at fault. What I chiefly wish to impress on bee-keepers is the fact that at this time of year a spell of weather like the present means ruin to the bees if they are not assisted. Prophesying after all is over, and telling people what they ought to have done, is rather like insuring after a fire, and is about as satisfactory.

If a farmer had a herd of cattle or a flock of sheep in a field, be it ever so large, and drought and heat made growth impossible, would he not be thought an arrant fool, and criminally cruel, if by neglecting to supply his flock or herd with the means of existence from other sources, he allowed them to die of starvation?

Bees, however, may be penned in their hives by the weather like a lot of pigs in a stye, or sheep or cattle in a barren field, yet in the name of common sense why have not bees as much right to assistance as the animals aforesaid? The law holds it criminal to starve either of the latter; but millions of poor bees are annually starved to death without a thought of the cruelty inflicted, or the great waste of wealth to the country at large. In England, the crop of honey in summer, like the crop of ice in winter, depends entirely upon the weather, yet from want of thought and care, the greater parts of both crops are allowed to waste themselves, while thousands of pounds are expended annually in importing similar articles from foreign countries, or else John Bull manufactures them at home for himself.

Hanwell, June 8. C. N. Abbott.

USEFUL AND SCIENTIFIC NOTES.

The Fireweed.—The epilobium, or fireweed, a species of cotton plant, springs up spontaneously on evergreen lands that have been burnt over. Hundreds of acres of this plant are to be seen in the north woods of New York. It is perennial, grows to the height of 4ft. to 6ft., the stem being ½in. in diameter, and some 2ft. from the top, putting out a dozen to twenty branches, each bearing from fifteen to twenty pods, that, in August, open and display a white fibre like that in the boll of the cotton plant. The seeds are very small and numerous, but do not require ginning to separate them from the fibre. The plants grow close together on poor or rich soil, and in any climate from 40° north to the Arctic Circle. Its southern limit of growth is the northern limit of cotton, and is very similar to cotton. Mr. Miller, of Utica, made candle and lamp wicks of it, and ropes that proved as strong as cotton ropes of the same size. Carded and spun, it made excellent yarn, from which a stocking was knit. Its fibre makes the finest of paper, being almost equal to silk for this purpose.

Preserving Cucumbers.—A Russian correspondent of the *Revue Horticole* thus describes a method of preserving cucumbers:—The cucumbers are washed, placed in a barrel in layers with herbs such as fennel, parsley, tarragon, onions and rose leaves intermixed. Sometimes allspice or long pepper is added. When the barrel is nearly full, a solution of salt (1lb. to 123 litres of boiling water) is poured when cold into the barrel through a small hole in the top, which is afterwards tightly corked. The barrels are kept in a cellar or in a house, and when required for use the cucumbers are sliced and sent to table. Sometimes a little vinegar is used in addition to the salt.

Sea Water at Home.—A scheme for supplying North Shields with salt water is being rapidly completed. The reservoir at the north-west end of the town is about finished, and two-thirds of the pipes have been laid. It is anticipated that, besides providing themselves with water for flushing the sewers and cleaning the streets, and likewise supplying the public baths, the corporation will be able to connect many private residences with this novel scheme.

Hydro-Electric Telegraphy.—According to *Les Mondes*, M. Ferdinand Tourmasi is the inventor of a new method of telegraphing through tubes full of water, which he is at present exhibiting at Paris. The tube is of copper 1-16th of an inch in diameter. The experiment is made with a length 3,280ft., and the inventor hopes to obtain, first a speed of transmission of at least 600 signals a minute, even through a length of 1,000 miles; second, a simultaneous exchange of correspondence by the same tube—that is, to signal both ways at once; third, the facility for printing despatches; and fourth, a very small cost of construction. The thread of water is in communication at each end with two pistons of the same diameter. One of these pistons is slightly pressed, and the motion is immediately transmitted to the other piston. The tube and its pistons are in connection with an electro-magnetic apparatus to facilitate the transmission and the reception of messages.

Boiled Rice.—"Ixion" says:—It is an interesting and important physiological law that the same food, if mashed, will not nourish, whereas, if cooked firm, it will nourish adequately. The Irishman eats his potato with a "bone" in it, while the Scotchman likes his brose gritty. It is a perfect study to see an Irishwoman boil a potato. She does it with skill intuitive. I have often watched her as I have watched the West African cooking his rice, the grains of which roll over, just like the Irishwoman's potatoes. Dame Nature, too, cooks baby's breast-milk with a bone in it, which ignorant mothers and nurses esteem a mistake. And now as to rice. Immersion in boiling water, loose or in a cloth, for thirty minutes, cooks it perfectly and beautifully. It may take a minute more or less according to the state of the barometer and quality of the water.

New Green Pigment.—A new green has been discovered, which is said to be brilliant enough to replace the poisonous colour produced by arsenic. It is composed of twenty parts of oxide of zinc and one of sulphate of cobalt, mixed into a paste with water, and exposed to a red heat.

To Preserve Pegged Boots and Shoes.—If pegged boots are occasionally dressed with petroleum between the soles and upper leather, they will not rip. If the soles of boots and shoes are dressed with petroleum they will resist wet and wear well. The pegs, it is said, are not affected by dryness after being well saturated with the liquid.

The progress of all real science is towards compression and condensation, and its whole aim to supersede the endless detail of individual cases by the announcement of easily remembered and readily applicable laws. —*Sir J. Herschel.*

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[11120.]—**A Question of Sight.**—Steel need not be "a dense solid." It is sometimes a dense but perfectly mobile fluid, and the rate of propagation of impulses depends, not on the solidity or fluidity, but only on elasticity, which may be equal (for aught that is known) in solid or fluid steel, as it is nearly in ice and water. Mr. Barwick did not call the velocity of light in any medium 17,000ft. per second, that I am aware; but he copied this as the velocity of sound (and therefore of any kind of impulse) in steel—that is probably near the mark, and if so, it follows that if the "cosmic fluid" were replaced by steel (probably either fluid or solid steel), then any impulse from the sun (call it light or what you will) would take 2½ years to reach us, instead of 8¼ minutes. Mr. Barwick is wandering utterly out of his depth, and becoming a second "T. A.," or if possible, worse.—E. L. G.—[This controversy must end here.—Ed.]

[11416.]—**Cross-bow** (U.Q.).—Make a bow as described at p. 180, reply 11471, then get out a stock of deal, resembling in every respect a single barrel gun-stock except that the groove must not be so deep, but longer—*i.e.*, a few inches longer than your arrows, which must be double-feathered. The brass trigger resembles a roughly formed 7, riveted to work freely through the stock, and held in its place by a strong spring. The bow is fixed horizontally at the end of the groove. The string is pulled back over the trigger, the arrow lying in the groove.—Hedera.

[11457.]—**Motive Power for Amateurs.**—Our friend, "A Barrister," is in error if he supposes that I, for one, can produce motive power from a fly-wheel (that is to say, in the light he took my explanation). A circular or rotatory motion is required for a certain purpose, say to drive circular saw. Steam is not obtainable! Consequently, what is next best? Most decidedly not the lever—*i. e.*, pendulum. I stated in reply to query 11457 that I would produce more power from a fly-wheel than "Zoo Andra" can with his lever—*i. e.*, pendulum—that is to say, for the same person to exert his strength in turning a fly-wheel as will swing the pendulum. Now, it is a well known fact that the larger the fly-wheel of an engine (in reason), so much the better the working of the same—for instance, a two horse-power steam-engine, nominal, in good working order, with ordinary boiler room, and limited to a pressure of (say) 40lb. to the square inch; the power derived from the said engine used for the purpose of driving a small saw bench, the workman cannot get sufficient power. What is the cheapest and best mode of remedying the same? I can, from experience, say a larger fly-wheel on the engine will allow more work to be done from the same—that is to say, if the fly-wheel is of the ordinary size. On the other hand, a quicker and equally good plan would be, if allowed, to raise the pressure of steam from 40lb. to 60lb. per square inch, as it is far cheaper to drive at a high pressure than a low. "A Barrister" says the best plan to fit a manual saw bench is to fix a fly-wheel on the saw spindle. I am afraid "A Barrister's" experience with saw benches is, well for him, brief. In the first place sufficient speed could not be obtained. The plan I have found answer when steam, or, in fact, any other than own labour could be obtained, was to fix a fly-wheel on a crank under a table made for the purpose; above the fly-wheel a saw spindle running in two centres, with a wood pulley fixed on the spindle; a leather band (1in. wide), from pulley to fly-wheel, and a treadle same as on an ordinary lathe; but, as I have in previous numbers of the Mechanic stated, sawing without steam power is very hard work.—Samuel Smither.

[11529.]—**Dermestes** (U.Q.).—As no other correspondent has come forward to give the required information concerning this beetle, I have ventured to acquaint "Redivivus" with the little I know of it. In the first place he has given the wrong name, by which means it escaped my notice for a time. The name of the beetle referred to is, *Dermestes lardarius*, not "Vermestes" as given by "Redivivus." The *D. lardarius* belongs to the family of Necrophagous beetles, six genera of which have been found in Great Britain. They are easily distinguished by their black heads and abdomen, and a rather broad gray band across the back, with three black spots on each wing case. The larvæ are known by their long slender body, which is divided into thirteen segments, and thickly covered with reddish brown hairs of a bristle-like shape. They very carefully conceal themselves from sight in the object they are engaged in devouring, and their presence is only made known by their cast-off skins, which they shed several times during their larval state. They are particularly partial to the preserved skin of any animal that happens to fall in their way, therefore they prove very destructive to collections of natural history, where they gain access to them. Bacon and hams form a favourite diet of these destructive insects, which invariably attack them for the skin's sake, and having by nature a ravenous appetite often extend their depredations to the flesh. As "Redivivus" requires them for preparing skeletons of small animals, I must confess my doubt as to whether they will attack freshly killed specimens, as their food generally consists of preserved natural history subjects.—Henry Blake.

[11531.]—**Water Wheel.**—I certainly understood "P. W. H. J." (p. 156) to mean a rotary water engine, not a turbine wheel, but in his subsequent letter (p. 258) he says a rotary water engine is usually called a turbine, distinguished by the name of the inventor. This may be the practice of our friends in Massachusetts, where it is said they can produce turbines which give out 185 per cent. of the gross power produced by the fall. Unfortunately for us in this country we find it as impossible to create power as it is to create matter. For this reason no class of motive power engines can ever be made or expected to give out the same amount of power as that due to the driving body, whether it be water or steam. The rotary water engine, of all others, may be said to give the greatest power, the reciprocating steam-engine the least. At best it never exceeds 9 or 10 per cent. of what is due to the power of the water vapourised, and in many instances not even 3 per cent. of useful effect is obtained. This is certainly to be regretted, as the expense or economising of fuel is a matter of considerable importance to the employers of the steam-engine, and I fear so long as the reciprocating principal is continued so long will it remain a prodigious destroyer of power. If my rotary engine can in anywise tend to suggest improvements in the reciprocating steam-engine I am quite willing to place it at the service of "P. W. H. J." or any other respectable person, on condition that satisfactory security can be given for its safety, and if it does not beat any other class of motors by 6 per cent. (Schmid's water pressure engine included) "P. W. H. J." or any other party accepting this challenge shall receive my engine, dynamometer and all appliances connected therewith, as a reward for his or their trouble.—D. S. [Any one accepting the challenge must advertise his address so that we may communicate direct.—Ed.]

[11554.]—**Pedestrian Tour.**—May I ask "Philo" whether his canvas shoes (mentioned at p. 232) will stand a walk through long wet grass, or a ford across a stream? "Philo" seems to speak as though he used linen shirts, but flannel shirts are infinitely preferable; with them a cold in the head is not a necessary consequence of a five minutes' halt.—Hedera.

[11572.]—**Compressing Water.**—"A. J. V. G.'s" correction is not by any means "carping criticism." I cannot find any notice of the *state* of the water in either Ganot, Miller's "Elements," or Deschanel's "Natural Philosophy." The latter work says, "The true compressibility of water, according to recent experiments conducted under the direction of M. Jamin by MM. Amaury and Descamps is, at the temperature of 15° C., ·0000457 per atmosphere." Nothing is said about the water being free from air. It seems singular, too, that the compressibility of water free from air should be greater than when air is present in that liquid, 51·3 as against 49·5 millionths. I cannot agree with "C. S.'s" notion of "where the water goes to" (p. 234); for if the water can enter the pores of the cylinder sides, I see nothing to prevent it coming out at the other side, and under these circumstances it would be impossible to keep up the pressure all night without touching the pumps, an event of daily occurrence in any large printing-office where books are turned out.—Saul Rymea.

[11625.]—**Deaf Dog** (U.Q.).—I know no certain cure, but this query being unanswered, I will give a suggestion. Let one or two drops of Dellar's essence for deafness (obtained at any chemist's), fall into each ear once a day. I have tried it personally with good results. It is painless.—Monte Christo.

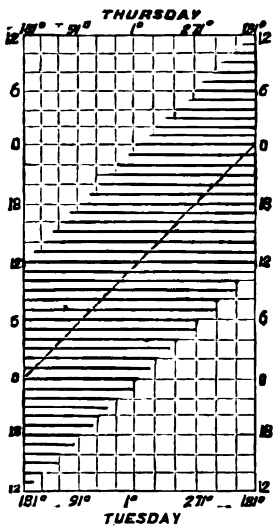
[11532.]—**Debility.**—As I said before, on page 207, there is no occasion for an insignificant individual like "Saul Rymea" to defend allopaths against the charges of either "Amateur" or Charles Rooke. The "principles of allopathy" are, or, rather, the main principle is, to assist Nature in her endeavours to throw off disease and its effects; whether the best means for effecting that purpose are adopted and put into force I do not know, but I do know that the practitioners of this system of medicine think they are right and are quite willing to listen to any better method that may be pointed out to them, on the "si quid novisti," &c., principle. Mr. Rooke says that "till lately" the lancet was the sheet anchor of the medical profession, and I suppose the "drastic purgatives" were the trusty cable. He also puts the question, "What shall we say of a system which can thus repudiate its grand procedure, and yet claim the adhesion of a community not void of common sense?" Well, "till lately," we used to travel by coaches, and employ special messengers with relays of horses on business of importance; but what would a "community not void of common sense" think of the individuals who adopted the same means nowadays? What would a "community not void of common sense" think of a system of medicine which clung to the lancet and drastic purgatives in spite of the progress of the last half-century? Mr. Rooke asks me to explain how it is that of three men subject to the same influences one takes cholera and dies, another takes it and recovers, and the third escapes scot-free. Well, old-fashioned people have an [illegible] on this point which the "Peculiar People" carry out on the "rest and be thankful" principle; but I prefer to leave this aspect of the question to the "Deluge" correspondents. The theology of one scientific subject is quite enough at a time for the readers of the ENGLISH MECHANIC, so I reply that the two men who were attacked with cholera were more susceptible to the poison than the one who was not attacked, and the man who died had not sufficient strength of constitution to enable him to throw off its effects. I never said that heart disease was "inconceivable as a result of nervous debility," but what I did venture to ridicule was the preposterous notion that nervous debility was the cause of diseases of characters so opposite as typhoid, eczema, rheumatism, and heart disease, and *all* other ailments. Surely, no one who understands the subject will assert that nervous debility is found as a normal condition in the healthy man. Nervous debility is, in fact, an effect—not a cause; and the causes which give rise to such an effect may, of course, render the human system susceptible to the poison-germs of disease. But what does Mr. Rooke mean by "nervous debility"? What does the author of the *Anti-Lancet* intend to imply by that term? Probably, *his* nervous debility is something as extraordinary as those "two most noble medicines" which cure every disease under the sun, and enable every one to live to the "allotted span" at least. It is my misfortune never to have seen or read the *Anti-Lancet*, and I am afraid, after what I have heard, that I am not likely to read it unless it be on some very unlikely occasion, when I have nothing else to do—and can't *sleep*. "Non amo te, Sabidi, nec possum dicere quare: hoc tantum possum dicere: non amo te." ("I do not like thee, Dr. Fell; the reason why I cannot tell; but this I know right well—I do not like thee, Dr. Fell.") It is very easy to sneer at medical men and their art (not *science*, mind), but these very sneerers are often the first to seek the aid of the doctor; if left to the tender mercies of the quacks, how long before they would be improved off the face of the earth! If Mr. Rooke seeks to make capital by calling up the forgotten errors of medicine, I think he will find himself mistaken; if he, or the author of the *Anti-Lancet*, knows of any means of curing the ills which flesh is popularly said to be heir to, in the name of Humanity let him make them public. I do not believe in panaceas, neither can I conceive such a thing possible as that the Designer of the human economy left his work in so unfinished a state that man found it necessary to "mend it." I am not above learning anything that is worth knowing, but I hate quackery, while I pity its dupes.—SAUL RYMEA.

[11632.]—**Debility.**—*Ignatia amara* (St. Ignatius' Bean) will cure nervous debility and various painful and irritable conditions of the brain and nervous system. Hooper, in his "Medical Dictionary," page 638, fifth edition, says that "in the Phillipine Islands the ignatia is used in all diseases." Chambers, in his "Cyclopædia," folio edition, 4 vols., published in 1799, says, "The ignatia is much celebrated for its medical virtues, being recommended in vertigoes, lethargies, epilepsies, asthmas, quartian agues, and worms." Huc, in his "Travels through Tartary, Thibet, and China," a work published in 2 vols., at the office of the Illustrated Library, 227, Strand, says, in Vol. 1, page 158, "That the ignatia is called Kon-Kono; that if taken inwardly, it modifies the heat of the blood and extinguishes all inflammations. It is an excellent specific for all sorts of wounds and contusions, and enjoying a high character in the Chinese Materia Medica." The plant is common in the West Indies and the Phillipine Islands, and may be procured of the herbalists, Covent Garden Market. The extract is prepared by pulverising the bean and subjecting the powder to the action of alcohol for 10 or 12 days, observing to shake it occasionally; at the expiration of this period it should be filtered through blotting-paper, and the filtered liquor put into a basin placed over boiling water. In a few hours the spirit will have evaporated, and the extract will be found at the bottom of the basin ready for use. The proportion of the extract and the bodies necessary to bring it into the form of pills, are as follows:—Alcoholic extract of the ignatia amara, 30 grains; powdered gum arabic, 10 grains. Make into 40 pills, and take one an hour after breakfast, and one an hour before supper, or at least an hour before retiring to rest. Half a pill night and morning will be found sufficient for very young, very aged, or very delicate persons. The pills may be easily cut if laid on a damp cloth for a short time to soften them, or they may be made of the half grain size at the time of preparing them.—E. PARKER.

[11652.]—**Tasmania (U.Q.).**—There is a small pamphlet entitled "Practical Hints to Emigrants to Tasmania," by H. M. Hall, Esq., clerk to the House of Assembly. Apply for it to Charles S. Bailey, Esq., Secretary to the Emigrants' and Colonists' Aid Corporation, 84, Lombard-street, London.—HEDERA.

[11711.]—**Time at our Antipodes.**—I cannot conceive what elucidation this very simple, not to say puerile, question, can need. Surely, the slightest consideration would show any one that there can be no meridian nor spot where the same sunrise is reckoned the beginning of Sunday and of Monday. Which, then, shall it be? A ship arriving from Europe westward would find it Sunday, when one arriving eastward, having passed through another night, calls it Monday. The name of the day, then, can only depend on whether the first European settlers or missionaries arrived at the island *viâ* Cape Horn or *viâ* the Cape of Good Hope. Of course there are islands about the mid Pacific that were first approached each way, and so, though very near together, have to call the same day Sunday in one island and Monday in the next. This is unavoidable, and there might be a sinuous line marked from Behring's Strait to the south pole (of course, crossing no land) as the line where "the day begins." But in all probability, islands discovered from the east and from the west are so mixed up that Monday may begin in some before Sunday begins in others, and the line would have to be accompanied by detached bits of each, like the bits of English counties "situate in" another county, as gazetteers say. I believe all our furthest colonies name their days as if reached round the old "Cape," therefore begin and end every date before us; and so, if you go there by Suez or Cape Town you find no change of time; but if you go by the Horn or Panama, and arrive on the ship's "1st of January" or what not you will have to call the next day the same.—E. L. G.

[11711.]—**Time at our Antipodes.**—Although the fog has not yet cleared away from some of us, there are others who see the thing so clearly as to satisfy "Kelby," and set the question at rest. "Seperator" quotes the reckoning, at the Fiji Islands as being in advance of ours, and that when it is noon in England it is twelve the previous night at Fiji—*i. e.*, the Tuesday, for example, is ending, and the Wednesday beginning. So far we have a starting point from which to reckon our absolute day. Tuesday, twelve o'clock at night at Fiji, is Wednesday, 6 a.m., at New Orleans, noon at London, and 6 p.m. at Calcutta. "T. S." clearly shows the reckonings at London and New York to be of the *same* day by the dispatch and arrival of telegrams at 11 a.m. and 4 p.m. respectively at New York and London, and reasons that New Orleans being one hour west of New York the time there is 6 a.m. of Tuesday, at which his telegram would be dropped, and he finds himself landed at his original starting point—viz., the arrival of the message dispatched from London at noon, at the Antipodes at both Tuesday midnight and Tuesday break of day, meaning, of course, the ending and beginning of the same day, Tuesday, and this is his perplexity. I am sorely afraid that by introducing another diagram I shall not only make "confusion worse confounded," as "F. N." has it; but accumulate confusion upon confusion until at last the whole subject will be such a mass of confusion that the truth of this knotty question will disappear, and there will be no unravelling it; nevertheless, I must claim your indulgence, Mr. Editor, and ask for the admission of the accompanying diagram. "T. S." does not doubt that every day has an absolute commencement somewhere on the earth's surface, and imagines that every country fixes its own time. That the absolute day is independent of arbitrary settlement is, I think, obvious. Time is not as we choose to reckon it, otherwise I might not have erroneously assumed 270° as the meridian at which the day commences, and which "T. S." finds does not fit nor will 180°, that of our Antipodes, fully meet the question. The diagram, which is



arranged to show the latter half of Tuesday, the whole of Wednesday (the thick horizontal lines), and the first half of Thursday, is to be read from right to left, and from bottom to top. The commencement on the right of each partial dark line signifies the midnight between Tuesday and Wednesday. The thick diagonal line 0—0 shows the progression of Wednesday's noon from 181° to 181° in the reverse order of the longitudes—*i.e.*, from east to west, and the upper terminations of the dark lines represent midnight between Wednesday and Thursday. Now, applying this diagram, in the first place, to the perplexity of "T. S.," we have the middle line 12—12 right across the diagram, signifying that all over the world it is Wednesday and nothing else. For clearness of expression we may regard the meridian 1° east as that of London, from whence the message is dispatched (in this case Wednesday instead of Tuesday); the 12 on the right hand under 181° is midnight, between Tuesday and Wednesday, the time of the reception of the message. The meridian 6 hours to the east is 271° corresponding to New Orleans, where it is 6 a.m. Wednesday morning, noon occurring at London, and 6 p.m. at Calcutta. The line terminates at 12 on the left, also under 181°. Now to find the true value of the second 12 under the same meridian we must take these facts into consideration. All the meridians east of 1°, the central vertical line of the diagram, have afternoon hours, therefore their natural *termination* is 12 at night of Wednesday, or the commencement of Thursday. All the meridians west of 1° have morning hours, the natural *commencement* of which is the moment after 12 at night on Tuesday. It would appear from this that on the meridian of 181° both Wednesday and Thursday were commencing at the *same* instant, but it is actually not so, as there is really the 24 hours of Wednesday between them on the earth's surface, the absolute Tuesday just expiring, and the absolute Thursday commencing. These 24 hours, however, begin and end on the same meridian, consequently, the intermediate hours between beginning and ending apparently disappear at that meridian, and the reckoning from the eastern meridian 181° to the one immediately west of it, 180°, passes suddenly from Tuesday to Wednesday, explaining the facts mentioned by "F. N." of a ship going to the westward skipping over a day, and a ship sailing towards the east gaining one. This leads me to the consideration of the second difficulty of "T. S." —viz., the occurrence of 7 a.m. 5 hours west of a meridian, at which it is noon of a given day, and 6 a.m. of the succeeding day, at a meridian still farther west, which "Kelby" styles a *reductio ad absurdum*. In applying the diagram to this case, instead of the noon meridian being 1°, it is 271°, the lowest 18 — 18 line represents 6 a.m. at 181°, the dot on this line over 271° signifying noon at Tuesday at New Orleans. Now, it is midnight at Calcutta between Tuesday and Wednesday at this moment, and 6 a.m. Wednesday at 181°. There being six hours of Wednesday and eighteen hours of Tuesday in existence, the diagram shows that 7 a.m. of Tuesday falls on meridian 196°, or one hour east of 181°; a similar case to that supposed between New Orleans and New York, and may be thus expressed—

164° West longitude, 7 a.m. Tuesday,
179° " 6 a.m. Wednesday.

Perhaps "Kelby" can show that this also is a *reductio ad absurdum*, and if so, perhaps he can still further show how the change from Tuesday to Wednesday can be effected without it. As the greatest portion of the meridian 181° is on the ocean, no inconvenience of any moment can arise from the circumstance that a sudden change of reckoning from Tuesday to Wednesday, for example, accompanies it as it approaches to and recedes from the sun. Let us take the earliest noon of Wednesday, which occurs, according to the diagram, in longitude 181° at the time when it is 1 p.m. of Tuesday, in longitude 196° or 164° west. If in my last communication, June 7 (p. 308) the meridian 181° be substituted for 270°, and diagram No. 2 (p. 284) for No. 1; the lowest line 12 — 12 representing the establishment of Tuesday over the whole world in the present diagram—will correspond to diagram No. 2 (p. 234), and the whole of the present diagram will illustrate my last communication.—W. R. BIRT.

[This controversy has exhausted all the space we can spare for it.—ED.]

[11731.] — **Hair Wash.** — I don't know why "Excelsior" fails, because I know that borax and camphor is a very good thing, as I have often used it. The camphor does not dissolve except in very small proportions in water, and if the lumps are big enough may be used to fresh water and borax over and over again. But why use *any* wash? Impurities from the body are secreted on the scalp as on other parts of the body, and there is nothing a person can use cheaper, or more effectual, than soap and water, a brush, and a small quantity of ammonia.—E. T. S.

[11743.]—**Humea Elegans.**—This is generally considered a sub-tropical plant, but is easily raised from seed with a little heat. It may be planted out in May. Any good compost will do—rotted turfs, stable manure, and sand. It will not grow so well in such a season as the present as it would if we had a little summer warmth.—K. T. L.

[11756.]—**Water Wheel.**—I promised in a former issue to supply the required information, provided your correspondent would give some more explicit data; however, I must crave his patience, being still in want of one of the most essential points—*i.e.*, the velocity per second, which I omitted in my former query, not being wishful to encroach upon your space by merely assuming velocities, as I see two of your correspondents do. If your correspondent "Water Wheel" will kindly furnish the velocity, I will reply to his query.—J. GILLAIRD.

[11760.]—**Soldering Jewellery.**—If "New Pivot" will fuse together 3 parts gold, 2 parts silver, 1½ copper, then add ½ part zinc, he will have a solder that will flow at a dull red heat, suitable for gold brooches, guards, &c.—H. B. B.

[11772.]—**Black Lacquer.** — Brunswick black, recipes for which have recently appeared.—K. T. L.

[11781.]—**Lathe.**—In section 2, read "beading tool" for "treading tool."—SAMUEL SMITHER.

[11809.]—**Cool Air in Hot Climates.**—I am surprised that if the "new and excellent sun-screen "(reply 11845), is so easily made by silvering small glasses, no sheets of "sheet plate" glass are so treated for use either in tropical windows (with a partly translucent film), or (quite opaque and reflective) for covering the boards of jalousies, and even roofing. A conservatory-like structure wholly so glazed would certainly be the coolest possible place in sunshine. The silver film, I would suggest, might be fixed on the glass by a coating of fusible earthenware glaze, fused upon it in an oven.—E. L. G.

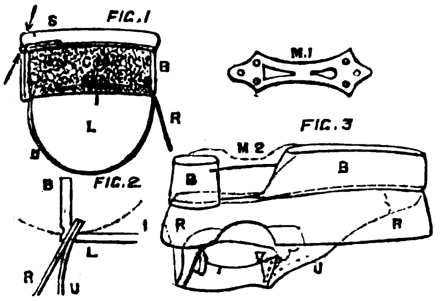
[11813.] — **Oatcake Making and Baking Machine.**—There is a machine for that purpose, made and invented, I believe, at Shipley in Yorkshire.

I am well acquainted with a baker who purchased one, but he soon gave it up, as he could do it far quicker by hand. If I remember right the cost of the machine was about £25.—A Would-be Baker.

[11872.]—**Carbonic Acid Gas and the Atmosphere.**—The proportion of carbonic acid is nearly four times as much as "Philanthropist" guessed—more exactly, three-and-a-third times as much in the open country and from four to five times as much in towns. In Dr. Angus Smith's "Air and Rain," the smallest proportion stated as observed is ·03 per cent.—*i. e.*, three parts by measure in 10,000, the mean of a large number of country places in Scotland, is ·0336 per cent.; and that of specimens in London is ·04394 per cent. As carbonic acid is heavier than air, the weight of that in the atmosphere may be assumed to be about 5 parts in 10,000, or one in 2,000. As to the increase that might be borne without injury to animal life, but little is accurately known. When the enormous proportion of 88 per cent., or 90 times that of pure air is mixed, animals die quickly, not, as some suppose, from direct deficiency of oxygen, but from the presence of carbonic acid, for if that be absorbed by lime or otherwise, air still more deficient in oxygen may be breathed with impunity. Close rooms sometimes contain air with twice or three times, occasionally as much as ten times, the natural proportion of carbonic acid, which, if produced, as it usually is, by respiration and combustion, renders it dreadfully oppressive; but air containing a similar proportion of pure carbonic acid, produced when making soda water, is neither unpleasant, nor, I believe, injurious. Certainly, the unpleasantness, and, probably, the injuriousness of ordinary close rooms is caused, not by the carbonic acid, but by other products of respiration, nor are those products themselves injurious in moderate quantity until they have undergone some change, for, as "M.R.C.S." a short time since reminded us, we are constantly drawing back into our lungs some of the air which has just left them, but remained in the windpipe or other air passages, while the lungs themselves must be always filled with air containing a very large proportion, probably ten per cent. of carbonic acid, together with moisture and pulmonary excretion. It is evident, therefore, that it is not either carbonic acid or pulmonary excretion which is, *per se*, injurious, for they are always present. There must be either a considerable excess of carbonic acid, or the presence of pulmonary excretion, which has undergone a change in the air to render it injurious; and if it be removed before it has undergone such change, we shall not suffer from it, as all experience proves.—Philo.

[11875.]—**Spectrum Colours.**—The impossibility of making a coloured spinner appear white in the presence of a real white (equally illuminated) is absolute, arising from the nature of light, and need not imply any imperfection in the paints, as "H. P. H." fancies (p. 262). But "Utile Dulci" will find it possible, after a few well noted trials, and with care and thought, to make sectors of either two, three, seven, or any intermediate number of colours, combine by rotation into so clear a gray that the contrast of a black border and middle will make it (in the absence of white) pass for a very tolerable white in the sunshine. He should repeat the series (whether two or seven) four or six times, that is, complete it in each quadrant or sextant of his disc. The following pairs are nearly complementary, or will produce white, the latter of each pair exceeding the former one in depth, and also in space, possibly as three to one in space, or less, as found by trial:—Pale chrome yellow and smalt; orange chrome and cobalt blue; vermilion and bluish verditer, or verdigris (equal); emerald green and magenta, or burnt carmine. Of course, what each pair will do separately, any two or more of such pairs will do together.—E. L. G.

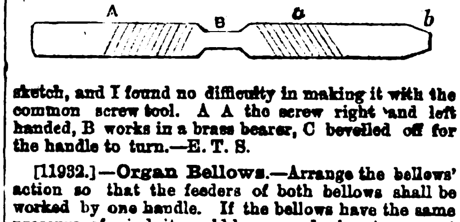
[11886.]—**A Thick Soled Shoe.**—These soles are of cork, and to build them is considered a crack job, and those crack hands who do them are few and far between. Years ago many elderly ladies had corks made for winter wear, and your humble servant has had a round sum for building them. If "Wee Pet" can work to or understand a sketch, I send him one. The upper is the same as the ordinary one, the inner sole rounded upon the last, but the chamfer is more upright than for welts. The box for cork is a rann of



tight rainge leather, prepared the same way with chamfer as the ordinary welt, but is not sewn on the same as ordinary welts, but vertical, or at right angles with the sole (see B, Fig. 2, which is a section). The rann proper is a piece of good kipp or calf, tough, and not too tight. This is laid down upon the upper and sewn between the box and upper. The box piece should be long enough to pare to shape and thickness required. After the cork is fitted in with good resin paste, draw the rann over and lace it, and stitch the sole to the rann edge (see arrows, Fig. 1). The dotted line figured is the sewing of rann and box or welt. The heel is best filled up with light wood; a piece of willow is best. The outer sole is stitched on to the edge of the rann with a round awl, not what is usually termed a round awl or sewing awl, which is oval, but a perfectly round needle awl, such as is used or was used for wood heel work for staff ranne in olden times. Description: S, outer sole; C, cork; L, last; U, upper; R, rann; B, box. The same letters show same parts. M1 is a brass plate to shield the cork and shoe, and forms a bridge, M2, put under the sole and top piece.—Jack of All Trades.

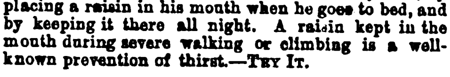
[11887.]—**Hair Dye.**—Would T. I. Preston (p. 287) oblige me by giving the formula for the terchloride of gold hair dye, and the directions for using it?—Another Gray Beard.

[11897.]—**Fastening Fret Saw.**—"G. W. C. H." must make a movable joint between the end of the ash spring and his saw catch. I send sketch; the joint



is at A, the lower part must work on a bearing; by that means a vertical motion can be obtained.—Samuel Smither.

[11901.]—**Grip Chuck.**—Why does not "F. G. T." make the screw in the lathe? I have a chuck I made, which is worked by one, and will take in from 3in. to ⅜in. The screw is somewhere about the size of the



sketch, and I found no difficulty in making it with the common screw tool. A A the screw right and left handed, B works in a brass bearer, C bevelled off for the handle to turn.—E. T. S.

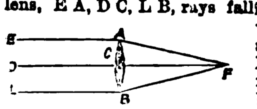
[11932.]—**Organ Bellows.**—Arrange the bellows' action so that the feeders of both bellows shall be worked by one handle. If the bellows have the same pressure of wind, it would be a good plan to connect them with a wind trunk also; if the pressures are different, don't use the trunk.—Pneumatic Lever.

[11948.]—**A Bad Sleeper.**—The disagreeable symptoms of which "N. K. R." complains may be alleviated by his leaving off the use of alcohol, supposing him to be a drinker of spirits; by smoking less, if he indulges in the weed; or, in any case, by placing a raisin in his mouth when he goes to bed, and by keeping it there all night. A raisin kept in the mouth during severe walking or climbing is a well-known prevention of thirst.—Try It.

[11950.]—**Sewing Machine Difficulty.**—The needle-bar goes down, then rises again a little way to form the loop for point of shuttle to pass through, then goes down again to enlarge the loop while the shuttle is passing through; when the needle is at the lowest point the second time the shuttle should be rather more than half past the needle. If the upper thread catches the shuttle when the needle-bar comes up to tighten the stitch; move it a cog forward.—H. A. S.

[11965.]—**Dandelion Roots.**—April and May are the most popular months with the old Yorkshire dames. They use the large roots only, slicing them and boiling them down well. The liquor is said to be a tonic, and "good for the liver complaint."—Hedera.

[11991.]—**Focal Length of Lenses.**—The focal length of a lens for parallel rays:—Let A C B be a lens, E A, D C, L B, rays falling upon it, these converge nearly to a point at F, C F is the focal length, or if the thickness of the lens is to be considered I F is



the focal length. One very simple way of determining it is to use the lens as a burning glass and observe the distance of the object which produces the best effect, or else use it in a telescope tube with one eye lens of known focal length. When the best definition is obtained the distance between the lenses is measured, if the eye-lens be concave, as in an opera glass, its focal length added to this distance will give the focal length of the object glass. If the eye-glass be a convex one, showing an inverted image, subtract its focal length from the distance between the lenses. As applied to photography, *cæteris paribus*, a lens of short focus acts more quickly but does not give so good a definition, except in the part focussed for, the centre of the field.—Philanthropist.

[11993.]—**Photographic Process.**—There is no dry process yet discovered which has the rapidity of exposure and development peculiar to wet plates. But, if "Anon." wishes, I will (with permission of our kind Editor) send particulars of a dry-plate process which gives very good results indeed, with one to two minutes expose; good light; single stereo. lens three-sixteenths aperture.—J. David Smith.

[11995.]—**Patent Rights.**—The result of any party patenting a machine similar to another, which has been in use previously, is that the second patent is invalid and worthles.—A., Liverpool.

[12000.]—**Insects in Tables and Chairs.**—The seat-framing of chairs, and possibly the parts of the tables mentioned by "Fox," are usually made of beech and English wood, peculiarly liable to attacks of the wood worm. For such ordinary articles, I know of no remedy if the means adopted by Mr. W. G. Rogers in restoring the world-famous carvings of Gibbons is inapplicable or too expensive. The carvings in the chapel at Chatsworth were restored by Mr. Rogers in the following manner:—To destroy the insects, he placed the carvings in a strong solution of corrosive sublimate (chloride of mercury) in water. The original tint of the wood, being impaired by this, was restored by ammonia and muriatic acid. An infusion of gum or gelatine was afterwards injected to fill up the worm holes, and strengthen the fabric of the carvings. An after-varnish of resin, dissolved in spirits, restored them to their original beauty—sound, I believe, to this day. All English woods are liable to attacks of worm—English walnut, oak, beech, or any others used in furniture, perfect immunity from which is noticed in the case of foreign woods.—Before Noon.

[12001.]—**Nitrate of Soda** is met with in Spain, and in various parts of India, but the most remarkable deposit occurs in Peru, in a tract of country about thirty-five miles from the coast, where no rain falls, and even wind is hardly known, with scarcely a trace of vegetable matter. The depth of the deposit varies from 5in. to 5ft., and extends over the country for several leagues. Genuine nitrate of soda should not contain more than 7 per cent. of impurities. The nitrogen which it contains in the form of nitric acid is the element that stimulates the wheat plant to a healthy growth. I shall be happy to give further particulars, if necessary, regarding its manufacture and uses, &c.—Soda.

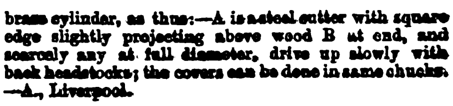
[12009.]—**Photographic Lens.**—It is possible to take a picture by a single bi-convex lens; but it will require a pretty small stop in front, and so will be slow. An arrangement must also be made to allow the plate to lie a little nearer to the lens than the ground glass is, as the chemical focus is shorter than the visual focus. If I remember correctly, the difference is about the one-twentieth part of the focal length of the lens. A lens with a focal length of about 5in. will give a very good picture the size mentioned. If "A Beginner" is going to purchase a lens, he should get an achromatic on at first, and then he will have no difficulty about the chemical and visual foci. An unmounted achromatic view lens to take pictures 8½in. × 4¼in. will only cost about 5s. "A Beginner" will also find the collodion process much easier to manage than the calotype.—Occasional Photo.

[12012.]—**Water-Power.**—Better than assuming a deprecatory title, such as "Ignoramus," would be a careful attention to, and a plain and full description of, a case requiring an answer. Would not "Ignoramus" see, with a little consideration, that his question is so vague as not to admit of an answer? What is a "3in. run of water (through a 3in. pipe)" as to quantity? I am sure I do not know. Now, if the question had been put in this form: There is water at A, and it runs through a 3in. pipe from A to B. The point B is ft. from A, horizontally, and ft. below it, vertically. The quantity of water, whatever it may be, is sufficient to keep the pipe constantly running full. At the point B there is a sudden drop, or fall, of ft. What would be the best, &c.? Such a question would admit of a definite answer. Different persons might give different answers, according to their opinions, but at least they would have data upon which to give them.—C. S.

[12014.]—**Organ.**—If "E C." will look back at "our" Mechanic of January 26, 1872, on p. 488, he will find both drawing and explanation of what he requires.—York.

[12020.]—**Tireing Cart-Wheels.**—In answer to "U. V. W.," if the wheel is merely dished—that is, if the tops of the felloes are upright with the wheel, the tire will not require bevelling; but if the felloes are bevelled to make the tire wear even, shut the tire up a little smaller than the front or smallest edge of wheel to draw it up tight when on, then hammer round towards one edge of tire to bevel it to fit the largest edge of wheel, which may be tried by running both tire and wheel with the traveller, with which I suppose you are acquainted. For wheel 3ft. 8in. high, tire 2¼in. by ⅝in., say ⅜in. smaller than the wheel in circumference. For wheel 4ft. 10in. high, same size tire, say 1½in. smaller. The size varies, the thicker and larger the tire the smaller in proportion it should be, as it will expand more in heating.—A. B.

[12021.]—**Turning.**—All you require is a metal chuck with a piece of hard wood driven in, to chuck up cylinder to bore, which is easily done as follows: When chucked up, turn the mouth perfectly true, take a piece of hard wood turned to size of bore, and tapered off, run a cut with tenon saw across the diameter, and insert a piece of sheet steel, say part of the busk of a pair of stays, or crinoline steel will do if



brass cylinder, as thus:—A is a steel cutter with square edge slightly projecting above wood B at end, and scarcely any at full diameter, drive up slowly with back headstocks; the covers can be done in same chucks.—A., Liverpool.

[12022.]—**Forest and Rainfall.**—I am not aware that it has been asserted that "the destruction of forests causes a diminution of the rainfall" if we understand by that the rainfall over a considerable length of time, but it has been noticed on the European continent (and I believe first in France) that the effect of clearing the forests has been to cause the total amount of rain to flow off the ground more unequally during short lengths of time, therefore causing floods at some times and drought at others; and it was after an excessive flood which swept away a railway viaduct and part of an embankment that, as far as I know, attention was first drawn to this question. At present I can only echo the question put—"Where can the best information on this subject be found?"—C. S.

[12024.]—**Photographic.**—It is likely that the glasses are all right, but a smaller stop is wanted to give sharpness all over the plate. This is how the glasses of a portrait lens are placed:—The front pair are cemented together and are placed with the convex side towards the sitter. The back pair are separated by a ring, the concave glass with its convex side next the front lens and the double-convex glass with its most convex side towards the concave glass.—OCCASIONAL PHOTO.

[12024.]—**Photographic.**—Let "One in a Fix" insert a suitable stop in front of his lens. I think his difficulty will be then overcome. It will, of course necessitate a longer exposure.—J. DAVID SMITH.

[12026.]—**Greenheart Timber.**—Greenheart is used for wine laths—that is to say, a great quantity is cut for such purposes; the exact way of using I cannot tell. The size the laths are cut is one inch by one half inch; any length over 4ft. Greenheart is also used for gun carriages, and I have had portions of old ships made of such. I do not know if it has any special use apart from what I have stated, with the exception of a few fancy goods requiring hard woods—such as office rulers, draughts, &c. I should expect it would stand any amount of sun and weather. Santa Maria timber, as regards the cabinet trade, was a failure. I have cut a great quantity of it. It very much resembles mahogany, but it differs from mahogany when being made up. It very soon splits—for instance, chair legs turned out of Santa Maria, when being mortised, split sooner than deal. It also contains a kind of grit that dulls the tools and notches them. I should not advise it myself for cart shafts or cart panels, or any kind of work likely to receive rough usage, unless of any bulk. Most of the woods purchased at the sales at the dockyards are the remains or refuse of ship building and manufactories of gun carriages. I have attended many sales at Woolwich and Deptford, and never saw much greenheart or Santa Maria. The wood principally consists of teak, mahogany, birch, beech, elm, and at intervals greenheart, African oak, English oak, American oak, fir, and deals.—SAMUEL SMITHER.

[12027.]—**Albert Durer's Engravings.**—The distinguishing marks on Durer's etchings are his monogram, his softness, and his touch. A number of his plates can be seen at the British Museum.—XYLOGRAPHER.

[12029.]—**Object Glass.**—The layer of air between two lenses will always cause a loss of more light by reflection than a similar layer of balsam would, the latter having nearly as refractive a density as glass, and at the surface dividing equally refractive media, there is no reflection at all. But some object glasses have the two surfaces that meet of very different radii, and then the inclosed lens of air is necessary, and balsam would not supply its place.—E. L. G.

[12031.]—**Hot Peas.**—Let the peas stand in cold water all night. Afterwards place them in a pan of water, just allowing the water to cover them, add a good-sized ham bone. It must have ham on, of course. Place the pan upon the fire, and as the water boils add salt and pepper. After a time the whole will become soft. After which nothing remains but to eat them with a little vinegar. Numbers of hawkers prepare them this way. I often indulge in them myself, with sundry misgivings as to the quality of the meat employed, which is often mere slink.—JOHN HOPKINS.

[12034.]—**Ordnance Map of London and Environs.**—Trinity high-water mark at London-bridge is 12·48ft. above approximate mean water at Liverpool.—H. C. L.

[12035.] — **University of Turin.** — Unless "Silex" intended to enrol himself as a candidate for one of the Government examinations, no special inquiry would be made as to his nationality, and no fees are expected. As, however, a five years' residence in the kingdom gives a foreigner the right of citizenship, no fear need be entertained of rejection on the grounds of nationality, but a small fee, amounting I believe to about 100f. per annum—£4—is required of those who intend enrolling themselves as candidates for examination. Learn Italian and French tolerably before going, as otherwise you will lose much time; take Bulwer's advice and avoid Englishmen abroad; attend the really excellent classes in German, French, Spanish, Latin, Greek, besides Chemistry, Botany, Physiology, &c., and you cannot fail of coming home a better and wiser man. But avoid all gambling, be it billiards or cards, for the Italians are crack players at the former, and rather too strong for an Englishman at the latter. Above all, do not let the delightful softness of the climate superinduce a like softness in your purpose.—S. BOTTONE.

[12039.]—**The Pressure of the Wind.**—This question is put in a wrong form. The intention is, I will assume, to ask what effect the wind of a given force, acting at right angles to a plane surface one foot square, would have in moving it horizontally, supposing it to be laid flat and horizontal, and taking no account of the thickness of its edges. And then the questioner, in the latter part of his question, assumes that the wind acts obliquely to the surface of the plate. But this is a form of "begging the question." If the plate in the first instance is to be supposed to be at right angles to the direction of the wind acting horizontally, then there is no oblique action at all. The action of the wind blowing horizontally upon a flat and horizontal surface, tending to move it, is that of friction only. In order to determine what the force of friction would be we must know the velocity, and this is not stated. It is left to any answerer to guess, or assume, what velocity would correspond to a pressure of 1lb. per square foot. Let the inquirer tell us what is the velocity of a wind that will exert a pressure of 1lb. per square foot, on a surface placed at right angles to its direction, and then one may be able, by reason of mechanical laws, to say with what force such a wind would tend to move a plate horizontally.—C. S.

[12039.]—**The Pressure of the Wind.**—A late number of the *Mechanics' Magazine* contains a series of experiments on this subject. An inclined plane having an inclination to the horizon of 15°, experienced an upward pressure of about four times as much as the horizontal resistance. We might have expected such results from the theory of the resolution of forces. When $\theta = 15°$, cosine θ^2 is about four times as great as sine θ. I do not think that the wind blows in a horizontal direction, but at a slight angle downwards.—PHILANTHROPIST.

[12041.]—**Burnishers for Brasswork,** either for use in the lathe, or at the vice by hand, are nothing more than pieces of steel hardened, polished, and coloured on an emery top, and of the shape suitable for the description of work. Brass is lacquered after it is burnished to prevent its tarnishing.—W. ALLAN.

[12045.]—**Analysis.**—In order to determine the relative quantities of sulphur and beeswax in the mixture which your correspondent "Lictor" wishes to analyse, the only accurate method will be to convert the sulphur into sulphuric acid, and then into sulphate of barium, and from that to calculate the amount of sulphur present. In order to effect this, weigh out (say) 100 grains of the mixture and add pure nitric acid, then warm and add gradually portions of chlorate of potash. So soon as the sulphur is oxidised add hydrochloric acid and evaporate almost to dryness, and then filter. To the filter add a quantity of water, and then a solution of chloride of barium and boil; allow to stand till almost cold, then pour the clear liquid upon a filter (the amount of ash which is left on burning being estimated); add a fresh quantity of water, and repeat the operation several times; and, lastly, pour the precipitate upon the filter, dry, and ignite upon a platinum or porcelain dish; allow to cool, then add a few drops of sulphuric acid, and heat gradually; then weigh. From the following data the amount of sulphur may be calculated. 233 parts of sulphate of barium = 32 parts of sulphur.—ANDREW F. HARGREAVES.

[12047.]—**Radius of Sector.**—If it be a sector—that is, if the two cuts would meet at the common centre of the curves—their radii are in the same ratio as their lengths, or the lengths of their chords. "T. E. G.," therefore, has only to work the "rule of three" sum:—As the difference of the two chords (or of the two curves) is to the outer chord (or outer curve, as the case may be), so is the difference of the two radii to the outer radius.—E. L. G.

[12048.]—**Trip to Ireland.**—Black's or Bradshaw's Guides to Ireland, and tourists' handbooks. I forget the exact titles.—PHILANTHROPIST.

[12050.]—**Socotrine Aloes.** — Any intensely-coloured, but transparent (or non-opaque) body, necessarily, by the laws of optics, appears of deep colour in the mass, but a very pale shade when ground small. Thus, you may grind the deepest blue glass used ornamentally (or any mock gem, or real either) into a nearly white powder. The blue glass ground to make even the palest smalt blue is in the mass merely jet black. Dry gamboge will illustrate the same fact, being slightly transparent, but with the singular property of turning opaque when wetted.—E. L. G.

[12055.] — **Works on Pedal Playing.** — The most useful studies out for the pedals are those by W. T. Best, Esq., Organist, Albert Hall, Kensington, and St. George's Hall, Liverpool. Novello and Co. Price 12s. If "A Struggling Organist" wishes to master the pedals, get the book, learn the first study before the second, attend to the directions given, and by the time he gets to the last study, he will find no difficulty in any pedal obligato he may meet in organ music.—YORK.

[12055.]—**Works on Pedal Playing.**—I don't think you could have a better book for instructions on playing the pedals than George Cooper's "Introduction to the Organ for the Use of Students." Price 6s. Rinck's are also very good. Cooper's may, perhaps, be out of print, as I have had mine about ten years.—W. H. SKELTON.

[12056.]—**Echo.**—A curtain of thick woollen cloth, hung from the point, and fastened to the sides of the roof, will stop the echo complained of. "J. T. O." must find out by experiment the depth required, as, of course, that will depend upon the height of the building, &c.—SACRISTAN.

[12058.]—**Bees.—Swarm or Brood.**—It is just possible that a swarm of bees has taken possession of the hive, but the great probability is that the hive contained a quantity of honey which some neighbouring bees have been plundering, hence the busy appearance. It would be absurd to suppose the heat of the sun in June could revive the bees that have perished of cold in the previous winter. If a swarm has taken possession "C. R. H." will observe the workers bringing home loads of pollen on their legs in fine weather, when we get any, and the bees will remain in his hive all night, but if they are robbers they will bring nothing to the hive at all, and except a few benighted or benumbed bees none will be left in the hive after dark. It was culpable carelessness, at least, on the part of "C. R. H." to leave a hive in which bees have perished, and which might contain the germs of disease, to be preyed upon by a neighbour's bees; but if "C. R. H." placed it on its stand to become, as it were, a trap to catch a neighbour's swarm, the action was simply dishonest.—C. N. ABBOTT, Hanwell, W.

[12061.]—**Chemical.**—Chlorate of potassium is easily distinguished from chloride of potassium, as the former does not form a precipitate with nitrate of silver, whilst the latter produces a white curdy precipitate, which turns blue in the daylight, and is entirely soluble in liquor ammoniæ.—F. T.

[12061.] — **Chemical.** — In answer to "Emily Jane," chlorate of potash (or, more correctly, of potassium) when melted in a test-tube evolves oxygen, and a match dropped into the hot liquid deflagrates vividly. With concentrated sulphuric acid the solid salt gives a deep yellow explosive gas, possessing bleaching properties, while the chloride evolves hydrochloric acid gas, reddening litmus paper and soluble in water. The solution of a chlorate gives no precipitate with nitrate of silver, but a chloride produces white, curdy, silver chloride, insoluble in nitric acid, and gradually darkening in the light. Consequently, if the chlorate contain chloride, which is often the case, a precipitate will be produced on addition of silver nitrate. To detect small quantities of chlorate in solution, and in the absence of chloride, acidify with dilute sulphuric acid, and make blue with solution of indigo. Then add gradually a solution of sulphurous acid or sodium sulphite. In the presence of a chlorate chlorine will be liberated, which will discolorise the indigo; excess of sulphite will prevent the reaction. If a chloride be present in a liquid together with a chlorate, they are best detected as follows:—Add nitrate of silver to the solution, and filter from the precipitated chloride. To a solution of sodium sulphite add nitrate of silver till a permanent precipitate is produced, then add dilute nitric acid till clear. Mix the solution with the filtrate from the chloride of silver, when a fresh precipitate of chloride of silver will be produced if chlorate is present. The precipitation is immediate and complete on heating, but only occurs slowly in the cold. If sulphate of silver and sulphuric acid are employed instead of nitrate and nitric acid the test is still more perfect, and the presence of nitrate may readily be detected, if desired, in the filtrate from the second precipitate of silver chloride.—ALFRED H. ALLEN.

[12061.]—**Chemical.**—In reply to "Emily Jane" (p. 313) potassium chloride may be distinguished from the chlorate by precipitating it with nitrate of silver, which will leave the chlorate in solution.—J. BOSKELL.

[12062.]—**Induction Coil.**—1. It is indifferent which way you lay the secondary wire; but it is usual to coil it in the same direction as the primary. 2. Yes, when you have laid one coil from end to end varnish it, when dry cover it with a layer of gutta-percha, and then proceed to lay on another coil. Full illustrations have been given in back numbers.—S. BOTTONE.

[12072.]—**Magnetic Moment.**—The quotation which "Beacon Lough" wishes explained is one which presupposes that the reader understands the technical mathematical term "moment," and of the readers of Ferguson probably not one in a thousand does this. The *moment* of any agency is its relative power in some especial application; the *moment of a magnet* is its power to return to its position of N. and S. after disturbance, or rather the force required to deflect it from that position; this depends on the actual intensity of the magnetism, and also on the length of the magnet—*i.e.*, the leverage exerted by its energy supposed to be concentrated in its poles (not its ends). As this is comparative any units may be used; but the absolute units are the only ones desirable to employ.—SIGMA.

[12073.]—**Scarlet Runners.** — Scarcely worth while, even if possible, these beans being so peculiarly subject to thermometrical changes.—HENRY NEWMAN.

[12078.] — **Cabbage Planting.**—**Rhubarb.** — I would advise George Richardson to obtain seed of the Early Dwarf York, as one of the best early cabbages. If his garden is in an exposed situation, and in the North of England, I say do not plant cabbage in winter, as they very rarely grow to any size. Dig in manure in autumn, and let the ground lie in a rough state all winter, and merely turn the top soil over when he puts in his plants. When he is digging in the manure he may trench it to the depth of 18in. As to rhubarb, it ought to be planted in autumn and watered freely with soapsuds.—BED OF STONE.

[12079.]—**Detonating Crackers.**—A small piece of fulminate of silver is mixed up with small pieces of gannister. When thrown upon the ground the friction upon the fulminate causes the explosion.—ELECTRIC.

[12080.]—**Analysis of Manures and Assaying for Certain Metals.**—This is a commercial query, and crept in by mistake. "X. Y. Z." must ask for his information through an advertisement, and he will get replies.—ED.

[12081.]—**Chemistry.**—In answer to "Molecule," for the detection of phosphoric and arsenic acids, make a solution of ammonium molybdate in water, or boil molybdic acid with ammonia. Add this solution to moderately strong nitric acid, taking care that the nitric acid is in excess; filter if necessary. This solution when added in plenty to any acid liquid containing a phosphate or arseniate produces a yellow precipitate, which is promoted by stirring with a glass rod, the precipitate having a tendency to become deposited in streaks on the sides of the vessel wherever the rod has touched. Moderate heating much promotes the precipitation. If much hydrochloric acid is present in the solution to be tested, it is best to evaporate to a small bulk with some nitric acid before applying the test. Silica, when present, should be separated by evaporation to dryness and re-solution in nitric acid. The test is very delicate and reliable when carefully performed, and is especially adapted for detecting small quantities. To ascertain whether the yellow precipitate is due to arsenic or to phosphoric acid, filter off the liquid and wash the precipitate with a little cold water; then pour ammonia on it, in which it will dissolve. To this liquid add a clear mixture of chloride of ammonium, ammonia, and sulphate of magnesium, and stir well with a glass rod. Streaks will be produced on the sides of the tube. Decant the fluid into another tube. Wash the streaks well with distilled water, and then pour in some nitrate of silver (free from acid). The streaks will become brown if arsenic acid is present, but yellow if produced by phosphate. If both be present together, gradual addition of weak acetic acid will dissolve the yellow first, and the brown colour will become better developed. If further confirmation be required, the liquid decanted from the streaks may be filtered, the precipitate washed with cold water, and dissolved by pouring dilute hydrochloric acid over it. Add sulphite of sodium to the solution, boil well, and treat with sulphuretted hydrogen, when any arsenic will be thrown down as a yellow precipitate, while phosphate will remain in solution. Arsenic and phosphoric acids present the closest resemblance, and the above reactions are the only ones by which they can be distinguished, and in the method described they are employed in the best manner. By following the directions carefully, "Molecule" may insure success. If the molybdate solution and magnesia mixture are kept ready prepared, the process is not a long one. At any rate, it is the shortest there is for the given conditions—namely, acid liquors containing various metals in solution. If "Molecule" meets with any difficulty from the presence of antimony or tin, I can help him out of it.—ALFRED H. ALLEN.

[12081.] — **Chemistry.** — Arsenic will be distinguished most often by the red yellow precipitate it forms with sulphuretted hydrogen, the red precipitate it forms with nitrate of silver, and still better by the ring it produces in the Marsh apparatus. For the research of phosphoric acid try the action of magnesium sulphate, which produces a white crystalline precipitate soluble in acids; that of nitrate of silver which forms a yellow precipitate, soluble in ammonia and diluted nitric acid; and that of molybdate of ammonium, which produces in a solution of phosphate acidulated with nitric acid a yellow precipitate, which appears sometimes immediately, sometimes after a moderate heat has been applied to the test tubes.—F. T.

[12086.]—**Velocipedes.**—Guttapercha cement will answer "Bob C.'s" purpose. He can get it where shoemaker's materials are sold, and the shopkeeper will tell him how to use it. Half-round rubber is much better than flat. This cement will last for hundreds of miles, and when it gives out can be renewed in a few minutes.—SACRISTAN.

[12088.] — **Cleaning Jewellery.** — Probably jeweller's rouge.—ELECTRIC.

[12089.]—**Felt Hats.**—Perspiration, or grease, or both, soaks through. Dissolve some ammonia in warm water, and wash the hats with it, using a piece of cloth, black or light according to the colour of the hat. —SACRISTAN.

[12094.] — **Preserving Caterpillars.**—Kill the caterpillar by immersion in boiling water. Cut a small slit at the posterior segment, from which you must extract the intestines and fatty matter. Fill up with cotton wool, which has been previously soaked in an alcoholic solution of camphor and mercury bichloride. This is about the best means known, but it is very unsatisfactory.—S. BOTTONE.

[12097.]—**Venetian Blinds.**—Procure some ordinary paint, and add spirit of turpentine till the paint is very thin indeed, then lay it on in the usual way. Blind-makers dip the laths into the paint; but unless "F. A. R." has a great many laths to colour, I think he had better not do that. At least three coats will be required; then varnish in the usual way.—SACRISTAN.

[12098.]—**Dandelion Roots.**—I am not a medical man, so that I should not feel justified in recommending anything of which I had not personal experience. With regard to Taraxacum, or dandelion, it is usually held to be an excellent remedy for the disease mentioned by my interlocutor. But I should certainly not advise him to make his own extract, as that necessitates the use of a vacuum pan. Let him go to some respectable manufacturing chemist, such as Morson, Bell, Burton, &c., and ask for extract of taraxacum, and he will get a much better article than he could possibly prepare, at a very low figure. The process usually adopted in its preparation consists in washing the roots, crushing them between rollers, expressing the juice from the pulp by means of a screw or other press, and finally evaporating the juice in a vacuum pan, until it attains the consistency of stiff jam.—S. BOTTONE.

[12099.]—**To Advanced Chemists.**—Drink large quantities of pure milk, after it has become sour, as the lactic acid which has been thus produced forms with magnesia a compound soluble in water. This remedy has very often been applied with success by Prof. Bouchardat, of the Faculty of Medicine in Paris. —F. T.

[12100.]—**Venomous Serpents.**—The "snake stone," and every other so-called antidote that could be obtained, was tried in India and found useless. It should be mentioned, however, that they were tried on cases in which there was no doubt the poison had been injected. The case which "Cireb" refers to as having witnessed was probably one of many in which no venom was ejected by the cobra: hence the recovery. I believe there is a reward offered for the discovery of an antidote, and if "Cireb" is acquainted with one he can claim the money and make himself famous. The appalling number of deaths annually occasioned by snake bites in India would seem to contradict the notion that any snake stone or snake bean is successfully employed as a remedy. Further and complete information on what has been done in the matter will doubtless be furnished in the monograph of the "Indian Thanatophidia," by Dr. Fayrer, which I see is announced to be shortly published.—SAUL RYMEA.

[12105.]—**Equation.**—1st.—$x^2 + xy = 28$. 2nd. $xy - y^2 = 3$. From the 2nd, $x = \frac{(y^2 + 3)}{y}$. Substituting this for x in the 1st, $\frac{(y^2 + 3)^2}{y^4} + y^2 + 3 = 28$, $\therefore \frac{(y^2 + 3)^2}{y^2} = 25 - y^2$, $\therefore (y^2 + 3)^2 = 25\,y^2 - y^4$. Squaring the first part, $y^4 + 6\,y^2 + 9 = 25\,y^2 - y^4$, $\therefore 2\,y^4 - 19\,y^2 = -9$, $y^4 - \frac{19}{2}\,y^2 = -\frac{9}{2}$, $\therefore y^4 - \frac{19}{2}\,y^2 + \left(\frac{19}{4}\right)^2 = \frac{19^2}{4^2} - \frac{9}{2} = \frac{17^2}{4^2}$, $\therefore y^2 - \frac{19}{4} = \frac{17}{4}$. $\therefore y^2 = \frac{36}{4} = 9$, $\therefore y = 3$. From equation 2nd, $3x - 9 = 3$, $\therefore 3x = 12$, $\therefore x = 4$.—SUMMA.

[12105.]—**Equation.**—1st.—$x^2 + xy = 28$. 2nd.—$xy - y^2 = 3$. Let $x = vy$. Then (1st) $v^2 y^2 + vy^2 = 28$, $y^2 (v^2 + v) = 28$, $y^2 = \frac{28}{v^2 + v}$. 2nd.—$vy^2 - y^2 = 3$, $y^2 (v - 1) = 3$, $y^2 = \frac{3}{v - 1}$. $\frac{28}{v^2 + v} = \frac{3}{v - 1}$. $3\,v^2 + 3\,v = 28\,v - 28$, $3\,v^2 - 25\,v = -28$, $v^2 - \frac{25}{3}\,v + \frac{625}{36} = \frac{625 - 336}{36} = \frac{289}{36}$, $v - \frac{25}{6} = \pm\frac{17}{6}$, $v = \frac{4}{3}$ or 7. Then $x = \frac{4}{3}\,y$ or $7\,y$, $\frac{16\,y^2}{9} + \frac{4\,y^2}{3} = 28$, $\therefore y = 3$, and $x = 4$; or $49\,y^2 + 7\,y^2 = 28$, $\therefore y = \sqrt{\tfrac{1}{2}}$, $x = 7\sqrt{\tfrac{1}{2}}$.—WILLMOTT HENDERSON.

[12105.]—**Equation.**—All simultaneous homogeneous equations can be solved by putting one variable equal to a multiple of the other. Let $x = yv$ solve with respect to v. If you find such easy equations as this too hard for you get the key to the book. —MATHEMATICIAN.

[12108.] — **Confusion in the Head.** — Let "Agent" try half-rations, or at least abstinence from meat and beer (especially stout and porter) once a week, and get all the fresh air and exercise he can. An occasional dose of Epsom salts will do him good.—SACRISTAN.

[12109.]—**Old Locomotive Tubes.**—Plug one end, fill with molten lead. When cold, bend as you require. Then apply sufficient heat to melt out the lead.—S. BOTTONE.

[12110.]—**Silver Plating.**—If "Electro" will place his solution into a large open pan and then add sulphuric acid very carefully the silver will be precipitated in the form of sulphate of silver. When it is settled he may pour off the supernatant liquor, collect the sulphate, dry it, and then send to the refiners. Perhaps the cause of the silver depositing brown is, if a bright solution, an excess of bisulphide of carbon. Remove the gold by the porous cell process, when the gold will go into your gilding solution. If "Electro" lives in the neighbourhood of Sheffield, I shall be very glad to put it to rights for him gratis.—ELECTRIC.

[12115.] — **Battery.** — The description of my arrangement of battery shall be given at an early date in my papers on "Electro-metallurgy" now commenced. It has given me great satisfaction.—SIGMA.

[12124.]—**Voice Weakness.**—Speaking and singing loud are good, but you can't sing to the accompaniment of a "light catarrh." Is the fault occasional or constant: in the larynx or lungs?—HENRY NEWMAN.

London Association of Foremen Engineers. —At the last monthly meeting, on Saturday, June the 1st, Mr. J. Irvine, vice-president, in the chair, a paper on cast iron was read by Mr. Laird. The main points touched upon and considered were the effects of contraction from cold and expansion from heat, the laws which regulate the action and reaction of cast iron under the conditions of motion and rest, the bearing of chemical equivalents on mixtures of metals, and the improvements to be effected in the cooling of molten metal as well as the ameliorations of form desirable in castings. The paper was discussed by several members, and the discussion ultimately allowed to stand over until the next meeting, on Saturday, July the 6th. The candidates, Mr. W. Daubney and Mr. W. Ladley, were elected members of the association. Mr. Charles Leager was put into nomination.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "Hedera" has answered 11416, 11652; Henry Blake, 11529; "Monte Christo," 11625.

QUERIES.

[12126.]—**a Draconis.**—Will "F. R. A. S." oblige me by referring to query No. 11716, which he kindly answered on p. 171? Then, however, I did not obtain the answer I required. I took my idea from the following passage, which is from a paper by P. Smyth, on the Great Pyramid. Will "F. R. A. S." kindly explain it? "The writer ascertained also that the entrance passage had been pointed at a Draconis when crossing the meridian below the pole, at a distance of 3° 42' therefrom." But the question which puzzled him was, "which of the two times of the star being that distance from the pole, could have been the one intended to be typified?" For two such conflicting times there were, seeing that the star's closest approach to the pole, and within only ten minutes thereof, occurred near the year 2800 B.C.; and on that account, both 600 years before such date, equally with 600 years after it, the star must have reached (though on opposite sides) by its uniform "precessional displacement, the typical 3° 42' indicated by the entrance passage." It is the latter part which I wish particularly to have explained.—J. X. T.

[12127.]—**Herbs.**—Can any one recommend to me a good (cheap) work on the medicinal properties of the common English field herbs?—HEDERA.

[12128.]—**Portable Dark Tent.**—Will some of your numerous readers favour me with instructions for making a portable photographic dark tent, for working small plates in? Any hints as to the construction, material for covering the person, mode of applying it, &c., will greatly oblige—OCCASIONAL PHOTO.

[12129.] — **Fire Bars.** — Will some correspondent inform me whether cast-iron fire-bars last longer than wrought-iron bars, and why the latter are always used in locomotives and never in stationary or marine boilers? The fusing point of cast iron is, no doubt, less than that of wrought iron; but some authorities state that cast iron resists the wasting action of heat and flame up to a certain point better than wrought iron. Perhaps the chemical properties of the coal have something to do with the duration of the bars, and will affect cast iron less than wrought. Does Welsh steam coal of the best quality require a less air space between the bars, or a greater one than wrought iron?—ROBERT JOHNSON.

[12130.]—**Electricity.**—Will some one of your electrical correspondents be so good as to inform me to what extent a current of electricity from a common machine is similar to one from a galvanic battery? How far will it produce the same effects?—E. T. S.

[12131.]—**Electricity Applied to Engraving.**—Has electricity been applied to engraving and copying writing? If not, I should like the opinion of correspondents on a suggestion. Suppose a metallic plate, thinly coated with wax, to be subjected to the action of a galvanic battery (the engraving or writing being previously drawn with a steel point to remove the wax on the parts to appear in the engraving), we should have a deposit of copper, &c., in relief, and the plate, when taken from the battery and the wax removed, might be printed from as in a wood engraving.—PHILANTHROPIST.

[12132.]—**Polariscope.**—I have endeavoured to construct a polariscope thus:—I have arranged two layers of crown glass plates (16in. each) at an angle of 56° 45' in two different pill boxes, holes about the size of sixpences being cut in lids and bottoms of the boxes, but upon revolving either layer the light at 90° or 270° is but slightly dimmed. I have placed various crystals between the analysing and polarising layers, but can get no colours. I wish, if possible, to do without tourmaline, selenite, or Nichol's prism. Should dimness or perfect darkness be produced at 90° and 270° by revolving either analyser or polariser? Should the tubes be blackened inside? Can brilliant colours be obtained by simple brindles of glass, arranged at 56° 45'? If so where do I fail? Pray help the—NEEDY.

[12133.]—**Hard Water.**—The water from the well in my house is very hard, and a medical man gives it as his opinion that it will cause gravel, if used for drinking purposes. Can anything be done to it? Will Condy's fluid be of any use?—J. PEARCE.

[12134.]—**Restoring Brass Wire.**—I have about a ton of brass wire, varying from Nos. 8 to 16 in thickness, but which has been exposed to the air and is now rotten

Are there any means to bring it back to its former state of quality?—KEIGHLEY.

[12135.]—**Chest Expander.**—I am in the habit of using a chest expander, but I find that after using them a short time they generally break at the junction of the indiarubber with the handle. Will "Jack of All Trades" or some of "our" mechanical contributors kindly tell me how to make one to act by the compression of a spring, and to be capable of being set to suit different degrees of strength?—THOMAS SOUTHWELL.

[12136.]—**Monkey or Jamaica Nut.**—What is this nut's real name? I have planted a few of them, which have now sprung up; they grow very quickly; the nut is of a yellow-brown colour, rough, and is like a small sausage, 1in. long, and slightly squeezed in the centre. It generally contains two kernels, which taste like an uncooked broad bean and are situate at each end. The leaf is lilac-shaped and is made of three petals or branches. Will the plant outlive an English winter?—J. D.

[12137.] — **Liquid and Solid.** — What are the generally received definitions of the words liquid and solid? In a book before me mercury is called a solid, while in Ganot's "Natural Philosophy," it is ranked with the liquids.—C. P. E.

[12138.]—**Chemicals that Absorb Moisture.**—Will some one give me a list of chemicals that absorb moisture from the air? Not such as lime, which does not thereby become damp, but such as become and remain wet from the moisture absorbed.—LXXXVIII.

[12139.]—**Mechanical Education.**—Will you or any of your readers inform me of a school where they give a thorough practical mechanical education?—QUADRANT, Nottingham.

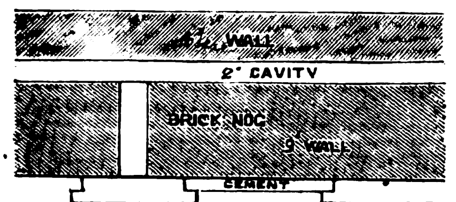
[12140.]—**Chemical.**—Can any one tell me if the mode of making potassium by Professor Dolbear, and described in last week's MECHANIC is at all dangerous? I have hitherto understood that it is not the cost of the materials so much as the danger incurred in making it that is the reason of its being so dear. Also, how would it be separated from the coal-oil completely, so as to be fit to use?—J. S. HOYDES.

[12141.] — **Watchmaking.** — Will "A Yorkshire Pivot" kindly inform me how to put an isochronous hairspring to a lever watch? Also, how to put a new jewel hole in the 'scape wheel cock of a Geneva watch?—NO AMATEUR.

[12142.]—**Leaky Tubes.**—What is the proper way to stop the tubes leaking in a portable engine, firebox end. The tubes are very good?—F. G. R.

[12143.]—**Cayenne.**—I have to pack occasionally a gross or two of small packets containing cayenne. I generally have a cold after it, caused, I believe, by the cayenne. Can any of your readers give a plan so that I can escape its disagreeable effects? It also causes me to sneeze very much.—J. G.

[12144.]—**Timber Houses.**—I shall feel obliged if some of your numerous readers will inform me of the



7×7¾ REBATED TO RECEIVE CEMENT

best mode of constructing half-timber framing for outside walls, giving the best method of keeping the weather from the interior. I propose doing it thus—BEE.

[12145.]—**Small Steam Boiler.**—I have a table engine, cylinder depth, 5¼in.; bore, 2¼in. Would any brother reader state through the columns of the MECHANIC the dimensions of the boiler I should require to drive it with facility? Also best shape, thickness of copper, whether riveted or brayed, and probable cost?—J. R. C.

[12146.]—**How to Procure a Patent.**—I have constructed a new apparatus which I am desirous to protect by letters patent, but have no means to employ a law agent. Will any of my fellow subscribers to this journal kindly inform me how I may proceed to obtain a patent myself? and they will greatly oblige—G. Y.

[12147.] — **Cochineal.** — The other day I made a fixateur for the hair, after a recipe in Beasley's "Useful Druggists' Receipt Book," adding mucilage of trajacanth to a solution of cochineal in spirits of wine, scenting with otto of roses. Instead of being coloured red as one might expect, the resulting compound was of a dirty grey colour. What was the cause of this?—D. N. E.

[12148.]—**Boiler Query.**—I have a boiler of sheet-iron three-sixteenths inch thick, riveted with ½in. rivets 1in. apart, 2ft. 6in. high, 1ft. 10in. diameter, with six tubes of 1in. internal diameter of iron external fire-box. What is the greatest pressure it is safe to work at, and what horse-power is it?—LANCA.

[12149.]—**Fellmongering.**—Will any readers inform me how wool is taken off sheepskins by means of spirits, or recommend a work on "Fellmongering?"—CAPE COLONY.

[12150.]—**Photography.**—Could any subscriber of practical experience advise an amateur which would be the best process for him to adopt—viz., the old plan of collodion and silver bath or the new collodio-bromide process? I should work either process in the wet state and chiefly for portraiture. A hint or two as to the advantages and disadvantages of either process and short working details, would oblige—TRIPOD.

[12151.] — **Concrete Engine Beds.**—I wish to know if there are any concrete engine beds in use, and, if so, how do they answer? Are they as substantial and firm as those of ashlar stones? Does the concrete take long to set?—NORTH-WEST YORKSHIRE.

[12152.]—**Dyeing Raw Cotton.**—Would some of "our" brother readers kindly inform me the cheapest and quickest way to dye raw cotton a good black, if possible, by only one immersion in the dye?—F. E.

[12153.]—**Ant Hill Earth.**—Could "Khoda Bux" kindly put me in the way of importing some of the ant-hill earth, mentioned a year or so ago by "Eos" (who for some reason seems at present eclipsed), as used by native jewellers, &c., as moulds for casting metals into? A quart or so would be sufficient. I will give my fellow readers the benefit of any success I may obtain by using it. In a former letter I mentioned 2 brick dust and 1 plaster as answering for brass, &c., and so it does, but I want something harder and not so friable as this mixture heated red hot becomes.—PROVEN.

[12154.]—**Coloured Printing Inks.**—Will "Zoo Andra" be kind enough to mention the name of the varnishes used in mixing the above?—H. W.

[12155.]—**The Suspended Shilling.—Another Reason Wanted.**—Like the problem of lifting heavy weights without difficulty, the following is an old experiment, but may, like that, afford food for the ingenuity of some of "our" experimentalists, in trying to discover the raison d'être. Tie a shilling to one end of a piece of thread, and hold the other end between the thumb and forefinger of the right hand; rest the elbow upon the table and throw back the hand so that the thread shall pass over the ball of the thumb, and let the shilling be suspended in the centre of an empty tumbler. Premising that the hand of the operator be perfectly steady, the shilling will in a few moments become perfectly steady also, and will maintain a state of rest for a moment or two, when it will assume the motion of a pendulum, increasing in velocity until it strikes against the sides of the glass, which it will do a number of times equal to that of the hour which is nearest at hand—*e.g.*, if the operation be performed at (say) a quarter to twelve, it will strike the glass twelve times; if at a quarter to one, only once. Its motion will then gradually subside until it again remains suspended at perfect rest, after which it will move no more. I have repeatedly performed this experiment successfully, and have witnessed others do the same. I have also seen others, whose hands appeared equally steady, utterly fail, the shilling persistently refusing to oscillate. The former part of the experiment may be explained, I imagine, by the action of the pulse, but how to account for the shilling striking the hour is the desideratum.—H. G. W.

[12156.]—**Mice Eating Peas.**—I have sown both peas and beans in my garden twice, but mice or something else eat them. Please say what would prevent these marauders doing so.—SEAGOE.

[12157.]—**Smell of Paint.**—Will some one be good enough to say what will take away the unpleasant smell of new paint?—SEAGOE.

[12158.]—**Packing Rings of Piston.**—Would Mr. J. C. Molton or any brother reader of "our" valued MECHANIC, tell me how to turn up and fit the packing rings to a piston? Mine is 3½in. diameter; are they merely sprung on for such size?—M. L. DODSWORTH.

[12159.]—**Lime Juice.**—Will Mr. S. Bottone or some chemical friend inform me what lime juice and lemon juice are made of, and how?—J. R., Leicester.

[12160.]—**Size of Iron Tool, &c.**—Thanks to Mr. Purkiss for the kind and satisfactory manner with which he has answered my questions, but I wish to trouble him once more. Will he be kind enough to say what proportion he finds best of iron tool to mirror? I may, perhaps, just say I am anxious to arrive at perfection with my mirrors, hence the reason of my troubling Mr. Purkiss. I have made some very good mirrors, and have one at present with which I can read (under favourable circumstances) the Inventor's column 180 yards distant.—OPTICAL BRICKLAYER.

[12161.]—**Mangle.**—Will some kind mechanic help me? I wish to make a mangle. I want the sizes of timber in the frame, length and width of frame, and what sort of wood would stand best. The sort I want is one of those that works with a chain.—MANGLE.

[12162.] —**Machine Punches.**— Will any reader kindly give a short description of any machine punches other than the lever, the screw, and that exerting force by an arrangement of cog-wheels?—TRY AGAIN.

[12163.]—**Meerschaum Pipes.**—Will "Zeta" describe the process of re-waxing a pipe? Can it be done by a non-professional? Also, how can I remove the colour from a pipe, which has not coloured nicely?—W. ALLAN.

[12164.]—**Temperature of the Planets.**—In the article on "Jupiter" in the number for May 24, p. 244, it is assumed that an intensely heated planet is "unfit to be the abode of living creatures." Are there any scientific grounds for believing that our own temperature is the only one suited for living beings, or the best one? Does the great heat of Mercury, for instance, preclude that planet from swarming with creatures as delicately and wonderfully adapted to surrounding conditions—of which temperature is only one—as we are ourselves?—TELLUS.

[12165.]—**Cream Cheese.**—Will some subscriber kindly inform me how to make a good cream cheese? Also, how to prepare or make rennet for the same?—FLAX DRESSER.

[12166.]—**The Enfield Rifle.**—Why is the Enfield rifle bored out to ·577 of an inch?—WILLIAM MILLAR.

[12167.]—**Dry Soap.**—I should be very glad to know, through the MECHANIC, the ingredients of, and *modus operandi* requisite to produce, the dry soap, such as Shaw's, now so much in use.—AN OLD WESTON SUBSCRIBER.

[12168.] — **Limelight or Electric-light for Magic Lantern.**—The Committee of a Young Men's Christian Association are desirous of obtaining replies to the following queries from one of the many readers of the MECHANIC who has had practical acquaintance with the matters inquired of:—1. The first cost of a superior single and double lantern with limelight, and also with electric light, all necessary apparatus to be included. 2. The cost of working each for each occasion on which it might be used. 3. Which is the cleaner and more easily worked? 4. The advantages and disadvantages of each kind. 5. How many cells would be required for the electric light, and which kind of cell the best? 6. To what other uses could the electric light be put that the limelight could not? Any other information that might seem necessary would be thankfully received.—HON. SEC.

[12169.]—**"E. L. G." and the Yorkshire Wold-Combes.**—May I ask "E. L. G." (1) how the "Lyellists" account for the Yorkshire wold-combes? (2) How does he account for them?—HEDERA.

[12170.]—**Dyeing.**—Can any reader inform me if there is an association for the special instruction of dyers in the chemistry of dyeing, in any town in the United States? If so, where?—JEUNE TEINTURIER.

[12171.]—**Utilising Chemical Products.**—Will Mr. Bottone, "Sigma," or any other competent kind friend, inform me of a method to save the following valuable products, which I am convinced ought not to be thrown away? In electro-plating establishments silver is stripped from articles by means of saltpetre in hot sulphuric acid, and then precipitated by common salt. I am not a chemist, but I suppose when the chloride of silver is taken from the solution, there remains nitrate of soda and sulphate of potash diluted with about eight times their volume of water. How can I crystallise out these salts to pay? I should like to take them out in the form of caustic potash and soda if possible. Can it be done by means of lime?—SUBSCRIBER.

[12172.]—**Constipation.**—As a regular subscriber may I ask for advice of your numerous and talented correspondents for the following:—I am a dreadful sufferer for most obstinate constipation. Perhaps some of your correspondents have received relief from this annoyance, and would gladly give their experience for the benefit of a sufferer. I have been under eight doctors, and they give me no relief—at least only temporary.—H. S. A.

[12173.]—**Coloured Ink.**—I have used Judson's dyes, which I find advertised in the ENGLISH MECHANIC, to make various fancy inks with, yet they all seem to want lustre when they become dry on the paper. I would be glad if some correspondent would tell me what to add to impart this required quality.—E. B. F.

[12174.]—**Agriculture.**—I am anxious to know how to discern between red clover and American cow-grass, and beg to submit the query to the kindness of some of "our" agricultural readers. These grasses, so seemingly alike in appearance, are strangely different in the effects they produce on cattle fed on them. The cow-grass may be eaten with impunity, but the red clover, if eaten to excess, generates such quantities of gas in the cow's stomach, that it swells to an immense size, ruptures and bursts, so that the cow dies speedily.—E. B. F.

[12175.]—**Soundboard.**—"The Harmonious Blacksmith" has told us that the tones of a musical box can be increased in loudness by placing the instrument on a soundboard. Will he kindly say what size, and how I am to construct a soundboard suitable for a musical-box which is about 2ft. in length by 8in. square and would it not be better to take the mechanism out of the box, and screw it directly on the board?—E. B. F.

[12176.]—**Hydrogen Flame.**—I want to procure a good hydrogen flame, and for this purpose I have frequently put zinc with sulphuric acid and water, into a bottle fitted with tube, with small bore as directed in books; but I have invariably been rewarded by an explosion of the whole affair, and though I have repeatedly tried, I have always failed to attain my desire. I wait some time for the air to escape, but it is no use. I am well acquainted with the theory, but very deficient in practice. Perhaps "our" practical friends can help me. I desire to express my thanks to "F. R. A. S." for his kind answer to my inquiries respecting Jupiter.—WHITAKER.

[12177.]—**Algebra.** — In Todhunter's "Algebra," section 147, the author says that the expression

$$\frac{a}{(a-b)(a-c)(x-a)} + \frac{b}{(b-a)(b-c)(x-b)} + \frac{c}{(c-a)(c-b)(x-c)}$$

may be written

$$-\frac{a}{(a-b)(c-a)(x-a)} - \frac{b}{(a-b)(b-c)(x-b)} - \frac{c}{(c-a)(b-c)(x-c)}$$

Will some fellow reader kindly explain how this transformation is effected, and give the rule?—W. M.

[12178.]—**French Magazine.**—Can any subscriber to "ours" give me the title, price, and name of the publishers of a French magazine combining science and light literature, like "Chambers's Journal"? The "Revue des deux Mondes" is too much of a political periodical.—W. M.

"JACK OF ALL TRADES."

SINCE we went to press last week we have received from—

	£	s.	d.
Solicitor	£1	1	0
G. H. G.	1	1	0
Curative	1	1	0
Manus	1	1	0
J. Halden	1	0	0
T. Wheatley and Rev. Gerard Smith	0	15	0
	5	19	0

We intended at first to confine the sum to £10, but as others have signified their desire to subscribe, we can have no possible objection. And if two others will send us £1 1s. each, we will transmit to "Jack" another cheque for £10 10s. "Jack" is at Matlock, and has been there a week, and is likely to derive much benefit from change of air and scenery, and the curative treatment he is undergoing. One reason why we willingly fall in with the desire to make the sum £21 in all, is that Jack has a large family solely dependent upon him for a livelihood.

After the £21 are subscribed the list will be finally closed. This must not be looked upon as a general subscription, but as a sum presented to a kindhearted, industrious, and deserving man, by a few brother readers who appreciate and respect him.

CHESS.

All communications intended for this department to to be addressed to J. W. Abbott, 7, Claremont-place, Loughborough-road, Brixton, S.W.

A gathering of chess players will take place at the Crystal Palace on July the 18th and 20th, under the auspices of the British Chess Association.

TO CORRESPONDENTS.

J. K.—You will see that we have availed ourselves of your smart little problem.

R. A. Proctor (Clapham).—We are much obliged for the problems, which shall receive our best attention.

Argo.—Your problem shall be examined. In the mean time have the goodness to forward your name and address.

A. R. Molison (Swansea).—The variation is wrong. If (1) K to Q Kt 7; (2) Q to K B 6 will not solve it, compare the published solution.

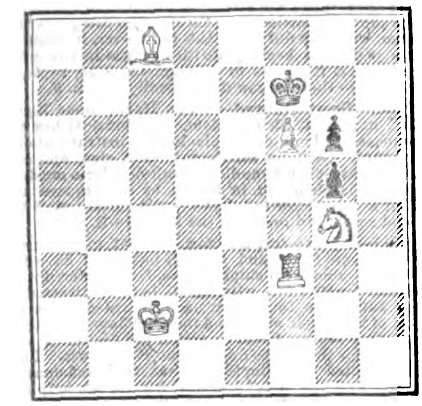
T. T. D.—Thanks. Next week.

F. Owden (Hoxton), and Wiseaf (Dulwich).—Problem No. 1 cannot be solved in the way you propose.

Correct solutions to Problem 1 have been received from R. A. Proctor; J. Beresford (Vauxhall); and C. D. (Clapham).

Problem II.—By J. Kling.

Black.



White.

White to play and mate in three moves.

Solution to Problem I.

White.	*Black.*
1. K to Kt 7	1. Kt to Q B 3 or (*a*)
2. Q to Q 5 (ch.)	2. Kt. takes Q.
3. Kt mates.	
	(*a*) 1. P to K. 3.
2. Q to B 8 (ch.)	2. K moves.
3. Q mates.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, June 11, and unacknowledged elsewhere:—

J E. Crowther.—J. B. Ward.—D. H. G.—Capt. D. F Allan.—Wm. Cooper.—J. M. Mayfield.—R. A. Proctor. —Charles Brewer.—B. C. Hughes.—H. B.—Geo. Sant. —Frank Mason.—H. T. Miles.—Rev. Gerard Smith.— E. Colling.—J. C. Lambert.—T. A.—Wm. Milroy.— John Bailey and Co.—Cunningham and Co.—Dr. T. C. Burton.—R. Starkie.—General Thompson.—S. Hewitt. —P. H. Gosse.—Shasloden.—Rev. J. C. Carrick.— W. L. Nash.—J. Hewitt.—E. W. Gadsby.—J. H. T.— S. H. B.—M. Paris.—E. L. G.—W. F. Potter.—495.—One Anxious to Learn.—F. M.—Aroma.—A Newport Lad.— En Avant.—H. B. E.—M. H. B.—M. N.—J. Marsden.— C. A. S.—Constant Reader.—E. H.—A. Woolsey Blacklock.—M. D.—Lenia.—A Subscriber.—A. R. Molison.— J. U.—Vulcanite.—Another Gray Beard.—R. Tausley.— J. Tolver Preston.—Canis Manor.—Scrutator.—Kelby. —T. H. F.—Cottager.—Trigo.—D. T. L. R.—W. Hooper. —J. W. Taylor.—Aleph.—Maica.—C. B.—A New Subscriber.—Gaucho.—W. Rose.—Rat-Tat.—Excelsior.— P. France.—W. Bush.—P. H. Holland.—J. T. B.—F. Packman, M.D.—E. B. Fennessy.—William.—W. S.— Henry Newman.—T. S.—W. H.—Young Student.—T. R. —Rev. T. W. Nichol.—Wondering Willy.—M. Pike.— Beacon Lough.—Henry Bailey.—Zoo Andra.—Tripod. —R. G. B.—Citrus.—W. H. T.—Noturb.—England.— J. C.—Joshua B. Rayner.—W. L. Pendered.—Francis M. Crichton.—Francis Weatherhoff.—R. Walker.— John Fielden.—John Hick, M.P.—Assoc. Inst. C. E.— Bisnatus.—W. H. Skelton.—The Harmonious Blacksmith.—A Constant Reader.—A Fireman.—Cyclone.— W. Marquand.—R. G.—A Sub.—R. Tervet.—R. S.— Amateur.—Jas. Ford.—John Hopkins.—R. C. T.— A. Tolhausen.—James Hastie.—An Old Subscriber.— Nemo.—Charles Watson.—X. Y.—Sheffield.—R. A.— A Plain Man.—G. H.—Flax Dresser.—Sheffield Blade. — C. J. Recordon. — Andrew Wilkie. — Dane.—An American Amateur.—Countryman.—Tom the Tinker. —W. Allan.—J. W. Fennell.—P. W. Wyatt.—Philo.—A., Liverpool.—A Practical Man.—J. Foster.—Manns.— H. Hargreaves.—B. R. B.—A. H. Allan.—A. J. V. G.— W. L. G.—J. F. E.—S. T.—Edward Slaughter.— C. H. W. B.—W. S. and H. M.—W. Bush.—H. G. M.— C. H.—Thetamu.—T. B.—W. R. Hall.

W. Smith.—Your reply is an advertisement.

W. P.—Consult our advertisement pages from time to time.

J. Wilkins.—There is some force in your observations, but correspondents must be allowed a certain amount of latitude. We decidedly question the wisdom of striking out every passage that might run against the susceptibilities of every reader. If such a policy were resorted to, our letters "to the editor" would lose much of their piquancy and charm, and become to a large extent "stale, flat, and unprofitable." Besides, no correspondent who has anything worth saying would submit to it.

E. W. R.—Not suitable. Try again, and if unsuccessful try once more.

G. H.—Have done with shams. Try and deal with realities.

R. B.—Your solution of the "Fifteen School Girls" is interesting, but we cannot afford more space for a consideration of the subject.

Communications which can only appear as advertisements to hand from Ovo, G. E. Crick, R. Whitham.

York.—Write T. R. Willis, who advertises in these pages, or some other manufacturer.

Neil Downie.—The advertisement is that of a quack.

J. F. Wilkinson.—You must put your first question more plainly before we can answer or insert it. For your second see indices to back volumes. Your third would occupy too much space; try the experiment yourself.

Nautilus.—By constant and reiterated application, and a determination not to be repelled.

Philanthropist.—We think not.

J. Barwick.—Your letter on Scientific Education is inadmissible, on account of its theological comparisons. It is, moreover, somewhat incorrect. In the matter of scientific education the State "helps those who help themselves." If you and a few of the leading inhabitants choose to form a school of science, and put yourselves in communication with South Kensington, you will obtain help and increased facilities. If none of your townsmen have sufficient energy or public spirit to move in the matter, don't blame the Government. Do we understand from one part of your letter that you think the public libraries of all towns should be entitled, like the four great libraries, to demand free copies of every book and newspaper published? We think not. At present the tax is comparatively insignificant, though even now it presses with some force on the authors or publishers of expensive works, but we protest very strongly against any such gratuitous addition to our circulation as you appear to contemplate.

F. E. D.—We do not know.

F. Perry, J. F., Great Walker, T. Baker, and Young Mechanic are referred to indices to back volumes.

James Cunliffe.—For different reasons we cannot undertake the responsibility of answering either of your questions. See indices to back volumes, for information on imperfect hearing.

Hobes.—There was no necessity for your second letter. If your request were particularly complied with, some one else would be disappointed. Though you have taken in the work for so many years, you have not sufficiently appreciated its character and purpose. Every attempt that has been made to supply "the mechanic class," as you call it, with an organ exclusively devoted to mechanics has failed; and if we followed your advice, we should most likely fail too. The English Mechanic is what the mass of its readers make it. It is based on the principle of *mutual* help. As a rule, each subscriber finds in it something he likes and other things he does not care for; and, as a rule, he contributes to its existence, not merely for his own sake, but for the sake of others. Though you have taken in fourteen volumes of the English Mechanic, you appear not to exactly understand its essence. You are a watch and clockmaker, and the English Mechanic contains week after week fragments of useful information on watchmaking. But there are watchmakers and watchmakers. Some are only interested in their craft; others like to know something of other industries and sciences, of the laws and constitution of nature, and of the motives and movements of man. It is for the latter section that the English Mechanic exists, and by them it is partly sustained. It is the same with photography, with engine-making, with turning, with fiddling, and the thousand and one things discussed from time to time in our pages. We try to give something for the craftsman and more for the *man*. Judging from your letter, the English Mechanic, with its multifarious information, its wide-reaching intentions, and the true freemasonry spirit which exists amongst its readers, is not the journal best fitted for you. We are sorry for it. We must do our work, and the English Mechanic must endeavour to fulfil its mission notwithstanding.

E. L. G.—Your long letter on "Who Invented Noah's Comet" next week, and then we must close the controversy, as it is pushing aside more demonstrable and practical matters. We have no objection to the discussion of the widest reaching theories, but they should be treated as sandwiches between meals, and not as the meals themselves.

J. B. Sharpley.—Ask for as much information as you may want, and give in return as much as convenient.

William Hughes.—We cannot undertake to recommend articles that are advertised. The one you inquire about is supplied by a respectable house.

Pistol.—No.

G. W. K. L.—Thanks for your information on the *Anti-Lancet* philosophy. To publish your able letter would only advertise still further a piece of barefaced quackery. Some people don't care what is said about them as long as they can get talked about. They live by notoriety, and they would rather be exposed and painted in their true colours than treated with silence. We will not even gratify them by your withering exposure. Whoever will help us to put down shams, whether great or small, and to counteract the influence of humbug in any direction, has our heartiest thanks. We hate, with an inextinguishable hatred, quackery of all kinds, and we will take good care that the quack who has been trying, rather adroitly we admit, to advertise himself through our query columns shall not do so again. Once more, "G. W. K. L." our thanks.

G. T.—Yours about Westminster clock has been answered.

Equilibrium.—For what purpose.

S. M. Drach.—Your corrected diagram arrived too late.

Joseph Roskell, T. C. S., and Analyst.—Query 12080 was a commercial one, and got inserted by mistake.

Pneumatic Lever.—Yours on "Defects in Harmoniums" next week.

A Careful Reader.—See our footnote to "E. L. G.'s" letter.

. M.—Certainly not.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING JUNE 4, 1872.

1611 A. C. Hobbs, St. Martin's-le-Grand, and J. M. Hart, Cheapside, City, for improvements in safes and other depositories for property and other articles of value, and in doors for such and other places, and in locks or fastenings for the same, part of which improvements is applicable to other structures.

1612 C. A. C. Eckhold, Green-street, Leicester-square, for an improvement of an apparatus for supplying ink on a pen fixed in a holder.

1613 H. B. Barlow, Manchester, for improvements in machinery or apparatus for washing, dyeing, and otherwise treating fibrous substances and other materials. A communication.

1614 A. M. Clark, Chancery-lane, for an improved engraving, cutting, and carving machine. A communication.

1615 S. Duer, Harewood-square, Middlesex, for an improved mode of and apparatus for lifting ships out of the water.

1616 J. H. Dennis, Liverpool, for improvements in the treatment of copper precipitate and in the utilisation of impurities contained therein.

1617 J. Pickup, Tong, Bradford, for improvements in grate bars.

1618 W. R. Lake, Southampton-buildings, for improvements in the manufacture of railway rails, and in apparatus employed therefor. A communication.

1619 W. R. Lake, Southampton-buildings, for improvements in the manufacture of railway carriage and locomotive wheels, and in apparatus employed therefor. A communication.

1620 J. Riddale, Minories, City, for an improved means of concentrating light for signalling purposes, and in appliances connected therewith.

1621 P. A. Ducros, Bordeaux, France, for improvements in tricycles and like carriages. A communication.

1622 E. Burstow, Horsham, Sussex, for a new or improved sash stop or fastener.

1623 D. Pidgeon and W. Manwaring, Banbury, for improvements in reaping machines.

1624 W. Hibell, Balsall Heath, Worcester, for improvements in annealing pots.

1625 H. K. Doria, Liverpool, for improvements in miners' safety lamps.

1626 A. Dawson and H. T. Dawson, The Cedars, Chiswick, for improvements in typographic etching and engraving, and in apparatus employed therein.

1627 J. Gathercole, Loughborough-road, North Brixton, for an improved machinery for making bricks, tiles, and articles of various sizes and shapes of plastic, cohesive, and other materials, and for measures of capacity of various sizes and shapes.

1628 T. Slater, Euston-road, for improvements in apparatus for obtaining electric light, and in magneto-electric machines to be used therewith, which machines are applicable for other purposes.

1629 H. L. Muller, Birmingham, for improvements in instruments for extracting or withdrawing nails, spikes, and bolts, and for other like uses. A communication.

1630 T. Corbett, Shrewsbury, for improvements in winnowing and grain-dressing machines.

1631 L. A. Guay, Paris, for improvements in buttons for cuffs, shirts, and other similar purposes.

1632 C. Martin and H. Martin, Great Winchester-street, City, for improvements in anchors.

1633 T. B. Hawkes and C. J. Freeman, Weymouth, for improvements in the construction of tables to be used for billiards, dining, and other purposes.

1634 L. G. Lyons and H. V. Forbes, Gloucester, for improvements in the manufacture or composition of paints or substances for covering or coating various surfaces.

1635 R. Long, Liverpool, for an improved case or book for containing postage, receipt, and other stamps, and tickets and labels.

1636 E. Keirby, Rochdale, for improvements in machinery or apparatus for recording low water in steam boilers.

1637 C. Moseley, Manchester, for condensing the vapours of coal-tar naphtha.

1638 H. Highton, M.A., Putney, for improvements in galvanic batteries.

1639 C. Whiting, Lewisham, for improvements in portable elongating dining and other tables.

1640 F. H. Wenham, Chadwell, Essex, for improvements in achromatic object glasses for microscopes.

1641 C. Boullier, Paris, for improvements in labels for stuffs and other similar purposes.

1642 R. Faulkner, Kensington, for improvements in the preparation of photographs and other prints for colouring.

1643 J. H. Dickson, Harefield, Middlesex, for an improved process of and machinery for treating fibre-yielding plants for the purpose of obtaining useful fibres therefrom.

1644 R. Hanson, Halifax, for improvements in steam boilers.

1645 A. N. Porteous and G. C. Bruce, Edinburgh, for improvements in and applicable to lamps.

1646 W. R. Lake, Southampton-buildings, for improvements in railway sleepers or cross-ties. A communication.

1647 J. F. Ollard, Lloyd's, City, and R. K. Barrow, Royal Exchange-buildings, City, for a new description of playing cards. A communication.

1648 T. J. Smith, Fleet-street, for an improved means of producing and maintaining musical tones, and in apparatus for the purpose. A communication.

1649 M. Doubelt, Berners-street, Oxford-street, for improvements in the preparation of iron for purposes where great tensile strength is necessary. A communication.

1650 T. Everitt, Norfolk, for improvements in feeding troughs or bins for sheep and other animals.

1651 J. Bolt, Halifax, for an improved stopper for bottles.

1652 E. T. Hughes, Chancery-lane, for improvements in safety valves for steam boilers. A communication.

1653 N. S. Walker, Liverpool, for an improved metallic bale tie or buckle.

1654 C. Turner, Lenton, Nottingham, for improvements in machinery for scudding or puring skins or hides.

1655 W. R. Lake, Southampton-buildings, for improvements in kilns for burning bricks. A communication.

1656 W. R. Lake, Southampton-buildings, for improvements in metallic packing for making steam, air, gas, or water-tight joints. A communication.

1657 D. Nicoll, St Paul's-churchyard, for improved preparations applicable to woven and other fabrics for the purpose of rendering the same uninflammable.

1658 A. V. Newton, Chancery-lane, for improvements in the manufacture of sugar and in apparatus to be used therefor. A communication.

The English Mechanic
AND
WORLD OF SCIENCE AND ART.

FRIDAY, JUNE 21, 1872.

ARTICLES.

REPORT OF THE COMMISSION ON SCIENTIFIC EDUCATION.

THE report of the royal commission appointed to inquire into the arrangements at present in force for affording scientific instruction to the masses, and for promoting the advancement of science, was published some few weeks back, and many of our readers will doubtless be interested in learning the recommendations of the commission as to the improvement of the means in vogue for achieving these desirable objects. The commission consisted of the Duke of Devonshire, the Marquis of Lansdowne, Sir John Lubbock, Professors Huxley, Stokes, and H. J. S. Smith, Dr. Sharpey, Sir J. P. Kay-Shuttleworth, and Mr. B. Samuelson, with Mr. Norman Lockyer as secretary, names which afford sufficient guarantee that no points worthy of consideration have been overlooked. Commencing with the state of scientific instruction in training colleges and elementary day-schools, the Commissioners, while approving the principle laid down by the Revised Code of 1861 that the money grants should depend to a considerable extent on the results shown by individual examination, consider that the limitation of such examination to the "three r's" has unfortunately narrowed the instruction given in elementary schools, and curtailed the syllabus of the training colleges, producing a very prejudicial effect on the education of the country. They do not underrate in any way the necessity for a thorough grounding in reading, writing, and arithmetic—subjects, which are, in fact, the very foundation of education, but they consider that the introduction of "extra subjects" into the curriculum would in no way interfere with the requisite amount of drilling in the "rudiments." With this opinion most of those who are practically acquainted with teaching must, we should think, agree; for as a matter of fact one at least of the three elementary subjects can be made to contribute in no small degree to the teaching of the rudiments of the natural sciences. Suitable books are ready to hand, or might soon be written, the language of which, while adapted to the requirements of the scholars learning reading as reading, is still sufficiently "technical" to convey a sound idea of the facts of which it treats. The New Code of 1871, there is only too much reason to fear, will have practically but little effect in widening the range of education in elementary schools; the grants are given almost wholly on the attainment of the required proficiency in the "three r's," and little encouragement is offered to the study of other subjects—even history and geography. Under the present arrangement, if 75 per cent. of the scholars pass in reading, writing, and arithmetic—a result almost invariably attained in fairly good schools — the maximum money allowance is awarded; and as a matter of fact the existing schools did earn last year almost the full grant without requiring the assistance of the "extra subjects." To alter this, in one sense, undesirable state of things, the Commissioners do not propose to raise the standards in such a manner as to reduce the passes below the 75 per cent., because they think, and very properly too, that such a course would tend to discourage both masters and pupils; but they consider that instruction in the principles of natural science can be and ought to be made an essential part of the course of instruction in every elementary school. They submit that the scale of payments may be so arranged as to encourage regularity of attendance on the part of pupils, to secure a sufficient staff of qualified teachers, and, at the same time, to insure the successful teaching of the rudiments, while a sufficient reward is given for proficiency in extra subjects. This, however, is a mere detail which can easily be arranged by the Education Department. What we desire more especially to draw attention to, is the repeated expression of the opinion of the Commissioners that scientific instruction must form a sine quâ non in the curriculum of every elementary school. Whatever difficulties may at present stand in the way are not insuperable, and "there can be no good reason why such elementary scientific instruction as has *long been given* in the primary schools of Germany and Switzerland should not be bestowed upon English children." Several of the school boards have already determined to make elementary physical science and social economy essential subjects in all schools under their jurisdiction—and the lead once taken others must follow.

The instruction which the Commissioners desire to become the rule and not the exception, though scientific in substance, would be free from needless technicality, and would be almost entirely confined to those facts which can be brought under the direct observation of the pupils. It is, in fact, that kind of instruction which is understood by the term "object-lessons." These would be so arranged and methodised as to afford an intelligent idea of the prominent phenomena which lie around the every-day life of the inhabitants of a civilised world; and are the very facts which children do not notice, and which have hitherto been held in slight regard by the arbiters of the primary education of the country. These "object-lessons" would not, of course, necessitate expensive apparatus or a complete mastery of the sciences by the teacher; they are, there can be but little doubt, the very best means of awakening in the juvenile mind the perceptive faculties, and the principles of the sciences thus mentally grasped are never afterwards forgotten. It is a question, too, which we should like to see discussed, whether it would not be advisable to "sacrifice" one of the half holidays, at all events in the winter months, to that "devouring element," science. We even venture to think that the children themselves would answer this question in the affirmative; for the afternoon's instruction which could be provided by an intelligent master at an expenditure in the first instance of a few pounds, might be made the source of much amusement, which would in reality, however, only serve to make the knowledge it is desired to impart stand out all the clearer and more prominent. It is true, as the Commissioners say, that in order to make the scientific instruction in these schools as successful as possible, the teachers must not only have acquired the needful amount of scientific knowledge, but must also have been carefully trained in the special methods of teaching science. It is not to be expected that all, or, indeed, any of the masters will display the skill of a Tyndall or a Huxley, and explain the transformation of energy into heat and the various branches which spring from that scientific tree, by means of a lucifer match or a hammer and a nail; but just that amount of ability is necessary which can put facts before the children in such a manner that they find no difficulty in comprehending and appreciating them. It is just at this point that the Commissioners are compelled to express their "fear" that the present machinery of the training colleges is inadequate to supply the necessary training to the students, and that an extension of the curriculum could not be expected to succeed until the means of scientific instruction are more complete, and the students receive a better preparation, or remain at the college for a longer period. Under these circumstances the Commissioners have made the following recommendations, the first two of which would appear to depend mainly on the speedy carrying-out of the third; for we are afraid that by far too many "certificated" teachers are as utterly ignorant of the natural sciences as the pupils under their care. 1. We recommend, say the Commissioners, that, as regards the elder children in elementary schools, the teaching of such rudiments of physical science as we have indicated should receive more substantial encouragement than is given in the regulations of the New Code. 2. As regards the younger children, that her Majesty's inspectors should be directed to satisfy themselves that such elementary lessons are given as would prepare these children for the more advanced instruction to follow. 3. That the mode of instruction of pupil teachers; the conditions of admission to the training colleges; the duration of the course of study, and the syllabus of subjects taught should be so modified as to provide for the instruction of students in the elements of physical science.

With regard to the scientific instruction given in science classes under the Science and Art Department, the Commissioners acknowledge that the system has given a "remarkable impulse" to elementary scientific teaching, the increase in the decade from 1860 to 1870 being, in the number of schools, from 9 to 799, and in the number of students from 500 to 34,283. This "remarkable impulse," however much it may be a cause of gratification when compared with 1860, is still far, very far, below the result it is desirable to obtain, for 34,283 spread over the various branches of study on the syllabus of the science classes shows but a very small percentage of the working population of this country as seeking to acquire a knowledge of the great scientific principles on which the commercial life of their industries and consequently their own well-being, so largely depend. There is no doubt, however, that with the scientific education fairly commenced in the primary schools a large influx of attendants on the science classes will follow; and it is fair to assume that the number of teachers will increase *pari passu*. The necessity of a more thorough system of inspecting science classes is strongly enforced by the Commissioners, for although they have "derived the impression" that substantial advantages result on the whole from the system pursued, yet, from the large number of failures which occur and from the character of the answers given, it is only too apparent that the vicious method of cultivating the memory instead of the intelligence is still adopted by a large number of science teachers. The instruction is derived from books, and the information thus acquired is tested and aided by the class examinations of the teachers, without being illustrated by specimens or experiments, the use of apparatus, or the out-door study of nature. Not only is apparatus wanting, as a general rule, but one of the examiners complains that even so simple an expedient as the blackboard and chalk is avoided in teaching geology; while the Commissioners affirm that "too often the teachers confine their instruction to the same routine of book-learning and class-questioning with which alone they were made familiar in the rudimentary classes in which they received their own *imperfect* elementary knowledge." With regard to payment by results, the commission recommend that higher rates of capitation grant should be allowed, according to the abilities of the teacher, which would be ascertained by "further examinations." Thus the student who passes the first examination would be recognised as an Elementary Science Teacher, and the increased money payment would be offered as an "inducement" to prepare for the further examinations to qualify as Second Grade and First Grade Science Master. The Commissioners think it "worthy of the consideration of the Department" whether it would not be possible to increase the resources of the science classes by greater payments from pupils and by local contributions. Some arrangement of this kind will become necessary in proportion as practical instruction is introduced—and if the instruction is valued there ought to be no difficulty on this head. The efficiency of the teaching is diminished, according to the Commissioners, on one hand by imperfect organisation of the classes and the absence of practical instruction, and on the other hand by the irregular and unsystematic manner in which scholars have taken up the subjects taught. The recommendations attached by the Commissioners to this section of their report are of some length and great importance; and they cannot fail if carried out in the spirit which has suggested them to be the means of disseminating the best of all knowledge far more widely than it is at present, and of imparting an immense stimulus to the scientific progress of the country. How necessary progress of this kind is will be apparent to any one who will inquire into the position of scientific inquiry in the United Kingdom. In another column we reproduce the opinions of Mr. Gore on the subject, and corroborative testimony could be found in abundance. Even as regards Chemistry, the President of the Chemical Society recently lamented the fact that the original researches laid before that society have fallen almost to zero. The cause of this state of things is easily discovered, for, as Mr. Gore says, there is absolutely no provision in this country for the support of scientific investigators, and thus the great source of new trades and improvements in manufactures remains undeveloped. It is too much to expect of men whose talents can be turned to account in a profitable manner, that they will devote themselves with self-sacrificing industry to the common wealth. Such instances are rare, and we have no right to expect them. But what has been done in Germany and Switzerland can surely be done in the richest empire in the world.

ELECTRICITY: WHAT IS IT?—III.

By B. Thompson.

(*Concluded from p.* 294.)

The Modification Heat Undergoes in Order to Appear as Electricity.—Before striking directly at the most important part of this communication, as to what modification the motion of heat must undergo in order to appear to us as electricity, it will be advisable—indeed, I think necessary—to notice two or three peculiarities in other modes of obtaining current electricity.

If we take a common battery, as Smee's, which differs very little from the one before described, the copper being replaced by platinised silver, we notice that there is a rapid decrease in its power when working, usually attributed to the adherence of molecules of hydrogen to the silver plate, which set up contrary currents, and thereby hinder the action of the primary one; but the importance attached to this may be over-rated; there is no doubt as to its being a hindrance to the action, but were it the only one, washing the plates ought to restore the energy of the battery, at least with no more decrease than there would be were it a constant battery of the same electromotive force, such as Grove's or Bunsen's; but the fact is it has lost a considerable amount of heat and electric force by the passing off of the hydrogen, which cannot be replaced save by recharging the battery, and this gives another reason—perhaps the principal one—why a two fluid battery is more constant and powerful than a one fluid battery; in the former kind the hydrogen is for some time retained and reduced, thus preventing the loss of power which would be occasioned by its passing off, adding generally to the conducting power of the liquid it passes into, and, of course, giving up again the force which liberated it.

Again, let us look at one of the batteries whose action it is rather difficult to understand by the common theories—Grove's gas battery. When the two platinum plates of a voltameter containing dilute sulphuric acid are connected with a battery the water is decomposed, and H and O pass to the two tubes respectively; in these two gases, as we have shown, is stored up a large amount of force, viz., that which was expended in their separation, and which we are bound to admit is a modification of the motion of heat, or heat itself, for heat would be the result of their recombination.* If now we disconnect the voltameter with the battery, the two gases will, after a time, have combined to form water. Besides this, however, if we connect the terminals of the voltameter, which before led to the battery, a second voltameter containing dilute sulphuric acid, the water in it will be decomposed the same as in the first one, and nearly the same quantity of gas will be liberated; the first voltameter acting on the second the same as the battery did on the first. The teaching of this experiment is very important, for the oxygen and hydrogen themselves give rise to a current of electricity oppposite in direction to the one which produced them, but this clearly is not the result of any dissimilarity of metals, for both the terminals are platinum; but to a difference in the electrical states of the two gases, one being + and the other −. In whatever way we destroy this condition of the gases, we produce heat, whether by exploding them, or allowing them to combine peacefully in the form of an electric current; of course, if work be done by the current instead of heat, we shall find its equivalent in work. Apparently, then, these two gases contain each of them a part of the motion of heat, for H and H or O and O alone will produce no heat, yet their combination produces intense heat, except when it takes the form of an electric current.

How can we, then, regard the forces of heat and electricity as such distinct phenomena? For there cannot be an electric current without chemical action; without either an absorption or liberation of heat, and without *superior affinity* (which is electrical attraction), and this excess of affinity of a body for any component of an electrolyte supplies the heat or cold—real or vertical—to enable the constituents to take another form, or exist independently if they do not retain this form; as they do not in batteries, part of the force will again be given up, and constitute what we call an electric current.

Now, I am about to make a bold hypothesis, but one, nevertheless, which, I think, has been partly forced upon us by the former part of this paper, and which will be supported by what follows—viz., that a current of electricity is identical in the *kind* of motion with "polarised heat," though they may vary very much in the rapidity of the motion. I am aware of the great drawback to this, presented by the fact that it requires a more ponderable substance to conduct it than heat does. The two states, however, are quite distinct, and a diathermanous body may, under certain circumstances, be quite athermanous when the heat has been polarised; but even a vacuum does not prevent electrical induction. I have not the means to experiment on this subject, so am obliged to depend upon reason alone. We will, therefore, consider the points which more particularly have led to this hypothesis with regard to a current of electricity. Because heat can be polarised the same as light, we must regard heat as constituted, like light, of two motions at right angles to each other, and a body which conducts it must, of course, vibrate in the same manner. Electricity is conducted by a continuous polarisation of the molecules, and we have shown that these polarisations must be accompanied by a motion of the molecules in a body transmitting it; but whether this motion takes place vertically, horizontally, or in any other direction, it must, of course correspond with one of the motions of heat, and thereby be equivalent—as far as the kind of motion is concerned—to a polarised ray of heat in a conductor.

The application of this theory will explain many things not satisfactorily explained by other theories: for instance, take the case where a current of electricity is generated by heating the junction of two dissimilar metals, or one end of a nearly homogeneous conductor. It is easy to see that part of the heat supplied will be divided or polarised when the metals are dissimilar, or in dissimilar states, and offer resistance to motion in one direction more than another. A perfectly homogeneous conductor when heated will give no signs of electricity whatever, but let the homogeneity be disturbed in the least by bending or twisting, immediately part of the heat which circulated before as heat takes the form of an electric current. In the first case, the heat was transmitted equally in all directions, but in the second one of the motions constituting a ray of heat was retarded or destroyed, giving rise to what we call a current of electricity, but what, according to this reasoning, is a true polarised ray of heat. And the greater the heat supplied the more powerful the current of electricity. If the dissimilarity between the two ends of the conductor be still further increased, by cooling the opposite end to that where the heat is applied, the current again will be augmented proportionally. We find, too, that it is the most crystalline metals, as bismuth and antimony, that give the most powerful currents: really selenium and bismuth most effectually polarise the heat, but the property which in great part is the cause of this—viz., the low conducting power of selenium—prevents its usefulness.

Faraday found that when a solid unmetallic body becomes fluid it almost entirely loses its power of conducting heat, but acquires a greatly increased capacity for conducting electricity, again, showing the influence which a change in density, or in the state of aggregation, has on the propagation or conduction of either electricity or heat.

The experiment above of producing electricity by heat may be exactly reversed, and a current of electricity be made to produce the heat and cold at the respective junctions, where the heat and cold were applied to produce the current of electricity, a change in the point of application of the heat and cold and of the direction of the current exactly reverse the effects; but perhaps this theory receives its greatest confirmation in the experiment quoted below. Taking a simple thermo-electric element of bismuth and antimony, if the cleavage of the bismuth is parallel to the face of contact, the current is increased, but if at right angles, decreased; and just the reverse holds in the case of antimony. But more important than this is the fact that the element may be constructed of all bismuth or all antimony if the cleavage of the pieces in contact is at right angles. The significance of this has, I think, been completely overlooked, as it seems to point so distinctly to the cause of a current of thermo-electricity. The two motions constituting ordinary heat being divided between the two conductors, each motion takes the direction which offers the least resistance to its progress, and the result is two currents of electricity flowing in opposite directions, which, if they combine, form again heat. I think we can scarcely fail to see that, at least in the case of thermo-electricity, the current is due to the decomposition of heat, the two motions appearing to us as + and − electricity; and if the reasoning holds for this it must for all, as electricity is of the same nature in whatever way produced.

This theory may be thought a peculiar one, and I rather expect to be told that were it true the experiments on polarised heat would have shown some connection before this; but I do not say that a current of electricity is one of polarised heat, for I believe that the amplitude of vibration has been lessened considerably, and the length of the wave altered, before heat appears as electricity; the fact of bad or poor conductors being invariably used where a current of electricity of any strength is obtained seems to point to this; indeed, some resistance is always necessary, whatever form of apparatus we use for its production.

No doubt, there are some difficulties to the acceptance of this which I have not thought of or have not mentioned, and I expect there will be plenty to point out any very flagrant errors or omissions. If there are any I shall be very ready to acknowledge or answer them.

* Faraday discovered that a plate of platinum, with extremely clean surfaces, plunged into a vessel containing oxygen and hydrogen in the proportion in which they combine to form water, would effect their combination, and would itself become red hot, from which it appears that the platinum in attracting the two gases brings them within the sphere of each other's attraction, and the particles of water formed are either vaporised by the intense heat or run off.

SMELL.

(*Concluded from p.* 295.)

Having examined this subject from the physiologist's point of view, we propose now to look at it from those of the naturalist and chemist. The three natural kingdoms all supply odours. Among mineral matters, a few solids are odorous, and a large number of liquids and gases, the odours being more or less strong and agreeable, and generally characteristic. They proceed from simple bodies, as chlorine, bromine, iodine; from acids, as hydrochloric acid and hydrocyanic acid; from carburets of hydrogen, as those from petroleum; from alkaline substances, as ammoniac.

Animal odours proceed from hydrocarburetted and hydrosulphuretted gases; from various acids and salts, from the decomposition of fatty matter, and from some kinds of matter secreted in glands, as musk and ambergris.

In the vegetable kingdom there is a great variety—from odours which are soft and agreeable to those which are most repulsive. Plants without odour are rare; many that have no odour when fresh give forth, when dried, a very distinct perfume. The odour of plants comes from certain kinds of matter distributed variously in their organs. In some it is solid, as balm or resin; in others liquid, as what we call essences or essential oils. Such essences are generally concentrated in the flower, as, *e.g.*, rose or violet; but in some cases, as that of Florentine iris, the root only has perfume. In the cedar and sandal, the odorous principle is in the wood; in mint it is in the leaf; in the Tonquin bean it is in the seed; in cinnamon it is in the bark. Some plants have several odours quite distinct; orange has three—that of the leaves, giving the essence called *petit-grain*; that of the flower, furnishing neroli, and that of the rind or peel.

Nearly all the essences employed in perfumery are of European production. England produces lavender and peppermint largely. At Nimes, attention is given to rosemary, thyme, aspic, and lavender. Nice makes violet its specialty. Cannes extracts the essences of the rose, the yellow acacia, the jasmine, and neroli. Sicily furnishes citron and orange; Italy, iris and bergamot.

What is the chemical nature of the odorant principle in plants? The varieties of it, as chemists will tell us, fall under three heads, hydrocarbons, aldehydes, and ethers. Hydrocarbons are compounds of carbon and hydrogen, and represent the most simple compounds in organic chemistry. To explain the two others we all know what chemists mean by an alcohol; it is a definite combination of carbon, hydrogen, and oxygen, and may be considered as resulting from the union of a hydrocarbon with the elements of water. Spirit of wine may be taken as the type, and it takes the formula C_2H_6O; that is, its molecule is made up of 2 atoms of carbon, 6 of hydrogen, and 1 of oxygen. Now, an aldehyde is simply *alcohol dehydrogenatus*—that is, alcohol with some of its hydrogen taken away, and an other is formed from the combination of an alcohol with an organic acid. Here, then, we have the constitution of nearly all the essential oils in plants—carbon and hydrogen, with or without oxygen—and according to the proportions in which these occur, we have a hydrocarbon, aldehyde, or ether. This, however, is not all. We have now spoken of quantitative differences. But it may happen that two substances, entirely differing in some properties, have the same chemical composition, both qualitative and quantitative. Such are isomerous bodies. How, then, do they differ? By the arrangement of their molecules. Carbon and diamond are identical in their composition. Ordinary phosphorus and amorphous phosphorus are one and the same substance. And in the odorous principle of plants we have some curious cases of isomerism. The oils of terebinth, of citron, of bergamot, of juniper, of lavender, of pepper, of cloves, are isomers; they all have the same chemical composition. On analysis, all give the same substances in the same proportions. In each molecule of the essence there are 10 atoms of carbon and 16 atoms of hydrogen—expressed by the formula $C_{10}H_{16}$. We are thus led to see how largely the qualities of bodies depend on arrangement and internal motions of small component parts, about which we as yet know very little.

But chemists have not been contented with merely investigating the nature of the odorous principle of plants; they have sought to produce it artificially. In many cases they have succeeded, producing substances with constituent parts which are identical with those of the products obtained from the plants. An Italian chemist Piria, working in France in 1838, was the first to reproduce a natural aromatic principle. He prepared, by certain reactions, a salicylic aldehyde, which proved the same as the essential oil of meadow sweet, the penetrating perfume of which is well known. Some years later, in 1843, M. Cahour discovered methyl-salicylic ether, and showed that it was identical with the essence of *Gaultheria procumbens*, or winter-green. Wertheim followed with further discoveries. The thing caused considerable sensation. Since then the art has advanced, and chemists can now produce various oils artificially, as oil of camphor, of bitter almonds, of cumin, of cinnamon, &c., without, that is, having recourse to any of the plants.

Besides the substances now referred to, various others have been produced of the ether class, in which a very good imitation of the aroma from certain fruits has been effected. These have been largely used by perfumers and confectioners. Such artificial oils appeared for the first time at the London Exhibition of 1851. One of these was pear oil, giving an agreeable odour of jargonelles, and used for bonbons. This was a solution of amylacetic ether in alcohol. Apple oil was made by dissolving amylvaleric ether in alcohol. The most plentiful was that of pineapples, which was ordinary butyric ether. Grape oil was used for giving to brandy of inferior quality the flavour of cognac. Various others might be mentioned. This synthesis of odorous principles is one of the most striking triumphs of organic chemistry. The creative faculty is still at work. M. Berthelot has been seeking to reproduce the fatty matters of the animal economy. Some progress has been made towards the artificial production of sugar; and this will, doubtless, be followed up by an effort to work out the synthesis of albuminous substances.

Linnæus brought his powers of analysis and classification to bear on the subject of odours. He arranged them in seven classes, as follows:—Aromatic odours, as those of the leaves of laurel; fragrant odours, as those of fleur de lis, jasmin, &c.; ambrosial odours, as those of amber and musk; alliaceous odours, as those of garlic, &c.; Fetid odours, as those of orach, &c.; repulsive odours, as those of many solaneæ; and finally, nauseous odours. The terms used are mostly familiar in ordinary language; but they have quite a relative and conventional value. As formerly remarked, we cannot construct a scale of odours, as we can a musical scale. We can only compare one odour with another from its effects on the olfactory membrane. They have not such characteristics as can be vigorously defined. Any classification of them must therefore be imperfect.

Professor James C. Watson, in a letter dated Ann Arbor, April 4th, announces to the Editor of the *American Journal of Sciences* the discovery of a new planet, hitherto unknown, in the constellation Virgo. It shines like a star of the eleventh magnitude.

BRITISH MANUFACTURES AND SCIENTIFIC RESEARCH.

IN an article on the future extension of Birmingham industries, recently contributed by Mr. George Gore to the *Birmingham Morning News*, he calls attention to the character of those industries, and in pointing out their origin he takes occasion to inculcate the necessity for the encouragement of scientific research if this country is to retain its present pride of place in the manufacturing world. Mr. Gore commences by noticing the principal industries of Birmingham, tracing the manner of their origin, and the method of their development, and then points out the necessity—or at least the advisability—of endeavouring by indefatigable research to found new manufactures and improve old ones. Let us consider, he says, German-silver and its manufacture. That substance is an alloy of copper, zinc, and nickel; it owes its peculiar whiteness or "silver-like" appearance to the latter metal, and cannot be made without it; it is certain, therefore, that by whatever means that metal or the alloy was discovered, the discovery was the origin of the German-silver manufacture, and was essential to all manufactures, processes, or appliances, in which German-silver, nickel, or any of its compounds are used. Nickel was discovered by Cronstedt during the year 1751, and its compounds were chiefly investigated by English and foreign chemists. Cronstedt found it as a peculiar metal in the mineral called kupfernickel, whilst chemically examining the properties of that substance. The general method by which he discovered it was careful experiment, observation, and study of the properties of matter. I believe it is a fact that the Chinese and other nations made alloys of nickel long before nickel itself was known to be a separate metal; they had found, by experiment, that when ores of copper and zinc were mixed with a particular kind of mineral and smelted, a white alloy was obtained; but this also proves the general statement already made, that the German-silver manufacture was originated by means of experiment and observation. It was by a more skilful, but similar mode of procedure, that Cronstedt discovered the metal itself, and thus laid the basis of improvements in the manufacture of its alloys. I need not here enlarge upon the multitude of uses to which nickel has already been applied in Birmingham manufactures, nor speak of the large sums of money which have been and still are made by means of it and its compounds.

The manufactures of iron wire and copper wire for telegraphs are two other modern trades of great magnitude in this town, and were originated in the following manner:—In 1799, Volta, an Italian philosopher, was experimenting, observing, and studying the electric properties of metals in liquids, and discovered the voltaic battery. In 1815, Professor Oersted, of Copenhagen, was experimenting on the relation of electric currents to magnets, and observed that when a magnet was suspended near and parallel to a horizontal copper wire, through which an electric current was passing, the magnet moved spontaneously, and placed itself at right angles to the wire. From these two small experiments, made by putting matter and its forces under new conditions, observing and studying the results, all our telegraphs and the immense manufactures of iron and copper telegraph wire have arisen.

There is a saying that "all great things have had small beginnings," and this is true, not only of electric telegraphs, but also of the great trade of electro-plating, and of the magneto-electric machine, which is now largely used instead of the voltaic battery. After Volta had made his small and apparently unimportant experiments on the electricity produced by metals and liquids, various persons tried the effect of that electricity upon metallic solutions. Brugnatelli, in 1805, found that two silver medals became gilded in a solution of gold by passing the electricity through them. Mr. Henry Bessemer, in 1834, coated various lead ornaments with copper by using a solution of copper in a similar manner. And in 1836 Mr. De la Rue found that copies might be taken in copper of engraved copper plates by the electro-depositing process. Faraday discovered magneto-electricity in the year 1831, by rotating a disc of copper between the poles of a magnet, and he has stated that the first successful result he obtained was so small that he could hardly detect it. This simple experiment was the origin of the magneto-electric machine, and many of those machines are now used by Messrs. Elkington for depositing copper, silver, and gold, instead of the voltaic battery.

Another large manufacture of this district is that of phosphorus. The origin of it is due to the man, whoever he was, who first isolated that element. Histories of chemistry tell us that it was discovered by Brandt, a merchant of Hamburg, in 1669; but evidence exists that it had been obtained in the separate state very many years before by the early Arabian chemists. Brandt obtained it by distilling a mixture of dried residue of urine and charcoal. His discovery was also made by careful experiments, and observation of the properties of matter, and had it not been made there would have been no manufactures of phosphorus or phosphorus matches in this district.

Priestly made many experiments on the absorption of gases by water, and proposed such liquids as beverages, and those apparently trifling experiments have since expanded into the large manufactures of aërated waters.

Persons inexperienced in scientific matters are apt to think that discoveries are generally made by accident. The reverse is, however, the case; nearly all our great modern discoveries were effected by men who were constantly making careful experiments upon the properties of matter and its forces, by subjecting them to new and definite conditions. Nearly all persons look upon such discoveries as fortunate ideas, which, when once found, are quickly developed, instead of which they are in most cases, slowly developed results of most difficult mental labour. Discoveries in science are occasionally made, not by original scientific investigators, but by practical men engaged in manufacturing or technical employments. The hydro-electric machine originated in this way: a man at Newcastle was attending to a steam-boiler, and found that he received electric shocks when he touched the boiler. This circumstance was investigated by his employer, Mr., now Sir William, Armstrong, and led him to construct the hydro-electric machine. The accumulation of electricity in submarine telegraph cables was also first observed at the Guttapercha Company's Works, London. It was noticed on testing the cable by means of a voltaic battery (the cable being submerged in water) that discharges of electricity flowed from the cable after the battery was removed; this circumstance was investigated by Faraday, and led to improvements in submarine telegraphy. In these instances also the same general method was employed—viz., new experiments were made (though not intentionally) by putting matter and its forces under new conditions, and new results were observed.

Scientific discovery, therefore, by developing new facts and laws relating to matter and its forces, constitutes not only the basis of new manufactures, but largely, also, of the improvements in trades made by inventors and practical men; and if discoveries are not made, the means by which improvements are effected by such men will become exhausted. The great value of new scientific knowledge to such men is proved by the fact that when new scientific discoveries are published there are numerous inventors and practical men who immediately endeavour to apply them to useful purposes. Since the first application of coal-tar to the production of dyes, every discovery in that branch of chemistry has been closely watched for a similar purpose.

According to all our experience, scientific discovery provides the knowledge necessary for making inventions, and practical inventions lead to increase of trade. It might easily be shown that in this way scientific research has already resulted in the employment of whole armies of workmen, and in the expenditure and investment of a fabulous amount of money in railways, telegraphs, machinery, gasworks, chemical works, electro-plating, photography, &c., in this country; and Birmingham has received a large share of the benefit.

The future success of this town and district is dependent upon original scientific research to a degree of which persons in general can form but little conception. Hundreds of millions of pounds are being expended in covering the earth with telegraphs, and thousands of millions in covering it with railways, gasworks, waterworks, &c., and Birmingham and its district has its share in supplying the rails, the wire, and the machinery. In this country alone more than 550,000,000 of pounds have been already expended upon railways only. Original scientific research is the great fountain-head of industry, and its capability of developing increased trade is practically unlimited: it is at present quite in its infancy, and we are only on the very threshold of a knowledge of the forces of nature, and of the constitution of material substances; and if such enormous results are being produced by the beginnings of unaided science, what may be expected from its future developments, especially if scientific research is assisted in an effectual manner?

Numerous important subjects of investigation, capable of yielding valuable results bearing upon the trades of this town, exist in all directions. Researches in electricity and in inorganic chemistry, particularly the metals and their compounds, would probably lead, as they have done before, to the establishment of new trades, and to improvements in local manufactures, and thus lay the foundation of future commercial prosperity. Discoveries in science, however, are best made, not by trying to obtain some valuable commercial or technical result (that object belongs to an inventor), but by making new, reliable, and systematic investigations. By investigating the chemical action of electricity upon saline bodies, Sir Humphry Davy isolated sodium and magesium, which has led to the recent establishment in Manchester of the manufacture of those metals. By the abstract researches of Hofmann and others upon coal-tar, the immensely profitable manufacture of the splendid coal-tar dyes was originated.

Scientific discovery is the most valuable in its ultimate practical results when it is pursued from a love of truth as the ruling motive, and any attempt to make it more directly and quickly remunerative, by trying to direct it into practical channels, will decrease the importance of its results, diminish the spirit of inquiry, and sooner or later reduce it to the character of invention. The greatest practical realities of this age had their origin, not in invention or a search for utilities, but in a search after important new truths, entirely irrespective of what utilities they might lead to.

I do not intend by these remarks to imply that any new trades or improvements in manufactures have been or can be effected without the labours of inventors and practical men; but that there should be a more judicious division of labour, one man to discover new truths, another to put them into the form of practical inventions, and the practical business man to work them; because it is proved by experience that in nearly all cases these different kinds of labour require men of widely different habits of mind, and that the faculties of discovery, invention, and practical manufacture, are very rarely united in one man.

Our large manufacturers and men of business have accepted and employed the advantages of science in an endless number of ways in their occupations, and have thereby acquired great wealth; but, notwithstanding this, and that the greatest trades of this district were originated and improved largely by means of scientific investigation, scarcely any of the wealthy manufacturers or landholders of the locality, who have derived such great benefits from the increase of trades, give the least assistance to scientific research; that which is the duty of all has been attended to by none. The probable explanation is, original scientific research is a subject quite outside the experience and knowledge of persons in general. It may be objected that such research is not aided, because it sometimes takes a long time to acquire a practical shape and make it pay. We do not omit to plant an acorn because it requires many years to become an oak; we do not neglect to rear a child because he may not live to become a man; but we leave scientific discovery to take care of itself.

Our practice with regard to science is very different from the plan carried out in Germany. Within the last few years great laboratories have been erected in Berlin, Leipsic, Aix la Chapelle, Bonn, Carlsruhe, Stuttgardt, Griefswald, and other places, at the expense of the State, and special provision has been made in them for original scientific research. A glance at the frequently published list of scientific investigations made in different countries will show us that the Germans are making a far greater number of discoveries in science than ourselves. If we are to maintain our position as a manufacturing nation, we also must adopt special means to promote scientific research; for how can we expect to obtain new arts and manufactures, or improvements in old ones, if we do not make new discoveries in the properties of matter and its forces? I need not multiply instances of the essential dependence of our present commercial success upon abstract scientific research, but may safely affirm that nearly all our great manufactures have been originated by means of experiment, observation, and study of matter and its forces; and that the great bulk of the improvements made in manufactures by practical men could not have been effected had not scientific investigators discovered, and made known in books, the properties of bodies. The inference from these conclusions is obvious: by adopting similar means, but in a more effectual way, we shall obtain similar but more successful results.

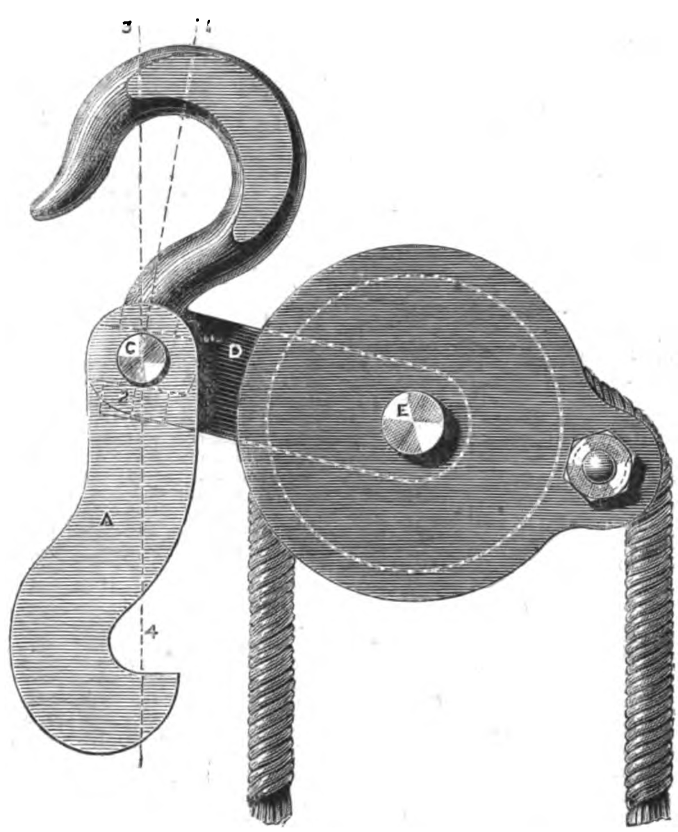
REMOVING SCALE IN BOILERS.

THE *Oneida Circular* says that the stoker who has charge of the boilers employed at its printing office has recently been making a trial of "tannate of soda" for removing the scale which accumulates on the inside of the boiler-pipes in consequence of using hard water. "After a two weeks' trial in our Root boiler, nearly half a bushel of broken-down scale and soft mud was taken out. The action of the tannate is to first loosen the scale. At present about 2lb. a week is used; but after the scale is once thoroughly removed, the occasional application of a much smaller quantity will keep the boilers free from any further deposit of it. The attendant thinks, if it continues to work as well as it now promises, it will make a saving of thousands of dollars in a few years in fuel alone, besides a saving in the wear and tear of the boilers, and relief from the risk of explosions. Tannate of soda has been in use for this purpose about three years, and is steadily gaining the confidence of the public."

It would have been an advantage if the *Oneida Circular* had said what is meant by "tannate of soda;" for, so far as we know, no chemical of that name is made in this country or imported from abroad, neither do we know of any formula for producing such a salt. Under these circumstances the value of the information thus made public is represented by an infinitesimal quantity. Possibly some of our American readers will be able to inform us what it is that is known as "tannate of soda" in the States.

IMPROVED SNATCHBLOCK.

THE improved construction of snatchblock shown in the annexed figure has been recently patented by Mr. G. Tangye, of Birmingham, who claims for his invention that the action of the weight or load automatically locks the movable strap or plate, rendering unnecessary the split pins or fastenings commonly employed, while the rope or chain may be more readily introduced or withdrawn than in those heretofore made. The illustration is a view of the snatchblock when opened for the adjustment of the rope or chain thereon. The movable strap A of the snatchblock is connected to the cross-head in such a manner that they will swivel together on the pin C of the cross-head which secures it to the strap D on the other side of the block. The free end of the movable strap A is formed with a hook, slot, or groove which, when the weight is on the block, engages with a pin or projection, preferably the pin, E, on which the sheave of the block revolves. By causing the movable strap A and cross-head B to swivel a space is left above the sheave, as shown, through which the rope or chain may be introduced or withdrawn. The hook being attached to the cross-head in the usual way by a neck and rivet, the action of the weight causes the cross-head and movable strap



to swivel and lock the latter securely on the pin or projection E; and in order to render this locking more certain the movable strap is so attached to the cross-head that when locked the centre line 1—2 of the hook makes an angle with the longitudinal centre line 3—4 of the pulley block. The action of the weight consequently tends to make these lines coincide and the movable strap engage with the pin or projection E.

CARRIAGE WHEELS.

ON the durability of the wheels more than on any other part of the carriage does the reputation of the builder rest. No matter how perfect all other parts may be, if the wheels are defective the vehicle is condemned. Knowing this, many first-class manufacturers employ none but the most skilful workmen, and have their wheels made under their own supervision, and any defect is detected before the wheels are finished. This is rendered necessary, says the *New York Carriage Journal*, from the multiplicity of causes that operate to injure the wear of the wheels—carelessness in mortising the hubs or in fitting the spokes, bad driving, inequality in the texture and stiffness of the timber, in spokes or felloes, badly seasoned or imperfect hubs, together with the injury inflicted by setting the tire or cutting out for the boxes—all to a greater or less degree produce defects that seriously impair the durability of the carriage. These defects are all the results of carelessness or ignorance on the part of the workmen, but there are other causes that operate against the durability of the wheel; the principal one is the failure to select those that are of proper proportions. Some manufacturers will make all parts of the vehicle as light as possible, but select a comparatively heavy wheel; others will act the reverse, and make the wheel as light as possible. In either case the result is injurious. If the wheel is too heavy it throws all the strain upon the axle, which is the cause of nine-tenths of all the broken axles where the break is at the shoulder; if the wheel is too light it receives all the strain, and is soon torn to pieces.

There are two classes of wheels—one class owes its strength to its elasticity, the other to its rigidity; in the first class might be placed all wheels having spokes 1in. and under, while the other class would comprise all heavier sizes. Any light wheel that is constructed with too great rigidity around the hub, or too great weight at the felloes, has not only the element of its destruction in it, but it also proves the destruction of the axle upon which it is placed unless this is unduly large. Then, too, if the spokes are too stiff they throw all the strain on the hub, and as a result the spokes are loosened or broken at the shoulder. In order to secure strength in light wheels it is necessary that the hub should be small and the throat of the spoke thin and flat, and as near the shoulder of the tenon as possible; the felloes and tire should be proportionately light. If a set of wheels are to carry 250lb., carriage and rider included, a hub 3in. to 3¼in. in diameter, three-quarters of an inch spokes, three-quarters of an inch felloe, and three-quarters of an inch by one-eighth of an inch steel tire is ample. If a set is needed for a top buggy that will accommodate two persons, the total weight to be carried being about 500lb., the wheels should be made with a hub 3½in. to 3¾in. in diameter, seven-eighths of an inch spoke, seven-eighths of an inch felloe, and seven-eighths by three-sixteenths steel tire, the axle being seven-eighths of an inch steel. If the roads are rough the wheels should be strengthened by adding one-sixteenth of an inch to the spokes, and one-eighth of an inch to the diameter of the hub, but nothing above this unless the axle be increased in size. Wheels are in some instances made lighter than those first mentioned, but when below that point there is danger of their lacking in power to produce a recoil if they become badly strained. A great mistake in making light wheels is in using too large hubs, under the mistaken idea that the hub, of necessity, is the point where there is the greatest amount of strain; for this reason a heavy hub will be selected, and light spokes, felloes, &c., be used, giving to the wheel additional weight and bad proportions, besides removing the point of elasticity too far from the centre, and thus increasing the rigidity and endangering the axle. The principal aim of inventors has been to secure great strength at the hub; for this purpose metal, and metal and wood combined, have been introduced; in some cases they have met with success, but this can be attributed as much to the manner in which the wheels are put together as in the advantages claimed in the patent. Heavy wheels with a wood and metal hub have proved valuable, and are taking the place of the large wood hub, but with light wheels the success has been less decided, and where it was most meritorious in preserving the wheel it was most injurious to the axles.

The trouble with wheel makers is that we have too many inventors and too few mechanics; but, after all the inventions have been sifted to the core and the best points combined, for light wheels there is nothing better than a good elm hub, clear young hickory spokes, and fine, close-grained hickory felloes, provided these are put together in a workmanlike manner. One of the latest inventions is the wheel line is the mortising of the hub with two sizes of mortise for the same spoke; the first mortise which is about one-third the depth of the whole mortised in nearly, if not quite, the full size of the spoke at the lower end; below this the thin mortise is made, the latter, however, being narrower than the former; and, strange as it may seem, it is claimed for this method of mortising that "the hub is not cut away so much in its centre, and a very small and light hub may be made to be very strong;" also, that "the wheel is more elastic than the old style of wheel, and therefore less liable to break axles;" more than this, "the spoke is strong just where it needs strength, namely, at the shoulder, and the hub is strong just where it requires most strength—at the middle." We confess ourselves to be at a loss to understand how the strength of a hub is increased by cutting it away to almost nothing at its extreme outside circumference, or how bedding a wide tenon into the hub in this manner increases its elasticity. According to our reckoning, a 3¼in. hub, made up with a spoke that has a half-inch face and a five-sixteenth tenon would have about 7in. of solid timber on the outside circumference, while the spokes would run together at the outside of a box of suitable size to receive a three-quarter of an inch axle, while with this improved plan there would be less than 3in. of uncut space, and by no manner of measuring can we discover where the extra amount of timber is located; but as a scientific paper gives the following endorsement, we presume they have a way of increasing strength by cutting it away. "The principle of construction is sound, and we have no doubt an excellent wheel may be made in this way." If any of our friends have an idea of trying this improved manner of mortising hubs let them make a diagram of a hub, cut off at the face of the spokes, laying off all the tenons full size, both with the old and new plan, and we think they will be slow to cut their hub away one-third more than is necessary, in order to secure greater strength.

There is another weak point in the fitting up of the wheels that impairs their strength; we refer to setting boxes. There are many good machines in use, but they all cut away the ends of the spokes on the same line as the bore of the hub, and when the box is forced in the spokes bear heavy upon the metal. The constant hammering that the spokes are subject to renders it necessary that they should rest upon the wood of the hub on account of its elasticity, whereas, if resting on the box, which is unyielding, it soon jars in the mortise and become loose. The right method is to cut away the ends of the spokes at least one sixteenth of an inch below the bore in the hub; a little more than this would do no harm, as it will need but one or two resettings of the tire to force them down as close to the metal as is consistent with the safety of the wheel.

ADULTERATION OF FOOD.

DR. WHITMORE, the Medical Officer of Health for Marylebone, writes:—

"Whilst the question of a pure and constant water supply is engaging public attention, some little consideration might also be advantageously given to the quality of our food supply. For some time past certain articles of food, principally those in daily consumption by the poorer classes, have been brought under my notice, which on examination I have found to be deficient in those nutritive properties, which, when genuine, they are found to possess. I may refer more particularly to milk, bread, and lard. With regard to milk, it has been a practice of late years amongst many dairymen to supply milk of a 'superior quality' for the use of the nursery, and to charge an increased price for it; but as this kind of milk can only be genuine at the best, the fair inference is, that all milk not intended for nursery use is not genuine, and that it is not I have in many instances been enabled by analysis to prove. With regard to bread, the principal adulterative article used in making it is the potato, which, although not injurious to health, is so far objectionable that it contains none of the vegetable fibrine which constitutes an important ingredient in wheaten flour, and to which it owes nearly all its flesh forming properties."

"Lard is not unfrequently adulterated with potato flour or the cheaper kinds of arrowroot, which is stirred into it when in a liquid state, and which gives to it when cooled an appearance of increased whiteness and purity."

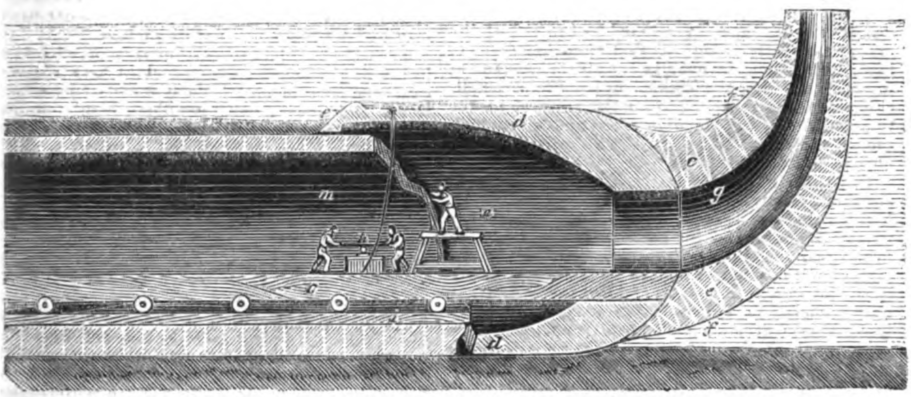
"I fear it will in time be discovered that many small shopkeepers, in their desire to compete in point of cheapness with the large co-operative stores, are resorting to a system of adulteration which in the end cannot fail to become an evil that will require stringent laws to repress."

SUBMARINE STRUCTURES.

OF the various methods hitherto adopted for forming structures under water, the most common is that which consists in surrounding the place of work with a dry inclosure called a coffer dam, formed by driving rows of piles into the ground, and filling the spaces between them with clay puddle, gravel, and sand.

Another system is that in which iron tubes, open at the bottom, are sunk into the water. They are then exhausted of air, and the material at the bottom, if soft, rises into them, while they, on the other hand, sink down into it. The material is then taken out and concrete substituted.

A third method is that which was adopted in making the Thames Tunnel. A sufficient thickness of earth is left between the place of work and the bottom of the river to support, during construction, the body of water above. M. Francois Durand proposes a new mode of making passages under water, which will not involve more expense than tunnelling in *terra firma*, and offering further advantages, which will best appear on description. He would apply the principle in



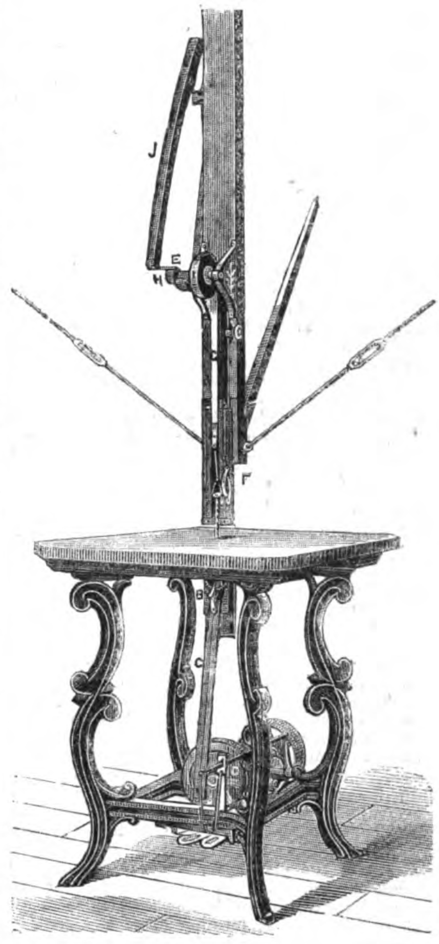
various ways, as for making a passage between the banks of a river, for laying the foundation of piers, breakwaters, &c. The principle of the invention consists in enveloping the structure which is in course of formation with a cloth texture impermeable to water. An iron shield of sufficient weight to remain at the bottom of the water, notwithstanding the air inclosed, supports this cloth, forming a work chamber, whose section is a little larger than that of the tunnel being made. The shield is represented in the drawing at *d*. This shield is crossed in its central part by metallic bars, on which are placed such weights as are necessary to the stability of the apparatus, and in such a way that its centre of gravity is between the wheels of the carriage C, which sustains it, and by means of which its advance is regulated. Lastly a pipe *g* rises to the surface, and is supported by a buoy, thus ventilating the work chamber. This pipe is surrounded by the cloth *e*, which has to be paid out, so to speak.

Suppose, now, a subway is to be formed under some river, and that the approach has been prepared to the surface of the water. Having dredged an even channel for the tunnel, gently inclining on either side, the shield is placed at the point of entrance into the water, and the extremity of the sack into which the shield is thrust fixed behind it, the rest of the sack being in front of the shield. The construction is then proceeded with, and the apparatus is gradually advanced to the opposite bank, the ring of masonry being always within the cloth envelope and metallic shield. The carriage is moved on rails fixed on that part of the bottom which is already constructed. The advance is effected by means of hydraulic pressure. The above apparatus can, with advantage, be adapted for tunnelling in *terra firma*.

IMPROVED SCROLL-SAW.

AN improved scroll-sawing machine, patented by Mr. J. Moseley, of Syracuse, New York, seems to be highly thought of by American mechanics, and has received several prize medals at the State fairs and exhibitions where it has been shown. Simplicity in construction and convenience in operation are its chief recommendations. It can be run, it is said, at a speed of from 800 to 1,200 "revolutions" per minute, and is equally serviceable in cutting heavy work as in shaping the lightest veneer or the most delicate fret. The following description and illustration will, however, enable our readers to form their own opinions of its capabilities:—

The saw passes through the table in the usual manner, and has its upper end attached to a suitable slide working in the adjustable guide, A, and its lower end attached to the sliding cross-head, B, fitted to guides underneath the table. The vertical movement of the cross-head, and consequently of the saw, is received from the pitman, C, connected with the wheel, D, the shaft of which also carries a fast and a loose pulley. The slide at the upper extremity of the saw is connected to



a strap, G, attached at its upper end to a wheel, I, on one extremity of the shaft of which is a cam, *c*. From a point on the periphery of this cam extends a strap, *d*, to the free end of a vertically arranged wooden spring, J, the elastic action of which tends to rotate the shaft of the cam and wheel, in such wise as to exert a tension on the strap, G, thereby straining the saw. The wheel, I, is made adjustable upon its shaft by simple devices, so that the strap may be adjusted either to different lengths of saw, or to exert any required tension or strain upon the same. The upper slide and the cross-head below are fitted so that the ends of the saw are gripped between clamping surfaces without the aid of pins, and devices actuated by a short lever, F, are so arranged that, when required in the exigencies of the work in hand, the upper end of the saw may be quickly and conveniently released from its fastenings. Means are also provided for readily raising the guide, A, out of the way under like conditions. At the base of the machine, and in convenient proximity to the foot of the operator, are pedals, so connected by appropriate mechanism with the fast and the loose pulley that one or the other of the said pedals may be used to shift the belt and to actuate the brake, accord-as the belt may be arranged to run in one direction or another in stopping and starting the machine. The upper part of the machine is secured to the roof by tie-rods in the usual manner, and the table and driving-shaft is mounted on a cast-iron frame, the whole apparatus weighing less than 400lb.

ON EARTHQUAKES AND VOLCANOES.*

By AUGUSTUS LE PLONGEON, M.D.

(*Continued from p. 221.*)

6.—How the Earthquakes are Produced.

LET us take it for granted that, owing to the living activities of the earth, a considerable quantity of these necessary chemical elements have collected, and that the waters of the sea having percolated and saturated them, a very active chemical action has taken place and evolved a considerable amount of caloric. This will soon reach the incandescence, particularly if the point where the chemical action is taking place happens to be in contact with the voltaic arch formed by the electro-magnetic current passing between the sun as positive element and the earth as negative. This is precisely what has occurred on the 13th of August, 1868, in the southern provinces of Peru, and three days later in the northern of Ecuador. It is a fact worthy to be noted, that the great and destructive earthquakes have always taken place at the time of some eclipse of the sun or moon. The moment a single atom becomes incandescent, irradiation takes place, and the surrounding atoms soon attain the same degree of heat as the first, the inciting causes being incessantly at work. From this focus of irradiation, caloric will extend from one molecule to another; and it will not be long before a large subterranean furnace will be in existence. What will then happen? It is perfectly obvious that the water existing in the neighbourhood will be converted into steam, and this constantly overheated into gases, which by their enormous dilatation will exert a tremendous pressure against the wall of their place of confinement.

Everybody is now acquainted with the force of expansion of gases. In their action on the superficial strata we shall find the explanation of earthquakes. These gases must find an issue. They press against the crust above in a perpendicular direction. This crust happens to be sufficiently resistant, composed of homogeneous materials that render it elastic—upheavals then take place, like those observed from the remotest antiquity to our times. All these upheavals are always preceded by earthquakes, with emissions of sulphurous vapours and sulphuretted hydrogen gas, smoke, &c.

If the crust is not sufficiently resistant, a new crater is opened, a volcano is formed. These are the boils on our mother earth's body, that having ejected all the matter contained in them, subside and even disappear. We have an example of this phenomenon a few miles from Granada (Nicaragua) in the volcano of Musalla, which has completely vanished since the conquest by the Spaniards, and the place where it stood is now a level plain covered with burned and blackened stones. Let us suppose that the superstrata are homogeneous, and so resistant as to withstand the enormous pressure of the immensely dilated gases. Then the soil will be convulsed, tremendously shaken; and the mighty works of men destroyed, levelled to the ground.

As deep as man has penetrated in the superficial strata of the planet, he has found them honeycombed; traversed in all directions by moats, conduits, caverns, and hollows, which contain large deposits of water, forming lakes and pools, originating subterranean currents, streams, and rivers. These moats, conduits, caverns, &c., &c., are separated by walls more or less thick. These walls in the vicinity of the furnace, being less resistant than the crust above, give way under the pressure of the gases; an issue is opened for their escape. They precipitate themselves into it with incommensurable force; hence the rumbling noise—the thunder-like explosions which always accompany earthquakes and precede them by a few seconds, giving warning of their coming. By the falling of the walls of the caverns and moats, the props of superstrata being destroyed, these cave in; hence the abasements of the surface, the rendings, the disappearance of some streams, the appearance of others—the changes that take place in the configuration of the countries where the catastrophe has occurred. The gases, in their onward rush, meet other openings; part precipitates into them. Soon they expand on a larger field; their forces, not being any longer concentrated, grow less and less as they find more avenues through which to escape; and as they are further from the centre of their generation, that is to say, from the furnace. Many of these furnaces, no doubt, exist that having communications with active volcanoes are not perceived on the surface; or have a vent in the shape of geysers, hot springs, mud volcanoes, &c., &c. The hot well discovered at Lacrosse, Wis., in the month of February, 1868, when some men were boring an artesian well bears witness of the truth of my assertion. The upward pressure against the ceiling of the conduits accounts for the waters in the wells overflowing, and for the changes of their level. The sulphurous nature of the gases accounts for the fetidity observed in subterranean waters, in caves and cellars.

Different and very distinct motions of the soil have been noticed during earthquakes. They are easily accounted for. The most common is known under the name of *undulating motion*. It may be explained in this wise. The walls and ceilings of the subterranean cavities are rugged and uneven, resembling somewhat the waves of the ocean during a gale, with more or less deep indentations; they are not composed of the same and homogeneous materials. In places they are more resistant than in others; and when gases come from a long distance, and somewhat disperse, they do not exert their power with so much force on the ceilings. They consequently give rise to a motion similar to that felt on board of a vessel at sea, and called for this reason *undulating motion*.

There is a second motion called *sussultaria*, eruptive. This has been observed many times, and always accompanied by great catastrophes. Such motion, foreshadowed by sulphurous vapours, occurred during the months of February and March, 1783, in the plains of Calabria and Mesina, when the tops of granite hills were clearly seen to jump up; the stone foundations of houses, even the pavement in the streets, were so lifted up as to be found turned upside down. The city of Riobamba was destroyed by one of these eruptive motions in the year 1797, and the bodies of some of the inhabitants thrown on the top of a hill 100ft. high. Palmeri and Scachi, in their report on the earthquake of Molfi, which occurred the 4th of August, 1851, expressly say that columns were broken at the base without losing their perpendicular position; that chimneys were heaved up into the air, falling again in their natural place. The city of Mendoza was destroyed in 1861 by a motion of that kind. The ceilings of the furnace, being homogeneous and resistant, will not swell or upheave, but sustain the shock occasioned by the puff of the gases incessantly arising, dilated from the focus of heat, in the same manner as the steam escaping at intervals through the escape pipe. The perpendicular shock is repercussed to the surface, in the same manner as if you give a sharp blow under a table; the table, to be sure, will resist, but the objects on it will be thrown up into the air.

The third motion (*moto vorticoso*) is rotary or circular. Many doubt its existence; but I see nothing that can be opposed to it. We read in the papers an account of the earthquake that was felt in the year 1868 in San Francisco, California, and a motion of that kind is said to have been observed in the lower part of the city. After the earthquake that occurred in Valparaiso in 1822, three palm-trees, placed at a short distance from each other, were found intertwined, and so have remained ever since. It is also reported that after the earthquake of 1783, in Calabria, two square obelisks placed in front of the Convent of S. Stephano del Bosco, were found turned round on their pedestals. Many other cases, similar to those, are reported, proving the existence of the rotary motion.

But how is such motion to be explained? In two different manners. Have you ever noticed how a rotary motion can be imparted to a small metallic wheel, supported on a steel or iron axle, on which it can revolve freely, merely by rubbing vigorously with a rough file one end of the axle? If so, you have seen it turn of itself, as it were, in the same direction as the file is drawn.

Why would not also a powerful stream of gases, rubbing against the rugged ceilings of the conduits, produce a strong electro-magnetic current, that would impart a rotary motion to the objects on the surface, in accordance with the laws that govern currents of induction. ?

Again, this rotary motion may be explained in this wise. When two currents of air, coming from opposite directions, meet each other, they give rise to a whirlwind. If these currents are very strong, a hurricane or tornado is the result. Well, there is no reason why the same phenomenon, which takes place above ground, should not also occur under ground, when two different current of gases, coming from opposite directions, meet in the interterrestrial passages and cavities. Nature works in the same manner in all its manifestations when the conditions are equal. Similar causes produce like effects; then two currents of gases meeting under ground will produce a tornado; and a rotary motion will be imparted to all objects within its boundaries.

I have reviewed in a very cursory manner all the effects produced by the convulsions of the earth, and, by the synthetic method of reasoning, tried to arrive at the understanding of their causes. I have not advanced an opinion which is not founded on facts acknowledged by science, on events recorded in history. I do not propose any theory, but merely give in these few lines the result of my own observations and investigations. If they satisfy your mind, as they do mine, then I am happy, for I have attained the object I had in view when I took the pen.

Let me then recapitulate, and sum up in a few words my

7.—Conclusions.

1. There is no central fire. It is unphilosophical, unscientific to uphold the opposite doctrine—for it merely rests on speculations, unsupported by facts and science. It must, therefore, be disregarded by all scientific minds.

2. The heat of the earth has its source: 1st. In the friction occasioned by its rapid motion through the cosmic matter that fills all space. 2nd. In the rays of the sun, that, however cold in themselves, carry light that, setting in motion the molecules of the atmosphere, generates heat, which is communicated to the earth. 3rd. In the constant chemical decompositions that are incessantly going on in its great interior laboratories. 4th. In the oxidation of the metallic substances that compose the superficial strata of the planet. All these phenomena are produced by the agency of electro-magnetism, which seems to be the life-sustainer of the whole creation.

3. The volcanoes are not the safety valves or vents of a central fire, which does not exist; but are merely local accidents produced by a conglomeration of materials, sulphur being one of the principal, that, being soaked by salted waters, enter into chemical decomposition, under the agency of electro-magnetism, and that the volcanoes are to the surface of the earth what boils are to the surface of the human body, which disappear as soon as the matter accumulated is expelled.

4. That the sun's immense reservoir of electro-magnetism, and the other celestial bodies, which are likewise reservoirs of the same agent, increases the action of the electro-magnetic currents that traverse the earth, according to their respective positions with regard to this, and hasten the effect of the chemical operations, if a point of the voltaic arch formed by them comes in direct contact with the place they are going on on a large scale.

5. That earthquakes and volcanoes stand in intimate relations, have a common origin, and will ever occur in those places where large chemical action is taking place. That, inasmuch as chemical action is alive in every part of the earth, earthquakes may be felt on any point of its surface.

6. That the origin of earthquakes may be found in the expansion of gases generated by the various causes enumerated, particularly chemical decompositions. These gases, being prodigiously dilated, press heavily against the wall and ceilings of the cavities in which they are confined, and in trying to find an issue through which to escape, produce the dreaded phenomenon.

7. That when a volcanic action is going on in the substrata of the surface of the earth, and earthquakes are impending, the phenomenon is foreshadowed by many precursory signs.

8. That among these forerunners the following are the most evident: 1st. Sulphurous vapours arising from the ground in the vicinity of the focus of the chemical action. 2nd. Strange and mysterious noises, produced by the activity of the gases. 3rd. Alterations of the mineral waters, occasioned by the percolation of the gases through the porousness of the superficial strata, and affecting its chemical compounds. 4th. Turbidity of the fresh waters in wells—phenomenon produced by the same causes. 5th. Changes in the level of the waters in wells caused by imperceptible upheaves and depressions of the superficial strata, affecting the sources or subterranean streams which feed them. 6th. Emanations of carbonic acid or sulphuretted hydrogen gas perceived in cellars, caves, wells, excavations. 7th. Electro-magnetic disturbances in the atmosphere suddenly taking place and without any apparent causes, manifested by the loss of power of magnets.

10. That the opinion of Pliny the Elder commends itself to the serious consideration of all men of science: that the evil consequences of earthquakes might in some measure be arrested by boring deep artesian wells in the countries subject to earthquakes, for those wells would act as vents through which the gases might escape, and their raging storm partly quelled.

A few years ago, four deep wells were discovered one at each corner of the cathedral in Lima which had been destroyed by the earthquake that laid that city to the ground in 1687. The church was rebuilt and these wells bored to act as protectors of the monument. They have well fulfilled their duty, for the edifice has withstood all the different shocks that since that epoch have visited the capital of Peru, and destroyed many of its strongest structures.

CARBOLIC ACID FOR PRESERVING HIDES

THE difficulty hitherto experienced by tanners in keeping raw hides during hot weather, according to the *Shoe and Leather Reporter*, is to be wholly obviated by the use of carbolic acid. It has been known for several years that the preservative properties of carbolic acid, when used on decaying substances of any kind, were of the most particular efficacy. This fact was very pointedly brought out by the experiments of the New York Board of Health, two or three years since, when it was found that nothing else would more effectually stop the decay of vegetable or animal substances than an application of carbolic acid. No matter to what state the decomposition had proceeded, an application of carbolic acid instantly checked its further progress, and rendered absolutely impossible any further decay.

Proceeding on the knowledge thus obtained, experiments were made at one of the large tanneries in Pennsylvania, as to the effect which carbolic acid might have on the colour and grain of leather, when the hide was thus treated. It was found that the decomposition or decay of the hide (without making any difference as to what extent it had proceeded) were instantly stopped by the application of carbolic acid, and that the colour and grain were in no way impaired. In fact, from the experiments thus far made, it would appear that both are somewhat improved and whitened by the use of the acid, but this matter has not yet been sufficiently tested to warrant the conclusion that either the grain or colour will be in any way improved, if, indeed, it is at all affected by this new agent.

PROTECTING SHEET IRON FROM RUST.

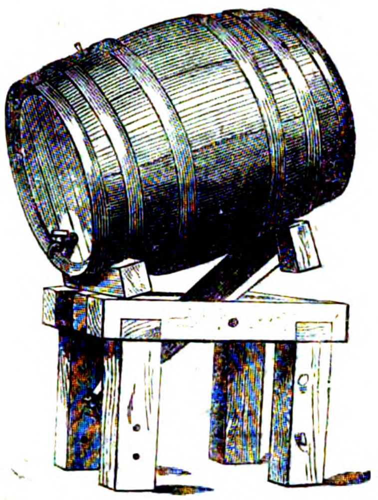
AN improved method of protecting iron from injury and deterioration has been introduced by Mr. B. Morrison, of Philadelphia, whose invention consists in deoxidising the scale oxide adherent to sheet iron, and amalgamating, blending, or intimately uniting with it any of the softer and more fusible metals, so as to render such scale oxide more flexible, soft, adherent, and less liable to rust, and the sheet iron also more perfectly annealed and flexible. It is essential that the sheets be made of the best charcoal bloom iron, and that the scale oxide thereon be even, or of uniform thickness and unbroken; and in order to produce such a scale oxide, it is recommended that the usual rough and imperfect scale be removed—by means of a weak acid, in the usual manner practised in galvanising iron, and that the sheets be then passed between a pair of smooth pressure rolls, and finally subjected to a sufficient heat to produce thereon a new and uniform scale of oxide.

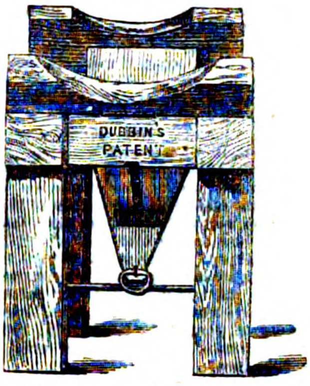
Having prepared saturated or strong aqueous solutions (say) of sulphate of zinc, chloride of zinc, chloride of tin, acetate of zinc, acetate of lead, and of any other readily fusible metal that will amalgamate, unite, or combine with the deoxidised scale on the iron at a strong or bright red heat under the hydrogen or carburetted hydrogen gas, immerse the deoxidised sheets either in one or a mixture of two or more of the said solutions for five or ten minutes, or apply the same by rubbing it on by means of a sponge or rough brush; let the excess of solution drain off, and the remainder crystallise or dry upon the surface of the sheets. Now place them in a box in the heated chamber of a furnace; then introduce the hydrogen gas, and slowly heat up to a scarcely visible red, maintaining the said low heat for (say) half an hour, more or less, to allow a perfect reduction of the oxide of the applied solution; after which the heat should be increased to a bright red, or heat a few degrees above that which may be required to fuse the now reduced softer metal and cause the same to amalgamate, blend, or unite with the deoxidised and, consequently, soft and porous scale on the sheet iron.

To obtain brightness of surface when desired, it is proposed to pass the sheets severally between and in contact with a pair of cylindrical rapidly rotating bristle brushes; and, if afterwards intended to be put up in packs for storage or shipment, the sheets may, as a further protection against dampness, be dipped into any suitable hydrocarbon oil, and then the superfluous portion drained or wiped off. The solution of the sulphate or of the acetate of zinc forms, with the deoxidised scale on the iron, an excellent coating. About three parts of the solution of chloride of zinc, mixed with two parts of the solution of chloride of tin, make, with the deoxidised scale on the iron, an excellent flexible coating of a whiter colour. Three parts of the solution of the acetate of zinc, mixed with two parts of the solution of the acetate of lead and one part of solution of the chloride of tin, make, with the deoxidised scale on the iron, a very suitable coating for sheet iron intended to be used in the construction of stoves, stove pipes, coal hods, &c.; but as the predominant metal in the coating is the deoxidised scale oxide of iron, the number and proportions of solutions of whatever metals are intended to be applied thereto may be increased and varied as the coating desired may require.

NEW CASK-STAND.

THE annexed illustrations of Dubbin's "patent self-raising and self-setting cask-stand for beer and other purposes" are almost sufficiently explanatory in themselves to enable our readers to understand the construction and appreciate its advantages. The principal feature of the invention consists in the adaptation of a lever actuated by a powerful indiarubber ring, so situated as to cause an almost imperceptible elevation of one end of the cask as the weight gradually decreases through the contents being withdrawn. The lever, it will be seen, is pivoted in the centre of the horizontal bars forming the stool or support; its front end being connected by a strong ring, or band, of indiarubber and a rod held between the two front legs. It is evident that as the cask

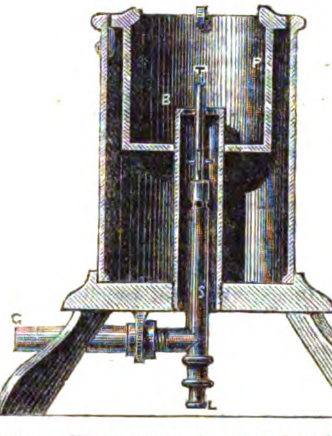




becomes lighter the rubber ring is enabled to contract and so tilt the cask, which is then supported in the required position by a ratchet-bar, as shown in the figure, thus relieving the rubber band from the strain produced by the weight of the barrel. The gradual nature of the motion thus imparted to the cask obviates the annoyance experienced with other contrivances for effecting a similar purpose, as the sediment is not disturbed and the waste is consequently reduced to a minimum. The absence of iron in the moving parts also avoids the inconveniences of rusty springs and screws, very natural results in the ordinary stands when placed in damp cellars.

HEATING BY GAS.

A SELF-ACTING apparatus for heating by means of gas has been patented by Messrs. Goldsmith and Dilkes, and the arrangement will doubtless be found serviceable for many different



purposes. The invention is adapted to the heating of sad irons or the melting of metals, and consists in principle of a combination of levers and springs so arranged that when the substance to be melted or the article to be heated is removed from the frame supporting it over the burners, the gas is lowered and waste prevented.

A rectangular or other shaped chamber is formed of sheet iron mounted upon a cast-iron bottom or stand, and is either covered or not by a hinged lid having a slot or slots made therein. It is also furnished with holes either at the upper or lower part thereof for the entrance of air. Within the chamber, and fitted to the upper part of it, is a cast-iron trough with an opening in the bottom; beneath the opening are fixed burners on Bunsen's principle, presenting a continuous or nearly continuous line of flame, the gas being admitted at the bottom of the burner from a pipe which extends to the outside of the chamber, where it is fitted with a valve. A lever which has its fulcrum within the chamber is so arranged that one end projects above the opening in the bottom of the cast-iron trough, while the other passes through a slot in the side of the chamber, and communicates with the valve. A spring is fastened near one end of the lever, which has the effect of keeping the valve in such a position as to admit but a very small quantity of gas to pass to the burner, but upon the introduction within the trough of the iron to be heated, or the melting pot containing the metal or other material to be melted, the weight will depress one end of the lever and cause the other end to rise and open the valve, so as to allow of sufficient gas passing to the burner to produce the requisite heat. On the removal of the sad iron or melting pot the spring will cause the valve to resume its former position, so that only sufficient gas will pass to just keep a light burning. It will be seen, therefore, that when the apparatus is not in active operation the consumption of gas is reduced to a minimum, but its full power is exerted the moment the material to be heated is brought within its action.

It is obvious that the shape of the apparatus may be variously modified. For the purpose of melting it may by preference be made round, and in this case the vessel containing the metal or other material may be made to press upon an upright spindle communicating with the valve without the intervention of any lever, as shown in the annexed figure, which will give a good idea of the principle, and suggest modifications to fit it for various purposes. In the drawing, which is a vertical section, a cylinder of wrought or cast iron or other suitable material is mounted upon a stand, in the top of which a piece of pipe forming the burner is firmly secured. Suspended from the top of the cylinder is the trough or pan P, into which the glue-pot or melting crucible is placed with its bottom pressing on the upright spindle T, which is forced upwards by a spring coiled in the interior of the tube S; B is the burner where the mixture of gas and air is lit, G the supply-pipe, and L is a nut used to regulate the quantity of gas supplied. When the melting-pot is placed in the trough, T is depressed, and the valve in S is opened to its full extent, so as to permit the passage of the gas to the burner B; when the pot is removed from the trough, the spring forces up the rod I, and only sufficient gas to just keep the flame burning passes through. There is, of course, nothing novel or original in the idea, but the arrangement may be found useful in many ways.

MICROSCOPICAL NOTES.

Pattern Lead Cells.—Mr. T. Charters White, the Secretary of the Quekett Club, says that he has been in the habit of using cells made of a thin kind of lead known as "pattern lead," employed by dentists for taking patterns for their gold plates. It is found to answer the purpose very well; the slide may be made almost red hot without melting the cells, and the cells are very easily stuck on with marine glue. For shallow cells a simple ring of gold size and gum dammar, put on thickly and allowed to get hard, answers the purpose excellently, and if Bastian's cement is used instead, the cell can easily be built up higher by adding layers upon those which have become dry. Another way is to use zinc cells, which stand any amount of heat; acid, however, affects these, but vulcanite cells resist acids. In making cells for mounting in fluid, Mr. White says, it will be found of great advantage to set up some standard size, and keep to it, as this enables the worker in a short time to estimate correctly the exact amount of fluid required for filling—a matter of some importance.

Staining Tissues.—Dr. Durnforth writes as follows on this subject in the *Lens*, a new microscopical journal published at Chicago:—"It is desirable to stain sections of all soft tissues, whether from healthy or diseased specimens. First, because it enables us more accurately to distinguish germinal or nuclear matter from formed material or tissue proper, by their differences in receptivity of colour; and secondly, because it brings into relief all constituents of soft tissue, and, therefore, renders their study easier and more satisfactory. The staining material which aids me most, and therefore suits me best, is the alkaline solution of carmine made after Beales's formula. The sections should be placed in the carmine solution as soon as they are made, and they should be made as soon as possible. No positive rules can be laid down as to the precise time required for the completion of the staining process. It will vary, within certain limits, according to the character of the tissue and alkalinity of the solution. In regard to this latter point, I may properly say that the carmine solution should neither be neutral nor intensely alkaline: in the former case, all portions of the tissue will probably be stained alike; in the latter case, much of the younger or softer portion of the formed material surrounding the germinal matter will be destroyed by the excess of alkali. I generally permit my own sections to remain in carmine for three or four hours. Having completed the staining process, the sections should next be immersed in a mixture composed of Price's or Sarg's glycerine and distilled water, 4 drachms of each, and 20 drops of acetic acid. This answers the double purpose of rendering the so-called nuclei (germinal matter, bioplast) sharp and clear, and of commencing the process of impregnating with strong glycerine; it will also remove the superfluous carmine. After being soaked in the glycerine and water mixture for from twelve to twenty-four hours they should be transferred to the following mixture: pure and strongest glycerine, 1oz.; pure acetic acid, 5 drops. They should be allowed to remain in this mixture until they are fully saturated therewith, which will take from two days to as many weeks."

Carmine Staining Solution.—The following is the formula for preparing Dr. Beale's well-known carmine solution:—Ten grains of carmine in small fragments are placed in a test-tube, and half a drachm of strong liquor ammoniæ added with agitation and the heat of a spirit-lamp. The carmine soon dissolves, and the liquid, after boiling a few seconds, is allowed to cool. After the lapse of an hour, much of the excess of ammonia will have escaped. The solution is then mixed with 2oz. of distilled water, 2oz. of glycerine, ½oz. of alcohol. The mixture being passed through a filter or allowed to stand for some time, the perfectly clear supernatant fluid can be poured off and kept for use.

Paraffin Oil Lamps.—Mr. John A. Perry, of Liverpool, suggests in *Science-Gossip* the addition of camphor to increase the illuminating power of paraffin oil and improve the quality of the light; this is a well-known fact, but here is Mr. Perry's recipe for those who have never heard of it. "I do not think it is generally known to microscopists that the addition of a little gum camphor to the paraffin oil in the microscope lamps burning that fluid is a very great improvement. About fifteen grains of camphor, put into an ordinary-sized lamp, about one hour before using, will cause the lamp to give a far more intense and brilliantly white light than the paraffin oil alone would give."

The "Germ" Theory.—At a recent meeting of the microscopical section of the Liverpool Medical Institution, Dr. Braidwood exhibited specimens of a very fine white powder deposited on the inner surface of the glass of a locket inclosing hair from a child who had died a year previously from malignant scarlet fever. After the child's death, a lock of hair *not disinfected* was placed below a well-fitting glass cover in the locket, and a lock which had been disinfected with Condy's fluid was placed outside the glass cover but inside the lid of the locket. On the locket being opened a year later a fine white powder was seen on the inner surface of the glass, next to the non-disinfected lock of hair. When examined with a one-twelfth inch lens, this deposit was found to consist of very minute spherical granules (like the microzymes in vaccine lymph), and of sharply-defined, acicular, crystalline-like bodies.

The Flavour of Butter.—The German *Agriculturist* says that a great portion of the fine flavour of fresh butter is destroyed by the usual mode of washing, and he recommends a thorough kneading for the removal of the buttermilk, and a subsequent pressing in a linen cloth. Butter thus prepared is pre-eminent for its sweetness of taste and flavour, qualities which are retained for a long time. To improve manufactured butter, we are advised by the same authority to work it thoroughly with fresh cold milk, and then to wash it in clear water; and it is said that even old and rancid butter may be rendered palatable by washing it in water to which a few drops of a solution of chloride of lime have been added.

Nitrogen in Plants.—M. Deherain (in *Comptes Rendus*) advances a somewhat novel theory of the reduction of atmospheric nitrogen to an available form for the support of plant life. He endeavours to prove that the free nitrogen of the atmosphere is brought into combination during the oxidation of organic matter in the soil. To demonstrate this, he dissolves glucose in a dilute solution of ammonia in water, placed in a large flask filled with a mixture of equal parts of nitrogen and oxygen. Having closed the flask, he heats the mixture gently for 100 hours, at the end of which time the whole of the oxygen has disappeared, and 5·9 per cent. of nitrogen has been taken up. The same process with humic acid and potash shows a loss of 7·2 of nitrogen. If these results are confirmed by subsequent experiments, they will throw light on the hitherto obscure subject of the production of nitric acid.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

WHO INVENTED NOAH'S COMET.

[4353.]—"P. SANTALINUS," "Sigma," and others, insist on taxing me with the crime of evolving a "pet" comet for Noah, as if the dullest intellect for these two centuries, ever since the relations of planetary and cometary motion were ascertained, could ever miss so obvious a lesson! "A legacy from Whiston," forsooth! (p. 303, let. 4289) as if, when Nature thrusts before the noses of you and your children sundry times per generation one of these "mythical" manufactures (let. 4240) waves before you such an ensign, as much as to say, "*There*, men! *Such things are.* Your world is tenant at will among such evictions as *that*, with no lease; you have never had one hour's lease;" it needed the man whom Newton chose as successor to make the historical application of this! As if it had ever been worth while, before more than children, to suggest how such a discovery established for ever the naturalness of the Noachian Story, the certainty of Nature's containing abundant means for any such catastrophe, at any moment; her redundantly superfluous displays thereof, and reiterations before each and every of you, again and again, that such catastrophes are, must have been, and must be, as long as she is Nature!

I have only this week alighted upon, probably, the first *written* statement of such a commonplace, and, of course (as I might have anticipated by only about one and a half "Sigma-fuls" of thought), by the first computer of a comet's return, a bigger than Whiston, though not, like him, successor to Newton's chair by Newton's desire. It is in the *Phil. Trans.*, Vol. 33 (1724), and entitled: "Some Considerations about the Cause of the Universal Deluge, laid before the Royal Society on the 12th of December, 1694, by Dr. Edmond Halley, R.S.S." In copying the following chief parts, I keep the capitals to substantives, that our neo-English ought, less than any other Teutonic language, to have dropped, if meaning to be understood.

"The account we have of the universal Deluge is nowhere so express as in the Holy Scriptures; and the exact Circumstances, as to point of Time, do show that some Records had been kept thereof more particularly than is wont in those things derived from remote Tradition, wherein the historical *Minutiæ* are lost by length of Time. But the same seem much too imperfect to be the Result of a full Revelation from the Author of this dreadful Execution upon Mankind, who would have spoke more amply as to the Manner thereof, had He thought fit to lay open the Secrets of Nature to the succeeding Race of Men; and I doubt not but to all that consider the 7th chapter of *Genesis* impartially, it will pass for the Remains of a much fuller Account of the *Flood*, left by the Patriarchs to their Posterity, and derived from the revelation of *Noah* and his Sons. . . . This we may, however, be fully assured of, that such a Deluge has been; and by the many Signs of marine Bodies found far from and above the Sea, 'tis evident, that those Parts have once or more been under Water; or either that the Sea has risen to them, or they have been raised from the Sea; to explicate either of which is a Matter of no small Difficulty, nor does the sacred Scripture afford any Light thereto. . . . What is meant by the Fountains of the *Abysse* being broken up, and the opening of the Windows of Heaven, seems not so easy to be understood, but is intended to indicate the *Modus* of the Deluge, which was, according to the *Mosaic Philosophy*, from the letting in of the Waters above the Firmament, mentioned *Genesis* i., 7, by the Windows of Heaven, and the rising up out of the Ground of the Waters under the Earth, spoken of in the Second Commandment"—[rather, in the human comment thereon, these comments being different in the *Exodus* edition, and that of *Deuteronomy*] . . . "so that we may reasonably conclude, that by one of those Expressions is meant an extraordinary Fall of Waters from the Heavens, not as Rain." [With much deference to Halley, I must quote, Yet seven days and I will cause it to *rain* upon the earth!] "but in one great Body (!): as if the Firmament supposed by *Moses* to sustain a *Supra-aërial Sea*, had been broken in." [The astronomer here lets the mislatinised word *Firmament* impose on him the vulgar error that the prophet regarded this *Rakia* (Expanse) as something solid, whereas the fowls were to fly "*in* the *open* Rakia of heaven."]. . . "But the Almighty, generally making use of Natural Means to bring about His Will, I thought it not amiss to give this Honourable Society an Account of some Thoughts that occurred to me on this Subject, wherein, if I err, I shall find myself in very good Company.

"In No. 190 of these Transactions, I have proposed the casual *Choc* of a *Comet*, or other transient Body, as an Expedient to change instantly the Poles and diurnal Rotation of the Globe; . . . but at that Time I did not consider the great Agitation such a *Choc* must necessarily occasion in the Sea, sufficient to answer for all those strange Appearances of heaping vast Quantities of Earth and high Cliffs upon Beds of Shells, which once were the Bottom of the Sea, and raising up Mountains where none were before, mixing the Elements into such a Heap as the poets describe the *old Chaos*, for such a *Choc* impelling the solid Parts, would occasion the Waters, and all fluid Substances that were unconfined, as the Sea is, with one *Impetus* to run violently towards that Part of the Globe where the Blow was received; and that with Force sufficient to rake with it the whole Bottom of the Ocean, and to carry it upon the Land; heaping up into mountains those earthy Parts it had borne away with it in those Places where the opposite Waves balance each other, *miscens Ima Summis*, which may account for those long continued Ridges of Mountains. And again, the recoil of this Heap of Waters would return towards the opposite Parts of the Earth, with a lesser *Impetus* than the first, and so reciprocating many Times, would at last come to settle in such a Manner as we now observe in the Structure of the superficial Parts of the Globe. In this case it will be much more difficult to show how *Noah* and the *Animals* should be preserved, than that all things in which was the Breath of Life, should hereby be destroyed. . . . Such a *Choc* may have occasioned that vast Depression of the *Caspian Sea*, and other great Lakes in the World; and 'tis not unlikely but that extreme Cold felt in the North-West of *America* about *Hudson's Bay*, may be occasioned by those Parts of the World having once been much more northerly, or nearer the Pole, than now they are; whereby there are immense Quantities of Ice yet unthawed in those Parts. . . . If this Speculation seem worthy to be cultivated, I shall not be wanting farther to insist on the Consequences thereof, and to show how it may render a probable Account of the strange Catastrophe we may be sure has at least once happened to the Earth."

Some further thoughts upon the same subject, delivered on the 19th of the same month, by the same.—"I have been advised since the last Day, by a Person whose Judgment I have great Reason to respect [Newton (?)] that what I then advanced ought rather to be understood of those changes which might have happen'd to the Earth, in Times before the Creation, and which might possibly have reduc'd a former World to a *Chaos*, out of whose Ruins the present might be formed, than of the Deluge whereby Mankind was in a Manner extinguished . . . that being much more gradually brought to pass" [but surely Halley here forgets that *the Day* that Noë entered into the Ark (Luke xvii., 26), they knew not till the Flood came and *took* them *all away* (Matt. xxiv., 39)]—"and with some Circumstances that this Hypothesis cannot admit of" [Yes, Halley, certainly, without a *Choc*, and with *Rain*, and "the same Day *all* the Fountains of the *great* Abyss," *i.e.*, all Volcanoes, "broken up and the Cataracts of Heaven opened"] "which abler Pens, perhaps, may account for" [or he should rather have said later knowledge]. "What I have advanced I desire may be taken for no more than the Contemplation of the Effects of such a *Choc* as might possibly and not improbably, have befallen this Lump of Earth and Water in times whereof we have no manner of Tradition, as being before the first Production of Man, and therefore not knowable but by Revelation, or else *a posteriori* by Induction from a convenient Number of Experiments or Observations, arguing such an Agitation once, or oftener, to have befallen the Materials of this Globe." [*Now*, of course, for a generation past, Elie De Beaumont has abundantly proved, how much "*oftener*" and *irregularly* as to time, and *generally* to the whole planet at once.] "And, perhaps" (adds Halley), "in due Periods of Time, such a Catastrophe may not be unnecessary for the well-being of the future World; to bury deep from the Surface those Parts which by length of Time are indurated into Stony Substances, and become unapt for Vegetable Production," &c. . . . "This may, perhaps, be thought hard, to destroy the whole Race for the Benefit of those that are to succeed; But if we consider Death simply, and how that the Life of each Individual is but of a very small Duration, it will be found that as to those that are to die, it is indifferent whether they die in a Pestilence out of 100,000 *per annum*, or ordinarily out of 25,000 in this great City, the Pestilence only appearing terrible to those that survive to contemplate the Danger they have escaped. Besides, as *Seneca* has it,

> Vitæ est avidus quisquis, non vult
> Mundo secum pereunte mori—

N.B.—The foregoing papers having been read before the Society thirty years since, were then deposited by their Author in their *Archives*, and not published, he being sensible that he might have adventured *ultra crepidam*; and apprehensive least by some unguarded Expression he might incur the Censure of the Sacred Order. ["Sacred" with a great S, observe, not a mere "sacred Scripture."] Nor had they now been printed, but at the Desire of a late Committee of the

Society, who were pleased to think them not unworthy the Press. Here the Reader is desired to observe that Mr. William Whiston's book, entituled, 'A New Theory of the Earth,' was not published till about a year after the date hereof, and was not presented before June 24th, 1696, to the Royal Society."

Of course, the possibility now of any such "choc" as the father of cometic science here imagined remains just as certain as when he wrote. No discovery has altered the possibility that any one of the comets of infinity (more numerous, as Kepler said, than fishes in the sea, and more various in quality) may have planetary density and solidity to do all that Halley or Whiston thought of. The only modification on their reasoning brought about by the modern discovery that the masses of this century's comets have been inappreciable, that is to say, none has yet been appreciable—two (and only two) having been observed in positions where any mass *over a trillion tons* or thereabouts *would* have been appreciable, so that *these two* were not denser than air, and hence, not improbably, the majority *may* contain no matter more dense than aëriform—the sole result is to dispose of Halley's difficulty about how animals' lives could be preserved; since a comet *might* (if resembling most of the present century's) be wholly vaporous, and therefore fall with *no "Choc."* So his chief difficulty is long ago disposed of. I should not say, however, the *only* modification, because there have come, besides this; (1st), the well-known properties of steam, the commonest or most abundant of all vapours, establishing, for every tyro, the certainty that a comet composed of this, the *only* material that *can possibly*, as Geology shows, have fallen in historic times on such a scale, *must* occasion exactly the kind of diluvial rain (or "cataracts of heaven") that Genesis describes; and (2ndly) the geological certainty of the mere filmy flotation of the terrestrial skin, on the molten abyss within, sensitive to the least variations of external pressure, and therefore certain to be remoulded by such equable additional load, and set moving toward a fresh equilibrium, exactly *the other* effect of the two in which Genesis makes the catastrophe consist; *the same day* all the fountains "of the great abyss,"—(epithet nowhere else found, observe, and term nowhere applied to the sea) —being "broken up." For this latter certainty, I need only, in answer to "Sigma," refer to Herschel's last work, *Familiar Lectures on Scientific Subjects*, p. 11; and to the hurricane lists showing that there are districts, as the Windward and the Virgin Islands, where the barometer has *never* sunk 2 inches below its normal height (which it has scores of times since their discovery) without an instant plutonic disturbance. The St. Thomas case is merely the latest of some hundred on record. There is a third modern principle, or circumstance indeed, I might name as having similar result on Halley's reasoning—viz., to confirm it—I mean the established certainty that Darwinism—*Natural Selection*—in all matters, without some such interruption, *won't do*. You see his last remark, about an occasional catastrophe being "not unnecessary for the well-being of the future World," is become pretty considerably clearer and less disputable. Darwinism would not have peopled a world (as now) with Noachides. Natural selection would have *abolished* Noah's family, or any such sort. Instead of any of us, the earth of these present ages, if retaining any human kind at all, would have contained only the breed of the *Nephilim* (Gen. vi. 4), on the improbable supposition that they had not long ago devoured each other, and left it to the less violent mammoths and cave-bears. And so, again, what manner of planet, think you, would natural selection, or the present social forces, uninterrupted by the *next* comet that is on its way, make of this in another century, or two, or five? A globe worthy of, or likely to be tolerated in, the universe of God, think you? I trow not. E. L. G.

MR PROCTOR AND NOAH'S COMET.

[4354.]—MR. PROCTOR'S demands (letter 4313, page 327) are readily satisfiable, but before telling more, I must first beg flatly to repudiate any such "*duty*" as he attempts, in italics, to fasten upon me. I have made no "case of religion *versus* the infidel," have never used the word "infidel," have attacked nobody's religion;" and though "Sigma" complains, in letter after letter (p. 303, 326), that the subject cannot be touched without "shocking many people's feelings," and being "charged with infidel attacks on the truth of Holy Scripture," I, the only writer whose columns he measures and grumbles at, have not been yet charged with shocking or attacking any one's faith, and only wish any reader so aggrieved, be he Christian, Jew, Mahometan, Bhuddist, "pure Deist," or Bradlaughite, would point out where I have offended his tenets, that I may make amends. My object has been confined entirely to matters of fact, physics and geology; and these, necessarily involving reference occasionally to professedly historic documents, where they strikingly agree with the indications of Nature, the only ones I have quoted happened to be the best known of any in this country; though I might and should refer, if allowed to pursue the subject, to Hindoo and other legends very *little* known here. But how on earth was a man to guess it would be such mortal offence to hint a probability that something you go on solemnly telling your God in your temples (at every baptism of a child, for instance) may possibly be true? Anywhere else, I believe, offence would be given by just the *contrary* suggestion, to worshippers, that they told their God something false instead of something true! And then, what *can* the reality or unreality of such a secular fact have to do with religion? To hear "F. R. A. S.," who called up the subject by his challenge (p. 61, middle), it would seem that so extreme is his dread of any influence from the "semi-barbarous Hebrews," he would actually seem to fear that if a man only admitted they had preserved us a single chapter of true history, he would forthwith be bound to swallow Heaven knows what mystical dogmas—the ten commandments, perhaps, or Trinity, or Papal supremacy at the very least! Why, save the mark, "F. R. A. S.," does admitting the naturalness of an event in an old history involve accepting the religion or ethics of its writers? May not the Hebrews' Flood story, if Nature happen to confirm it, be granted to be true, and their theology and commandments be rubbish all the same? And where have I implied I took them for anything but rubbish? Keeping, as I have, to a physical matter alone, apart from all men's faiths, and having started *no* "dangerous notion," it is no affair of mine what notions are started, or whose religion the facts of Nature adduced may square or not square with. Especially am I discharged from any such imaginary "*duty*" as Mr. Proctor italicises, when the editor has stopped the subject (p. 842), having obliged himself to do so by breaking his own rule against theology, and opening the floodgates to such abyssmal fountains as that of "Vertumnus" (let. 4291), of more theosophic wrangle, worthy of Milton's Pandemonium. Matters of fact, it seems, are to be decided by what "God's wisdom in adapting means to an end" will allow, or "not allow" "Vertumnus" to suppose! Probably it would not "allow, us to suppose" a sun as ruler, light, and life of a system, made to dispense momently twelve million times the utmost heat and light that the whole system can receive. So Mr. Proctor had better look to his astronomy, or rather, all current astronomy must give way to Hampden's, if indeed his dimensions for the sun be not exorbitant.

And after all, how *can* Scripture be attacked, if, as all these Christians are eagerly assuring us, any words thereof may mean anything whatever? Thus, according to "Vertumnus," the command, "Make thee an ark of squared timber . . . 300 cubits long, 50 cubits wide, and 30 cubits high, . . . and pitch it within and without," &c., may have meant, nay *must* have meant (or God was not so wise as "Vertumnus"), "Go and migrate with thy family and cattle to the district of Auvergne in Gaul, till the flood is over wherewith I am about to drown all the rest of thy race." If texts are thus adjustable to *any* meaning, what theories or discoveries can possibly hurt your Book? As it may have *any* meaning, surely it *may* mean the very thing the "infidel" is saying; or that the theory requires; or the thing discovered in Nature; or might even, in some cases, bear, as I have ventured to suggest, the grammatical meaning!

As for the comet's "elements," then, I will give Mr. Proctor the most probable, so far as data seem to exist:—

T = Julian Period, 1612 87 ± ·06 (*i.e.*, in November, 3102 B.C.).
ϖ = 58° ± 10°} From equinox of that date.
Ω = 58° ± 10°} (128° ± 10° from equinox of 1872.)
i = very few degrees.
q = between 0·99 and 1·0.
e = 0·68 to 0.7.
a = 3·1 to 3·3, motion direct.

At the fatal day the sun was entering or approaching Aquarius (thenceforth so figured), the moon Virgo, and the comet Taurus, where it had seemed stationary, but growing in size for seven successive evenings. It was tailed, and fishlike in form, and the spectators estimated the length of tail (ultimately), according to the only account I know of, at a million Hindoo leagues. They, our fathers, regarded it as an appearance of their deity—"Vishnu"—God the Saviour; and though never seen again after these seven nights, nor better represented to them than by their figure of *Capricorn*, they continued to believe that the divine Fish, having bound their vessel to his mighty horn, guided and protected it through the dark and raging Deluge.

Now the mass, I consider, may have been anything between a hundredth of a trillion and half a trillion tons. What volume, and therefore diameter of globe, this might at any moment occupy as steam, according to the temperature, its various coats would acquire in our sunshine, may some day be calculable, when Regnault's or Rankine's measures of the laws of vapour density are carried further. It might, for aught that appears, be as little as 100,000 miles in diameter, or 400,000, or even as large as the comet's head of 1811, for though it would in that case fall partly on the moon as well as the earth, the small portion taken by our satellite would doubtless disappear into the pores of her cindery crust. In the first of these three cases, the time occupied by the steam's falling, so as to be permanently attached to us, would be about 12 hours, in the second, eight times as long, or four days and nights, and in the last, perhaps ten. But whatever the time theoretically needed for this mere gravitational collapse, Mr. Proctor will bear in mind the actual fall took much longer, for two reasons: —First, the drops or rain-balls entering the air, say 50 miles high, with a speed of between 30,000 and 35,000 feet per second (according to the comet's diameter), and having to lose by friction in the upper atmosphere all but a 300th or 500th perhaps of this velocity, the heat thus evolved re-evaporated most of their bulk, so as to let them reach the ground or sea reduced both in weight and velocity to something like the moderate size and impact of ordinary raindrops, though many thousand times more abundant. Secondly, as tradition states (with all probability in its favour) that "*all* the fountains of the great abyss"—*i.e.*, all volcanoes became in eruption at once, a vast deal of such water as did reach the ground condensed fell on incandescent lava, to be violently revaporised again and again, rendering most of the lower atmosphere chaotic for weeks longer, with thunderous downpours (though only local) of both water and mud. And thus, however small the comet, and few the hours required for theoretical collapse, the stormfall, necessarily prolonged by these causes, might well last six weeks, and, indeed, must in any case till the subsiding of general eruption, or the fiery "fountains of the great abyss" began to be stayed (and in other than the Hebrew accounts, the action of fire is as prominent as as that of water). And note that the exact number of days these storms might endure, persons to be saved in an ark would need to be pre-informed of, though of nothing else. There was no need for their knowing how long they should be afloat, nor how long imprisoned, but of these 40 days they *must* be told. For as, from the moment that, wrapped in instant midnight darkness (a fact preserved in Hindoo accounts, though not in the Bible) their hatch-door slammed down, and "the Lord shut them in," it was one unchanging cataract for many hours, or possibly days, as if a return to chaos and primeval night, what could be done or thought of, or how suicidal despair be averted, but by an oracle having limited the very number of days that were to include all the violence their drifting vessel would meet, and the *very day* they were to expect a normal state of calm and sun re-established? And such seems to have been the impression made by that joyful and exact fulfilment, that I believe we shall find an account extant of not merely the years, but the *days* reckoned from the end of those 40, to the era of the Persian King Yesdegird, 16th June, A.D. 632. (Hales's "Chronology," I. 197. The years are Nabonassarean.)

But now, can Mr. Proctor fairly infer that the day Noah is said to have left the Ark (which he errs in making 875 from the Deluge, it was 365, the exact anniversary) this day marked in any special way the return of sea and earth "to their normal condition"? What does he mean by "normal condition," or a "return" to what precise quantities of land and water? What were the antediluvian quantities? Where are they stated? All I find stated is that Armenia had become habitable for eight persons and their cattle. The vast adjoining lowlands of Turan (as I said, p. 230) must have continued a sea for yet some centuries; and so the establishment of *the present* conditions was gradual. But a normal condition, so far as to be productive and sustaining animal life, *such* a condition the story implies land (and, for aught we know, *much* and *many* lands) to have recovered even before the 40 days' storms were over. I say it implies this, because how else could those beasts live whom a *Divine oracle* is recorded to have mentioned, and *not man* (for how could Noah or his sons know of their existence?) in Gen. ix. 10? This difference between oracles and mere statements of the writer (which are only sacred with a little "s") none of the critics seem to note at all. Thus it is quite true, as remarked by "E. L. B.," p. 327, that Shem twice mentions in his journal, the "breaking up" or earthquake and eruptions along with, and even before, the "cataracts of heaven," as if quite simultaneous to his mind, or rather the *unexpected* phenomenon impressing him the most of the two. But does "E. L. B." consider God or Shem the more likely to have given philosophical precedence to cause before effect? Where does he find the alleged *oracles* naming his "No. 1, the fountains of the deep?" Nowhere! The only thing predicted is the rain! Again, *who* said that all the high hills under the whole sky were covered, and by 15 cubits, the draught of the ark; and *who* that every living substance was to be destroyed off the face of the earth? There may have been (without falsifying a word) summits never submerged; but certainly not an olive leaf left, to be plucked (he seems to imply) either 8 or 11 months afterwards! Some expounders, as Professor Birks, make it 11. What leaves does "E. L. B." find, *without* a Deluge, to hang on a tree from November, and be worth a dove's plucking next autumn?

Of course, the fall of steam evolved much heat (which, please to observe, was not first considered by "Sigma," but by me, p. 230). But the same causes that prolonged the time of its fall, spread over far more time yet, and even prevented in great measure the penetration of this heat down to the sea-level. It was the upper strata of air that were warmed, and expanded far above their normal height, and whatever they did not radiate into space would be very slowly conducted downward. This, doubtless, was connected with the physical side of what is described as God causing "a wind to pass over the earth," though this breath or spirit is plainly more a spiritual than physical statement, like the parallel in Gen. i. At all events, there remained even after radiation of much heat, and melting of all the ice—which was more abundant than now—such a change of climates as must have precluded much of winter, except at the poles, for some years. The five months that our fathers were afloat were what would normally have been the coldest in this hemisphere; and the seven following hot ones they were imprisoned aground and being hoisted above the clouds. As our Japhetic Aryan fathers wrote, the same Almighty Saviour, who had appeared as the Shining *Fish*, now made himself a rooting *Boar*, to upheave the land and all its burden out of water, on the point of one of his mighty tusks (*i.e.*, the Great and Little Ararat). The waters, says the Hebrew, "were going and returning till the tenth month"—*i.e.*, the land upheaving and upheaving, by fits and starts, or as our Japhetic brethren learn it, the fire-gods perseveringly churned the sea with a mountain, down whose sides the streams of life afterwards flowed.

When five lunations had elapsed from the catastrophe, which five, owing to the earth passing her perihelion, were long ones, and only five new moons visible in 150 days, then the ark which had been caused, like Magalhaen's vessel at the first crossing of the Pacific to drift clear of all sight of lands, and to a late rising region, suddenly grounded on the upheaving peak, on the day Jews would now reckon 17th of Abib or Nisan. That is the first day their records *dated*, observe for anything good, the 17th of Nisan. When no land had been seen for 40 full days, on the 41st Noah sent forth the raven and dove. He would not have needed any such experiments 40 days after other land, Little Ararat, was visible, as Professor Birk imagines. The story plainly here *reverts* to 40 days from the grounding. The dove returning the same evening (which it would not if other hills were emerged only ten miles off) was kept seven complete days, and sent and brought the olive-leaf the 49th day, as we should call it (but Jews the 50th), from the grounding—*i.e.*, from the 17th of Nisan. No land was visible then, nor became so to Noah, not even Little Ararat, till the 1st of his tenth month—*i.e.*, the new moon of our July or August. He then began to unroof the ark and first saw how much was dry around him, because, till then, from his *lantern* or *clearstory* (mistranslated "window," a sense the word nowhere bears), he could only see the distance, no foreground, it being hidden by the ark's projection. His birth-month, Tisri, passed; and the next came, and the apparent (Umar) anniversary of the Deluge, and still he had to wait for a vision. At length, ten days later, came the command (revealing, perhaps, the true solar length of year, for he may not have been astronomical or one of the antediluvian learned), and on the 365th day he went forth and built his altar, which, like the ark itself (*Argo*), and the divine horned sea-monster (*Capricorn*), and the divine *Bow* of promise (that only we westerns have enlarged into Sagittarius), and other things then memorable, our father Japhet has taught us to figure in the stars. E. L. G.

THE HEAT GENERATED BY METEORS.

[4855.]—The observations of Professor Le Conte, of the University of California, on the heat generated by meteoric stones in traversing the atmosphere, may be of interest to many of your readers, in view of a recent discussion on cometfalls being the cause of deluges. It is well known, says Professor Le Conte, that the observations of Glaisher, Petit, Daubrée, and others, establish the fact that meteoric stones enter our atmosphere with velocities which are truly planetary. For example, the meteorite of Orgueil moved with a velocity of at least 12·48 miles per second, while in other cases velocities have been observed which could not have been less than from 15 to 30, or even 40 miles per second. The enormous resistance encountered by such bodies in traversing the air speedily extinguishes this high velocity, so that they retain but a comparatively moderate velocity on reaching the surface of the earth.

According to the "dynamical theory of heat," this loss of energy is replaced by a corresponding augmentation of heat, and the method of finding the theoretical amount of this increase is given by Professor Le Conte in mathematical language. To obtain a correct estimate, it is necessary, of course, to know the velocity of the meteor when entering the atmosphere, and also when it has approached near to the earth's surface, as well as the specific heat of the stone in relation to water. An estimate sufficiently near for most purposes is obtained by Professor Le Conte, by taking the velocity on entering the earth's atmosphere at about 30 kilometres a second, or a rate nearly equal to the orbitual velocity of the earth. This he assumes as reduced to 500 metres per second when near the earth's surface, and the specific heat is "certainly not under estimated" by putting it equal to 0·22. On these assumptions the Professor finds that the increase of temperature amounts to 492,184 centigrade degrees.

Of course, says Professor Le Conte, by far the larger portion of the heat generated by the loss of energy of the moving stone would be imparted to the air along its trajectory; but assuming that only the hundredth part of it is retained by the stone, it would be more than sufficient to account for the phenomena of fusion and detonation which frequently accompany the transit of such bodies through our atmosphere.

In the case of small masses, it is clear that their high velocities would be more rapidly extinguished by the resistance of the air than is the case with large masses. In the small mass the transformation of energy into heat being accomplished in a shorter time, a greater amount of the evolved heat would be retained by the stone than in the large mass whose velocity is more gradually checked by the resisting medium. Hence, when the smaller masses plunge into the upper atmosphere, the matter may be volatilised or utterly dissipated by the intensity of the suddenly-evolved heat. In this minutely-divided condition the material of the stones would float about in the atmosphere, and ultimately reach the surface of the earth in the form of meteoric dust.

It is well known that the observations of Benzenberg, Quetelet, Herrick, Newton, and others, assign to the so-called "falling stars" velocities equal to, if not surpassing, the velocities of meteoric stones. According to the foregoing suggestion, these may be nothing more than small meteoric stones which are volatilised in the upper regions of the atmosphere long before reaching the surface of the earth. Thus, the phenomena of the occasional fall of meteoric stones and the almost incessant appearance of the falling stars which nightly furrow the celestial vault, may be correlated with the principle of transformation of energy. At all events, all the luminous, thermic, and detonating phenomena attending the fall of such bodies seem to be fully accounted for by the enormous amount of heat thus generated by their passage through the atmosphere. G. J. H.

EXISTING EVIDENCE OF THE DELUGE.

[4856.]—It seems to be forgotten by some of "our" correspondents that the idea of the Deluge is no "pet" or "fancy" of "E. L. G." or any one else, but a matter of ancient history and world-wide tradition, supported, moreover, by much existing evidence. "P. Santalinus" undertook (letter 4240, p. 277) "to cull a few facts utterly subversive of 'E. L. G.'s' fancies"—that is, be it observed, subversive of all history written and unwritten; but these facts on examination turn out to be mainly questions, capable of being easily answered, as they deserve, by other questions. Now, as to existing evidences of the Deluge. It appears from the testimonies adduced by Lyell and others, and still more plainly from the reports of cave explorations in England, that there was a race of men roughly calculated as existing from about 7,000 to about 5,000 years ago, savages, as we would call them, some of them probably cannibals (the earth was filled with violence, says the ancient record), living partly at least in caves, struggling for existence with wild beasts, but getting the better of these by aid of stone and bone weapons; which race of men about 5,000 years ago became extinct, so as to show no trace of connection between them and the later races who gradually come down to historic times. Their bones, their instruments, and all memorials of them perished from view, buried several feet deep under the débris accumulated over them by the action of rain, frost, and air; many centuries passed by, in Britain as much as 3,000 years, before another race of men of superior civilisation came and lived in the same caves, all unconscious of their predecessors buried beneath them. This is the tale plainly told by the caves of Settle, in Yorkshire, of which an account is given on p. 323. The excavations in Kent's Cavern, in the Rhone valley, and elsewhere, lead to the same conclusion; they show the extinction of a race of savage men about 5,000 years ago, and the lapse of many centuries obliterating all traces of them before a new race prior to European history, but merging into it, arrived to people the same regions. And Lyell's evidences, apart from mere conjectures, seem to prove for these primitive men an antiquity of no more than between 7,000 and 8,000 years. All this agrees with the chronology of Moses rightly understood. I say rightly understood, for it is too generally forgotten or unknown that the chronology of the existing Hebrew scriptures, which our English version follows, differs very much from that of the oldest existing translation, I mean the Septuagint or Greek version, made about 300 years before the Christian era, which exhibits what the original Hebrew scriptures were at that date. Josephus also, in the first century of our era, recognises as the correct Biblical chronology, the only one known to him, that of the Septuagint. According to it, the oldest, and in all likelihood the correct version, made before the Hebrew text was tampered with, the date of the creation of man is given at about 7,400 years, and that of the Deluge about 5,000 years from the present time.

This, Mr. Editor, I have endeavoured to set before your readers as no theological question such as should have no place in a journal of science, but as a simple matter of science, of ancient history and modern observation, the one confirming the other in all essential respects. J. M. G. Brookwood.

"THE SEMI-BARBAROUS HEBREWS."

[4857.]—"F.R.A.S." has fallen into an error in stating that we have our account of the Deluge from "semi-barbarous Hebrews." The history containing that account was written by Moses, who, according to the narrative, which is confirmed by much internal evidence in his writings, was, though of Hebrew origin, an Egyptian prince by education, learned in all the wisdom of the Egyptians, and mighty in words and in deeds. He was vastly superior to the mass of the Hebrew people, whose leader and lawgiver he became, but who never quite understood him or heartily submitted to his teaching.

Whether the Hebrews themselves can be properly styled semi-barbarous is doubtful, if we compare them with the other nations of their time. Born in Mesopotamia, nursed in southern Syria, educated in Egypt, finally settled between and in contiguity to Egypt, Assyria, and Phœnicia, partaking of the civilisation and science of all three, and superior to all in their theology and code of morals, they must have had advantages at least equal to the most advanced nations of that age. It is also to be observed that the Hebrew records did not always stand alone as they do now; they were corroborated in their accounts of the early history of mankind, as Josephus frequently reminds his readers, by the most ancient historians of other nations, as Egypt, Phœnicia, Assyria, and Greece, whose writings then extant are now lost.

Perhaps "P. Santalinus" in his last letter (4240, p. 277) means only to talk nonsense in jest when he speaks of "Shem leaving his untouched journal to that accurate Hebrew scribe Samuel, the first of his race." There is no record or evidence that Shem left an untouched journal, whatever that may be; and Samuel was in no respect the first of his race.

Alphabetical writing does not appear to have been known to mankind till about 1500 B.C., that is the age of Moses. But if "P. Santalinus" disbelieves, as he seems to ignore the existence of Moses, what reason has he to believe in the existence of Samuel, or of any one else in particular? J. M. G. Brookwood.

SUNDRIES.

[4858.]—Alas! for all the old superstitions, the nymphs and dryads no longer haunt the fountain and the wood; their progeny, the fairies, have vanished from the glens; the pale ghost never now revisits the glimpses of the moon, or points with outstretched arm and melancholy countenance to the spot at which its mortal coil was rudely shuffled off. And here am I about to shatter another old legend. "H. G. W." (query 12186) wants to know why a shilling suspended from a thread, and hung within a tumbler, strikes the hour. I will tell him.

Hang any moderately light weight in this way, and, fixing your eyes and attention upon it, *wish* it to do anything possible (to swing, for instance, in one direction, weakly or strongly), it will do so; desire it to stop and to swing in another direction, or in a circle, it will instantly do so; put it inside a tumbler and wish it to strike the time, again it will obey, *provided you know the time yourself*; or if you prefer, it will ring a funereal knell. Now place your hand against some fixed substance and try to repeat these experiments; this time you will fail. The whole mystery lies in the fact that when you *will* or expect any motion, you unconsciously produce that motion—instead of fixing attention on the object, fix it on your hand and guard against its moving, and you may hold your shilling till you want your supper before it will tell you the time.

Will Mr. Rodwell (let. 4318, p. 328), who has actually seen the spot at Argostoli where the sea water flows into a cavern, tax his memory as to a few details? Can he say (accurately) the difference of level between the sea surface and that of the surface of the water of the well or cavern, whether the flow is continuous or intermittent, and what is at that spot the actual rise of tide (I know it is small), and whether boats can approach the exact spot at all times, or are stopped by anything like a reef at some little distance? Also, whether there is anything like a race or strong current between that and neighbouring islands?

Does not Mr. Petrie (let. 4345, p. 334) see that the expressions he quotes from Humboldt are pure colloquialisms, mere expressions in accordance with the apparent facts and the common modes of speech, that they therefore are of exactly the same nature as the scriptural statements referred to, and are in no sense scientific descriptions of facts. Mr. Proctor, in the paper commencing the number, uses just such a loose colloquialism when he speaks of the "sun's varying diurnal course." Therefore, we are *not* "to believe in the strict scientific accuracy" of such phrases. But what has this to do with the matter, or how does the fact that modern scientific men drop into commonly received expressions (knowing them to be incorrect) show that ancient similar expressions are to be taken as meaning and giving actual facts literally? Sigma.

CORK LOCK.

[4859.]—I noticed in last week's a lock cork. It reminds me of the way in which the Americans fasten all their pop and ginger-beer corks, and which, in my humble opinion, is a decided improvement to fastening the cork with string as the trade does in Manchester. A is a stout wire hinged in a loop B at each side under the neck of the bottle, said loop being formed of small wire having two or three turns round the neck. It is much easier and safer to open, and saves string and time to the manufacturer of those commodities. Alpha.

"SIGMA" AS A "SEARCHER AFTER TRUTH."

[4860.]—The Editor, blaming me, at page 331, for the term "buffoonish," which I had chosen for its mildness, as applied to "Sigma's" geological reasonings, declares his belief that "Sigma" is "an earnest and sincere searcher after truth," a position that I do not believe I have ever yet denied, though "Derf Errac" has incurred "Sigma's" wrath by doing so, as appears from the latter's first paragraph (letter 4312, p. 326). I have two reasons, then, for deeming it a duty to join "Derf Errac" in raising this question—first, because it does personally concern all readers of "Sigma's" letters to come to some decision whether "Derf Errac" or the Editor has had the better reason for their estimates; and secondly, because it seems I must be rated as "striking out from the shoulder," whether doing so or not, and may, therefore, as well deserve the rating. The following are grounds, I submit, for maintaining that "Sigma's" chief object in this Deluge matter has *not* been searching "for truth," and I am equally prepared to prove this of other correspondents than "Sigma," but that his chief object is the overthrow, anyhow, by sound or unsound means, as they may come to hand, of assumed mischievous error, namely, the error (as he holds) that the Hebrew early records are historical or trustworthy. He has dragged in references to these most revered and most hated of books, and most beslobbered with the slimy praise, "grand old legends," "grandest poem," &c., of those most hating them, on every possible occasion when there was not the slightest call for them. I have written most of the columns he has been at the pains "to measure" about geology, without naming or referring to the Bible; but what single paragraph thereon has "Sigma" written without? Surely, whether I quoted texts or not, my *primary* and *chief* subject has been physical geology, while "Sigma's" has been the Bible-the book that he at least twice endeavours to impress on his readers (letters 4193, 4312, pp. 252, 326) tells of the world being made and stocked in a civil week of time, and of the sun and moon standing still to enable the Israelites to complete a slaughter that the previous verses (11) say was *never* completed by *them*, but by hail. The Bible is dragged in as gratuitously, and these two supposed points thereof singled out to be harped upon exactly as by Voltaire or Bradlaugh. Now, with all deference to the Editor, I must flatly deny that any "sincere searcher after truth" of any kind, would (even if the Bible were the direct subject of discussion) single out these two popular, or rather grandmothers', errors about it, and thrust them forth as facts. A "sincere" truth seeker in these days would at least know that the Hebrew pentateuchist never dreamed of a creation in six human days, and was never supposed by educated *ancients* to have written of such a thing, even as long ago as Augustine in Christendom, or as Berosus and the oldest extant Gentiles influenced by the Hebrew cosmogony. (Neither are Psalms xc., civ., or many Biblical passages consistent with it.) Nor would any one whose chief end was truth be either ignorant enough, or count on such ignorance in others, as to quote the sun and moon "standing still" as a thing anywhere mentioned in *possibly* genuine Scripture. Joshua's miracle (for it *was* a miracle, as much as if Mrs. Guppy came through the ceiling) consisted in silencing for ever the Gibeonite religion, which he and his people had unawares bound themselves *not* to destroy by violence (ix. 19), like the other worships of the country, by calling on God, and saying to their oracular Sun-idol and Moon-idol, "Sun in Gibeon, be silent, and thou Moon of the Vale of Ajalon." His words, as preserved in Hebrew, have not a syllable about "*the* sun" or *standing still*, far less in the midst of heaven; and the two following verses (13, 14) of superstitious legend contradictory to all the rest of the story are from no sacred book, *as their inserter tells you*, but from that of Jasher, a mere lost novel of David's time (2 Sam. i. 18).

I challenge any one to maintain that a "sincere searcher after truth," or *any* matter as a chief end, would thus use long disproved errors that happen to be vulgarly current; and I undertake to demolish, though not so readily, what Mr. Proctor says "is certain" of, at least one or two of the authors he names in p. 327, last paragraph but one. And I beg the Editor to insert this with name or initials as he pleases, if writing anonymously is what he means by striking out, but being "unprepared for reciprocal action" (p. 331, note).

E. L. G.

[As stated last week, this almost fruitless controversy must terminate this week.—ED.]

SPINNING TOP.—UPWARD DEFLECTION OF BULLET.

[4361.]—"A BARRISTER" (4308) and "Vis" (4306) have upset my top, or rather my theory. Many thanks to them; let the truth prevail, and error come to nought. Once convinced that a top can maintain its position in vacuo, I can feel no difficulty in understanding that the duration of the rotary force will be greatly prolonged. Further experiments in vacuo may possibly throw more light on the subject. There is, however, no parallelism between my case and that of the philosophers whom "A Barrister" describes as "wasting their time and energy" in endeavouring to account for a fact before they had ascertained it to be one. The fact that I have endeavoured to account for is one well ascertained—viz., that a top, in spinning, is supported against the action of gravitation by some force as yet unsatisfactorily explained. I did not assume that a top would not spin in vacuo, unless the confidence I expressed in the result of the attempt to make it do so, in favour of my theory, be so interpreted. I deduced a theory from other grounds to account for a known fact, and asked for an experiment in vacuo as a crucial test of my theory. I considered, also, from repeated experiments, that the upward deflection of the bullet was an ascertained fact.

I cannot, however, set my experience against that of Mr. Whitworth, and it needs not, therefore that I should answer "A.'s" inquiry (let. 4305) on this point, or dwell on it longer. Another inquiry of "A.'s" I also pass over, lest discussion should sink into disagreement. I will only say that atmospheric resistance to motion is very formidable, sufficiently so to produce effects which may easily escape observation, as well as those which obtrude themselves on our senses most conspicuously. The rider must experience this resistance to progress as well as the bullet from a gun, in a degree proportionate to the velocity of the motion and area of surface offered to its action. There is, therefore, sufficient *primâ facie* reason for taking atmospheric pressure into consideration, when certain phenomena arise, during the motion of bodies, which, as "A Barrister" justly remarks in the case of the top, "no explanations yet attempted have accounted for." The spinning top shows a remarkable power to the overcoming of gravitation. The schoolboy's hoop remains upright, and can right itself when in motion, but falls as it comes to the state of rest. The bicycle-rider occupies a position which is stable in proportion to the velocity of his motion. We are all dark enough, as to the cause, in the face of these facts, and may well give fair consideration to any suggestion which seems likely, by analogy, to lead to a discovery of the cause or causes. The skimming of a stone along the surface of water, while in motion, and its sinking upon the cessation of that motion, looks like a parallel phenomenon, and, being manifestly due to fluid support excited by projectile force, suggests the idea of atmospheric support in the other cases.

"A.," of Liverpool, has brought his theory of the support of the top to a crucial test when he illustrates it by the cord and weight. We are thus able to deal with the principle in a simple form, and can follow it to its conclusion. Whirled round in a vertical line and let go either at the highest or lowest point of the circle, "it will not then," he says, "fall to the ground." Let go at either of these points, it starts parallel with the ground, and (throwing out atmospheric resistance) it will reach the ground in the same time, though not in the same place, as if it dropped from his hand. Can he possibly imagine that it will remain in a direct line, parallel with the ground, such as that formed by a tangent to his circle of gyration, until it has expended its force? Surely none will hold with him in such a thought. A stone from a sling is dismissed by centrifugal force, and is just as much subject to gravitation from the moment of its dismissal as if shot from a gun. The line of direction is simply a resultant between the direction of projection and that of gravitation.

J. M. TAYLOR.

Seer Green Vicarage, near Beaconsfield.

[4362.]—I WISH that "A Barrister" (let. 4308, p. 308), who rarely misses hitting the nail on the head, would show how the ordinary explanation why a spinning top does not fall is not satisfactory. A top at rest cannot be balanced on its peg, because it is so difficult to place the centre of gravity exactly above a mere point of support, so that it is almost sure to fall on some side or other; not indeed directly, but very soon. If, however, the top is spinning, it has not time to fall in a perceptible degree down towards its heavier side—say the north—before, by the revolution, the heavier side is to the south, and so of any other direction. For the like reason, though, I cannot balance a shilling at rest on the point of a pin, I can do so easily if I make it spin quickly enough to make its centre of gravity change from one side of the point of support to the other faster than it can fall. As the velocity of revolution diminishes, the top or the shilling begins to wobble; before it quite stops spinning, it slips off its support on to its edge, and rolls away along the floor. Thus, also, though I cannot balance a stick on my finger without constantly moving my hand so as to keep the point of support directly beneath the weight, I can make a circular disc spin on the top of the stick so as to keep the centre of gravity always above the point of support by very slight changes of that point. Of course, the weight of the top or of the shilling, or of the revolving disc, is just the same, whether at rest or in motion, only when in rapid motion there is not time for a perceptible fall in any direction before there is a tendency to fall in an opposite direction, and so the revolving body, not being able to decide in which way to fall, does not fall at all, just like the famous donkey that was starved to death between two stacks of hay, that attracted him so exactly equally that he could not decide which to eat first—a story quite as credible as that the Royal or any other learned society ever doubted that to add a fish to a tub of water without making the water run over would increase its weight.

I am obliged to "A Barrister" for supplying his illustration of pistol shooting, which so completely confirms my explanation at p. 204, of the real reason why musket bullets frequently rise in their course.

PHILO.

MR. PROCTOR ON SPINNING TOPS AND GYROSCOPES.

[4363.]—I AM surprised at Mr. Proctor's letter (4310, p. 326). He says, not in precise language, but by implication, that the problem has been solved, and then proceeds to attempt a popular explanation. His attempted explanation contains ideas so similiar to "A.'s," criticised by me in a letter sent you on the 11th, but not in your issue for 14th June—that I feel bound to demur to it as tending to encourage and propagate "A.'s" errors. It is not correct to say "the weight of the top is insufficient to change the direction of the particle's motion in a brief interval," however rapid the rotatory motion may be. I say the weight of the top is always sufficient to change, and is in reality always changing the directions of the particle's motions. In the last sentence but one of his letter, he speaks of a particle which should at one moment move downwards and at the next upwards; but if we are considering the action on a single particle and assume that gravity actually does make it move somewhat downwards at a time when it would otherwise move horizontally, we cannot assume that gravity is suspended the next moment, and if without gravity the particle would then move somewhat upwards, with it it would at least move *less* upwards. In fact, the downward effect would accumulate until the particle reached the ground. Mr. Proctor may, in the sentence be speaking of a top with its axis nearly vertical; but if that is so it ought to have been stated—besides, an explanation is not worth much unless it applies to the case when the top's axis is already sufficiently inclined for all its particles to be to one side of the vertical line passing through its point of support. I am inclined to think some points have yet to be elucidated in connection with this gyroscope question even by mathematicians, and with the view of myself attempting something in that direction, would ask Mr. Proctor to kindly inform me, briefly, what is at present the explanation accepted by mathematical astronomers of the action known as nutation, which is associated with the precession of the equinoxes? I have not access to recent astronomical works, and shall feel much obliged if Mr. Proctor will give the information.

E. H.

Glasgow, 15th June.

SPINNING TOP.—PERSPECTIVE.

[4364.]—IT is a great pity "A." (letter 4305, page 307), did not append the two other letters to his signature and save you the trouble. He says a weight will not, in certain circumstances he supposes, fall to the ground "as long as the velocity is maintained"! Really, he must learn again the rudiments of mechanical science. If the weight starts horizontally, and its velocity be maintained (say in consequence of its moving in a vacuum), it will touch the ground just as soon as if it had been dropped vertically, even with the greatest velocity "A." is able to give it by whirling it as described.

It is quite useless any one attempting to explain the action of a spinning top who has such extraordinary notions as "A.'s" of the ways in which the attraction of gravitation can be nullified or disposed of. The idea involved in his attempted explanation was elaborately worked out in a paper read to the Glasgow Philosophical Society about fifteen years ago, and was afterwards completely exploded.

It really would save time and trouble if "A." and M. Paris would refer to the former series of letters in the MECHANIC. The idea that particles moving (rotating?) in a plane cannot get out of it although solicited by gravitation, is quite a mistake. The very gyration or conical motion of an inclined spinning top is an obvious continuous change of plane. Of course, if the top is vertical, there is no change of plane, but in that case gravity acts vertically through the point of support.

M. Paris is quite in error in saying that a picture is a compromise. If a perspective drawing is to be true to what it represents, and such as to yield the same impression to the eye, it must be mathematically arranged.

E. H.

THE NEGRO.

[4365.]—IN the hope that a few remarks on the Negro may stimulate attention and provoke remark I send this communication. It seems to me in the books of natural history that I have read, that the claims of our black brother have been ignored. I wish, then, that some of "our" learned correspondents who have read the latest intelligence will enable us to form a correct opinion of the origin of the Negro. Josephus gives no clue as to his progenitors, and, like most other writers, leaves us to suppose that, like Topsy, the Negro grow'd, till it is found convenient to introduce him as a large nation with rulers and everything complete to adorn the history. Now, from what I have seen of the Negro, he seems to form a different species of humanity when compared with his white brother. I am aware that the human species, admits of five varieties, but the most distinct from the other four—viz., the Caucasian, Mongolian, American, and Malay—is the Negro—the greatest distinction its black colour and woolly hair; its remaining peculiarities may be found more or less elsewhere, as narrow head, retreating forehead, prominent eyes, elevated cheekbones, large spreading nose, thick lips, compressed chin, and crooked legs. It appears that the cause of the Negro's black skin is a membrane under the skin consisting of minute vessels charged with fluids of the deepest hues. But I presume that there must be a more interior cause than this, probably in the blood itself; analysis might determine this if some of our savants would only do the agreeable. There is another distinct peculiarity, the Negro's offspring is as black as himself, no matter where he emigrates, or under what condition of society he is placed. Now, Josephus and other historians make no mention of a Negro being with Noah in the ark, yet they state all mankind on the whole surface of the earth were destroyed. I am, therefore, unable to form an idea of the origin of the Negro. Some will have it (and this is a general opinion) that the extreme heat of the climate has acted on the surface of the skin and gradually rendered it darker. But I find that the Chinese are white, while the native of Hindostan is black, both existing under the same tropical sun. It is true that India is in some parts further south than China, but Arabia is still closer to the Equator, and the Arabians are anything but black. Does any one suppose that a colony of blacks, located for any length of time in England, would ever become white? But surely the learned world knows sufficient to be able to answer the question—What and where was the origin of the Negro race?

I should presume that if the climate changed the skin black in hot countries that there would be no exception to the rule, and that animals of all kinds would turn black also. Monkeys would be all black. Are they? Better still, the poor pigs, who have no covering, would do with a black *rete-mucosum*, which the East India species possess, not so the Chinese, who are piebald. Allow me to present the white elephant as a final proof that tropical climates do not produce black skins.

FIDDLER.

BALSAMED OBJECT-GLASS.

[4366.]—I RETURN many thanks to "A Fellow of the Royal Astronomical Society" (let. 4276, p. 300) in reply to my query about balsamed glasses, but it is not quite satisfactory. He states, as a rule, only terrestrial ones are balsamed, but I have seen many astronomical ones of 3in., 3½in., 4in., &c., balsamed. I want to know why balsam is used. I have a triplet Barlow lens balsamed, why should it be so?

I have been experimenting with a 2¼in. object-glass of 48in. focus, which I balsamed, and to my surprise it reduced the focus to 36in. focus.

Are glasses balsamed to shorten the focus when they have been worked longer than required? If "F.R.A.S." or some practical optician will enlighten me I shall be much obliged.

C. B.

ENTOMOLOGICAL.—(IV.)—PUPÆ.

[4367.]—Pupæ may decidedly be considered uninteresting things to watch compared with larvæ, for besides there being a great similarity between them very few move except to wriggle. But it is very interesting to notice the different ways that pupæ are found, some being in an earthy cocoon, principally the *Noctuæ* and *Geometræ*; many of these cocoons are bound together with silken fibres. Others, again, are found spun up in leaves of their food plant *A. caju* (tiger), whilst others make a hard cocoon inside the bark of their tree, as the puss and kitten larvæ; many, also, are quite unattached.

The best time for pupæ hunting is from the middle of August until the end of October, and at this season of the year a great number of good pupæ are to be met with in all sorts of places, though the best are open spots with few trees about and a soft soil; clay being very unfavourable, and as far as situations are concerned I think I may say that pupæ may be found from the tops of trees to nearly a foot under the ground. For the convenience of getting pupæ out of the ground a three pronged hand-fork is often used; though some prefer a flat trowel in preference. When pupæ are found attached to anything, if possible, a part of it ought to be retained—as the cocoon should by no means be broken, or the moth will often be crippled—and put in a box with a gauze top out of the way of vermin. Subterranean pupæ will require a box filled with loamy earth, which should be kept damp, not wet, and cool.

It will often be convenient to the collector to force pupæ that are subterranean; this is best done by placing a framework covered with gauze into the box that contains them, freely damping them, and placing them in front of a fire, with a piece of paper attached to the gauze to keep off the direct heat from the imago when it emerges.

Pupæ should never be sent from one part of the country to another unless absolutely necessary, as travelling does not agree with them, and will not add to their vitality. If pupæ are desired for a collection the best plan is to gum the case together neatly after the insect has emerged from it. Ento.

NEWS FROM "EOS."

[4368.]—After a continuation of sea voyages in four large steamships and a small sailing craft (having quitted Calcutta on 15th September last), I find myself snugly moored in one of the inland mountain districts of this beautiful land. Of course, your back numbers have only just reached me, after much erratic circumlocution, and I have consequently been disabled from replying to various pressing queries, which I much regret; but a traveller is necessarily *ex officio*, and subservient to the winds and waves in his communications. And now, in my own sylvan retreat, on a forest-clad slope of the flowery African Highlands (my third sojourn therein), I am teaching the young idea to love birds, and beasts, and flowers; and having the axe, the saw, and the pruning hook often 14 out of the 24 hours in my fist, I am compelled to say that I have no time to do pen work; and for nearly 12 long months to come do not expect to see the "seagirt" Isle of Great Britain.

South Africa, April 29, 1872. Eos.

MICROSCOPE CASTINGS.

[4369.]—A few of our most enterprising opticians supply amateur mechanics with castings of the various parts of model steam-engines, and thus afford them the rich and profitable treat of constructing mechanism, yet although the editor has reviewed the catalogue of one of those opticians on page 270, I fail to discover that any castings of microscopic stands are supplied, and I would suggest to the notice of Mr. Bateman and other tradesmen that if those parts were supplied at a reasonable price it would do much to popularise the microscope with those who can now only afford to purchase those cheap shaky instruments, which seldom fail to make the owner dissatisfied with the study of nature, and certainly never allow him to study unembarrassed the minutiæ of her attractions. I fancy the castings for a first-class stand could be profitably sold for a guinea, and hundreds of readers of the English Mechanic have abundant ability to file, fit, and finish them with necessary perfection.

E. B. Fennessy.

DR. PACKMAN'S STEAM-ENGINE.

[4370.]—Permit me to reply to your able and scientific correspondent "Saul Rymea" (let. 4302, p. 306) by stating that my new steam-engine works perfectly, without noise or anything visible from the steam. The speed is regulated by the furnace, which is controlled as easily as the flame of a lamp. The steam is condensed within one-seventh per hour of the water required at starting, without water or any mechanical means whatever. There is neither smoke, chimney, coals, nor water-tank. It is not protected yet, as there are doubts about the value of a patent, where the laws are made to "keep back the people" from progress, as those concerning road steam-engines in England do at present. Such noisy, cumbrous, frightful, and dangerous things as "traction-engines" require restriction. But, why should engines with silent and invisible machinery not have been exempted? However, the same principles being applicable to all high pressure engines, the promised description may see the light of day in due time.

F. Packman, M.D.

THE MYBORG BEE CABINET.

[4371.]—Ever since the appearance of letter 4187, on the 24th of last month, I have been hoping to see some notice of the interesting suggestions of our Danish correspondent. The "Myborg Bee Cabinet," as I will venture to name it, seems to promise an escape from some of the difficulties of the "Woodbury," but before constructing one I should like the opinion of Mr. Abbott or some other experienced bee master, lest in avoiding some known inconveniences we might be running into other and possibly worse ones. Allow me, though a novice, to ask one or two questions:—

1. Supposing the cabinet complete, and that a swarm has been obtained, how are the bees to be introduced into their intended homes?

2. Would it not be an improvement to interpose blocks at intervals between the two thicknesses of wood so as to have dead air spaces at the sides and front as well as at the back and bottom? (See letter 3162, No. 350.)

3. Might not the frames be made much longer so as to increase the space for the breeding cells? Mr. Abbott finds the ordinary Woodbury too small. (See letter 3533, in No. 359.)

4. But the point which seems of most importance is the waste of heat which would take place in the winter in the upper half of the stock compartment. (See the 3rd paragraph of letter 3162.) Can this be in any way obviated?

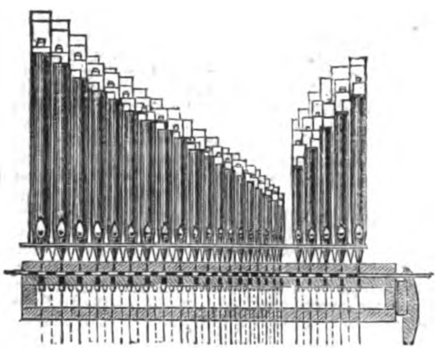
It would be very satisfactory if Mr. Abbott could spare time to notice these or any other points in the Myborg letter which may occur to him. Would he also explain what Mr. Langstroth means by "a tall hive laid down"?

When will our Danish friend give his promised description of his "honey taking machine"?

I hope an editorial note will soon put an extinguisher on the steam comet. E. T. Grays.

AMATEUR ORGAN BUILDING.

[4372.]—In answer to "Draughtsman" (letter 4282, p. 302), I believe many have ventured incautiously, without first knowing or contemplating what they intended to build. It is not necessary to go to CCCC



for a room organ: an ordinary 8ft. stopped pipe is sufficiently powerful for moderate use, which will constitute the same depth of note as a 16ft. open. If amateurs wish to combine reeds on the harmonium principle let them not ascend higher than tenor C, then they might have a 32ft. tone, while above tenor C, pipes being used, they can have every sweetness of tone. I will say more in a subsequent letter on new-shaped pipes, with the measurement appended of some of them. I inclose a section of the usual manner of laying out soundboards.

Joseph William Fennell.

THE HARP.

[4373.]—Will some one take up in our pages this neglected instrument? A few letters on its construction similar to those which have appeared on the piano, the organ, &c., would be appreciated by G. H.

NORTH LONDON RAILWAY.—GOODS TRAINS AND PASSENGER TRAINS.

[4374.]—It seems a great pity that goods trains should be allowed to interfere with passenger traffic to the extent they do by being run frequently in the day time. All passengers who are in the habit of travelling to the city by the North Western train due at Broad-street at 9.22 a.m., must, by this time, be thoroughly familiar with the following nuisance. Every morning, just as the above express train to Broad-street is due at Camden-road, a very long and very slow goods train passes the station on the express line, and crawls along to Broad-street, rarely arriving there till 5 or 10 minutes after it is time for the express train to get there. This has been so ever since the express trains commenced running, and it is often anything but cheerful or edifying to be in the carriage and hear the complaints of the passengers as the train keeps stopping and whistling all the way. What a pity that a train so punctual on the district line and other parts of the route, and belonging to the finest service of trains in existence, should have every journey spoiled by a miserable goods train, which might easily be run on the slow train line, or started a minute or two earlier or later. A Disgusted Passenger.

ON FIDDLES.—To "Fiddler" and Mr. P. Davidson.

[4375.]—"Fiddler" says: "You may bow a fiddle string of given thickness until it shrieks," quite true. That, because you can make your string shriek, therefore, it must be impossible that string can move more than one soundboard made of the same—I presume the same kind of—wood, is not, to the unscientific writer of this, quite self-evident. It may be true for anything experience has taught him to the contrary; for, although, he has some experience in the employment of more than one soundboard in pianofortes, he possesses none of their use in fiddles, his first funny fiddle, conceived in the depths of his consciousness, existing as yet only in imagination. "Fiddler" also says that the new fiddle would "do," if it had but one string to each soundboard, which seems very probable. What seems equally so is, that if the set of strings which generates each individual sound in the pianoforte had a separate soundboard, of sufficient size, it would also "do" admirably well. The question is, how are we, in practice, to provide each string, or set of strings, with a sufficient soundboard, unless each string or strings which generate sounds, whose pitches differ by only one semitone, be placed so far apart from each other as to become quite unmanageable either in a bow instrument—whose strings have to be "stopped" by human fingers of ordinary length—or in one having manual keys, for, unless a whole octave of the latter be within the space of about 6½in., human hands can't perform on it.

I advisedly wrote "a sufficient soundboard," but I really don't know how many superficial inches would be sufficient. Probably, for the necessarily but short treble strings of a pianoforte few superficial inches (say about 8in. or 10in.) would suffice, because mere increase of surface does not, in that part of its compass, seem sensibly to increase the loudness, however much it affects the timbre, of its sounds. Loudness seems to result rather from the ample vibrations of a comparatively small surface than from the very minute vibrations of a large surface acting as a soundboard; and very short strings can't vibrate a large area of soundboard (it is far otherwise in the case of long, thick, and heavy bass strings, hence we make a contra bass somewhat bigger than a kit), consequently, could we connect each set of strings with a separate soundboard, we should soon arrive at the limit of loudness, unless, indeed, we did exactly what I have done in my first funny fiddle, to wit, instead of one, using many and effectually connecting them together; but this is hardly to be termed connecting each string with one, for it is connecting it with many soundboards.

If it were desired to increase the power of strings so as to cause them to induce vibration of larger soundboards, increasing their lengths (supposing their material will bear a greater tensile force than that to which they are now subjected) or their thickness naturally suggest themselves as the means. The former has been done in the piano until their lengths have been about doubled, and their thicknesses more than doubled, nay, it has been increased from four to eight fold. Want of tenacity, even in the very best Roman strings, would, however, soon prevent us from much increasing the length of violin strings. I never had the good fortune to get a first string which did not break before its pitch was raised to G above the lines—i.e., a minor third, besides which, could they be made twice as long (say 26in. instead of 13in.) it must be remembered, that although the change might facilitate "stopping" in the upper octave, it would cause the "stops" to be almost as far apart as they now are on the 'cello. Now, I think "Fiddler" and all his brethren will admit that it is much easier to execute rapid passages on a violin whose strings are but 13in., or on a tenor whose strings are 14in. long, than on the violoncello or double bass; anything to the contrary notwithstanding Bottessini and Company may have "executed."

Increasing the thickness of fiddle strings is not open to the same objection—viz., rendering performance more difficult—as greatly increasing their length is; and, to my taste, the timbre of the sounds of the A string, raised to E, is much more pleasing than the ordinary tone of the first string; but, besides the unpleasant fact that A strings which will bear tuning a a fifth higher are not to be bought every day, I may remark, it is not every one who prefers the timbre of a thick first string. When, at my suggestion, the late Mr. J. A. Turner—who was one of the finest violinists I ever heard—tuned his A string to E, he thought it sounded rather "tubby;" its tone was not so satisfactory when the instrument was held close to the ear, which it ordinarily is during performance; and he thought the character of "tubbiness" was yet more developed when he played on his third string, the pitch of which was raised a fifth to A, although he agreed with me the tone of the D string was improved by employing thinner catgut, and loading it with very thin wire. However, well knowing that neither the organist, pianist, nor violinist are, while performing, best situated for listening, I changed places with my late friend, and let him hear, to the best of my bowing ability, the difference between the tone of the comparatively slack D and A strings at their original pitches, and their tone when tuned a fifth sharper. He then acknowledged that the tone of those strings, when their pitch was raised, "told" much better at the distance of some twenty yards.

I presume "Fiddler" will not deny that the thicker and tighter a string is, the more force—whether that force be applied to it by way of percussion, as it is in the piano, by pulling, as in the harp, the lute, the guitar, or harpsichord furnished with plectra, yea, even in ye fiddle, whose strings are as certainly pulled, by the rosined bow, as those of a harp by the fingers of the performer—will that string bear without shrieking, which is ordinarily the consequence of "cruel" treatment; hence, we may hope long and thick strings will communicate sufficient force to moderately large soundboards to induce their vibrations at a much further distance from that place on which the strings rest, or are attached to them. Consequently, we may reasonably expect that by the use of thicker strings, we may be enabled to employ larger single soundboards in violins, and thereby obtain louder sounds without deterioration, perhaps even with improvement, of their timbre.

I see "Fiddler" also suggests that the breast of the violin ought to be composed of two pieces of wood, because its bridge has two legs; possibly so, but the reasoning seemeth rather of the order which deduced Goodwin Sands from the erection of Tenterden Steeple. If the fiddle's breast ought to be made of two pieces of belly timber—I mean belly wood—why does "Fiddler," and all his fellow fiddle-constructors, glue those two pieces together, and thereby make them one piece of wood? Surely, the two "poor feet" of its biped bridge would "act and react" more perfectly if the two halves of the breast were disunited. When I read this rather odd notion, my original "savage" nature was so roused, that I was strongly tempted to recommend my friend "Fiddler" to perform that "happy despatch" which the Japanese term "Harikaru" (the word literally signifies "belly cut"), by ripping his belly—of course, I mean only that of his fiddle—up the middle.

It is my misfortune that the congenital density of my nervous tissue quite prevents me from clearly realising either my friend "Fiddler's" fiddle reflections—I mean his fiddle sound reflectors—or Mr. Schucht's peculiar theory of the law of vibrations. My ignorance of the latter is, I fear, partly due to your cruelty, Mr. Editor, for he informs me you (perhaps envying its profundity), instead of inserting, returned its lucid exposition to the writer. I can only lament our deprivation of that enlightenment which would necessarily have resulted from its publication in "our" journal, its insertion in which would certainly have saved so much valuable space. Had you printed it, all that space now devoted to the shallow theories of "The Harmonious Blacksmith" and other acoustically ignorant correspondents must needs have been rendered available for far more important matter. Mr. Schucht was kind enough to endeavour to explain his most satisfactory, to himself, theory to me when I last had the pleasure of calling on him; but the attempt was a wretched failure. No doubt the congenital density of my nervous tissue had much to do with the difficulty he experienced in explaining what he assured me was very plain and simple.

May I also suggest to "Fiddler" that when he rested the back of his 'cello against a board, whether of mahogany or other wood, he did something very like putting an additional soundboard to it, or rather putting it to the latter. Sure-ly the convexity of its back must—where it touched the board—have acted like a soundpost—*i.e.*, have communicated its vibrations to it, and caused the said board, so long as it remained in contact, to become a *sound* board. I don't think this 'cello case could possibly be a case of its reflection, but of the additional generation of sound—such, at least, is the result of my "reflections" thereon.

The material of a sound reflector, or, to speak more correctly, of a reflector of those aërial waves which we perceive as sound, ought to have a smooth (not to say polished) surface, just like that of a reflector of heat or light waves. Reflection, however, is mere change of direction: it cannot generate either heat, light, or sound. A sound reflector can no more increase a sound's volume than a mirror can increase the light of the sun; both light and sound may, however, be concentrated by reflection, which is just what I suppose the so-called ear trumpet effects for those who are as hard of hearing as I am of understanding.

THE HARMONIOUS BLACKSMITH.

P.S.—Among fellow fiddlers, whose judgment I solicited when my first funny fiddle was made known, I am sorry to say I omitted to include my fellow correspondent Mr. P. Davidson, who once did me the honour to request me to communicate information concerning violins to him. May I respectfully request his opinion on the probable advantages (if any) and disadvantages of my latest born infant, especially in the matter of what is likely to be the character of its "voice"? Allow me to add, I am trying very hard to understand Mr. Schucht's last letter on the violin (4308, p. 307), but I have failed to arrive at its meaning.

NEW DOUBLE STARS.—To MR. BURNHAM.

[4876.]—YOUR success in discovering close double stars in regions which were considered thoroughly worked up has been much noted on this side of the water. The subject was a matter of conversation amongst amateurs and others at the Royal Observatory Visitation on the first of this month, and every one seemed gratified, and wished you much future success. Touching your letters 4178 and 4258, I had a fair opportunity last night, June 11, of looking up two of the objects referred to—Virginis = L 23106, *s.f.* 6 Comæ, and Boötis = L 27106. The former is, indeed, a very beautiful object, but not quite so difficult as I expected to find it. The small companion was, of course, very easily seen with the full aperture of my mirror (12in.), and continued visible with all apertures down to 5in., which, in the condition of the air and twilight at the time, left it just perceptible by glimpses. I, therefore, conclude that the faint companion is fairly within reach of a good 4½in. achromatic.

Whether this double star is a new one or not I have no means of knowing, having only Struve's "Mensuræ Micrometricæ" to refer to, in which it is not found. I was not so successful with the more difficult pair L 27106; whether from smoke, twilight, or tremor, after long gazing I could not persuade the little companion to show itself. In cases of this sort the imagination needs to be suppressed, and nothing short of seeing the object absolutely and unmistakably ought to be allowed. In this I failed, but shall look again the first opportunity, when I hope to confirm your discovery. Much more interest attaches to close and difficult pairs when in the same field with conspicuous and well-known stars like ξ Boötis. Your fine double in this field is, however, not the only one. Looking over the small stars in the neighbourhood, I met with another, if not as difficult, by no means one of the easiest. It may be readily found thus: Place ξ Boötis at the lower margin of a wide field and low power; the double in question will then be just within the same field at the top, and a line produced from ξ across the star No. 1 of your chart (let. 4258) will almost strike it. I roughly estimated mag. 8·2 and 9·5, D 1·45", and P 170°. I may also mention another pair recently met with worth looking at, not in the Men. Mic.: R.A. 18h. 4m., N. 32° 45', P. 347, D. 1·6", 7·5, and 7·8. The place is only near enough for finding, and the rest approximate. I am sorry to say all the other stars referred to in your letters are now passed out of my range for the season; but I hope to look them up when opportunity serves.

F. BIRD.

INCUBATORS.

[4877.]—IN reply to "Hatcher" (let. 4175, p. 229), I would remind him that eggs require a certain degree of moisture, and so they do better when the hen's nest is on the ground. This should be provided for in any incubator; and then does not "Hatcher" know that when a hen is hatching its chicks they often require a little assistance in breaking up the shell? The chicks break the shell, but frequently have not strength to make the opening large enough. We lost two the other day, simply because we could not get to the nest.

E. T. S.

THE ROBIN HOOD SEWING-MACHINE.

[4878.]—As many of my brother subscribers seem interested in sewing-machines I send you a sketch of one I have invented and made, if you will allow me a

little of your valuable space. It works with ten needles, double-thread lock-stitch. Any needles may be left out or put any distance to suit work. It will make 2,000 stitches in one minute, and more stitches in two minutes than any woman can make in one day. Will any reader of our valuable paper tell me if there is such a machine at work.

R. TANSLEY.

RECENT DISCOVERIES OF DIAMONDS.

[4879.]—NATURE produces nothing more beautiful than the diamond, or more valuable, but it is truly astounding the ignorance that well-educated people show about it. Our emigrants either pass over the genuine stone as of no value, or send home paltry bits of crystal or topaz for the precious gem. It is curious that the constituent material of the diamond is the predominant component of every organic or living thing. As rock crystal is flint in a pure state, so is the diamond carbon in a pure crystallised form. All "our" readers know that crystallisation generally produces brilliancy; for example, carbonic acid gas, combined with lime, when crystallised, form the clear transparent double-refracting or Iceland spar; but when uncrystallised the same compound is opaque, as in various limestones. The diamond is an ingredient of all living things and corundum of soil.

The diamond generally occurs in regions that afford a laminated granular quartz rock called *Itacolumite*, which pertains to the talcose series. The diamonds lie often imbedded in flaky portions of this material like garnets in mica schist. In the collection of the late Mr. Ruskin is a conglomerated mass of quartz, pebbles rounded through having been waterworn, with two crystals of diamond and various grains of gold, the whole cemented together by oxide of iron, thus showing the association of diamonds and gold, and was found in the bed of a river in Brazil. When diamonds were first discovered in the Brazils they were used as counters in playing cards, till an officer took some to Portugal, and found out the value. In 1844, a slave was searching for gold in the bed of a river in the province of Bahia, and discovered diamonds, and it being a new locality, 297,000 carats were found in two years, which produced upwards of £300,000. In the gold mine of Adolph, Siberia, between the years 1833 and 1836, upwards of fifty diamonds were found, but only one of these was of considerable size. The most productive mines in the world are those of the Sierra de Trio, Brazil, which are computed to have yielded upwards of two tons of gems. In an exhibition of native productions held at Melbourne in 1855, numerous small diamonds were exhibited, found in various parts of the colony. In 1866, upwards of sixty diamonds were found at the Woolshed Diggins, in the Ovens district; but were all very minute, weighing from ¼ to 2 grains. Africa is without doubt the largest diamond-yielding country. Dr. Atherstone, of Graham's Town, received a letter from Mr. Boyles, Clerk of the Peace, Colesberg, inclosing a diamond, which was afterward sold to Sir Philip Woodhouse for £500. This was in March, 1867. Soon afterwards, twenty other good-sized diamonds were found along the Orange river; but in May, 1869, the world was startled to hear of a diamond weighing 83½ carats, found near Sandfontein, on the Orange river. Swalboy, the finder, sold it for 500 sheep, 10 head of cattle, and 1 horse. It was purchased by Messrs. Libenfield Bros., and was sent by steamer to England, and insured for the passage to the tune of £30,000. But this was thrown into the shade by a report in September that a diamond had been found in Australia weighing 900 carats, and estimated to be worth £10,000,000, as it would be five times as large as the Koh-i-noor, and the Koh-i-noor's nominal value is £4,000,000. After great excitement, and a thorough investigation, the stone was found to be a topaz, but the resemblance in this instance was very extraordinary. The stone in the Portuguese Treasury, weighing 1,880 carats, is probably, and almost sure to be, a topaz, or a white sapphire stone. But how absurd to report such a stone as the Australian specimen without first investigating. Nothing but a diamond will scratch a diamond; but if the stone is topaz, or white or yellow sapphire, it can be scratched by a splinter of ruby. It is, probably, simply not topaz, but a common bit of quartz worth nearer 10d. than £10,000,000

I will now proceed to give the method of distinguishing the true diamond. In olden times jewellers put a varnish made of ivory-black and mastic to the back of the stone. If genuine, this gave it great brilliancy, but if a sham it made it dull and lustreless, showing the black through its substance. Mr. King says that the "Novas Minas" white topaz of Brazil, better known as the "Slave's Diamond," is now the only stone which has any chance of being passed off as a true diamond. The genuine diamond may always be distinguished by its "single refraction"—a property which is also possessed by the garnet, but by no other precious stone. Others have a double refracting power—that is, to speak plainer, give a double image of a taper, or other object, when viewed through their facets. When diamonds are set it is easy to see whether the refraction is single or double by looking into the stone at the image reflected from the posterior facets. The diamond does not lose its lustre if immersed in water or alcohol; but sham stones will, arising from the inferior refractive power; a commoner method is to touch with the tongue, when genuines feel colder than shams. Pliny, in his "Natural History" (lib. xxxvii., c. 15), says, "a true diamond, if placed on an anvil and struck with a heavy hammer, will not split." Many fine stones must have been sacrificed at this. This would be my last experiment if I was testing a diamond; but diamonds could, it has been said, hardly have been known to Pliny. He must have been mistaken for white sapphire, the next hardest stone to the diamond (*vide* Dr. Billing's "Science of Gems." Diamonds were formerly polished by the East Indians by rubbing them one against the other, as was the case with the Koh-i-noor. Lavoisier made many experiments on the combustion of the diamond. By its first combination with oxygen it is converted into plumbago, by a second degree into common black charcoal, and by complete saturation into carbonic acid gas. Thus, this most beautiful of gems, exceeding by 100,000 times its mass in gold, is but a lump of coal dissipated by combustion into any insalubrious gas. There is, however, good reason for supposing that future discoveries will tend to diminish their cost.

H. B. E.

RADIUS OF SURFACE OF OBJECT-GLASS.

[4880.]—MR. OLDFIELD, in his letter (4149, p. 225), seems to have put the finishing stroke on the crown lens. But before applying the hammer, will he state from these symptoms if he still thinks the case hopeless? It is now four years since I bought my glasses from Messrs. Chance, and paid too little for them. They were, according to Messrs. Chance's tariff, 6in. square plates for cutting up. My object-glass is still an immense puzzle to me, and has introduced me to a host of optical phenomena I never bargained for, some of which I will state for the benefit of other intending adventurers. First, with regard to taking the specific gravity of the glass, I thought that the fragments of the ring of glass cut off the 5in. discs were handy, but imagine my astonishment at finding that not one of these fragments (in the case of the crown lens) gave the same results, but went something after the following order: 2·61, 2·59, 2·57, 2·55, 2·54, 2·44, 2·23, and so on round the square; so that if this is the density of the edge, what is the middle? Secondly, in the *Journal of the Society of Arts* appeared a paragraph on the subject of astigmation; this phenomena is, as Mr. Oldfield and Mr. Vivian may be sure, not wanting in my object-glass. To begin: Put in the eyepiece of the telescope—bad focus, look upwards by tilting the eye piece, I see a focus; look down, I see another. Which of these will-o'-the-wisps must I try to catch? By means of a little patience and the obliging adjusting-screws of the tube, you may catch either of them, not to forget the turning round the object-glass, or tilting its ring or cell a little. Mr. Vivian's suggestion of the best position of the edges of the lenses has not been forgotten; every little helps. But when got, best is bad. Its astigmation is an imperfect circle within the focus, either a badly-formed ellipse or a flattened circle. In pushing in the eyepiece, a sharp orange red point darts out of a star on each side, and lengthens. I am sure that my optical centre is very near the point; but, on the other hand, the cone of rays as cast from the object-glass is a wonder to the eyepiece, if not to me also. Why does it move round the eyepiece in that erratic manner, a good central focus appearing so near and yet so far? I must conclude by stating that the optical centre was got by running the lens on a small lathe, it being cemented to a piece of metal held in a six-screwed bell-chuck. A sharp point of brass was closely watched by a convex lens as to itself and its reflection, the edge being treated in the same way. The edge and surface next the headstock got true, the other was ground true, then all reflections stood still, and all seen through also.

It is possible, as Mr. Oldfield says, one of the surfaces is not true—most likely one of the first done. I have only one brass tool in my possession, having re-turned them up as I went on, so am free to start fresh. Some years ago I ground some lenses on soft hematite cast-iron tools. Could I use this metal again, or are they obliged to be brass? I do not wish, while thanking Mr. Vivian and Mr. Oldfield for their kind offers, to trouble them or take up their time with bad material, but shall start with 63in. focus and a piece of new crown glass, if this is really bad.

W. H. Cash.

SELENOGRAPHY.

[4381.]—Selenographical sketches are of general interest when they are neatly shaded, as that by Mr Birmingham (page 277); a mere outline, as those usually given by Mr Birt (see page 292), are only profitable to those who have large telescopes. Many readers, like the writer, who are not possessors of great telescopes, have a constant desire to understand how celestial objects appear when viewed through them, and however incomplete the best drawn sketch may be, it is comprehensive and of marvellous interest to us compared to the dry puzzling diagram of outline often given, which is perplexing to all but the astronomer. To him, as to the general reader, the more carefully-drawn selenograph would be pleasing, and equally, if not more, useful. I hope Mr. Birt will take a hint from

E. B. F.

NITROGEN IN PLANTS.

[4382.]—Mr. Lawes (p. 314) has, I think, proved by decisive experiments—first, that plants do derive much more nitrogen than is supplied from manure in the soil; and secondly, that it is not derived from the air itself, but from what is mingled with it. The first point he established by growing wheat crops for a long succession of years upon the same plot of land without supplying any fresh manure, with the effect of obtaining, first, a gradually decreasing crop, as the soil became exhausted, and afterwards a nearly regular one, the nitrogen of which must have been obtained from the air or the rain, or from something contained in them. The second point was proved by growing wheat plants under air-tight glasses, in soil containing the ashes of wheat plants but no nitrogenous matter, supplied with water and air containing carbonic acid, but no ammonia or other nitrogenous matter, the seeds germinating and forming stalks, and a leaf or two, which would wither and another form, there being nitrogen enough, but not more than enough, for a leaf or two at once. The air was deprived of nitrogenous matter by passing it through an acid solution, which absorbed ammonia or any nitrate or nitrite. Some have found it difficult to account for plants growing on land not manured obtaining more nitrogen than appears to be contained in the rain and dew supposed to fall upon them. I believe the explanation is that very much more dew is deposited upon the leaves of plants than upon artificial surfaces, and that therefore the quantity of dew falling is much under-estimated, while much of the nitrogenous matter in the air is obtained from it by the dew. This subject needs experimental investigation.

Philo.

THE DISTRIBUTION OF ANIMALS AND PLANTS.

[4383.]—I do not regret the revival of the comet question, notwithstanding "E. L. G.'s" arguments in favour of future collision with a comet, but I must protest against any direct or implied misrepresentation. I do not know whether a comet ever existed, or could exist, composed of steam, and doubt whether "E. L. G." has any better foundation, judging from what we have yet received. But "E. L. G." brings forward the wide diffusion of many fresh-water plants and animals as one proof of the occurrence about 5,000 years ago of a universal deluge of fresh water! Now, it is very easy to set aside the facts brought forward by Darwin in explanation of this wide diffusion; but people must judge for themselves whether "E. L. G.'s" hypothesis or Darwin's explanation be most reasonable. Birds frequenting the vicinity of water do get muddy feet, and it is quite possible for the seeds of aquatic plants, &c., to be conveyed by that means. But whether "E. L. G.'s" universal deluge would result in diffusion or destruction seems to me, at least, questionable; but supposing the former, should not the result have been more complete than we actually find it? But are the rivers and lakes of fresh water such isolated localities as "E. L. G." would lead us to suppose? The sources of the tributaries of many streams are frequently separated by short spaces of land, so they may be described as a network of ramifications, and I am under the impression that, as a rule, water plants are more tolerant of removal than land plants; the mouths of rivers form a means of communication, for a great many seeds will bear immersion in salt water for a shorter or longer time. It is very easy to see how such fish as the salmon, &c., would gain access to new rivers by this means. "E. L. G." expresses surprise at Darwin's statement that the condition of oceanic islands accords with his theory (that wide spaces of sea or deep narrow channels form effectual barriers to the free migration of species), and asks the question whether, according to his hypothesis, the terrestrial mammalia might not have been developed there. Certainly, but time and favourable circumstances are necessary to bring it about; assuredly a much greater length of time than "E. L. G.'s" 5,000 years.

J. C.

THE WONDERFUL GUN-BARREL.

[4384.]—Looking over some back numbers of the English Mechanic, I found a wonderful gun, or rather a somewhat deficient description thereof. What can this wonderful gun-barrel (mentioned in let. 3887, p. 38) be made of? The writer says it was "cast" on the Bessemer principle, whatever my old acquaintance's "principle" of casting may be. N.B.—He is far from being a man "without principle;" but as regards iron and steel, I always thought his principle was the reverse of casting, it being to render iron malleable. The writer also says: "If a bad ingot, it can stand a heat equal to any iron—no small heat, by the way, in the case of nearly pure iron—and bear rolling down to the thickness of No. 32 wire-gauge for conversion into a locomotive tube." He also says his barrel can be produced cheaply. Now cheapness, when not associated with nastiness, is, according to the French wit, the characteristic of modern civilisation, to which in all probability rifled gun-barrels contribute. Will Mr. Minshes be so kind as to inform us what the cheap material is in which this gun is cast which, like Sir J. Whitworth's compressed steel castings, stands so much greater an amount of strain than any gun in her Majesty's service ever could be subjected to in actual warfare?

The Harmonious Blacksmith.

SCIENCE AND EDUCATION.

[4385.]—The following remarks on this subject are by Dr. Cobbold, F.R.S., in his concluding lecture of the Swiney course for 1872, in the Lecture Theatre of the Geological Museum, June 1. He commenced by remarking how much of the general teaching given in certain forms in this country is opposed to the teachings of science in general, and of geology in particular. It is not pleasant to any man of science to have to oppose men who, perhaps, in their private life, are better than himself; but in the interests of truth it is necessary that one should stand up for what is true, quite independent of all personal feelings whatever. Further, the methods by which children are trained are such that when they grow up they are unable to draw conclusions for themselves quite independent of all dogma and authority.

The method of science is in itself attractive, simple, and grand; there is nothing difficult in science. You ask for a definition of it, and you have Professor Huxley's "Science is organised common sense," or Sir J. Herschel's "Science is the knowledge of the many, orderly and methodically-arranged, so as to become comprehended by one." Every subject is capable of being regarded in the light of a science, all that comes within the cognisance of the human mind may be classed under one or other of the heads of the following scheme:—

Constituents of the Universe.				Human Knowledge.
	Organic.	Vegetable (Botany) Animal (Zoology)	*Biology.*	
	Inorganic.	Mineral (Mineralogy) Aqueous (Hydrology) Aërial (Pneumatology)	*Abiology.*	

We first speak of everything of which the human mind can take cognisance under the term "Constituents of the Universe," and then, by a process of analysis, proceed to subdivide it into various subclasses, which subdivision can be carried out as far as desirable; the whole may again be synthetically combined, and come ultimately to what we started from.

I will commence my remarks on education with a general proposition, the truth of which will become clearer as we proceed; all real superiority, whether national or individual, depends upon the degree of culture of the human mind. Reflect, if with all our wealth as a people so stupendous, with our love of liberty so unshaken, and with a religion so patronising, we are advancing, even at the slow pace of our much-abused German neighbours. If it were a mere question of brain power we could point to Mills, Carlyle, Tennyson, Huxley, &c., than whom there are not abroad men who are more than their equals, at all events. If our advancement depended upon these few bright intellects, then undoubtedly we should be proud of our position as above, and, probably, beyond all other nations. But it must be allowed to any one who looks at things broadly, that as a consequence of the not general diffusion of high intelligence, the national chariot wheels are clogged with vices, one of which is intemperance. While this implies a want of intellect, it displays a want of mental and moral culture. People combine—honestly combine and form societies—temperance societies, amongst others, with a view of crushing these follies. Legislators seek to stamp it out by restrictive measures, but to what purpose? Some little good is effected, but the cancer remains. The remedy lies in our hands; alter the conditions of existence of any living thing, and you can alter its character *in toto*. Take the case of the apple; who does not know that the most delicious apple will become a crab when removed from the genial culture of the garden and subjected to the wild influences of the atmosphere. The apple and pear will revert to the old crab-tree when these gracious influences of culture are removed from them. Or, take the case of an animal: say dogs, when they run wild, as they were allowed to do years ago in Australia, they revert to the wolf. The Australian dingo is scarcely different from the wolf, the parent of all dogs. And so it is in the higher forms of life. Place a child in an artificial condition, and what developments do you not see! Look at the features of fashion. The child, which in itself is so beautiful and so expressive of much that is lovely, is taken and brought up in a way in which it shall, before it is grown a woman, have all the airs and ways of a grown up person. It becomes artificial, its manner spoilt, and those elements in its constitution which are altogether lovely are effaced from its character. We are all creatures of circumstances, and our outcomes are the consequence of the conditions in which we have been placed or in which we have placed ourselves. Unfortunately there is, in too many cases, no desire to depart from these circumstances. This is a large subject, and one which leads us in many directions. I feel with Mr. Carlyle in regard to this that those who would stamp out these features which are so agreeable little know what misery they entail upon future generations. The object of man in life is to be honest and straightforward, and what we want is not less sound religious principles, but less of those surroundings about which people trouble themselves, and which are scarcely worth the trouble. As to remedies, it is not by the building up of systems, or devising of methods, that people will become more honest and more intelligent, but by encouraging in every way and in every direction all sorts of progress, both mental and material. There are at the present time some large-hearted people in authority with abundance of power, who would like to see such gatherings as this every Saturday evening. Those gentlemen would like to see it carried out on a scale infinitely larger than at present obtains, who would like to see the places of intellectual improvement open to the public on the only day when many of them, for honest reasons, can avail themselves of them. To see these classes read, mark, learn, and inwardly digest the glorious truths laid open to our view by the study of Nature. But some will say, why do not these men use their power? The fact is they cannot; they are opposed by a party more powerful in point of numbers.

There are other helps more material, which may be employed to bring about a better state of things than obtains at present. Look at the conditions of existence in which multitudes are brought up; much of this ignorance and debasement might be spared if only the conditions could be altered. Now, these conditions cannot be altered by a *revolutionary* process suddenly, they may be by an *evolutionary* one. One of the factors concerned in this eventual improvement, I believe, would be obtaining the assistance of recognised men of great power and capacity to organise a system by which the great and glorious truths of science should be diffused throughout the land more effectually than at present. I do not wish to disparage the honest efforts of those who are working so energetically in the matter, but I think that whilst at present it is necessary there should be compulsory education of the young, when the value of the practical results are realised by persons who have grown up under a better system there would be no compulsion necessary—it would be a matter of course and delight.

A museum is grand, no doubt, in itself, and is instructive, as it gives people a general idea of the nature of the various forms of life, &c., which exist on the earth; but, unless you have living and earnest men capable of explaining the value of the treasures of the museum, nine-tenths at least of the value of the museum teachings is lost. I have ofttimes wandered through the British Museum, and have noticed the wonderment which appears in the eyes of our country friends as they pass too and fro, and thought "You get an idea, certainly." But might not that instruction lying in the museum be turned to account in the way I have mentioned. In this the most splendid museum in the world there positively is not a lecture room, and no means of getting instruction except by going round a few at a time.

But another objection will be started. Where is the money to come from? To that I answer, scientific men are very modest in their requirements; a little satisfies a man if he has an honest desire to convey a knowledge of truth. I think there is no doubt but that if the people do but express their desire on this account with sufficient firmness, not only the education, but the money and the men, will be forthcoming. I have no interest in disparaging the present existing machine at all; I merely wish, knowing the great results which must at length accrue from science, to see these principles gradually diffused until the whole mass is permeated. A few years' space of action in the direction I have spoken of would do more to put down ignorance and vice than all the compulsory measures of legislation. As sure as our planet revolves on its own axis, and also circles round our great luminary, so sure is it that science and reason will one day have their ends.

We may regard science in this aspect at present as a little cloud no bigger than a man's head. But it will increase; it will grow and form cumuli and nimbi, and will at length descend in refreshing showers upon the earth. We have the proof of this in the facts of development in time. Place yourself in ancient Siluria: can you realise the possibility that the organisms of Siluria will culminate in the development of man? Doubtless, by-and-by precious fruits will be reaped, but there are rewards now for all, and those are the rewards of independence; it is no fabled reward, I assure you, to pass through life doing your duty in that particular area or sphere of action to which you are called, and one which no dogma can destroy. Therefore

Let us all be up and doing,
With a heart for any fate:
Still achieving, still pursuing.
Learn to labour and to wait.

W. H.

ON EDUCATION.

[4386.]—I WISH to make a few observations on the practical part of this important subject. I consider that our public school and university systems have two serious faults, they are unnecessarily expensive, and from their prestige and the advantage to be derived from them being much overrated, they educate more men than there is suitable employment for, either in this country or the colonies; learning is a drug in the market; the supply of educated men is largely in excess of the demand; this leads to two evils, firstly, from the severity of the competition to obtain situations: those who are successful must accept terms, which remunerate them very inadequately for their expenditure of time and money. A public school education costs about £500, perhaps more, according to circumstances. The expense of graduating at Oxford or Cambridge is about £500, this makes a total of £1,000. The writer took his passage to Australia some years ago, willing to do any work he could find, and yet he had taken a better degree than five-sixths of our graduates, and in a practical point of view he not unnaturally looks at university education as little better than time and money thrown away. I extract the following from Dilke's "Greater Britain" (fifth edition), p. 244:—"Another account says that none but members of the older English universities are admitted to the force (the Gold Coast Police). There are here upon the diggings many military men and university graduates, who generally retain their polish of manners, though outwardly they are often the roughest of the rough." I conclude my letter by asking what practical benefit have these men derived from wasting a moderate capital on a useless education.

ROBERT LYON, B.A.,
Ex-Scholar of Clare College (7th senior op., 1865).

PERFORMANCE OF TELESCOPE, &c.

[4387.]—I DESIRE to express my thanks to "F.R.A.S." (let. 4224, p. 274), and also to the Rev. H. C. Key (let. 4248, p. 279), for their kind replies to my questions. I shall feel much obliged to either of those gentlemen for a little information so as to clear up the following difficulty. We are told that the separating power which ought to be possessed by a first-class telescope may be calculated by dividing the standard number 4·83, by the diameter of the object-glass or speculum in inches. According to this, my 5¾in. speculum ought to divide stars whose distance is not less than about 753·0″. I should like to know what magnitude the stars experimented on should have, and also what power should be expected to produce the result desired, also whether the experiment should be tried on a clear night in the absence of the moon, or by moonlight, twilight, or daylight, or with the field of view artificially illuminated, or with a slight fog or haze. What I wish to convey is that on the clear night with no moon, no artificial illumination, and no haze, the spurious discs of the stars will be larger than under any other of the conditions specified, and consequently more difficult to separate. As an instance in illustration, I may mention that "F.R.A.S." has frequently specified δ Cygni as a crucial test for a first-class telescope. I have therefore looked at this star on several occasions without distinguishing the small companion with my highest power, which I find is 250 (not 270, as I supposed). On one occasion, however, I believe I saw the companion during a rather dense haze, which rendered the principal star scarcely visible to the naked eye.

Another point also suggests itself to me. In referring to any catalogue of double stars, we find it remarked respecting some faint companions of bright stars that they bear magnifying remarkably well, or, on the contrary, that they are extinguished with a high power. Some of these objects are used as light tests, and therefore it seems worth while to seek an explanation of this peculiarity. First, I would inquire whether the stars in question behave similarly with all telescopes. If so, the difference must be in the stars themselves, and those that bear magnifying well are single stars seen as spurious discs, while those that are extinguished with high powers are either aggregations of much smaller stars, that is to say, minute clusters at such a distance as to appear like single stars, or possibly nebulæ, or they have real discs. In any of these cases the increase of magnifying power would produce a corresponding dilution of the light.

On the other hand, if the objects in question behave differently with different telescopes, then we must look for the cause in the instruments. Here we touch upon the great question of the relative merits of reflectors and refractors. I can see no reason, other than those enumerated above, why one star should bear a higher power than another in a well-figured reflector. We, however, know that the spectra of the bright stars are not all alike, and it is fair to presume that the spectra of the faint stars also differ among themselves.

We also know that the best (so-called) achromatic object-glasses are only partially corrected, and that with all there is some outstanding light or secondary spectrum.

Now it seems to me, that if the light of a certain star consists principally of those rays that are well corrected in the object-glass used, that that star will bear magnifying better than another apparently similar, but whose light is composed principally of those rays that go to form the secondary spectrum. Hence, I should suppose it possible that one of two stars might bear magnifying better than the other with one object-glass, and the state of matters be reversed when another object-glass is used. I should also suppose, that those nebulæ or comets whose light is found to consist of two or three bright lines would bear magnifying or not, according to the position that those lines occupy in the spectrum.

It would seem to follow as the result of the above considerations, that in the case of minute stars the magnitudes assigned by observers who use refractors will vary according to the particular object-glass employed, and that a very difficult object for one telescope may be comparatively easy for another.

T. Godfrey, (query 12112, p. 314), says that he tested his 10¼in. mirror on Arcturus with a power of sixty diameters only, and did not use a high power from want of light. It may interest him to know that I tested my 5¾in. mirror before silvering, but with a silvered plane with a power of 250, and with that power divided ε Boötis and λ Ophiuchi. I had, however, the advantage of having the telescope and stand complete and in perfect order.

Godalming. A. WOOLSEY BLACKLOCK, M.D.

MUSICAL-BOXES ON SOUNDBOARDS.

[4388.]—NOT having tried the experiment, I am unable to inform "E. B. F." (query 12175) if the resonance would be more powerful were "its innards" taken out of his musical-box and affixed to a soundboard. Probably it would, because the less matter is interposed between a vibrating body and the soundboard to which we desire to communicate its motion the less the transmission of its vibrations can be obstructed, so we may reasonably expect the motions of the soundboard would be more ample and the loudness of its sounds increased in proportion; but this don't seem a very easy thing to do as musical-boxes are ordinarily made.

Theoretically, the elastic bars or springs which form its "comb" ought to be directly connected with the soundboard, as they would be if affixed to it; but this is manifestly impossible. They might, however, be affixed to a transverse wooden bar glued on the soundboard, which happens to be the very means employed in Mr. Goldsworthy's pianoforte without strings. (See his patent, No. 6498, price, with drawings, 6d.). This would, perhaps, induce the greatest possible resonance; but it may be doubtful if even beech wood would resist compression enough to afford a sufficiently firm surface unless a plate of metal, by which that compression was distributed over a large surface, were interposed between the wood and the vibrating spring bars, were the latter in single pieces. This is the method adopted in my small portable pianoforte without strings, whose compass, by the way, is but three octaves from tenor C to C above the treble staff. It is also, I believe, the method employed in Mr. Crawford's so-called "bell" pianette. Of course, it could not be required for the comb of a musical-box, which might just as readily be screwed on the transverse wooden bar as on its ordinary support, assuming its proper position in relation to its pinned barrel be maintained. The transverse wooden bar might, probably to advantage, be made of pine wood (which, I think, transmits vibrations more readily than beech), for, from its necessarily great thickness, there could be no want of strength.

I don't think it desirable to make the soundboard very much larger than 30in. × 20in., because I doubt if the (comparatively to those of violin, harp, and piano strings) feeble vibrations of the prongs or teeth of the comb of any musical-box I have yet seen—and I have seen some pretty big ones—could excite the sonorous vibration of a surface much exceeding 600in.; but as I know no harm which can ensue from augmenting its size, "E. B. F." can, if he prefers doing so, make his soundboard (say) 10in. or 12in. longer and (say) 8in. wider, but certainly not any thicker (I have a suspicion it would act better if yet thinner), and glue two more belly-bars of the same section on its under surface. I should prefer them to be placed one at each of its edges. This will increase the superficial area to 1120in. or 1176in.—quite as large as we can expect to be put into "audible" vibration by any musical-box simply standing on it. Probably, however, were its comb screwed on a pine wood bar glued on its middle, we might hear sounds whose loudness would be "pretty considerable, I kalkalate."

THE HARMONIOUS BLACKSMITH.

CO-OPERATIVE STORES.

[4389.]—"F. C. S.," in a very clear and clever letter (Vol. XIV., p. 608), asks why a village co-operative store does not yield the satisfactory results expected—viz., a profit on a return of £30 per week, where the estimated profit of 10 per cent. produces a loss, although the expenses are under forty shillings.

A great many answers have appeared to this letter, some very well written, and containing useful information; but I think I am right in my thought that not one word has been written in answer by any one who has had the practical experience of employment in such a store. In my early life I passed some years in the management of a business of exactly the same description. I can hardly expect to obtain space in the ENGLISH MECHANIC to give all the information "F. C. S." requires. I will take one of the most important articles first—viz., flour. I will suppose the store is buying at 39s. per sack of 20 stones, and selling at 2s. 2d. per stone, leaving the apparent profit of 10 per cent., as stated in the question, and so it would if the sack of flour was sold whole just as received, but let us trace the sack of flour from its entrance to its exit. The miller delivers and empties the sack of flour from his sack into the flour-bin; the sack, if shaken quite clean, would only weigh 5lb., the tare allowed for it; but the process would cover everything in the shop with dust, so that it is more advisable to fairly empty the sack and make less dust, and the sack of flour in the bin would now be very nearly two pounds short weight. The customers are now served as they require, some with larger, some with smaller, quantities, not one will be satisfied unless they see the turn of the scale in their favour, and with the best scales you could obtain, and with only fair average care in weighing, and in the twenty, thirty, or forty turns you would find three or four pounds weight loss, and the case, with common second-hand scales, which for cheapness (! ! !) were very probably provided in this case, would be worse than I have stated, and if the store is not provided with a flour-bin the waste would be much greater in weighing direct from the miller's sack. How does the case now stand? Why, the first two pounds loss, and the next four pounds waste, at 2d. per lb., just reduces your apparent profit 25 per cent. I have in the above instance taken one of the best articles in your store, and one in which there is the smallest waste. Had I taken cheese, or soap, or treacle, the result must have been not a small profit, but a direct loss of from 7 to 10 per cent. To make it pay the store must either charge a higher rate of profit to meet the unavoidable loss and expense in supplying goods in the very small quantities the customers require them, or refuse to sell except in larger quantities, when they could not buy them at all; but by going between the two alternatives you can make the store pay—viz., refuse to sell ¼oz. of tea, ¼lb. of cheese, ¼lb. and ½lb. of treacle, for this article, if sold in these small quantities, would, I have no doubt, entail a loss of more than 20 per cent. R. R. SMITH.

ARE ANTS PIRATES?

[4390.]—I AM afraid your readers will think me an awful bore with my reiterated queries about the habits of ants, but the fact is, being rather shortsighted and without spectacles, I am compelled to take the opinions of others, instead of observing for myself. Horace, I think, sang of the "little ant with great labour" storing up food for the winter, and the moral of the little creature's life is enough to make one pause before rashly destroying it. I find, however, no less competent an authority than the Rev. W. F. Radclyffe, writing in the *Gardeners' Chronicle*, that "ants are one of the greatest fruit scourges I have to contend with. I have this spring killed legions with hot water and by hand, yet they still swarm. I am uncommonly obliged to 'C. L.' for his recipe. Immediately on reading it I got some sweet oil and put a little in a saucer in my vinery, where there is a nest under the wainscoting; in a few hours the saucer, sunk in the mould up to the brim, was replete with dead ants. It is a most valuable recipe. The whole horticultural world will feel obliged to 'C. L.' I am truly sorry to destroy them, but they make the first impressions on wall fruit, and blue-bottle flies, hornets, bees, and woodlice, take advantage of the first impressions." The recipe above referred to is as follows:—"Fill small phials two-thirds with water, and add sweet oil to float on the water to within half an inch of the top. Plunge these upright in the ground, leaving only half an inch standing out, near the nest or runs of the ants Every ant will come for a sip, and go home to die. No insect can exist with oil in its throat, yet ants are very fond of it."

I am obliged to "J. C." for his attention to my question; but with all the inclination to think as he thinks, I am continually upset by these repeated assertions of the piratical habits of the ant. SAUL RYMEA.

CANADIAN WATERCOURSES, HOUSES, STOVES, &c.

[4391.]—MANY thanks to "Tubal-Kain" for his full and careful reply, with drawings (p. 103), to my query "Water-Power to Work Saw Bench," I hope soon to turn the same to advantage. Ontario presents a large field, overrun in all parts with water-courses, falls, &c., well supplied from the several inland lakes; offering abundance of driving power, which would open up the largest manufacturing district, to be found in no other country. Railways are now making great progress throughout the north-west of Ontario, amongst those districts containing so much available water-power; thence they will connect with the great North-West Railway, the line of which is now being surveyed through British territory to Vancouver's Island—a port that in no very distant day will be the market of the world. Lake Simcoe—on the shore of which I am now writing—has the greatest elevation; its waters flow through the course of the river Severn, which contains seven waterfalls, into Georgian Bay and Lake Huron, 595ft. above the sea; thence along Lake Erie 564ft. high, on through Niagara River, over the falls, into Lake Ontario, 235ft.; and finally down the noble river St. Lawrence into the ocean. These falls denote a rocky country, and four-tenths of which is unfit for cultivation. In places where the rocks abruptly terminate the soil is rich and very productive. The densely wooded bush abounding on such lands furnishes the most correct example of its produce. The wealth of Canadian soil is prominently illustrated above the earth; the yield of minerals has as yet been few; coal there is none. Nature has produced wood in superabundance to counteract the effect of long and severe cold seasons; but the most durable production of heat has been withheld from the soil. Nine-tenths of the dwelling-houses here are built entirely of wood; frames are covered outside with weather-boards, inside match-boards, with "shingle" roofs; shingles are sawn from pine, about 16in. to 18in. long, one end being ½in. thick, the other end 0in., and varying in width from 4in. to 8in.; they are nailed on a close boarded roof, breaking joints, and exposing some 4in. of thick end to weather; very much resembling plain tiles on roof, but laying closer like slates. These shingles will last some thirty to forty years on a roof. Fireplaces in houses are not required, as the cooking stoves in use have pipes run through roof, or one side of house, in an opening surrounded by air-chamber. These stoves stand independent on one side of room, having oven, hot-plate, with several openings and covers, whereon the cooking pots are placed; are heated with wood sawn into various lengths of 18in. to 24in., giving out great heat through the house—in fact, saving all that "waste of fuel" in English houses passing up the chimney. (See pp. 436, 514, 561, 589, 609, Vol. XIV.) The flues from these stoves may be carried up through ceiling, with elbows about the upper rooms, and give the whole house a genial temperature. These stoves are also constructed in the United States for burning coal. They have a good draught, no smoke escaping; are clean, as no ashes come from them during the day; and they are the greatest utilisers of fuel and heat. They have seventeen articles of furniture with them at the time of purchase, and cost from to 20 to 30 dollars, or £4 to £6. Canadian farmers know well how to economise everything to advantage; the ashes from these stoves are carefully preserved for the purpose of making soap. The maple trees growing in the bush are tapped, and rough hewn troughs are placed to catch the sap for making sugar; and other trees also for vinegar. The bush produces abundance of fine wild strawberries, cherries, plums, nuts of various kinds, all of which are of larger size than grown in cottagers' gardens in England.

Canada, May 30. GILLEM.

THE RECENT DISASTROUS EFFECTS OF LIGHTNING.

[4392.]—It is worthy of notice that lightning has latterly been more destructive than has been known for upwards of half a century. Various physical commotions of serious import have also occurred—such as the earthquakes in California and at Antioch, in Upper Asia, Australia, and Iceland. The commotion of Vesuvius, too, has been notable, and still we find hurricanes, as at Zanzibar and Madras, and the lightning in this country more destructive than usual. It is recorded no less than thirteen churches have been struck by the electric fluid in less than two months; the most notable are, for instance, Bampton, where the fluid struck the spire, and the force displacing ten courses of stonework on the north side, or about 15ft.; the church at Mashbury, Essex, was set on fire, and with difficulty subdued; and at Rainham, East Kent, the spire, I believe, was completely destroyed. Several people have been struck and injured; the most notable case being the detachment of volunteers at drill who were caught in a storm somewhere in Dorsetshire on Whit Monday, and several more or less injured and paralysed. Trees innumerable have been levelled to the ground in various parts. Houses, at several places, as at Tamworth and Deptford, have also been struck and set on fire by the electric fluid. H. B. E.

COMPRESSIBILITY OF THE ATMOSPHERE.

[4393.]—Under the above heading (letter 4040, page 151), Mr J. M. Taylor asks an explanation concerning "the well-known phenomenon the rise of a bullet from a gun above the line of aim," having also previously stated in same letter "that the bullet fired horizontally from a gun must be deflected upwards." Is Mr. Taylor referring to the line of sight or to the axis of the barrel? If to the former, he would be right. All guns are thicker at the breech than at the muzzle, and the line of sight, therefore, taken along the outside of the gun, is not parallel to the axis of the bore. This, though not very apparent in a rifle, is plainly manifest in a great gun, and the consequence is that the bullet crosses the line of sight at a greater or less distance from the muzzle according to the disparity of thickness between the breech and muzzle. But if Mr Taylor imagines that the bullet, after discharge, is really deflected upwards, that is to say, rises above a prolongation of the axis of the bore, he is labouring under a great, though possibly a popular delusion. If Mr. Taylor will refer to "Rifle Exercises and Musketry Instruction," pp. 155 to 168, or to "Gunnery Instructions, Great Guns," pp. 32 to 35, he will find everything fully explained with diagrams which will soon disabuse his mind of such erroneous ideas. Either of the above books, price 1s., can be obtained from any bookseller who keeps military books. I observe that Mr. Taylor (letter 4250, page 279) states that he has by experiment satisfied himself about this upward deflection. I am curious to know the nature of his experiments, and strongly suspect he has been practising with the old "family blunderbuss," of whose capabilities I am willing to believe anything. T. S.

COLOURED SUNS.

[4394.]—In the article on Mr. Proctor's "Essays on Astronomy" (No. 376, p. 291), five misprints which occur in that volume are given. I find, also, an error in the essay on "Coloured Suns," reproduced in your No. 376, p. 297, where the components of that beautiful double star (Mirac) ε Boötis, are given as "nearly equal." Webb, in "Celestial Objects," gives the magnitudes as "3 and 7," which accords with Mr. Proctor in that useful little book for beginners, his "Half-hours with the Telescope," p. 60. The merest tyro with the telescope has only to examine them to discover that they are unequal.

We all know how easily errors creep into the most carefully-written book, and the wonder is how so few are found in Mr. Proctor's works, from the great number of papers which have emanated from his pen; as you truly say in the above article, "Scarcely are the sheets of one of his books dry from the press, when he is again before us with another." LINEA.

THE SUN.

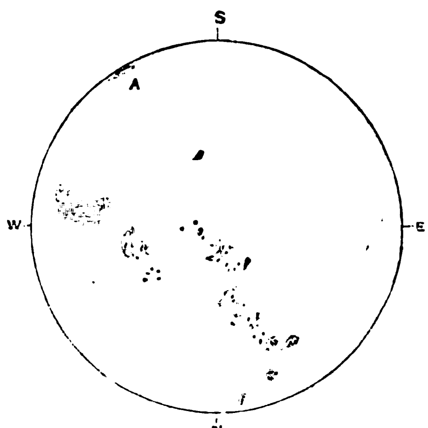
[4395.]—The faculæ observed on the sun on May 27, and of which I gave a description in letter 4284, p. 302, have given place to a large and scattered group of spots in their return at the opposite edge of the disc. Through continued bad weather I was prevented from seeing their first appearance, and even on June 8, doubtless the third day from their arrival, I was only for a few minutes enabled to observe them. The group is headed by a large and oval-shaped spot containing 6 (?) umbræ, followed by a confused mass of light penumbra. Round these are a quantity of small outlying fragments detached from them. The group is closed by a second and smaller oval spot also containing several umbræ.

The time which I was allowed for observation was too short to enable me to see much detail; but I could, however, distinguish that the neighbourhood of the group was still brilliant with luminous matter.

P. W. WYATT.

SUN SPOTS.

[4396.]—I beg to send you a sketch of the sun, taken June 9, 1872, 4.30 p.m. Greenwich mean time, with a 2in. achromatic, 90 diameters.



The three groups were very beautiful and well defined. The spot marked A was nearer to the edge of the disc than I have before seen one, in fact, it appeared like a rent in the usual sharp outline of the edge of the disc. T. H. F.

PIANOFORTE BELLYING AND BRACING.—II.

[3497.]—With regard to the thickness of soundboards, I may remark those constructed by different makers of good instruments vary considerably. Some makers prefer rather a thick belly, others a very thin one, rather stiffly barred. Probably, the latter affords the loudest sounds, especially while the instrument is new, and it is its tone—next to the beauty, *alias* gorgeousness, of its case—which sells the piano; occasionally, the purchaser also. Some men, like the Cremona fiddle-maker of old, work for posterity; they are content to sacrifice some power of sound, and to produce great present excellence, combined with durability, and the capability of improvement in the future. Such men make pianos with rather thick soundboards, others (who are disciples of the wise Irishman, who said, "Posterity never did anything for me, so I can't see why I should do anything for it") prefer making more noise in the world (or rather that their instruments shall), so they make pianos with thin bellies that their sounds may be as loud as possible at first, wisely leaving posterity to take care of itself. Probably, they are not far from being (commercially) right, thinking their instruments will last their time—at least, long enough for them to make their fortunes.

The thickness of soundboard ought, I think, to be in proportion to the hardness of the wood of which it is made, as well as in proportion to the weight and tension of the strings with which it is to be connected. Probably, the kind of wood employed is of far less importance than is generally supposed, but I believe good proportions to be of far greater importance than is generally known. I once saw a belly made of good beech wood, barely three-sixteenths of an inch thick, which yielded very pleasing and powerful sounds, and I have heard excellent pianos whose bellies were made of clean spruce deal, also others with American pine bellies. As a rule, the softer the wood, the thicker it should be. I think it would be preferable to make soundboards for trichord instruments a trifle thicker than for bichords, besides increasing the depth of the belly-bars for the former, and for very thick strings I opine the soundboard ought to be thicker than for thin strings, just as the soundboard of a harpischord, the middle C of which was of No. 6, or at most No. 8 wire, was made much thinner than the belly of a modern piano is, whose middle C is strung with from No. 17 to 19 wire. It should also be more stiffly barred because—supposing the down bearings, or rather the amount each string is deflected to remain the same—it is obvious three strings of the same length and thickness must press on the bridge with 50 per cent. more force than two can do, but, strange to say, many pianoforte makers use the same bellies for both bichord and trichord instruments, which may account for the trebles of so many of the latter being inferior to those with only two strings to each note.

The soundboard of the instrument represented by Fig. 1 (p. 618, No. 362) was to have been made of best Swiss pine for about half its height, three-tenths of an inch thick, for about the two upper octaves, and its thickness gradually reduced to two-tenths of an inch at the lowest bass. I don't think I can improve these proportions. The grain of the wood seems best horizontal, or nearly so, say at the angle of 90, with the strings of pitch C. Assuming this belly to have ten bars, I should make them of ⅞in. spruce deal, their sections 1¼in. by ⅞in., and taper them pretty regularly, not suddenly, as is commonly done, from beneath the bridge to their ends, which I should leave about two-tenths of an inch thick. The form of their top surfaces should be a circular arc, not two straight lines meeting at the bridge. As I before stated, I think it would be an improvement to introduce two more belly-bars in the high treble. If this be done, probably they would be quite rigid enough if made ¼in. shallower, but it is far preferable to err on the side of excessive stiffness, especially in the treble, because a weak soundboard is quite incompatible with fine quality of tone in that part of the compass. Should the belly be found on trial to be too stiff for the strings, the application of the chisel or a small thumb-plane to its bars will readily correct that fault. On the contrary, as I know from old experience, to my sorrow, it is far more difficult to correct weakness of the belly, in pianofortes, for this can only be done by the judicious employment of additional belly timber, applied either to the old bars to make them deeper, or to the belly itself in the form of additional bars, not very easily jointed to it.

With regard to the adjustable down-bearing of the strings on the solid metal bridge (on the wrest-plank) mentioned, I should have thought my remarks could only have been understood as referring to the bridge on the wrest-plank. A solid metal bridge is now often cheaply made by grooving the wooden bridge to fit and receive half the circumference of a brass—or what, perhaps, is preferable, a copper—wire, from three to four-twentieths of an inch diameter. To make the best possible job of this, the wire should have a flat (whose breadth is about half its diameter), filed on that part of its lower surface which is not imbedded in the wooden bridge. N.B.—This flat ought to extend up to the highest part of its circumference, so that the strings cannot possibly touch the wire bridge below its centre. The purpose of making this flat is to prevent the possibility of the strings chattering against the bridge below the centre of the latter. Unless this flat be made, they sometimes do so to an extent which (although, perhaps, not recognisable by the unpractised ear as chatter) is readily recognisable as impurity of tone. So the writer—who is a man of few words—hereby cautions an intending constructor to take the precaution to file this flat (which prevents what other flats are often guilty of) on his wire bridge, so that neither he nor the writer may be annoyed by what the latter detests—"mere chatter."

If this wire bridge be well fitted in its groove, and sunk therein about four-sevenths of its diameter, there is no risk of its coming out before the strings are put on; and, considering every one of them helps to press it down in its groove, it can't well come out of it after they are on. It may, however, be yet further secured by a few wire pins about one-twentieth diameter, driven through holes bored in it into the wood beneath it. Or, yet better, by a few staples which embrace it similarly driven. I prefer not trusting entirely to the carefulness of the workman—usually, rather a doubtful quantity—who "routs" out the groove for the wire; he may not "bed" it perfectly throughout it's length, so I think it preferable to divide it into pieces about 6in. long, and introduce into the groove a moderately thick coat of my "patent adamantine cement." See article on Bracing in No. 362. Before fixing the wire bridge, it is also desirable to subject it to pressure, by go-bars, or otherwise, until the cement has become hard; but as that pressure should be applied throughout its length pretty equally, not locally, which might bend it, a piece of thick wood ought to be interposed between the ends of the go-bars and the wire bridge.

I know no good reason, but only a very bad, if sufficient, reason, why the strings of a piano should not rest on, and be confined to the belly-bridge by the same means. If short pieces of half-round wire, each just long enough to support the strings of one note, be fixed on the belly-bridge, and a small wood screw—about ⅝in., No. 6—employed to deflect, or what would be far preferable, to clamp the strings on this short transverse wire, they might be firmly held to the bridge without deflecting them any more than is needful to give them the proper amount of down bearing, which, for very heavy strings, may be very small indeed—not more than 2 to 1½ per cent. of the tensile force at middle C, and below that note. I have repeatedly advocated this simple and cheap method of connecting piano strings with their belly-bridges, but the pianoforte manufacturers, who employ tuners, say the latter can't be trusted to slacken the clamping screws, which affix the strings to the bridge when it becomes necessary to "pull up" the piano, and that if this be neglected, they must needs "pull up" the bridge and the soundboard along with its strings. Probably, the pianoforte-makers are not far wrong. *Experientia docet*, they should know best how far tuners are to be trusted; but to an outsider like the writer, it seems no more than just that any tuner who neglected to slacken clamping screws ought to be "pulled up."

If it be preferred to cause the strings to bear firmly on the wire bridge, by deflecting, instead of clamping, them to it, which I think it generally would be, at least, on the wrest-plank, it may be done several ways. By far the cheapest, simplest, and most effectual method I have yet seen is that employed by our ingenious fellow-correspondent Mr. Schucht, which I now proceed to describe.

Mr. Schucht inserts a common rose or cheese-headed wood screw between the strings of each bichord note, and deflects them to any desired extent by turning the screw. No doubt, as he don't employ any washer or cross-bar, he rounds the edges of the under surface of its head, so that its original sharp edges may not injure the wire. Probably a metal, a hard leather, or a vulcanite cross-bar, with its lower surface which touches the strings rounded, or formed a segment of a cylinder, would be preferable to the employment of the naked screw-head; but, so long as its position remains unaltered, it cannot much matter. It is obvious that the lower the head of this screw is the more it must deflect downwards the strings which are supported on the wire bridge, so he thus obtains the "adjustable down bearing" very cheaply—in fact, you may increase it to your heart's content. By the same means, if a cylindrical-faced washer and two screws be employed, trichord notes may have their strings deflected—nay, this may be done effectually with only one rather stronger screw, say No. 10, if the washer be of metal, and long enough to press on the six strings of two adjacent notes. Sooth to say, this is the very method intended to be employed for all the trichord notes of the piano partly specified on p. 562, o. 360.

It must be obvious that this method might be applied to the strings of a piano throughout its compass to great advantage, instead of single or double pinning the wrestplank bridge and trusting to side bearings for determining the lengths of their vibrating portions, and keeping the strings firmly attached to their bridges; indeed, Messrs. Erard actually employ almost identical, but rather more costly, means in their pianos with upright strings. It might add a trifle to the cost of construction, but the instrument thus made would certainly be well worth the small additional expense it entails. There can be no difficulty in carrying it out when used for the single strings of the lowest bass notes for one screw, and a cross-bar or washer would as certainly deflect or clamp the strings of two such notes as it would the six strings of two adjacent trichord notes. No doubt this is but the old transverse pressure bar cut into short lengths, but the doing of this is attended by the advantage of not obstructing the putting on of new strings in lieu of broken ones, for they can just as easily be passed under the transverse washer as passed alongside a bridge pin.

I notice "T. C. L." represents the wooden brace in his drawing in No. 364, p. 665, with a portion of its material removed extending from the centre of its back nearly to its ends. May I request him to inform us the purpose of this? Certainly it cannot be to make the brace any stronger, for addition to, rather than subtraction from, its material would be required for hat purpose.

THE HARMONIOUS BLACKSMITH.

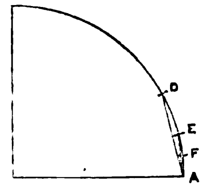
A WONDERFUL CRATER.

[1398.]—AT p. 95, of the second London edition of Tyndall's work, "Heat as a Mode of Motion," is the following note: "Professor William Thompson has recently raised a point which deserves the grave consideration of theoretic geologists. Suppose the constituents of the earth's crust to contract on cooling, solidifying, as the experiments thus far made indicate, a breaking in and sinking of the crust would assuredly follow its formation. Under these circumstances it is extremely difficult to conceive that a solid shell should be formed round a liquid nucleus." In reference to this matter I would say that, on this island there is an active volcano, in the crater pit of which I have seen phenomena that would certainly go to corroborate any experiments, the result of which would indicate a breaking in and sinking of the crust. Allow me to describe a wondrous scene. The crater of "Kilanea" is a huge black pit, the walls of which are 1,000ft. deep. Its diameter is three miles. The floor and walls are formed entirely of lava. In this gigantic laboratory of Nature I saw seven "lakes" of boiling lava—in its action as free as water. In the largest of the lakes the lava was rolled and tossed into waves just as is the ocean by the wind. Entranced, for hours I stood and watched the wondrous sight, the night being dark and fine. In the other lakes the agitation I have spoken of was absent—*i.e.*, the rolling and tossing into waves; there was some action, however, but not of anything like the same intensity. And now let me speak of what I especially desire to call attention to. Ever and anon the surfaces of these six lakes would cool, and as the heat radiated the brilliant red of the molten lava became less bright and the thin liquid state changed for one of rigid solidity. The lake, in fact, became crusted over by rock. This condition lasted but a few moments, the cooling and contracting proceeded so rapidly. What but a few seconds before was brilliantly red molten rock, was suddenly transformed into dark, black lava. This immediately cracked in a hundred directions. The crust broke up into innumerable pieces, toppled over, and sunk into the molten mass below. Again, it became a lake of liquid fire, only after a few moments to be crusted over as before, which incrustation in its turn cooled, cracked, and sunk. And so the process continued. When the surface cracked, the eye felt smitten with the vivid beauty of the scene—the intensity of the light streaming through the breaking lava with electric brilliancy.

Hawaii, April, 1872. C. F. HART.

GEOMETRICAL APPROXIMATION TO $\frac{\pi}{2}$.

[4399.]—YOU may, sir, think the following result worth communicating to your readers, if I state that, after careful study of the subject, I know of no *geometrical* approximation to the quadrature of the circle, combining in an equal degree simplicity of construction with an extraordinary degree of approximation. It is one result of a theory which I published some years ago, and with which I will not further trouble your readers.



Let A D B be a quadrant of a circle, A E D one-third of it; bisect the latter at E, and A F E at F; join A D, A E, A F, then shall the expression 17 A F $- 3\,AE + \frac{AF + 5\,AE + AD}{15}$, which, in the form given here, is of very easy geometrical construction, exceed in value the quadrant A D B by less than $\frac{\pi^8}{5040 \times 24^6}$, or one-1001840000th of it.

To form an idea of the degree of approximation thus obtained, imagine the construction applied to a quadrant ten million metres in length (equal to an earth-quadrant), and the error committed would be less than one centimetre, although the smallest chord used in the construction would exceed 800 kilometres in length.

Denoting the ratio of the chord of an angle α at centre to the radius by *chd.* α (which means simply that *chd.* $\alpha = 2 \sin. \frac{\alpha}{2}$), it follows that $17 \text{ chd. } \frac{\pi}{24} - 3 \text{ chd. } \frac{\pi}{12} + \frac{1}{15}\left(\text{chd. } \frac{\pi}{24} + 5 \text{ chd. } \frac{\pi}{12} + \text{chd. } \frac{\pi}{6}\right)$ exceeds $\frac{\pi}{2}$ by less than $\frac{1}{10^9}$ of its value. C. J. RECORDON.

SOME THOUGHTS ON THE DEFECTS IN HARMONIUMS.

[4400.]—THERE are a few little defects to be met with, and improvements wanted in the generality of cheap and even good harmoniums. If these defects were remedied and the improvements carried out, these instruments would be much more pleasing and popular than they are at present. The following are the most noticeable imperfections:—

1. The Reediness and Harshness of Tone.—The tone of the harmonium depends principally on the voicer; a good and proper quality of the brass for the reeds, and a suitable pressure and supply of wind are indispensable.

2. The Preponderance of the Bass.—This is a serious fault, in most instruments we find the bass is much too powerful for the treble. I think that the reason of this is, that if the bass reeds were made softer, they would be slow in speech. How often do we hear people say that the harmonium is so "noisy," or that it makes such an unpleasant "buzzy" sound; now, if a little more care were given to the reed work, these remarks would seldom be heard. If the tone of the instrument is bad it is not only offensive to the player, but also to the hearers, whereas, if the action is at fault the player only feels its effect.

3. The Forte Stops.—The utter uselessness of these stops in many instruments is very apparent. The principal object seems to be to increase the number of the knobs over the keys; in other words, for "display." I have seen and tried several instruments where they do not make the slightest alteration in the volume of sound.

4. The Sourdine.—This stop is for a somewhat similar purpose as the forte stops—viz., "display." The principle of it is bad, as the supply of wind to the reeds is of such a limited quantity as to prevent the full articulation of an ordinary four-note chord in the bass; and if the valve is opened enough to supply a chord of four notes, it becomes similar to the stop from which it borrows.

5. The footboards are frequently placed at a very inconvenient angle for the foot; this is easily remedied by lengthening or shortening the connection from the boards to the lever. The springs inside the feeders are often too strong, causing fatigue to the player.

6. The drawstop action is frequently noisy; the stops fly in with the least touch. If there were less play at the centres this would be remedied.

7. The Rest for the Music.—The want, and in many cases the utter absence, of a proper rest for the music is easily to be rectified, and it would conduce not a little to the comfort of the player; for what is more annoying than for the book to slip down on to the keys, or for the leaf to turn over in the middle of a page.

I next come to consider briefly a few improvements which might be introduced with good result in the cheap harmoniums, at a very little cost.

1. The shape of the cases might be much improved by letting the keys stand out (say) 6in. from the front of the case; this would bring the keys into a very convenient place for the performer, and would enable him to play without having to stretch so far. If the centre part of the lid were made to slant similar to a "secretaire," the shape would be much more elegant. Messrs. Mason and Hamlin have introduced some great improvements in the form of the cases in their American harmoniums.

2. The introduction of a wind indicator is a great boon to the player; it enables him to tell the quantity of wind in the reservoir. This contrivance is placed over the keys.

3. It is very desirable that in instruments where there are two or more sets of reeds, the tone of each set should vary. As a rule, the bourdon and clarionette stop (especially the bass) is much too heavy in comparison with the other stops. I think that the 16ft. stop should form the *third* set of reeds, and not the *second*, as is generally the case. If there is but one set of reeds in the instrument, of course it should be of 8ft. pitch; if there are two sets, they should be of 8ft. and 4ft. pitch, the latter voiced softly. This plan is carried out in the Mason and Hamlin harmoniums with good effect.

The drawing-room models by Alexandre, and the cabinet harmoniums by Mason and Hamlin, are very free from the defects I have noticed. The tone is very fine. The two-knee swell pedals in former are immense improvements, one is applied to the treble, and one to the bass. The swell in the Mason and Hamlin instrument has a fine crescendo, as nearly approaching the swell of the organ as possible; these instruments have castors on the bottom, on which they can easily be moved to different positions in a room. PNEUMATIC LEVER.

ANTS IN THE ISLE OF MAY.

[4401.]—As I have lately seen in your paper some correspondence about getting rid of ants, I think that it may interest many of your readers to hear that in the Isle of May, off the coast of Fifeshire, the whole soil is simply swarming with ants, of which there are, I believe, two kinds on the island, neither of which is common on the mainland. A short time ago a trip was made by some of the authorities, together with some scientific gentlemen, to try various methods of getting rid of this pest. Dilute carbolic acid was found to answer well in killing the ants, but, of course, the whole island could hardly be irrigated with this mixture. A suggestion was made, of a more practicable nature, to turn up the soil to the rain and frost of a winter, at the same time applying lime. I have not, however, yet heard whether any plan has been finally settled upon.

N. OR M.

FINDING INTERNAL RESISTANCE OF A BATTERY.

[4402.]—I SEND the following method of finding the internal resistance of a battery, which, as far as I am aware, has not yet been suggested, and which recommends itself from its simplicity and accuracy. If a battery be connected up in circuit with a galvanometer to any resistance R, and the deflection be observed, then if R be reduced in value to r, and at the same time a shunt S be adjusted between the poles of the battery b, until the deflection is the same as before, we have between the resistances the simple and readily proved algebraic relation $b : S :: R - r : r$. Hence, by a device, we may make $R = 2\,r$, in which case $R - r = r$, and therefore $B = S$. The following simple rule, therefore, presents itself by which the resistance of a battery may be at once found by simple inspection: Connect the battery up to any convenient resistance with a galvanometer in circuit, noting the deflection; then take out one-half the total resistance (if the resistance of galvanometer be comparatively small it may be neglected practically), which includes that of galvanometer, and adjust a shunt between the poles of the battery until the same deflection as before is given; then the resistance of the shunt equals that of the battery. One advantage of this plan is that being a null method (it being merely a question of equal deflections) any galvanometer, even one without an accurately graduated scale, suffices; also, no calculation is required—the operation may be performed in a few minutes. I have also practically proved the accuracy of the method by means of a Thomson's reflecting galvanometer and accurately adjusted resistance coils, the correctness of the principle being further checked by comparing discharges of a condenser connected first with the insulated pole of the battery, and, secondly, to the same pole after being connected to the resistance found, when the value of the throw of the needle in the latter case was ex[illegible] half that in the former. If any of your readers w[illegible] like the algebraic proof, I will send it for your [illegible] number.

S.[illegible]

BRANNAN'S SYSTEM OF MONOLITHIC BUILDING.—To "KHODA BUX" AND OTHERS INTERESTED THEREIN.

[4403.]—WHEN, about a year and a half ago, I put forth—in Nos. 291, 296, and 320 of the ENGLISH MECHANIC—my notions how carriage wheels, chairs, sashes, and other articles of utility might be cheaply constructed by forming their skeletons of steel wire, placing them in metal moulds—which might be heated to any temperature found desirable—filling up some of the interstices with fibrous materials, and then cementing the said materials and wire skeletons into single masses, whose forms are those of chairs or wheels, which would, for all practical purposes, be without any joints (and joints, however carefully made, almost certainly yield to the strains chairs and wheels are subjected to in ordinary use), I only published an idea which had long been familiar (at least to myself), for the method of construction I suggested is but a modification of the manner in which articles have been constructed in *papier-mâché*. Certainly I had no thought that my suggested application of that old principle, on which all mill boards and papers are made, deserved to be termed an invention in the sense of being sufficiently novel to be the subject of maintainable patent right, although it must be admitted it was—to the best of my knowledge—a novel application of old and familiar means to the cheap production of many articles of domestic utility and personal comfort which, when thus made, would be almost everlasting. I may remark, *en passant*, that this kind of furniture might be made in the most elegant forms—a thing of beauty is said to be a joy for ever—which our æsthetic taste, or the want of it, is capable of designing, for as little, or even less, cost, than the usual cost for which our ordinarily very ugly furniture is now produced. That some younger man, with more energy and enterprise than a life of labour—at least of brain work—has left in the writer, will in time improve on and work out his idea—probably with great commercial profit to himself and, he hopes, with some social benefit to his fellow-humans—the writer feels a confident hope. He, however, never anticipated the application of wire skeleton-framing to the construction of the walls, floors, stairs, and roofs of houses, although this really bears about the same relation to its employment for chairs, &c., as the door-mat is popularly said to be to the doorstep; it being, in truth, but a step farther in the same direction. Now, I am glad to find this "stepfather" has been taken by Mr. P. Brannan, C.E., who constructs not only the walls of houses on this system, but also their internal and external stairs, their sashes, floors, doors, roofs, and even their architectural ornamentation on this same principle.

In Mr. Brannan's system the floors, instead of being supported on beams or joists (which can only resist pressure and percussion by their strength and rigidity, the latter depending, *cæteris paribus*, on their depth) are, if I rightly understand, simply a network of wire filled in by concrete, which resists those forces by its tenacity. To obtain sufficient rigidity the thickness of the floors is increased far beyond what is necessary for mere strength. They are yet, however, but from one-fourth to one-third as thick as wooden floors and ceilings of the same area. So remarkably rigid and tough are the floors he constructs that one only seven weeks old, measuring 14ft. × 10ft. (which was supported on but three of its sides, it being attached to walls on three sides only and one side left without any support) only communicated a slight jar to the hand held against its under surface when an anvil, weighing about 2cwt., was suffered to fall on it from the height of about 2ft. This is a trial few cottage-floors may I not say few of those of even high-class houses—would bear without a dangerous amount of vibration being induced. After this *experimentum crucis* a large wood fire, which well-nigh filled the room, was lighted on this floor (whose flames played against the ceiling) and kept alight for more than two hours, but, the materials of this house being quite uninflammable, no damage was done excepting that the steam generated caused some flaking off of portions of the new ceiling which had been plastered too recently to have become dry. The floor and walls, so far from being damaged, were rather improved by this not very gentle experiment, they being semi-vitrified.

As I before stated, I fully expect chairs, wheels, &c., constructed on my system would come out at a much lower cost than those made of pieces in the usual manner, because those pieces of wood must be cut out of timber previously sawn into planks with much waste of labour and material, besides which, their jointing, carving, smoothing, finishing, and polishing by hand is necessarily expensive, and likely, from that general rise of wages which now prevails, to become yet more so. Now a chair or wheel, literally *cast* in a smooth metal mould, could at most only require the two latter operations—perhaps only its polishing done by handwork to prepare it for use; and if this be the case with chairs, doubtless Mr. Brannan's moulded sashes, chimney-pieces, and doors may be produced at comparatively little cost by the same means. Like my chairs and wheels, they could hardly tumble to pieces, seeing they are not formed of pieces, but in one piece only. In fact, as he expresses it, perfectly monolithic, like the houses he constructs.

With regard to the cost of the latter, we may expect—from their cheapness and the comparatively small quantity of materials required for walls of given strength—it to be low. He states it to vary from 15 to 40 per cent. less than that of building with brick and timber, according to local facilities for procuring materials; he also says no "skilled" labour, using that word in its ordinary sense, is needed for building walls, &c. Sure-ly, as my correct cockney friends pronounce the word, something like this must eventually be a boon to us of the "great middle middle" class, who find our families, rents, and "income tax" so heavy; not to mention that if three labourers' cottages, enormously more durable and of a quality vastly superior in sanitary qualities to the hovels they now—I was going to write live—well, exist in, can be erected for perhaps rather less than two of such "suburban villas" now cost, we may hope to effect both sanitary and some moral reform also, for then our agricultural population need hardly continue to rival their pigs in the matter of sleeping "accommodation." In other words, the young (human) pigs might "enjoy" a separate dormitory, and no longer "pig in" along with their remarkably "moral" piggish parents.

I am informed some erections on this system have been made on this system at Bell Busk Village, Edmonton, and some others near Bow (where eighty houses have been commenced), an extensive reservoir near Durham, and a large villa near Sunderland. It is also intended to build about thirty houses on this system at Islington, so we have, or shall soon have, ample means of testing its work, although I think "it stands to reason," as the ladies say, that a wall or floor in which the tensile strength of iron or steel wire is employed to resist force must needs be much stronger than one which depends for its power of resistance on the tensile strength (query weakness) of mortar.

THE HARMONIOUS BLACKSMITH.

P.S.—May I request the favour of "Khoda Bux's" opinion on this method of monolithic construction; also the criticisms of others of my fellow readers who "knaw zummat aboot" building, which is, alas, a very expensive luxury, when our notions are carried out for us by architects and builders who only know how to employ stone, or brick and timber, in their constructions, some of which—even when in the desired form of suburban villas—are not quite so tough as wire, or even so strong as first-class concrete, without wire ties, not to mention that, being extremely inflammable, they are occasionally burned, and have to be insured, which adds something to their cost, and also, of course, to the rent we have to pay for the privilege of inhabiting them, besides which, I have found the keeping of ordinary houses in repair cost just a "little something" of money.

USEFUL AND SCIENTIFIC NOTES.

Distillation of Wood.—Mr. Watson Smith gives the result of his experience in the distillation of wood, principally oak, on the large scale, as follows:—Using retorts from 6ft. to 7ft. long and from 3ft. to 3½ft. in diameter, which were charged every morning, the distilling operation lasted eleven hours; using old oak timber, cut in pieces 2ft. to 2½ft. long by 3in. or 4in. square, the yield was, of charcoal 327 parts, of wood-acid 509 parts, and of tar 55 parts from a thousand of wood. To carbonise a ton of wood required 10½ cwt. of coal. The wood-acid has a specific gravity of from 1·025 to 1·027, and contained acetic acid in the proportion of 20 parts for each 1000 parts of wood distilled. Of wood-spirit, 1000 parts of wood yielded from 56½ to 85 parts. This, after two rectifications from lime, constitutes the wood-naphtha of commerce with a specific gravity of 0·880.

Continuous Battery. — In the cell contrived by Herr Kohlfurst the negative plate is formed of a truncated hollow cone of copper, closed at the top. The inside of the cone being protected with varnish, it is filled with sulphate of copper in crystals and inverted in a glass vessel deeper than itself. The cone is notched around the rim, and the apex is pierced with a small hole. For the positive element, a thick cake of zinc is used (suspended over the face of the cone); it has a hole in the centre, through which is passed a covered wire connecting with the copper. The glass cylinder is then filled with water, and the sulphate of copper begins to melt, the rapidity of the deliquescence varying with the access of the water through the notches in the cone; and so long as this latter maintains a uniform rate, the current will be uniform in power. If common or Epsom salt be used in the water, the current will be intensified. The inventor states that 1½ pounds of the copper salt will continue the battery in operation for a year.

A Pretty Parlour Ornament.—An interesting ornament for the sitting-room or parlour may be easily obtained by growing one of the club moss tribe under a glass shade. Procure an ordinary glass shade, such as are used to protect small vases and other articles, and of any size that offers—also a china dish that is two or three inches deep, or a common flower-seed pan. Fill the latter with light soil, as vegetable mould or sand, and get from a nurseryman or florist a plant of one of the common varieties of club moss—place this on the soil in the pan, and then the glass shade over it, pressing it down a little into the soil. The earth being kept moist, this moss will grow rapidly, and will climb up and fill the inside of the glass. It requires to be kept in a window near the light, and soon becomes a pleasing object from the delicate texture and form of its ramifications. Although the moss requires to have a constantly moist atmosphere within the glass, yet it takes but little water, because the evaporation from the soil condenses on the inner surface of the glass shade, and descends in the form of water down it again. The shade should never be taken off. When the water is needed, a small quantity may be poured between the outside of the shade and the side of the pan, which will find its way under the edge of the glass to the earth which is inside.—*Cor. Country Gentleman.*

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[10478.]—**Pork Diet.**—In the first place, I ask "Sarah" seriously is she playing a joke with her fellow correspondents? if so let her refrain from doing so again. I might partly believe her about shell-fish, which I never eat, not that I think them unfit for human consumption, but do not like them. What cause has "Sarah" to imagine that the meat of the pig is not fit to eat? Perhaps because the Jews do not eat it, or perhaps because the pig is a dirty animal; and why does she consider rabbits also unfit to eat? Why does she not include the hare, which tastes much the same as the rabbit? I hope "Sarah" will bring forward some proofs evident of the unfitness of pork and rabbit meat and shell-fish for human consumption. I hope there will be many letters on this subject, at the same time hoping my letter may find room in the widely circulated ENGLISH MECHANIC.—A. H. COOKE, Cologne, Prussia.

[10661.]—**Angle of Reflection and Incidence.**—With all due deference to "F. N.," I think "Billiardist" has established his theory (p. 100). Will our kind correspondent oblige me with the details of the experiments of M. Athanase Dupré with balls suspended by threads, striking each other horizontally?—JACK THE FLUKE-MAN.

[11378.]—**Stings of Bees.**—Amongst the various cures for stings, I have not seen the leaf of the common dock mentioned. Now this I have always found very effectual. As boys we used to say a nettle sting did not matter, as where nettles grew we were sure to find docks to cure the sting at once. And so with wasps, &c. Some time ago a wasp stung me in the neck when I was out; I got a leaf of dock and applied it and felt no more. When stung take care the sting is not left in. Bruise a fresh dock leaf and rub it on the place.—E. T. S.

[11554.]—**Pedestrian Tour.**—"Hedera" asks me if canvas shoes will stand a walk through wet grass, or a ford across a stream. The canvas lets the water in, but some do not object to that if they have dry stockings to change and slippers. I soak into mine a preparation of oil, wax, and lamp-black, used for rendering leather shoes soft and waterproof, and my feet keep as dry in my canvas shoes as in my leather ones. Stockings are more frequently made damp by perspiration than by water from the outside. My canvas shoes have triangular pieces of elastic at the side. "Hedera" is quite right in preferring flannel to linen shirts, or even to cotton or merino, any of which are preferable to linen for a pedestrian. He may, if he likes, wear a linen front, but a linen shirt will probably give him a cold.—PHILO.

[11564.] — **Blackberry and Strawberry.**—"E. L. G.," on p. 307, speaks of the red raspberry being produced from seeds obtained from a barrow skeleton. I can inform him that in the neighbourhood of King Alfred's Tower, visible from the railway between Salisbury and Templecombe junction, near Wincanton, Wiltshire, this kind of raspberry grows abundantly, as also a wild strawberry of good flavour. The locality is reputed to be the scene of a great battle between the famous Saxon King and the Danes, who suffered a defeat on the slope of the hill, where the slain were buried in great trenches. When travelling between Keswick and Penrith, just after rising the hill beyond Greta Bridge, I once enjoyed a banquet of raspberries growing wild in a large patch of bushes on the wide open road, and apparently indigenous.—P. FRANCE.

[11589.]—**Dry Steam.**—I do not think that either "Caloric" or "E. L. G." understand my position correctly, so I will endeavour to explain more fully. If we take a boiler with steam at 8lb. per inch and pass that steam through tubes in a furnace, it becomes what is popularly called superheated, but what I term higher pressure steam; and if the communication is open to the atmosphere, it will fly out, because of the pressure above that atmosphere in the boiler; but if we close the valve it will rush into the boiler, but will produce little, if any, increase in the pressure, because the area of boiler is so much greater than the surface of pipes, and the loss by radiation so great, added to which the diminishing power of conducting heat due to its smaller quantity of water in a given volume prevents its being generated sufficiently rapid to counterbalance these losses. Let me ask "Caloric" to put some water in a pipe and stick in the fire (having previously effected a policy upon his life in favour of next of kin), does he imagine that when all the water was converted into steam, he could go on increasing the heat without also increasing the pressure? As for "E. L. G." he carps at terms, but evades my statement, that in a given volume of low pressure steam there is more water than in the same volume of high pressure steam. If he places his hand in the steam issuing from a high pressure boiler he will find that it is very hot, but being a bad conductor, owing to the small quantity of water contained in it, it does not burn like the low pressure does. Although well aware that the temperature is lowered as the steam escapes into the atmosphere, I have not observed any considerable blocks of ice about the safety valves of high pressure engines lately.—A., Liverpool.

[11632.]—**Debility.**—Noticing a few remarks made by Charles Rooke upon the above subject, on p. 308, I beg leave to ask him if he can put some of us in the way of curing indigestion, arising from the above complaint. I have suffered more or less from it for years, and have tried nearly everything, but I think hydropathy did me more good than anything. I only tried home treatment, and now it seems to lose its effect upon my system—I suppose from continued treatment. I am now trying cold baths upon rising (5.30), and take a glass of cold water, and at bed time every other night two pills, composed of 1 part quinine (sulphate), 1 part sarsparilla (extract), and 2 parts of a root that comes from Susquehanna, but I cannot pronounce a judgment upon them yet. If Charles Rooke would give me a few hints he would greatly oblige.—AROMA.

[11656.]—**Boiler for Small Steamboat.**—I stated the dimensions of the boat as 21ft. × 7ft.; it should have been 21ft. length and 4ft. beam.—W. SHEPHERD.

[11656.]—**Boiler for Small Steamboat.**—In the boat you have mentioned the tonnage by the old builders' way of reckoning is about 8¾ tons. In the best examples of modern steamships, both large and small, the proportion of indicated power to the tonnage ranges from 1 to 3 to 1 to 6. Now, in the design I have given I have the nominal power as 2 and tonnage 8¾, so that the ratio is 1 to 4½, about. But I stated that the engine would develop probably 3 or 4 horse-power, so the ratio would be as 1 : 2, which would produce a very fast steamer indeed, probably about five knots an hour. This would be a satisfactory performance for so small a vessel. Mr. Shepherd is quite right in his surmise about the error. It must have been a slip of the pen. As for the double eccentrics, they are for link motion with an elevation. I could not show the link. Where the two rods appear to meet is their junction, one with one end of the link and the other with the other. If there is any difficulty about any detail I will send another drawing. In the drawing I did not go into any detail of the engine, because from the wording of the query I thought that it was only a secondary feature. That was how I omitted to shew the fly-wheel. This should be solid to save room. It should weigh 2cwt., or 1cwt. might do if pinched for space. A governor might be used with great advantage, but in so small a vessel it is questionable whether the extra room, weight, and attention, that it would require would not overweigh all its advantages.—P. W. H. J.

[11663.]—**Steam Power.**—I must claim the pardon of "T. W. J." for not replying to his question sooner. The reason is this, I appear to have lost the number in which his query appeared, and I have forgotten the substance of it. As far as I see, there ought to be four brass tubes ¼in. or ⅜in. diam., ordinary brass or copper pipe. When I used to make models, I tested the boilers in this manner. I got a small brass boiler about 1½in. diam., and 1¼in. high. In the centre of this I drilled a ⅜in. hole, and tapped it. I then screwed a pipe firmly into it, 3in. long. I also screwed another ⅜in. pipe near the top for the supply. From an optician I bought 5ft. of glass tubing that would just fit inside the brass tube; this is then made steam tight with red lead. From a joiner's I obtained a piece of mahogany 5ft. 6in. long, and 2½in. wide, and made a groove along it for the glass tube to fit in, and likewise made an excavation for the small brass reservoir to fit in, to be level with the glass tube. Every 20in. I drove into the wood clasps made of wire to secure the tubing in its bed. I also had two clasps for the reservoir; I then got two strips of paper 1in. wide, and pasted them on each side of the glass tube on the mahogany. On one side I divided it into inches, and every 2in. reckon as 1lb. pressure. On the other side was marked the temperature corresponding to that pressure. The reservoir is to be filled with mercury. It will then test boilers up to 30lb., which is as far as models generally go. The way that I used to do was this—I connected pressure gauge by union joint to boiler, and the boiler with the water tap, which had generally sufficient pressure for my purpose. This is a safer way than testing by safety valve, but would hardly be worth while if the inquirer had not a number to be tested. The model makers sell very fair got-up pressure gauges as regards appearance, but I never heard any one who had one, and who was practically acquainted with its working—which, by the way, with these amateurs is another thing—speak well of them. They may be regarded as wonders if they are correct to 10lb. The fact is, they are got up so cheaply—that is to say, considering the rate at which most opticians charge—that they can't apply first-class labour to them. In the "bent-tube principle," which is *the* form, the tube requires a deal of experience in its manufacture. If there is the slightest variance in its composition, a good maker would throw it aside, but not so these knowing opticians. If they bend a common brass tube, it is almost enough for them. From experience they know that the general run of amateurs buy things to look at, or be put under a glass shade, or be worked only once or twice a year. I would advise "T. W. J," not to have a pressure gauge at all, to be a permanent fixture. If studying appearance, make one of wood nicely painted. For models rely upon the safety valve, and that only; model pressure gauges, which are model in every sense but the right one, only give a sense of false security.—P. W. H. J.

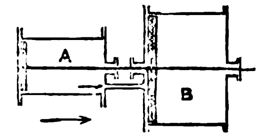
[11711.]—**Time at our Antipodes.**—For the last word, "same," I should have written "third."—E. L. G.

[11711.]—**Time at our Antipodes.**—In an American atlas, called "Johnson's Family Atlas," I find that both the maps of the world, bicyclar and Mercator's, have a dotted line seemingly intended to mark the boundary "between Sunday and Monday," that has so puzzled your querists. But it only extends from 40° N. to 50° S., leaving it doubtful which of the Aleutian Isles, and those about Behring Strait, follow the American or Asiatic day date. It starts from 40° N., in 160° W. from Greenwich, and takes a SE. course to the equator, which it meets in 108° W., or thereabout, and then southward along that meridian, whereon no land is known to exist between California and the South Pole. The nearest islands it leaves as American, beginning at the N., are I. de Paxaros, Copper I. (very near), Gallego I., and Sal-y-Gomez (called Salas on some maps). These it leaves on the Asiatic side. Proceeding northward, are Easter I., Waihou (the nearest), St. Paul's, "American Group," Mellish's, and Donna Maria Laxara. It would seem that what Mr. Birt calls the "absolute day" must begin when Waihou Island (about 109° W. of Greenwich) begins to call it day (whether at midnight or sunrise). But what a pity that "Easter Island" is a few miles behind it! Could not these two islands exchange names? or could not Waihou become Sunrise I., or Dagmar, or Dayspring? This is 16h. 40m., at least, before the day of the same name begins at Greenwich, and the date continues to be used till the sun has set, and midnight been reckoned by the westernmost habitation (or place ever to be inhabited) in Alaska that the Russians have lately sold to Jonathan, say Cape Prince of Wales, about 167° W.—that is more than 11h. after Greenwich has begun the next day, or 35h. after it began to use the same date, and 51h. 40m. after Waihou Island did so. Consequently, there can be no moment when (as Mr. Birt fancies) it is Tuesday all over the globe. For 3⅓h., between Waihoo midnight and Behring midnight, it is Monday, Tuesday, and Wednesday at different places. For the remaining 20⅔h., it is but two days, always two, because whatever day it be at Sal-y-Gomez I., it is the succeeding day at Easter I., about 100 miles west, and when it is about 1 a.m. of both (the former calling it Tuesday and the latter Wednesday), it is still Monday evening to the whole of California, Oregon, Vancouver, Sitka, Queen Charlotte's I., and Alaska (whenever it shall have settlers).—E. L. G.

[11746.]—**Coil Construction (U.Q.).**—All the power "Zeta" will get out of his coil will not be much, but he can increase the effects by using a stronger battery.—W. BOLTON.

[11787.]—**Electric Signal Bell (U.Q.).**—As this has appeared in the list of unanswered queries, I take the liberty of answering it as well as I am able, although addressed to Mr. Tonkes. "H. G. N.'s" magnet is probably not made of soft iron, and therefore retains its magnetism. I am afraid this could not be remedied without getting a new core for the magnet. I take this opportunity of thanking Mr. Bottone for his reply to my query about the brass springs.—GLATTON.

[11792.]—**Compound Engines.**—The proportion between the areas of high and low pressure cylinders in compound engines varies with the pressure and distribution of the steam. Some makers employ one proportion, others another, thus, in the engines of the *Elbe*, one of the P. and O. boats, the diameters of the cylinders are, high pressure, 42in.; low pressure, 68in.; or areas as 1 : 2, nearly; whilst in those of the *Sir Bevis*, of the Union Company, the diameters are 26in. high pressure, and 52in. low pressure, or areas as 1 : 4. With regard to the steam receiver, my advice is don't employ one at all. If a compound engine is indispensable, exhaust as direct as possible from the high to the low pressure, and also exhaust into the condenser from both high and low pressure. The receiver is not only useless, but wasteful, the steam in passing from the high pressure into the receiver must expand, or there would be no motion, and during this expansion it loses so much power of performing work. This is seen in the space between the diagrams of compound engines, indicating the pressure not utilised when passing between the cylinders. I will illustrate roughly the principle that has been applied with advantage, without employing an intermediate receiver. Suppose the engine to be horizontal; A, high pressure cylinder; B, low pressure cylinder. The engine is about to make a stroke in the direction of the arrow. A is filled with steam that has propelled the piston of its cylinder in the opposite direction. At the commencement and (say) during one-half the stroke, A exhausts direct into B. The communication between A and B is now closed, and A is opened to the condenser. The steam in B is expanding works till the end of the stroke if desirable; it is then exhausted into the condenser, &c. But why will "Falstaff" employ compound engines? They are by far more expensive to construct than single high pressure condensing engines, and it is exceedingly doubtful whether they are so economical. Did "Falstaff" see an account of the trials between the *Swinger* and *Goshawk* at Plymouth on Saturday fortnight (*vide Engineer* or *Engineering* two weeks back), the one employing compound, and the other simple engines? If not, let me tell him the result was by no means in favour of the compound system.—C. E. STEWART.



[11801.]—**Question in Trigonometry.**—In answer to the queries of "Triangle" and "Theodolite," I have much pleasure in stating that both the construction and calculation are adapted to the general problem, whatever be the values of the angles about P. Provided that it is situated within the triangle on which all its angles will be = 360°, only the triangles must be isosceles, with the angles at their vertex = supplement of their opposite angles at P, from the centre of which describe circles through A B C, the point of whose intersection will still determine the point P, as in the present instance. Through a blur in the printing I mistook 1044 for 1040, and calculated as such, which will account for the small discrepancies between the solutions. Those of "Triangle" and "F. M." are right. "F. M.'s" solution would only be applicable when all their angles were 120°. The following, perhaps, is as concise and elegant solution as the particular case mentioned admits, but not applicable to the general problem of different angles about P. Thus, the construction and figure as before, since sin. A P B : A B sin. A B P : A P, and sin. A P C : A C sin. A C P : A P. Then A B : A C sin. A B P : : sin. A C P. Also

$$AB + AC : AB - AC :: \tan. \frac{ABP + ACP}{2} : \frac{ABP - ACP}{2};\ \text{but } ABP + ACP = 120^\circ - BAC.$$

Whence, calculating B A C = 51° 57′ 26·4″ = A B P + A C P = 68° 2′ 33·6″, A B P − A C P = 2° 57′ 24·2″, A C P = 35° 29′ 58·9″, A B P = 32° 32′ 34·7″, and A P = 700·0363, B P = 600·0297, and C P = 499·9216.—W. H.

[11825.]—**Testing Bleaching Powder.**—According to the researches of Kolbe (Ann. de Chim. et de Phys., 1867), bleaching powder contains water as an essential ingredient, and a carefully prepared specimen gave numbers corresponding to the formula

$$(Ca'')_3H_6O_6Cl_4.$$

Theory: Chlorine, 39·; lime, 46·2; water, 14·8.

Muspratt also found water as an essential ingredient, but places the theoretical amount of chlorine at 48·9 per cent.; but he says "the best commercial product rarely exceeds 36 per cent., and generally averages 30 to 33 per cent." The general average found by the writer, on testing some hundreds of casks by different makers, was 33 per cent., and rarely fell under 30 per cent. The bleaching powders examined by S. Bottone must have been very inferior if they yielded only 20 per cent. of available chlorine. His method of testing bleaching powder is valueless.—BRIDGETON.

[11825.]—**Testing Bleaching Powder.**—Mr. S. Bottone's reply to this query is calculated to mislead. He says that he has never found a sample of bleaching powder to contain more than 20 per cent. available chlorine. Permit me to state that a good commercial article contains 35 per cent., analyse it which way you will. I have analysed hundreds of samples, and reject all below that mark.—ANALYST.

[11825.]—**Testing Bleaching Powder.**—On the appearance of this query I meant to have replied, giving the arsenious acid method, but was unable to do so in consequence of a pressure of business. However, I find that the subject has been ably taken up by two correspondents. My object in writing is to disabuse Mr. S. Bottone's mind on the strength of commercial bleaching powder, and also the theoretical quantity of available chlorine contained in it from the formula given by him $\left(Ca \begin{cases} Cl \\ OCl \end{cases}\right)$. He asks "Ethyl" where he obtained samples of chloride of lime containing 35 per cent. available chlorine. The writer is in works where 120 tons are manufactured weekly, and can assure him that 98 per cent. of it tests from 35 to 37 per cent. available chlorine as it leaves the works; if under, buyers refuse it. I will forward him a sample provided he pays carriage. As regards the theoretical quantity of available chlorine being less than 35 per cent., I beg to remind him that from his formula of chloride of lime, I find it to contain 71·7 per cent. The two atoms of chlorine are available to the consumer when acted upon by sulphuric acid. (See Fresenius' "Chemistry," fourth edition, page 603). We take CaO, ClO, CaCl + 2HO as the symbol of chloride of lime, which gives 48·96 per cent. available chlorine. You will observe that we take two atoms of water over and above that which Fresenius gives, as it requires the lime to be in a state of hydrate to form bleaching powder.—A PRACTICAL CHEMIST.

[11826.]—**Tinning and Soldering.**—"A., Liverpool" (page 309, No. 376), recommends resin for soldering lead and zinc. I have been 24 years in the trade, and find resin and grease is best for lead (it can be wiped off when hot), muriatic acid for zinc. Any amateur will do best to keep chloride of zinc corked up in a bottle (best known in the trade as killed spirits), that will suit any purpose he may want. Tin, zinc, brass, copper, Britannia metal, wrought iron, and even cast iron with a little trouble.—TOM THE TINKER.

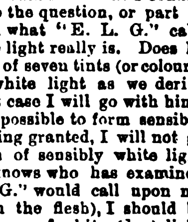
[11826.]—**Tinning and Soldering.**—I have to apologise to "W. T. M. D." for inconsiderately controverting his statement that "clear water will remove the stickiness of the hands caused by using chloride of zinc," as I find now that if there has been no oily or greasy contamination used in conjunction, that this peculiar sensation can be removed by washing the hands in plain water.—A., Liverpool.

[11842.]—**Indiarubber Gig Apron.**—I suppose no one has answered this query, because no one knows how easily to prevent an indiarubber apron from sticking together when sat upon. The only way to do it is to cover the indiarubber surface with some powder—such as French chalk or silex—or keep it thoroughly wet with water. These articles are not meant to sit upon; but if you must sit upon it, *don't* try oil to prevent it sticking.—Saul Rymea.

[11855.]—**Hygrometer Motive Power.**—Hair, catgut, and ordinary string are the substances usually employed in the so-called hygrometers, which are nothing more than hygro*scopes*; that is, they indicate when the air is moist (some little time after it has become so, though), but do not measure the amount of the moisture.—Saul Rymea.

[11875.]—**Spectrum Colours.**—The remarks of "E. L. G.," in criticism upon my reply to "Utile Dulci," are not intelligible to me as a criticism. A careless glance at my reply would show that I confine myself to a simple answer to the question, or part of it. I don't quite understand what "E. L. G." calls white light, or what his white light really is. Does he mean to say that the mixture of seven tints (or colours) will not produce the same white light as we derive (say) from the sun? In this case I will go with him; but if he means that it is impossible to form sensibly white light, pure pigments being granted, I will not go with him. The composition of sensibly white light differs widely, as every one knows who has examined into the matter. If "E. L. G." would call upon me if he happen to be nigh (in the flesh), I should be happy to show him that a beam of white (day) light may be passed through white substances, and although sensibly unaltered, so far as regards ordinary vision, shall yet have the larger proportion of its colours extinguished, as shown by the presence of innumerable black bands in its spectrum. Of how many colours that white light which I would show him was composed, I would leave him to discover, but I would convince him, at any rate, that the presence or absence of a large proportion of the different waves does not sensibly affect the whiteness of the light, provided the withdrawal of the different colours will be according to a well-defined law of proportion. At the risk of "catching it," I "make these few remarks."—H. P. H.

[11891.]—**Contents of Cistern.**—This query has been badly treated. If the arc cannot be referred to a circle, the area of section could be found by the method of "Equidistant Ordinates," as given by Chambers, Elliot, and other writers on "Practical Mathematics." In the case of a circular segment, having ascertained whether the segment be greater or less than a semicircle, the following method may, perhaps, satisfy the querist:—To make the matter as plain as possible, an example in numbers may be necessary. Referring to diagram, having given the chord DE = 16, and versed sine AC = 0, to find the area of the segment DAE. Eucl. 1·47, $DC^2 + AC^2 = AD^2$, or AD (chord of half the arc) = 10. By the rules of Mensuration, arc DAE = $\frac{1}{3}$ (8AD − DE) = $21\frac{1}{3}$ nearly. Euclid III. 35. AC × CB = DC × CE, or CB = (DC × CE) ÷ AC = $10\frac{2}{3}$. AB = AC + CB = $16\frac{2}{3}$. Hence radius DF or AF = $8\frac{1}{3}$. AF − AC = $2\frac{1}{3}$. The area of the segment will, therefore, be (approximately) $\frac{1}{2}$ (DAE × AF − DE × CF) = $70^2/_9$. This for the lesser segment. The area of the greater segment DBE = 218·16 − $70^2/_9$ = $147^{17}/_{18}$ nearly. Taking the lesser segment to illustrate the method, it only remains to multiply the area of the segment by the depth of the vessel, and for gallons, to divide the product by the capacity of a gallon. Taking the area of segment = $70^2/_9$ square inches, and depth of vessel = 4ft, the contents in gallons would be $70^2/_9$ × 48 ÷ 277·274 = 12·1564 + gallons. Now, to show the fallacy of "C. B.'s" rule, take the above example as an illustration. The rule, as given, may be expressed thus $(3(\text{radius})^2 + \text{height}^2) \times \cdot 5236 \times$ depth ÷ 277·274 = gallons. Or $(3(8\frac{1}{3})^2 + 6^2) \cdot 5236$ × depth ÷ 277·274. Or 127·93293 (area of segment) × depth ÷ 277·274 = contents in gallons. But the area of this segment has been shown to be $70^2/_9$ nearly, while "C. B.'s" rule gives 127·93293 for the area of the same segment.—Jas. Hastie.



[11924.]—**To Millers.**—In the last issue of "ours," at p. 310, three correspondents have answered this query; but, as I think, erroneously. Each size of stone, from 3ft. 8in. to 4ft. 8in., has its peculiar advantages as well as disadvantages; a 4ft. stone is, undoubtedly, a good useful size, but it is not necessarily the most powerful. Your correspondents seem unaware that the 3ft. 8in. is fast coming into use, and assuming their point of reasoning (if mere assertion can be so called), the latter size must perforce of necessity be the most powerful. There can, however, be little doubt that small stones will eventually supersede the large; they are lighter to move, occupy less space, and their first cost is much less—three most important points; they also occupy much less time in dressing. The dress will, not, however, last so long, and they must be driven at higher speed, consequently the saving in driving power consumed is very questionable, although the dead weight of stone is less; they will, however, do a good share of work. A good speed for a 3ft. 8in. stone is about 120 revolutions per minute; 4ft., 100 revolutions per minute; 4ft. 6in., 80 revolutions per minute. This produces a speed at the skirt (the real point in question) of about 1350ft., 1220ft., and 1100ft. per minute. Under these conditions, all things else being equal, the powers are so nearly equal that there is scarcely a choice between; but it nearly all depends upon three conditions—viz., the quality of the stone, the dressing, and the condition of the grain; some grain will bear double, or even more, speed than others, and a judicious foreman in a large manufactory will ever endeavour to suit his different classes of grain to the nature of the stones. In small country mills, where this is not possible, we overcome the difficulty by speed and dress, damp tender grain working best in a free open stone driven slowly. Where the grain is dry and strong, the stone rather fine-grained and hard, the speed may be raised almost indefinitely. It is sheer nonsense to talk of a large stone being more likely to heat the meal and kill the flour than a smaller one; the fault lies in the workman, not in the stone. Drive gently, feed lightly, and you never need fear doing mischief to your goods. A general fault amongst millers is over-driving and over-feeding. As a matter of simple opinion, I greatly prefer a large stone for real excellence of work; the time revolutions being slower, the grain is less lacerated on entering the stone, owing to the low speed at the eye, consequently, the grain is crushed more, and less torn, and is thus better prepared for the actual grinding. Our object is (or should be) to thoroughly disintegrate the flour and clean the bran without tearing it to pieces, otherwise the colour of the flour will be deteriorated. As a general rule, large stones do not require laying so close to accomplish their work as smaller ones do; the dress consequently lasts longer, and the stone works cooler, and throws the bran in larger flatter pieces; but so many circumstances will vary the results that no absolute rule can be laid down. The nature of the soil on which the grain grew exercises a wonderful influence on the successful working of the manufacture. I would respectfully caution all the readers of "ours" against implicitly receiving all the statements put forth by "our" numerous contributors. We are thankful for ideas put forth, but each one should judge for himself if they will bear the scrutiny of common sense, as it is quite evident that too many of our number avoid exercising their own natural gifts of one of the most useful of nature's endowments.—Epsilon.

[11945.]—**Leaky Tap.**—This is probably caused by frost. The remedy is to allow the water-way to empty itself. This may be effected by boring two pin holes half through the plug into the water-way, one above the other; one to let the air in, the other to let the water out.—T. S. U.

[11946.]—**Imitation Bronze.**—Well clean the articles to be bronzed; if old, to be boiled in soda or potash lye, to free them from the old lacquer, &c.; if new, to be pickled in diluted or stale aquafortis for leaf work; filed and papered up for plain work; and scoured with sand where required; tubes, &c., may be cleaned with emery cloth and then dipped (or a brush used, if more convenient) in the bronze solution, composed of one quart of the best vinegar and 4oz. of corrosive sublimate, washed in clean water and dried in sawdust, or a mixture of about a gallon of sawdust and 4oz. of blacklead is better; well polish with dry blacklead and lacquer with green lacquer, heating the articles on a hot-plate to about 180°. Tubes are easier done by steam, a common tea-kettle will do almost as well as anything. Use a camel's hair-brush for the lacquer, which you had far better buy than attempt to make; most wholesale chemists and drysalters sell it, or wholesale gas-fitters.—W. Bolton.

[11960.]—**Brewing Query.**—The reason why the copper is dark after boiling is from the sulphur used in the growth, and also curing of the hops, forming a compound with the metal. Compound formed would be sulphate of copper, I should think. All hops that act thus upon the copper should be avoided if possible, as your yeast is liable to get out of order from the effect of the sulphur acting upon the fermentation.—Aroma.

[11985.]—**Machine to Cut Leaves.**—A machine almost exactly similar to the circular saw and bench would cut the leaves as "Anon." wants. The outer rim to be furnished with flat steel knives placed a few inches apart, and the wheel to revolve in bearings underneath the bench or table. Two handles may be attached to the axle, or one, as may be deemed suitable. One boy may feed it with small bundles of leaves, which fall down an inclined platform when cut, while the other is working as "Anon." suggests.—Rat-Tat.

[11987.]—**Draft Holes in Fireplaces.**—Used so that the smoke may be consumed by admitting a constant supply of air, as in the patent louvre arrangement and other more simple plans, where the draught is regulated by a system of chains, weights, and levers. "The green tea leaves" are more rapidly and efficiently dried by passing over and through the trays a current of heated air, which is found more beneficial than exposing the damp leaves to the direct action of the fire. Kilns of damp corn are also occasionally dried by tubes of heated air. The pipes are pierced with small holes and stand upright, or empty spaces are formed with wire netting.—Rat-Tat.

[11991.]—**Focal Length of Lenses and "F.R.A.S."**—No one is under any obligation to reply to a question he thinks need not have been asked, but those who do reply should reply civilly, and correctly if they can. "F.R.A.S.," at p. 300, tells "Anon." that he might have found his question, which he calls "so ridiculous," answered in any fourpenny catechism on optics, and then proceeds to answer it inaccurately. No doubt "Anon." asked the question because he wished for information, perhaps did not know any more than I do anything about fourpenny catechisms, or possibly he preferred paying twopence for the English Mechanic, which would give this and other information, to giving fourpence for a catechism which would answer this one question only. I submit, Mr. Editor, that it is very undesirable that inquirers who ask for information should be snubbed because they have not the information they seek. It is desirable, also, that the answer should be accurate, which that of "F.R.A.S" is not quite. The focus of a camera lens is not, as "F.R.A.S." well knows, the point at which the rays of the sun would be converged to form a distinct image, and the plate holder must not be placed at that distance, but generally at a considerably greater distance—namely, at that at which the actinic rays (not the luminous rays) from objects at a small distance will converge—*i.e.*, the congregate focus of diverging rays. Neither is it quite accurate to say that the eyepiece of a telescope has to be placed in the principal focus of the object-glass, for its distance has to be adjusted according to the distance of the object and the eye of the observer, as of course "F.R.A.S." is quite aware. He disclaims any attempt to give a scientific answer to such a question, and none was needed, but he might at least have given a civil one or none at all, and an answer may be incomplete without being inaccurate. Originally, by the focus of a lens was meant the point at which the heat rays of a lens used as a burning glass converged, lenses being at first used as burning glasses, being fit for little else, and the point of greatest heat was naturally called the focus, the hearth, or fireplace. It does not exactly correspond with the point at which either the light or the actinic, or photographic (light drawing) rays converge.—Philo.

[11994.]—**Instrument for Measuring and Recording the Amount of Light for Photographic Purposes.**—The most simple way to make an actinometer is to take a piece of cardboard and double it into two leaves like the covers of a book, then paint one of the outsides with a kind of chocolate colour, as nearly as possible of the same tint as albumenised paper assumes when exposed to the light; then cut a hole about the size of a shilling through the centre of the painted part of the card. Now, to use this, open the leaves and place between them a piece of sensitised paper, close them again, and expose to the light. Now, as the paper will darken quickly or slowly, according to the chemical power of the light, it is only necessary to note the number of minutes required to darken the paper to the same shade as the surrounding card, and the difference of time occupied at different times, and in different places, will give the difference of actinism in the light, which does not correspond with illumination; or the card-leaves can be made large enough to have half a dozen or more holes, and a scale of tints, then expose for a fixed length of time, and see with which of the tints the paper matches and the same end will be gained. But no rule can be laid down for the exposure of the plate in the camera, because some subjects will require a longer exposure than others, whatever may be the nature of the light.—W. Marquand.

[11995.]—**Patent Rights.**—Errata.—For second patent, read said patent, and put another s to worthless.—A., Liverpool.

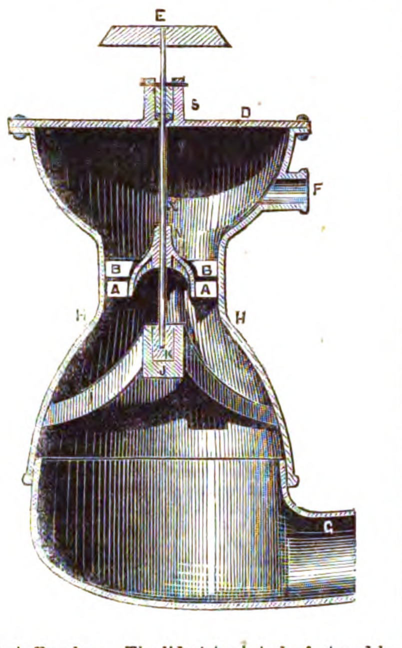
[12000.]—**Insects in Tables and Chairs.**—Have the furniture newly varnished. A little camphor dissolved in the varnish used will prevent the recurrence of the depredators. Tobacco juice driven into the holes with a syringe will also destroy the insects.—Rat-Tat.

[12002.]—**Zinc for Aquarium.**—In answer to "A Three Years' Subscriber," I beg to offer the following advice how to make, stock, and preserve it:—Various kinds of receptacles are used for both the marine and the fresh water aquaria. The square or rectangular glass tank is the most expensive, while an ordinary propagating glass turned upside down and placed in a stand forms a very good shaped and even elegant vase, especially for fresh-water animals. It may be purchased cheaply at almost any glass warehouse. Next comes the filling and stocking. First, a substratum of soil in which the plants may grow is necessary—just enough of sand, stones, and clay to cover the bottom; but no mud—nothing that is easily removable or apt to discolour the water. Then the weeds, and, lastly, the animals. Ordinary pond water will do admirably for fresh-water aquaria, while good sea water is necessary for the marine tank. Weeds require very little soil. One of the most successful plants for the fresh-water aquarium is the *Anacharis alsinastrum*, the weed which so often chokes our canals and rivers. It can be obtained in Covent Garden Market, or, indeed, of almost any gardener. It is a pretty moss-like plant. But almost any weed may be naturalised in the aquarium—the water crowfoot (*Ranunculus aquatilis*), for instance, may be transplanted from almost any pool during April and May, and placed in the tank; it takes root and flourishes abundantly, as also do most of the pond weeds. Now for fish:—The ordinary stickleback, if kept by themselves, are most amusing inhabitants, or the gold fish, the carp, or the minnow may be profitably introduced. But in order to keep down the green *conferræ* a few snails are absolutely necessary. To these may be added water newts or efts, or a good-sized toad, which is by no means so repulsive an animal as is by many believed. But you must be careful not to introduce some kinds of water beetles, but the diving spider (*Argaroneta aquatica*) will be found a most interesting addition. The aquarium is a scientific toy that costs nothing beyond the first expense of purchasing, and it provides an almost endless source of delightful study.—R. C. T.

[12004.]—**Nitrate of Soda.**—This valuable ingredient for the agriculturist may, as stated by S. Bottone, be procured in slight quantities on the frontiers of Chili and Peru, but the bulk of the supply, which is unlimited, is obtained in the interior of Bolivia (see Darwin's Travels), and shipped from the port of Iquique, whence a railway of ordinary gauge runs to Tarapaca, the great mining centre. Narrow gauge lines of 30in. connect here, and both systems are worked with powerful Fairlie locomotives; the larger ones made at Bristol and the others at Warrington. Continuous and heavy inclines extend from the coast to the mines, and the difficulties of the line serve to illustrate the special and admirable qualities developed by this improved kind of engine.—P. FRANCE.

[12008.]—**Cork Cutting.**—If "Cortex" can spare a visit to the Mechanical Department in the Crystal Palace, London, he may there see different working models of cork-cutting machines. It would be difficult to say which machine for the purpose is best.—RAT-TAT.

[12012.]—**Water Power.**—The reply of "Philanthropist" is of no use practically, I am sorry to say, although I will do him the justice to say that he appears to be perfectly correct in theory. He has calculated the natural effect due to a fall of water, but he has not gone any further; of the four horse-power stated, above three-quarters of it will be absorbed by friction of one kind and another. The reply of J. Gillaird is more to the purpose, but superficial. The actual power will in some measure depend upon the length of pipe from the reservoir to wheel. This would act by diminishing the velocity, and consequently the power, on account of the friction entailed by the greater length of pipe. The theoretical velocity due to that head, regardless of friction, is 1,180ft. per second; so, being ignorant of the length of pipe, we can conveniently suppose the actual velocity to be 1,000ft. This, of course, will only give an approximate result, but it will not be very far from correct. The diameter of pipe = 3in., so that area $= \frac{9 \times 11}{14}$ square in., ∴ number of cubic inches $= \frac{9 \times 11}{14} \times 12000$, or $\frac{9 \times 11}{14} \times \frac{12000}{1728}$ cubic feet of water supplied per minute. That is, $\frac{9 \times 11 \times 12000}{14 \times 1728 \times 60}$ cubic feet per second. The cheapest plan, as regards first cost of utilising this power, would be a water-wheel; and, considering the small amount of fall available, I think that an over-shot wheel would be best. This would have a cheap first cost, but would not give as good a modulus. It would probably give about ¼ horse-power. It would have to be 6ft. diameter, and 3in. broad between the sides. There are to be 12 buckets. It could be made of either wood or iron; but I prefer iron axle and bracings, and the rest wood. It is then easier to repair, make, and it costs less. The wheel itself would cost from £5 to £15, dependent upon the locality. The other descriptions of water-wheels would cost about the same, but would not be so efficient. For a motor that will last for ever, and be able to increase its power when the fall increases from a heavy shower, &c., give me the turbine. The fall can't be too high for it within reasonable limits, and this is one of the advantages that it possesses over all other wheels. The greatest disadvantage is the speed at which they run, necessitating long bearings and care in fitting. Nevertheless, I think that the manufacture of this one would not be difficult to a tolerable mechanic, with a foundry handy, and set of tools. The speed which I have designed this one to run at is 420 revolutions per minute. The cost is a variable quantity, depending upon the country that the inquirer is in. The price might range from £10 to £30. With that head of water, it would be about ½ horse-power, but it would be strong enough for all additional heads, so that in the rainy season it might be upwards of 2 horse-power. I send sectional drawings of turbine that will last a long time, all the parts being easily replaceable. I will describe parts. N is a bell-shaped iron casting, of straight cylindrical pattern, for 2in. from bottom, and then sweeps up with an easy curve of section shown, to the top of casting. It should be a semicircular curve of 5⅜in. external radius, and 5in. internal radius. The casting to be ½in. thick in curved part, and ⅜in. thick in straight part. The top straight cylindrical part is to be 1½in. diameter and 3in. long, with ⅝in. hole bored and key way filed, or what is better, slotted ⅛in. deep, and ¼in. wide. There is also a flat to be filed on shaft ⅛in. deep, and length of boss. The buckets to be ⅛in. thick, 1½in. deep, and 5¾in. long. They are to be made by taking a strip of sheet iron 7in. long, and bending it at right angles at 1¼in. from one end. This has then two three-sixteenths of an inch holes to be bored in it at the smaller end in order to rivet it to bell casting. They are to be placed at an angle of 24° with the horizontal line. The best number of buckets or vanes is 49. They are to be riveted with three iron rivets each, and corresponding holes are to be bored in the bell casting. The guides are to be made of same thickness of iron, and in the same manner to the buckets, and cut to correspond to the curvature of the bell casting. They are to be at an angle of 66° with the horizontal, and to be riveted to the inside of the main casting. In the main casting there rises three arms or ribs to support. The ribs to be 1in. by ⅜in., step block to be 2in. diameter, and 4in. long, having hole eleven-sixteenths of an inch diameter bored in it for reception of the gun metal step. The step to be eleven-sixteenths of an inch diameter, 3½in. long, with flange turned at top, neatly turned about ¼in. thick, to fit on top of step block. It is then to have hole bored seven-sixteenths of an inch diameter, and 3in. deep for shaft to work in. The main casting is to be 20in. internal diameter at top, with flange 1½in. wide, ⅜in. thick all round. The lid, or cover, to be cast 23in. diameter, and ⅜in. thick, with stuffing box in centre, to be of section as shown. The stuffing box is to be 1½in. deep, and 1¼in. diameter. To be ⅜in. thick in flange where the bolts go through. The stuffing-box gland is to be 1¼in. diameter, and 1⅜in. deep. This is to have flange ⅜in. thick and ⅜in. wide, and fastened by three ¼in. bolts to the stuffing-box. The bolts might be cast in



top of stuffing-box. The lid at top is to be fastened by six ⅜in. bolts on main casting. It is to be fitted to top with steam-tight joint. It would be best turned, but a very fair joint can be made with the rough casting, if the scale is taken off by roughly grinding for a few minutes with river sand. The cementing materials are red lead and an old rope. References: E, bevil-wheel to communicate power; G, stuffing-box; D, cover; H, casing; I, arms supporting the step block J, which supports the step proper K. The axle X works in it, and the bell casting N is keyed on it. B B are the guides, and A A are the buckets or vanes. C is the elbow for carrying away tail water. F, the supply pipe.—P. W. H. J.

[12013.]—**The First Watch and Clock Made.**—The invention of the coiled spring in watches dates from the close of the fifteenth century. It is claimed for Nuremburg, then famous for watches, but the priority is much disputed. Their introduction into England is equally uncertain. The watch of Abbot Whiting, dated 1536, is of accredited antiquity, and Count D'Albanne's silver watch, of English workmanship, is dated 1529. Henry VIII. had a watch that went for a week; Anne Boleyn possessed another, as well as a small gilt clock, now in Windsor Castle. Edward VI. had, in 1542, a "watch of iron." Mary Queen of Scots possessed a death's-head watch and a skull watch; one in a case of crystal, coffin-shaped, and another in which a piece of catgut supplied the place of a chain, but all these were foreign watches. A watch was found on Guido Fawkes; and of this period is a curious oval-shaped watch, in a silver case ornamented with mythological figures. In 1635 the value of a brass watch was forty shillings. In 1658 was constructed the spiral or pendulum spring, invented by Dr. Hooke and improved by Tompion. Next, Jaare, by applying the pendulum spring, added (to the hour hand) minute hand and wheel hand. He also added the repeating movements in watches; one of the first presented by Charles II. to Louis XIV. of France. Jaare also made repeating watches for James II. and William III. From 1698 all makers were compelled by law to put their names on their watches. In 1724 was invented the horizontal escapement by Graham, who also invented the mercurial compensation pendulum. At the beginning of the last century was invented jewelling the pivot holes of watches to prevent friction. Arnold made the smallest repeating watch ever known, for which George III. presented him with 500 guineas. Among the celebrated French watchmakers was Brequet, who paid some of his workmen 30fr. a day, and none less than a Napoleon. He invented the touch watch, by which a spring touched at any time struck the hour and minute; one cost the Duke of Wellington 300 guineas. Amongst the earliest of the wheel clocks seen in England was that of St. Paul's Cathedral, London, in 1286. In the year 1869 the good citizens of Beauvais placed in its Cathedral a memorial clock, composed of 14 different movements, and 90,000 pieces (weighing 35,000lb.), and costing £5,000. The body of the clock is 36ft. high, of carved oak.—ANCIENT AND MODERN DURSTON.

[12020.]—**Tireing Cart-Wheel.**—The best way to tire a dished wheel is to shut the tire up the size you require it on the smallest edge of the wheel, and dish the tire by hammering the edge you want largest inside the tire, which is very easily done.—T. G. R.

[12022.]—**Forests and Rainfall.**—Those interested in the relations of the above are referred to "Des Climats et de l'Influence qu'exercent les Sols Boisés et non Boisés," par M. Becquerel. Paris, 1853. 8vo. Boussingault, J. B., "Economie Rurale," 2nd Edition. Paris, 1851;" or the English translation, published by Bailliere. "Man and Nature, or Physical Geography as modified by Human Action," by G. P. Marsh. London, 1864. The last-named is a work of extraordinary merit.—G. J. SYMONS.

[12036.]—**Engine.**—A boiler 3in. diameter by 9in. long would drive it. At 30lb. pressure, with the piston making 1,000 strokes a minute, it would be ·1192 horse-power.—AMICUS.

[12040.]—**Navigation.**—I could procure a Norie's, second-hand, of a friend of mine who has left the sea in disgust, if querist 12040 wants one and will advertise his address.—AROMA.

[12047.]—**Radius of Sector.**—I am sorry that I did not put it plain enough; what I meant by curves is the arc A F B and C F D by chords from A straight line to B and C to D, in No. 363, p. 650, query 11161.—T. E. G.

[12048.]—**Trip to Ireland.**—"A Wanderer" can procure all the maps he requires, including the geological sheet, from Stanford, of Charing-cross, who is the agent for the ordnance sheets. I would recommend him to procure the illustrated guide books to Wicklow and Dublin, published by the Graphotyping Company. This season they have issued a guide to the Shannon and Limerick, which, as "A Wanderer" intends bending his steps towards Parsonstown, may be useful to him. This guide supplies the most recent information, is nicely illustrated, and most agreeably written, and is furnished, too, with a good map of the South of Ireland.—E. B. F.

[12052.]—**Rust in Brewing Water.**—Pass the water through a tube containing a layer of fine sand or charcoal. The last is the best filtering medium for "Cromwell."—RAT-TAT.

[12056.]—**Echo.**—Does J. T. Oakley mean what is commonly known as an open roof—not ceiled? If so, I would recommend its being ceiled about 6ft. or 8ft. from top of wall or eaves. If ceiled, put in an end gallery opposite the pulpit; or if the pulpit is standing against the wall move it out about 6ft. These remedies have been successful in removing the above, which, to a public speaker or preacher is most unpleasant.—BERKS FARMER.

[12056.]—**Echo.**—Put in false ceiling, which generally effectually stops the complaint.—AROMA.

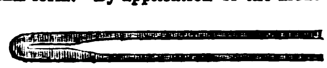
[12058.]—**Bees.—Swarm or Brood.**—Is "C. R. H." certain there were no living bees in his hive when he removed the intruders he mentions? I was deceived once or twice myself, until by accident I examined the comb of one I thought dead. I then, and since, have proved that when very weak, the remaining bees, either for warmth or safety from mice, beetles, &c., insert themselves in the half-empty cells; and when examined, and enemies removed in time (*i.e.*, before hatching commences), I have had stocks recover, and do well, when not a bee could be seen without breaking up the comb. The time of examination I refer to is March and April. If he is certain the old ones were dead, he may rest assured it is a swarm, either one of his own or a runaway; for if the larva was not destroyed by the cold (consequent on the absence of bees) or vermin, it would be impossible for them to rear themselves; for, according to Hubert, Kirby, and Lardner, vide "Museum of Science and Art," the infant bee requires the greatest care and constant attention of that class of the community known as nurses. As to advice, if they are busy working, you can do nothing, let them work on. I do not know if it is punishable to leave empty hives on the stands during swarming seasons, but on three occasions I have thoughtlessly done so, and each time they were tenanted, once, I know, by a strange swarm. I knew a beekeeper in Oxfordshire who always kept a spare hive for visitors, and he has told me (in confidence, of course) he always has one runaway swarm, and sometimes more in the season. I suppose a house ready furnished has attractions.—BERKS FARMER.

[12058.]—**Bees.—Swarm or Brood.**—As a cockney who has lived but three years in the country, I accept Mr. Abbott's scolding on the score of ignorance; but I plead "not guilty" to the charges of wilful neglect, and for setting a trap for my neighbour's bees. It has been a bad season, even in this mild country, for bees; my neighbours were losing theirs at the time I thought I had lost mine, about the middle of April. My query (p. 313) was written, I believe, on May 27, a bright day, on which I found, for the first time, bees swarming about the mouth of the hive. Since I first wrote the bees have been always more or less visible, but I don't think they have done much work; certainly the weather is against them. But yesterday and to-day, (June 14th) have been bright hot days, and the bees are in such numbers that they will hardly let me get near them. Some seem to be returning from the fields, and to be attacked, and, if possible, robbed at the entrance. I don't think there can have been any honey in the old comb from the light weight of it, but I think it might have contained brood which the warmth hatched. At all events, the bees a month ago let me lift out all the boxes from the case and wipe out the floor with a feather, without once stinging me. I may be able to report progress if this warm weather continues; meanwhile, I am much obliged for the cautions contained in Mr. Abbott's letter.—C. R. H., North Devon.

[12060.]—**Glass Blowing.**—The following may be of use to the querist. Professor J. Lawrence Smith recommends a Bunsen burner, flattened at its extremity so as to give a thin, broad flame, for bending glass tubes. This is certainly a great improvement on the commonly employed burner, but an ordinary fish-tail or batswing gas-burner will be found to give, if possible, still better results. Mr. H. Carrington Bolton says that he has employed for some years an ordinary batswing burner attached to a small, short stand (8in. high, burner included), so as to rest low upon the table, in order that raising the arms inconveniently high may be avoided. Such a burner insures a broad flame, by which the tube is heated for two or more inches in length; the tube is turned while in the flame, and removed for bending as usual. The deposit of carbon which at first sight might seem an objection is really one of the chief advantages of using this burner. On placing the glass in the flame the deposit begins immediately, and prevents too rapid a rise of temperature and consequent cracking of the glass; during the heating the carbon tends to distribute the heat equally over the surface of the tube; and finally, on withdrawing the glass from the flame, too sudden cooling is prevented, and the glass is, as it were, annealed. The black deposit is readily removed by a dry cloth. This plan was commonly employed in Hofmann's Laboratory, Berlin. In bending tubes of more than ⅝in. in diameter one end should be closed tightly with a cork (or wax), and air blown into the other end at the moment of bending the tube; by regulating judiciously the pressure of the air upon the sides of the somewhat softened tube, the latter will neither bulge out nor collapse, but will retain its proper calibre. This cannot be effected, however, with very large tubes, or with very thin ones, which require the nice manipulation of the professional glass-blower.—A. M.

[12060.]—**Glass Blowing.**—Heat tube in spirit lamp, turning it round and round, but neither stretch nor compress it; when warm enough, bend. For bulb heat as before, twist until the tube is stopped, take it out of the flame and break it, then heat again, and blow in the end of the tube. For a bulb with two orifices stop one end of tube, heat where the bulb is to be as in bending, and blow as before. If you cannot get heat enough with your lamp, use your blow-pipe, the great secret in the use of which is to keep your cheeks tightly puffed out while you inspire through the nose.—Henry Newman.

[12060.]—**Glass Blowing.**—Thin glass tubes are most easily bent in the common batswing flame. Hold the tube so as to expose an inch of it to the heat at once, which will be completely covered with soot. When it softens, it may be, with careful handling, neatly bent to any angle without flattening. Care must be taken not to bend too soon or too quickly. To blow a bulb on ¼in. glass tubing, if at the end of the tube, close the tube in the blow-pipe flame, and by prolonged heating cause it to thicken till it has assumed this form. By application of the mouth at the open end, and careful blowing, at the same time keeping the tube constantly revolving, an even and strong bulb may be blown of any size. For full particulars, refer to Williams's "Chemical Manipulation." If it be required to blow the bulb in any other part of the tube, one end must be closed, the glass thickened in the same way, with like precautions to keep the tube constantly turned.—Analyst.



[12060.]—**Glass Blowing.**—Glass blowing is only excelled in by practice. See that your tube is perfectly dry, hold the part to be bent over the flame, gradually bringing it down to centre of flame, so as to warm it gradually, then turn the tube constantly round until the part is red hot, and then the glass will bend generally from its own weight; don't use much pressure, as the glass will buckle in and almost stop the pipe up. For blowing a bulb, blow with blowpipe on the middle of your tubing, also turning it round; make it as hot as you can, then pull the two ends apart, then blow on one of the ends, which will stop it up; get it to a great heat, put the cool end in your mouth and blow gently at first, increasing pressure as it cools; also turn it round while blowing; you ought then to get a bulb. Cannot say more in limited space. Spirit lamp hardly gives enough heat, gas better.—A. R.

[12061.]—**Chemical.**—Chlorate of potash may thus be distinguished from chloride of potassium. With a solution of nitrate of silver, chloride of potassium gives a white curdy precipitate. Chlorate of potash gives no precipitate if pure; commercial chlorate generally gives a slight precipitate, owing to the presence of a trace of chloride. Chlorate of potash, treated with hydrochloric acid, evolves chlorine, which may be detected by paper soaked in a solution of iodide of potassium with starch, which is coloured blue. Chloride of potassium does not evolve chlorine under like circumstances.—Analyst.

[12062.]—**Induction Coil.**—"J. B. P." must coil the secondary in the same direction as the primary, and insulate the secondary from the primary with six or eight layers of tissue, and each layer of the secondary with three or four layers of tissue, well saturating each layer with shellac or sealing-wax varnish, but a mixture of ordinary black rosin and beeswax, about four parts rosin and one part beeswax by weight, and poured on hot with a spoon or ladle, is far superior, but more difficult to apply; when finished, the whole to be covered with eight or ten layers of tissue before the ornamental covering of silk or velvet is put on.—W. Bolton.

[12065.]—**Paint and Varnish for Portable Engine Boiler.**—The material used is a sort of paint and varnish in one, called varnish green or enamel green, made specially for such jobs, to be had at any paint and varnish warehouse; the price is about 1s. 8d. per pound. If too thick thin with turps.—B. R. B.

[12066.]—**Washing Baliste.**—Use fuller's earth, and only moderately warm water, rinse in cold, and before drying dip in a strong solution of common salt. This will prevent it running during drying.—Tnetap.

[12068.] — **Surgical Dentistry.** — "Joe" had better apply to Messrs. Jno. Churchill & Co., publishers, New Burlington-street, London, or, let him purchase Tome's "Dental Surgery" from that firm; he will find the work the one he wants. No man can efficiently practice dentistry unless he is thoroughly conversant with the contents of Mr. Tome's work. There are many other valuable works on surgical dentistry which I could enumerate; but grind well at "Tome's," and "Joe" will have the principle of dentistry, and with a few years' practice he may be able to fill a tooth with gold in a proper manner. That branch of the profession once acquired he may rely on a good practice; a small percentage of our English dentists fill teeth with gold, as they should do.—Tom.

[12069.]—**Trip to Australia.**—Speaking from eight years' experience of life at the Diggings, I may mention that a cousin of mine was supposed to be in a consumption, constantly lying on the sofa with clear water dribbling from the mouth. He tried a trip out to me, accompanied with a small cargo of notions, somewhere about the year 1854. Want of Colonial experience caused the venture to be a dead loss, but after sojourning with me for a few months he returned, and has since enjoyed capital health. I would advise any person in delicate health to take a trip there if possible. But take no ventures there in the expectation of making by them, as I was enabled to live very nearly as cheaply all through the height of the gold fever, by purchasing other people's ventures at less than they cost at home. If tolerably active, and (this is the rub) willing to work without being afraid of what Mrs. Grundy would say, you can get along very well there, as long as you keep out of the public-houses.—A., Liverpool.

[12070.]—**Electric Kite.** — The above may be made out of a common calico kite, in the following way:—Twist some wire on the belly-band. Now, fix some metal points (large pins will do) on the top of the kite, and connect them with the wire on the belly-band. The kite-string should be soaked in strong brine to make it conduct; or, better still, should have a fine wire interwoven with the strands throughout its length. A metal ring or a key must be tied to the end of the string, and to the ring is fastened a yard of silk cord to insulate the apparatus. In raising the kite, care should be taken to pass the string under an iron railing, or some conductor connected with the ground, lest the fluid should pass through the operator's body. You cannot be too careful in using the kite, as it is a most dangerous toy. Oiled silk is superior to calico for the material, as it is more waterproof.—Glatton.

[12073.]—**Scarlet Runners.** — If T. A. Slater will take the roots of the scarlet runners up in November, and place them in moderately damp mould in a cellar, away from frost, and plant out in single rows, 1ft. asunder, in April, the crowns being ½in. below the surface, they will come in bearing a month before scarlet runners sown at the same time.—M. N.

[12077.]—**Pyrethrum Parthenium: the Common Feverfew.**—In the double variety, the yellow tubular florets of the disc disappear, and are replaced by white quilled florets. It is very common in gardens, and seed may be procured of any seedsman.—William.

[12078.] — **Cabbage Planting.** — The cabbage tribe are gross feeders; they like fresh rank manure, and plenty of it, at the time of planting out. George Richardson should sow from March till August, so as to have always at hand thrifty young plants for planting out. The March and July sowings are the most important, as on these depend the supplies during winter and spring. The finest and earliest I have grown are Sutton's Imperial. I began to cut on the 13th of April. I have also fine cabbages of Sutton's Drumhead, Blenheim, and Early York. By taking the finest plants out of the seed bed as soon as fit to plant out, and a fortnight after taking the next finest, and so on—the cabbages will come in one after another. Savoy cabbages.—I prefer Sutton's Golden Globe for winter and spring use; main crops, Dwarf Green Curled. Autumn is the best time for planting rhubarb; plant in rows 4ft. apart from root to root each way; make a deep hole where each plant is to stand, and into it put a barrowful of rank manure; put over it a little earth, and on the earth plant the rhubarb with its crown level with the ground. In the course of next May you will get stalks worth looking at. I like Mayatt's Victoria for main crops; Mayatt's Linnæus for early crops.—M. N.

[12086.]—**Velocipedes.**—"Bob C." can try a trick with his velocipede which I have seen tried with success. Remove the iron tire; saw away about three-quarters of an inch deep of the felloe all round. Substitute for the wood cut away a ring of rubber, and screw on the tire again, using longer screws than before. Do not pack the rubber tightly; the flat kind is best, and its elasticity will be preserved, while the tire and rubber will last a longer time.—Rat-Tat.

[12088.]—**Cleaning Jewellery.**—The best way I know to clean gold jewellery is to use a soft brush and jeweller's rouge; but for gilt or Brummagem jewellery no brush must be used, the film of gold being so delicate that it would be injured or entirely destroyed. That sort of work must be dipped in a solution of cyanide of potassium and water, with the addition of a few drops of ammonia. When taken out to be well washed in pure water, and dried in box sawdust.—Tom.

[12088.]—**Cleaning Jewellery.**—The liquid is "liqua potassi"—*i.e.*, potash dissolved in water.—J. T. B.

[12089.]—**Felt Hats.**—The bad stuff used in stiffening has been driven out like oily matter by the heat of the head. It can be removed with a soft brush, decoction of logwood, and soda-soap.—Rat-Tat.

[12094.]—**Preserving Caterpillars.**—Having killed the caterpillar in spirits of wine, make a small hole in the tail, and gently press out the contents of the skin. Then fill the skin with fine dry sand, and set it aside to dry. When dry, in about three hours, shake out the sand, and gum it on to a piece of paper to set in the cabinet. The skin can, if preferred, be filled with coloured wax. Or else, having emptied the skin, fit a small tube to be drawn to a point into the hole in the tail. Blow through the tube into the skin, turning it round over a fire. A charcoal fire is best; but if you have not got one, and cannot make one, a lamp or an ordinary fire will do. When the skin is dry take it off the tube, and fix it in the cabinet. Caterpillars prepared by either of these ways may be anointed with a solution of resin in oil of spike unless they are hairy ones.—G. S. E.

[12096.]—**Copying Music.**—If the music has been registered, the teacher cannot use or copy it for circulation even among his own pupils without first obtaining the permission of the composer. See "Every Man His Own Lawyer," price 3s. 6d., published by law stationers in London and elsewhere.—Rat-Tat.

[12102.]—**Lightning.**—The speed of the electric spark has been measured by an ingenious apparatus, fully described in a back number of "Household Works" (but I regret I have not the number by me), and has been found to vary with circumstances, but these, I think, are not yet accurately known. Light is said to be the quickest traveller in existence; but, from mine own unscientific observation I should feel inclined to bet on the lightning.—Henry Newman.

[12105.]—**Equation.**—In Hamblin Smith's "Algebra" (p. 191), a similar question is worked fully. By question (1) $x^2 + x\,y = 28$. (2) $x\,y - y^2 = 8$. Let $y = m\,x$. Then (1) becomes $x^2 + m\,x^2 = 28$; (2) $m\,x^2 - m^2\,x^2 = 8$. Dividing (1) by (2) $\frac{x^2\,(1 + m)}{x^2\,(m - m^2)} = \frac{28}{8}$. That is, $\frac{1 + m}{m - m^2} = \frac{28}{8}$; or $28\,m^2 - 25\,m = -3$ (solving the quadratic one of the values of $m = \frac{3}{4}$). Thus from (1) $x^2 + \frac{3}{4}\,x^2 = 28$, $7\,x^2 = 112$, $x^2 = 16$, $x = \pm 4$, one value of x; and, using this value, a value for y can easily be found.—C. H. W. B.

[Solutions have also been received from W. H., Maica, Excelsior, A. R., Molison, W. L. G., Nemo, J. F. E., S. J., E. Slaughter, J. Hastie, W. S. & H. M., W. Bush, C. P., H. G. M., Thetamu, W. K. Hall, F. B., P. Carmichael.—Ed.]

[12110.]—**Silver Plating.**—To recover the silver evaporate the solution to dryness, and fuse the product in a crucible. As for the faulty deposition, remember that the surface of the silver-plate should be about equal to that of the article to be plated. If the plate of silver be of the proper size, and yet the deposit be dark, add a little cyanide of potassium.—W. L. G.

[12111.]—**Hot-house Boiler.**—There is no boiler better than the saddle, where little depth of boiler-house is a consideration. But to get clear of the water "W. E." can get a wrought-iron tank, say about 8ft. long by 4ft. wide, by 18in. deep, fix top of tank a little above the height of spring. If the boiler is not very large, "W. E." may fix his present boiler in one end of tank. If it takes up too much room through bricks in setting, "W. E." can purchase from makers one that would do without brick-work, and not take up more than 3ft. square at one end of tank.—H. Hargreaves.

[12118.] — **Gold Quartz.** — Taking the specific gravity of quartz at 2·66 (say 2⅔), and that of gold at 19·25 (or 19¼), we shall have the following equation. Let x = the quantity of gold in grains, ∴ $306 - x$ = the quantity of quartz.

$$\therefore 306 \times 3\tfrac{1}{4} = (19\tfrac{1}{4})\,x + 2\tfrac{2}{3}\,(306 - x),$$

$$994\tfrac{1}{2} = \frac{77\,x}{4} + \frac{8\,(306 - x)}{3},$$

$$\frac{1989}{2} = \frac{77\,x}{4} + \frac{2448 - 8\,x}{3},$$

$$11934 = 231\,x + 9792 - 32\,x,$$

$$199\,x = 2142.$$

Whence x, the number of grains of gold, $= 10\frac{152}{199}$ grains (say 10¾ grains).—Excelsior.

[12113.]—**Gold Quartz.**—Let W, w, w' denote the weights of the compound and the two ingredients, and S, s, s' their respective specific gravities, s being that of the denser ingredient. Then—

$$w = \frac{(S - s') \times s}{(s - s')\,S} \times W$$

$$w' = \frac{(s - S)\,s'}{(s - s')\,S} \times W.$$

By these forms, if W = 806, S = 8·25, s = 19·3, s' = 2·6, then w = 70·686 . . . . w' = 235·008, very nearly.—W. L. G.

[12114.]—**Dye for Cricket Cap.**—No remedy; the colour is faded, and cannot be renewed.—J. T. B.

[12116.] — **Hydrogen Lamp.** — In answer to "H. H. G." In his hydrogen lamp, the first effect is that a mixture of hydrogen and air impinging upon the spongy platinum, by slow combustion first raises it to a red heat. The mixture of hydrogen and air surrounding the platinum is an explosive one, which at a certain high temperature is ignited, and the flame is communicated to the jet of hydrogen issuing from the lamp. The explosion is caused, therefore, by the ignition of the small quantity of the mixture immediately surrounding the platinum.—ANALYST.

[12118.]—**Organ Construction.**—In using harmonium reeds, have a separate pan for your reeds, not on the same soundboards as your pipes; use the pipes in a manner described in a letter in this number. JOSEPH WILLIAM FENNELL.

[12122.]—**Driving Bands.**—From twelve years' experience I can unhesitatingly recommend leather bands as by far the best and cheapest in the end, and regarding all weathers. Have your bands made to order, and where you can depend on the leather being well seasoned.—BERKS FARMER.

[12123.]—**Worn Waterproof Bands.**—Boiled linseed oil, followed by boiled oil and lampblack, and thoroughly dried out of doors, is good; but whether the best is a matter of opinion.—HENRY NEWMAN.

[12124.]—**Voice Weakness.**—Try a mild course of galvanism to the throat, and I should recommend you to bathe the chest with moderately cold water upon rising and going to bed.—AROMA.

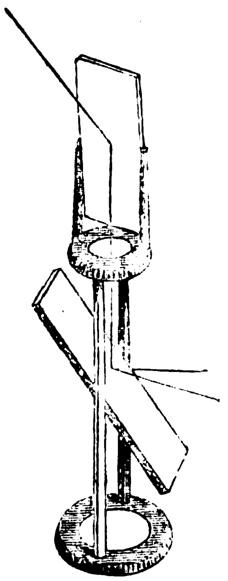
[12125.]—**Cover Plates.**—I don't exactly understand what "Excelsior" means by cover plates, without he means all the plates, both top, bottom, and sides. There are two kinds of plate girders, one of section of two tees joined at their bottom, and the other of the box form. In practice, the most usual plan is to have the depth one-twelfth of the length, but this varies according to the moving load.—P. W. H. J.

[12128.]—**Portable Dark Tent.**—The following description of a dark tent, taken from Hardwick's "Photographic Chemistry," might, perhaps, suit "Occasional Photo." The edition is ten years old, so, perhaps, something better has been invented since, but such as it is, I will give it:—1. Two boards, each 30in. × 15in., are hinged together by strong hinges; in the outer corner of each a hole is bored. 2. Four poles of light strong wood; each pole is formed of two parts, fitted together by a brass tube; the bottom part, 41in. in length, has an iron point to plant in the ground; the top part, 35in. long, has a smaller iron point at the end; the covering of the tent is formed of two thicknesses of yellow calico, and one of black; the seams must not correspond. This covering must have the shape of a cube, open on one side, which side must have the form of a sack, with a piece of elastic to go round the waist of the operator. In the bottom part of this cube are four openings, fitting exactly the poles, and corresponding to the holes at the corners of the boards; on the opposite side of the cube are four other holes precisely fitting the iron points at the top of the poles; all these holes ought to be bound with leather; the tent is packed by putting the eight half poles on the closed table, surrounding them with the covering doubled up, and strapping the whole together. To mount it, the table is opened with the hinges downwards, the bottom half poles are passed through the holes at the corners of the table and the holes at the bottom of the calico cube, a peg being inserted for the table to rest on; the four top poles are then put inside the covering, and each one fitted on to the corresponding bottom pole, and the iron points at the top being inserted into the superior holes of the calico, the whole now forms a convenient table on which all the operations of photography may be performed; a window may be cut out, which can be filled in with adyactinic silk. This tent appears to me to be portable and convenient, and I do not remember seeing any account of a better one.—P. SANTALINUS.

[12130 and 12131.]—**Electricity.**—A current from a machine is the same as one from a battery, but it is produced by a higher electro-motive force, and is very small in quantity. The suggestion of "Philanthropist" as to engraving was made by Spencer in the first paper announcing the discovery of the electrotype, and was one of the experiments he made in originating the art. It is also the basis of the well-known art of glyphography, which reverses the process. The copper deposited in relief, is, however, useless for printing from as suggested, because it cannot be obtained of sufficient evenness.—SIGMA.

[12131.]—**Electricity applied to Engraving.**—I am very doubtful whether in "Philanthropist's" proposed process the copper would adhere with sufficient tenacity to the metal plate to withstand the "sucking" action of the inking roller. At any rate the plan would be useless for copying "fine" work, although it might do for producing facsimiles of letters, &c.—*if* the writing on the plate was done "backwards"—a rather awkward contingency. But then, Cui bono? The lithographic process is considerably cheaper than "Philanthropist's" could possibly be.—SAUL RYMEA.

[12132.] — **Polariscope.**—"Needy" will succeed better if he takes two pieces of plate glass, backed with black velvet, and set in frames as in figure. The upper frame should be set in a collar, that it may be set at any azimuth as regards the lower frame. The frames in the figure are supposed to set at such an angle with the vertical that the incident beam shall strike at about 56°, the angle of total polarisation by single reflection from a glass surface. If "Needy" will consult the indices of back volumes, he will find directions for the construction of polariscopes where polarisation by refraction is made use of. The tubes, when made use of, should be blacked.—H. P. H.



[12132.]—**Polariscope.**—In answer to "Needy," I am surprised he cannot succeed in the way described. But he seems to use the transmitted instead of the reflected light, and should therefore use his plates at an angle of at least 70° instead of 56°. The angles are measured from the perpendicular to the surface of the glass, which "Needy" may not be aware of. If calculated from the surface of the glass the light should fall at angle of 33° 45' to obtain the best effect by reflection, and at not more than 20° when the refracted rays are to be used. I have a polariscope in which only glass plates are used, and it answers admirably, but it is next to impossible to get total extinction of a bright light such as a lamp or gas flame gives. "Needy" must remember that crystals only produce effects of colour when viewed in certain positions, and when not too thick. By arranging his analyser for darkness and trying thin films of mica and selenite in different positions, success will soon be achieved.—ALFRED H. ALLEN.

[12133.]—**Hard Water.**—Boil some of the water for ten minutes in a glass vessel (such as a test-tube), but without letting it evaporate. If it becomes turbid and forms a deposit on the glass, the water may be much improved by the addition of a small quantity of lime or some clear lime water. This will cause a deposit which must be allowed to settle, and the clear water decanted or siphoned off for use. Too much lime will make the water taste soapy. If too little has been used, a further addition will occasion a fresh turbidity. Practice will soon teach the requisite quantity of lime water to be used.—ALFRED H. ALLEN.

[12155.]—**Suspended Shilling.**—Entirely due to what may be considered a form of unconscious cerebration. Let "H. G. W." vary the experiment thus. Allow all the other conditions to remain as they are; but place the tumbler on three half-crowns of the reign of William IV., and he will find that the suspended shilling will strike eighteen at the hour of twelve, or nearest thereto. He must not omit the half-crowns.—H. P. H.

[12157.]—**Smell of Paint.**—Hay, sprinkled with a little chloride of lime, and left for an hour in a closed room, will remove the smell of new paint.—F. A. E.

[12168.]—**Lime Light or Electric Light for Magic Lantern.**—1. First cost of single lantern for use with lime or electric light from £5 to £8; double lantern from £8 to £15. Lime-light apparatus for single lantern (including blow-pipe, gas-bags, retort, &c.) about £5 to £7; for double lantern, £7 to £10. Electric light apparatus (including reflector, holder, and forty cells), from £12 to £20. These estimates are exclusive of slides and objects, a good collection of which can be had for £10 or £12; they are also lent on hire. 2. Dependent on the time in use; a few shillings an hour. 3. The lime-light is far cleaner, and more readily worked than the electric light. 4. The advantages of the lime-light are cleanliness, ready preparation, ease in using, constancy of light, cheapness, portability, easy removal after use. The advantage of the electric light is only one—intensity of light when in a good temper. Its disadvantages are—trouble in preparation, messing with acids and fumes in working, unmanageability in use, inconstancy of light, expense, and absolute necessity of careful and tedious washing up after use. 5. To get a really satisfactory electric light, at least thirty or forty cells should be used; Bunsen's and Grove's are the only batteries worth having, and the former is much the cheaper. 6. The lime-light will answer for every purpose, except a few experiments in spectrum analysis and radiant heat, for which the electric light is better, though, of course, the battery used for the electric light may also be employed for all the experiments in galvanic electricity. I use the former myself, almost invariably. By all means choose the lime-light, and use it for all possible purposes in preference to the electric light. I speak from experience. If "Hon. Sec." will write No. 1, Surrey-street, Sheffield, I can help him still further.—ALFRED H. ALLEN, Sheffield.

[12171.]—**Utilising Chemical Products.**—The products would never pay any one to separate; the most profitable use of them is to throw them away; if thrown on a manure heap they would render good service by the nitrates they contain, and by preventing the escape of ammonia.—SIGMA.

[12171.]—**Utilising Chemical Products.**—"Subscriber" is right in supposing his stripping solution to contain nitrate and sulphate of sodium and potassium; but he cannot extract the caustic alkalies by means of lime, nor in any other way that will pay. "Subscriber" speaks of using nitre. If he used nitrate of soda instead, he would effect a considerable saving, 85lb. doing as much work as 101lb. of nitre. He would then have only sodium in his liquor after treating with salt, and if he has any waste heat it might possibly be worth while to evaporate the solution, and sell the solid sulphate of sodium (or bi-sulphate of sodium, as it would really be) to a soda manufacturer. He would at the same time get off nitric acid, which he might readily condense and utilise. If "Subscriber" adopts this plan he should avoid a great excess of salt.—ALFRED H. ALLEN, Sheffield.

[12172.]—**Constipation.**—In answer to "H.S.A.," I would recommend him to try what I have tried myself, and treated patients successfully, as follows:—Early in the morning drink a tumbler of cold water, then go into a garden lawn and cut or roll the grass for half an hour three times a week, with an easy mowing-machine, as I possess, the Archimedian one; and I think after a short trial of this system, "E. B. F." will find what I have personally found, constipation to cease and nature act with comfort. The rationale of this treatment would occupy too much space to describe it professionally in your valuable journal. I inclose my card for further inquiry if "H. S. A." desires it.—PHYSICIAN.

[12176.]—**Hydrogen Flame.**—Take a small and wide-mouthed glass vessel and invert it over the tube whence the gas is issuing. When this is full, test it by applying a light, keeping it inverted, and of course, at a safe distance from the generating apparatus. If it explodes, try it again and again. When the hydrogen burns quietly in the glass it will be safe to apply a light to the tube.—CERVUS.

[12176.]—**Hydrogen Flame.**—Your mistake is simply that you do not wait long enough for the air to escape. For a half-pint bottle you should wait quite three minutes before lighting, and four or five minutes would be better.—GLATTON.

[12177.]—**Algebra.**—This is only an application of the rule which says that the numerator and denominator of a fraction may be multiplied by the same quantity without altering the value of the fraction. Here each of the three fractions is treated by 1 in this way, which has the effect of altering the sign of the number of each, and of one of the factors of the denominator (since by multiplying any one of the factors of a quantity we multiply the whole quantity), thus making the factor $(a - c)$ in the denominator of the first fraction become $(-a + c)$ or $(c - a)$; and the same in the others. We might, without altering the signs of the numerator, change the signs of any two of the factors of the denominator since multiplying twice by − is the same as multiplying once by +, on the principle that two negatives make a positive. The probable object of the operation in this case is to assimilate the denominators of the three fractions, and thus make it easier to find their L. C. M.—CERVUS.

[12177.]—**Algebra.**—I suppose "W. M." is aware of the fact that $a - b = -(b - a)$. Now, if he will examine the two expressions given in his query, he will observe that the only changes are in the signs prefixed to the fractions, and in the substitution in the denominators, firstly of $(c - a)$ for $(a - c)$, secondly of $(a - b)$ for $(b - a)$, and lastly $(b - c)$ for $(c - b)$. He will then perceive that the two changes balance one another, and that Mr. Todhunter's reasoning is legitimate.—NEMO.

New Disinfectant.—Mr. W. Crookes has taken out letters patent for a new disinfectant and deodoriser, which is claimed to be superior to any known agent hitherto in use. The invention consists in mixing together or passing sulphurous acid into carbolic acid in order to produce a compound possessing disinfecting, deodorising, and antiseptic properties of a nature superior to those of the constituents when employed separately. Cresylic acid or other similar homologue of carbolic acid, or the liquid known as creasote, may be employed for mixing with the sulphurous acid.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last, W. Bolton has answered 11746; "Glatton," 11787.

QUERIES.

[12179.]—**To Electricians.**—I should feel grateful to Mr. Tonkes (who is silent of late) or any other electrician who would kindly answer the following questions, or say in what recognised work I may find this particular subject treated, either practically or theoretically:—1. What office does hair fulfil in the human system? Is it a good conductor of electricity, and is the hair on the head, which is usually supplied from the earliest infancy, to be understood as a conducting medium whereby electricity, or a similar ethereal fluid, is transmitted to the brain placed directly underneath, and through it to the nerves and ganglions, which act immediately on the blood vessels, causing the circulation of nervous and other fluids synchronously through the body, one regulating and counteracting the other so as to maintain life in its normal state? Has not a fluid electrically excited a tendency to scatter and project through almost imperceptible openings and channels by the agitation and separation of its component molecules? Is this in part explanatory of the circulation of the blood, and how far does it accord with well-known and established theories? 2. Suppose an opening was made through the skull of a dead man immediately after death, and a wire leading from a powerful galvanic battery inserted chemically through the membraneous covering of the brain, and if at the same time warm, healthy blood was injected into the heart and artificial respiration commenced, would life be restored, even during the limited period a current would be generated and transmitted by the wire into the brain and nerves? 3. If one in a number of men forming an unbroken circuit, and to whom shocks are given simultaneously by an electrical machine, were to die suddenly while forming a portion of the circuit, would his death affect the remainder in any way? 4. If a number of men or animals, some having an infectious disease, are similarly connected and treated, would the disease be carried with the current from one to the other; or does atmospherical electricity act any part in the transmission or spread of infectious diseases?—Rat-Tat.

[12180.]—**Seasoning Pear Wood.**—Will some correspondent kindly inform me how long I ought to let a trunk of pear season? Would a hay-loft be too warm, for I have it in one at the present time? Does it turn well—if not, what could I use it for?—A. H. Cooke, Cologne, Prussia.

[12181.]—**Violin Case.**—Would any of your readers give me a few practical directions for making a violin case? I made an attempt at one, but failed in endeavouring to bend a piece of pine round the circular ends, by means of a number of saw cuts about half through. The wood broke in some places and sprung in others. I should like to know the best sort of wood for the above.—J. E. D.

[12182.]—**Roses.**—Could any of "our" horticultural readers give me a short outline of the sticking down process for rose bushes, how and when it is done, and the best varieties for same?—Aroma.

[12183.]—**Mottled Cary Wood.**—I have recently seen some fine cabinet work, made of a beautifully marked light brown wood. I am told it is a New Zealand wood of great value, called mottled cary, and the best wood grown in that country. Has any reader heard of this wood and can he give me any idea of its price here?—Yaah.

[12184.]—**Brown Varnish for Baskets.**—Can some kind reader inform me how to make it?—B. B. M.

[12185.]—**Madnip and Wood Laurel.**—What are their virtues and botanical names?—B. B. M.

[12186.]—**Cheap Farming.**—Which is the least land impoverishing method in farming? Is milking cows not so?—B. B. M.

[12187.]—**Repolishing Chimney Piece.**—I have a marble chimney-piece, which an unusually stupid servant has blackleaded. With an infinite amount of washing and scrubbing, I have succeeded in taking off all traces of the black lead, but have also destroyed the polish of the marble. Can any reader of "ours" give me a simple method of restoring it?—Ajax.

[12188.]—**Canoe Club.**—Would some reader of "our" valuable paper kindly give me some information about the canoe clubs (if more than one) established in London? What qualifications are necessary for enrolment?—H. R. H.

[12189.]—**To Mr. Tonkes.**—I desire to thank Mr. Tonkes for kindly answering my questions respecting 12 Smee cells (plates 3in. by 2in.), and shall feel grateful for advice on the following:—1. On starting these 12 cells at first they gave twice as much power as they now do with double the quantity of acid. Not requiring the full power, I put one-twenty-fourth of acid at first, and now one-twelfth. I am afraid I filled the cells before the liquid was cold, if so, are they ruined, or what is the remedy? The silver plates appear thoroughly platinised, and the zinc plates and connections are all right. 2. I have made a coil (primary), three rows of No. 16 cotton-covered wire. Contact breaker acts well, but the platinum wears away very quickly, soon becomes foul, and stops. Is there too much zinc in the cells? 3. Will Mr. Tonkes kindly explain to me clearly, how and of what Mr. Halse's coils are constructed?—Intensity.

[12190.]—**Trios for Male Voices.**—Will some one give me the names of connected works (if any) for two tenors and a bass, also, a few good trios for the same voices?—Trio.

[12191.]—**Surgery Abroad.**—I should be much obliged to any traveller of "ours" who could advise me as to the best place to emigrate to where a surgeon is likely to succeed, having a large family of growing sons, and the competition being so great at home it is hard to make ends meet. I am highly qualified and registered, and have had extensive army practice abroad, but wish to leave it now and settle down where I can get a fair amount of support, and be able to look after my (four) boys, who are motherless. My age is thirty-four, strong and healthy, but I should not like too hot a country. Can any one let me know the prospects of a good surgeon relatively in North and South America, Australia, Cape of Good Hope, or other favourable place. Is it necessary to have introductions? Any reliable information will much oblige—Mark Htwsstks.

[12192.]—**Concrete.**—Can any one tell me how to make and apply a concrete for flooring stables and sheds? It must not be more expensive than the ordinary pitching. Any information will be thankfully received by—J. W. F.

[12193.]—**Magenta.**—Will any one inform me how this colour can be made more permanent? I have been using it on paper, but find that after a few days' exposure to the light, it almost wholly disappears.—A. W. H.

[12194.]—**Enamelling.**—Will "Proven," "Ethel," or some other jeweller, please to give me some instructions in the above beautiful art, more particularly with regard to the composition of the different colours, the fluxes, and the preparation of the articles to be enamelled, such as monograms, &c., on lockets, studs, &c.? I would invite the attention of our jewellers to this question (it has been asked before, but not answered), as I have no doubt it would interest many others besides—G. P. B.

[12195.]—**Ventilating and Warming Buildings.**—I should feel obliged to any correspondent who could inform me what is the best modern work on the ventilation, lighting, and warming of buildings. I also wish to meet with a book giving the principles on which rooms are constructed with regard to the conveyance of sound.—P. Santalinus.

[12196.]—**Rendering New Rope Flexible.**—Can any one inform me how to soften a new 4in. Manilla rope? It is now so stiff that we find it impossible to use it in the pulley blocks.—W. B.

[12197.]—**Roses.**—As the budding season is coming on, would some subscriber well up in the subject, kindly give me a list of some of the very best roses in cultivation? I would be glad also, of the names and addresses of two or three of the largest rose growers in England.—Peacefield.

[12198.]—**Extracting Iodine from Seaweed Ashes.**—If not troubling you too much, could you find space for the following:—Seeing "A Barrister's" answer to query 11736, p. 209, I got some seaweed and dried it, but not being able to get it to burn, I put it in an earthenware pot and put it on the fire, and burnt it that way, and then followed out his instructions as near as I could, but did not succeed in getting iodine. I think, perhaps, I burnt the weed too much. Is the black oxide of manganese right, and how much kelp should it take to make (say) ½oz.? Is not the weed obtained already burnt, and do not the glass manufacturers use something of the sort? If "A Barrister," or any of the subscribers who answered "J. R." would kindly help me, I should feel obliged.—Kelp.

[12199.]—**Speeding Pulleys for Gut.**—How can I obtain a correct ratio between the large pulley of (say) 4 speeds and the small one of 4 speeds as generally used on foot lathes? I want them so arranged that the gut can be slipped from one speed to another, and be equally taut.—E. Williams.

[12200.]—**Levelling.**—Will any of your readers enlighten me on the following:—50·76 is a ground level. Is the 50 representing feet and the 76 the seventy-sixth part of a foot, supposing the foot to be divided into 100 parts?—Bricklayer.

[12201.]—**How to Reduce Pith to a Pulp.**—Can any subscriber kindly inform me how to reduce pith to pulp? Should any acid or alkali be used?—Janus.

[12202.]—**Boat Building.**—Could the editor of the English Mechanic or any of his numerous readers, tell me the name and price of any good work on boat building? I also wish to know the name and price of a good work on making and rigging model vessels.—A New Subscriber.

[12203.]—**Pictures.**—A friend of mine has a painting (a summer landscape), the dimensions of which are about 13in. by 10in., and the name of the painter is, I think, Van Brughols. Does the name suggest that the picture may be of some value. I also saw a lithographic print in colours (41in. by 18in.) of the ceiling of the Sistine Chapel by Michael Angelo, executed at the lithographic institute of Winkelmann and Sons, at Berlin (1852, 1853). Where can it be had in England?—Barbaros.

[12204.]—**Pansies.**—Which is the best way to strike slips of pansies? Will they strike in any common garden soil, or do they require to be a ruck under glass, as I have a small frame of glass about 3ft. long 2ft. wide? In getting a stock of pansies is it best to get slips or to get seeds? What kind of soil is best to raise them on?—One Anxious to Learn.

[12205.]—**Double Rockets.**—Are there any flowers now in cultivation of the double white and yellow rocket? How are they propagated, by seed or by slips? and when is the best weather to sow the seed or to get the slips?—One Anxious to Learn.

[12206.]—**Geraniums and Fuschias.**—Which are the best two scarlet geraniums, and the two finest foliaged fuschias among those that have been out for the past two or three years? Their price must not hinder a poor man from getting them.—One Anxious to Learn.

[12207.]—**Light.**—Could any of your numerous scientific correspondents enlighten me on the following points:—1. Can a beam of light by means of the rotation of plates of any polarising mineral, such as tourmaline, Iceland spar, mica, &c., be entirely intercepted? 2. In the progress of obscuration thus effected, from the maximum of brightness to the minimum (or to perfect darkness), does the diminution of light proceed in regular ratio with the regularly increasing angle of rotatory position? That is, while the second plate or analyser rotates on the first plate or polariser, through 1, 2, 5, 10, 20, 30, &c., degrees of the quadrant, up to 90°, the maximum of darkness, is the diminution of transmitted light equally regular? 3. If so, what is the polarising subject that will effect those desiderata in the most perfect manner?—Iris.

[12208.]—**Gold Fish.**—I have had a number of gold fish die lately full of spawn, and I am informed that the reason of their death was because they could not spawn. Can any brother reader inform me of a remedy?—Tripod.

[12209.]—**First Railway.**—Which was the first railway opened in England for public passenger traffic, and at what date?—H. L.

[12210.]—**The Manufacture of Blacklead.**—Will some correspondent inform me of the manufacture of blacklead for stoves, how manipulated from the raw plumbago, how adulterated, mixed, moulded and finished?—A. R.

[12211.]—**Sea Mouse.**—Will some kind subscriber furnish me with some account of this animal?—Scrutator.

[12212.]—**Yacht Building.**—I am about to build a small sailing yacht, 15ft. long, Carvel built, with bent timbers. Having got the keel, stem, and sternpost together, but do not know how to draught out the timbers to the curves required, before bending them. Perhaps some of your talented contributors can enlighten me.—J. U., Glasgow.

[12213.]—**Coffee.**—What is the cheapest, easiest to manage, and best machine for making coffee?—An Aggrieved Householder.

[12214.]—**The Game of Quoits.**—Will you kindly inform me as to the following things through your journal? 1. In the game of quoits, when wooden pegs are used, supposing the quoit pitches on the top of the peg and splits it down through the middle and "rings" half of the peg, would that reckon as a "ringer," or should it ring the whole of the peg to count? 2. What is the correct distance to play when the quoits are 4½lb. per pair? 3. How is the distance measured from the peg to the quoit—from the nearest part of the peg or from the bottom of it to the quoit? 4. Where can I get a set of rules for the game?—Tom-Tit, Pembroke.

[12215.]—**Fettling Materials.**—An article in the English Mechanic some time ago relating to Danks's puddling furnace states that a revolving pan or grate is coated with marbella, blue billy, ilmenite, or other suitable stuff. Would some reader please give the composition of the above three substances?—E. M.

[12216.]—**Transferring Marble Paper on Book Edges.**—Can any of your readers let me know something about the transferring of marble paper on book edges, if it is much practised, and if the edge has a good appearance when done? I have tried the marble paper prepared for the purpose—by dipping it in muriatic and other strong acids, and then pressing it on the edge of the book—but I cannot make it answer at all.—Bibliopegia.

[12217.]—**Violin Tuning.**—Will "Fiddler," or "The Harmonious Blacksmith," or any correspondent of "ours," please say if violinists tune their violins in just fifths, or how they tune them in each key?—W. Meek.

[12218.]—**Momentum.**—We have a very old bridge over the Ouse here, and the approach is very steep, I should think four or five degrees. Men who are taking a load up often put their horses to a quicker pace just before ascending this incline. Do the horses get over the difficulty any the better for a start at a quicker pace before ascending?—W. Jagger, St. Ives, Hunts.

[12219.]—**Turning Ivory.**—Is there any softening process required? If so, how is it done? Can it be turned in an ordinary lathe? Any information as regards speed, tools, &c., would oblige.—Charlie.

[12220.]—**Superheater.**—I wish to put in a superheater to my boilers (three 30ft. by 7ft. 6in.), and shall be obliged if some of your correspondents will say which they consider the best and cheapest.—Superheater.

[12221.]—**Brass Screws.**—Could any of "our" readers tell me the number of threads requisite for brass screws? I have a hydraulic pump to make, some of the screws of which are upwards of 2in. diameter. I am at a loss to know the number of threads per inch they should have.—Falstaff.

[12222.]—**Iron Castings.**—In letter 3996 of the 19th April last, "Proven" describes the method of making fine castings from airtight moulds. I shall feel greatly obliged if he or any of your contributors will tell me if iron can be cast in the same way; and if so, whether it comes out clean and without scale. I want it for very fine iron moulds.—Caster.

[12223.]—**Wheelbarrow.**—May I ask one or more of your correspondents to give a drawing of a wheelbarrow constructed so that the wheel runs in the centre instead of the end of it, if such are made?—C. T.

[12224.]—**Cemented Object-Glass.**—I have lately purchased a 2¼in. achromatic by Dallmeyer, with a cemented object-glass; and as I believe the latter to be of first-rate excellence, I am naturally most anxious to preserve it in the best possible condition. I note with much interest that "F.R.A.S.," in his reply to "J. R." on p. 300, gives it as his opinion that "the sun ought not to melt the balsam, as it transmits heat rays pretty freely." Will "F.R.A.S." have the goodness further to state what he believes to be the cause of the cement becoming disturbed or cracked, as it has been often known to do? and, also, whether he considers a cemented object-glass as durable and as good, with proper care, as an uncemented one? Will "F.R.A.S." kindly say if there is any perceptible loss of light in using a terrestrial pancratic eyepiece with the above for astronomical purposes?—ALBIREO.

[12225.]—**Lead in Sulphuric Acid.**—I have a quantity of sulphuric acid, which is of a dark brown colour, owing to the presence, I believe, of lead from the chambers in which it is prepared. Can any fellow reader inform me of a simple process whereby I can separate the lead, at the same time retaining the properties of the acid for chemical purposes?—TONY WHITE.

[12226.]—**The Portuguese Language.**—As I wish to learn a foreign language, a letter from "A Harrow Fellow" (8805, March 22) came very opportune (at least so I thought). I followed his advice, and went to Longmans for a handbook of the "Mastery" system, the pages of which I eagerly perused, and felt convinced that the "Mastery" system would of all systems be the best. Consequently, I went once more to Longmans to procure the volume I needed, which was the Portuguese language; but I was doomed to disappointment, as this language is not published in Prendergast's Mastery series. Now, can "A Harrow Fellow" or any of the obliging correspondents in "our" journal kindly tell me what to do under the circumstances, whether it would be of any use to study Spanish, or if I should get a Portuguese book of any other system? An answer to this would greatly oblige. Perhaps some of my fellow readers would join a class for learning Portuguese. My own intention is, after having learnt Portuguese, to emigrate to Brazil. I have heard that Brazil would offer very good advantages to emigrants. Perhaps some of my fellow readers could throw some light on this question. —CARL.

[12227.]—**Astronomical.**—I should feel much obliged if some of your numerous correspondents would inform me what are the inclinations of the axis of the following four planets to the plane of their orbits—Mercury, Venus, Mars, and Jupiter.—COUNTRYMAN.

[12228.]—**Wood Engraving Tools.**—In p. 288, Vol. IX., of the ENGLISH MECHANIC there is a short description of wood engraving with illustration of the tools used. I have bought a set from a private party, and the handles are not same as figured in Vol. IX., being about 8½in. long, and like an ordinary bradawl handle. The tools are the right shape, but about 4in. long, which makes, with the handle, nearly 8in. How is it possible to use the tools same as illustrated in Vol. IX.? The party I bought them of says they were supplied to him as wood engraver's tools. Would any reader tell me if it would be advisable to substitute shorter handles.—ZOO ANDRA.

[12229.]—**Telescope.**—I have for some time wished to purchase a telescope, the question being the size, and whether reflector or refractor. I see I can get a 6½in. reflector (silvered glass) for about £30; can I expend that amount better in any other way? In the article on "Coloured Suns" in the ENGLISH MECHANIC for June 7, frequent mention is made of the result produced by a powerful telescope. What size and kind of telescope does this mean? Of course, I want a good instrument for general use—sun, moon, and planets, as well as fixed stars; for instance, what would Mr. Birt recommend for his "telescopic work for moonlight evenings"? Information from Messrs. Proctor, Birt, and "F.R.A.S.," or others, would be received with many thanks.—CANIS MINOR.

[12230.]—**Platinum Solution.**—How can I make and use the solution of platinum for producing the black on microscope work?—AMERICAN AMATEUR.

[12231.]—**Iceland Spar.**—How can I cut and polish the Iceland spar for polarising prisms.—AMERICAN AMATEUR.

[12232.]—**Secret Spring or Lock.**—Will any one of our numerous correspondents furnish me (through the columns of the ENGLISH MECHANIC) with a drawing of a secret spring or lock for the purpose of fastening a clothes box. I should, of course, require to know how to open it myself when necessary.—AN EMIGRANT.

[12233.]—**Red Varnish for Patterns.**—Would any brother reader kindly inform me how to make a red varnish that will resist heat and moisture when in the sand.—ENGLAND.

[12234.]—**Hairspring.**—I should be obliged if some of your kind readers would tell me if watchmakers use a gauge for finding the different sizes of hairsprings. I have got a verge watch and I have tried above a dozen hairsprings in it, and not one of them will do. Which is the best way to put them in?—B. H. J.

[12235.]—**Carpenter's Tool Chest.**—Will "R.A.B." oblige me with dimensions, size of tills, &c., of chest described on page 311, No. 376.

[12236.]—**Glowworms.**—When and where should these be looked for? I live in the neighbourhood of Richmond Park, and remember finding them there many years ago, but I do not know the time of year.—CITRUS.

[12237.]—**The Organ.**—To "PNEUMATIC LEVER."—I am now in a dilemma. I have made pipes, bellows, wind-chest, and frame, and have put the last three together ready for the pipes, but when I fill the bellows they run down again in about ten seconds. I have carefully examined every corner of the bellows, and have placed fresh springs on the pallets, and still the wind rushes out of the holes where the pipes go in, and apparently all over the stock boards. "Without any joking 'tis very provoking," after having worked for about twelve months to get an organ, and surely I have got one, for it whistles all over without any pipes. But I am not yet utterly cast down; I have been very careful in the work, and with a hint or two from "Pneumatic Lever," or some other of my MECHANIC friends, I anticipate success. I advertised my address to "Pneumatic Lever" in the number for week ending May 31, but I think my friend did not see it. If he remembers, I inquired about voicing pipes and another question or two (query 11836) which I could not trouble our kind editor to insert again.—ALEPH.

[12238.]—**Honey Taking Machine.**—"Beekeeper," letter 4167, p. 351, promised a description of a honey taking machine; I for one should like to see it, as I intend to adopt his hive.—COTTAGER.

[12239.]—**Hens' Eggs.**—Some of my hens lay soft eggs, one in particular, laying them every day in all sorts of shapes, some eat their eggs while sitting; can some one give me a remedy.—COTTAGER.

[12240.]—**Photography.**—Would any reader of the ENGLISH MECHANIC inform me of the cause and reason of the following? I have tried several times to prepare dry plates; I use the ordinary wet plate collodion, and thirty grain bath solution, and then wash well in three dishes of pure distilled water, and preserve them with malt, I then dry them well and expose twice or three times, as long as I do with wet plates, and then soak the plate for a few minutes in a weak silver solution, I then apply an iron developer, but not a trace of a picture or any sign that it has been exposed comes out.—NOTURB.

[12241.]—**Organ Pipes.**—I am now making a set of stopped pipes for pedals. I made one 4ft., mouth cut up one-fifth, but as it did not give a tone so loud as I wanted, I cut it up to one-third; it now makes a very much less sound, whether I give it more or less windway, but if I put a piece of wood on the top of the cap and throw the wind more into the pipe, it then sounds very well. The block and lip are perfectly true. Will "Adept," or "J. D.," or any one kindly come to the rescue, and say where the fault is? Does the block want bevelling off, as "Adept" recommended for pipes when cut high up?—W. H.

[12242.]—**Piano Construction.**—We have had many really good and valuable suggestions from our old friend "The Harmonious Blacksmith" on the construction of pianos, which, to those of our readers who have some knowledge of the subject, would be very acceptable, but to those who, like myself, have little or no knowledge of the various parts of a piano, they are rather bewildering. We have had in "our" columns many lessons on the construction of the organ and harmonium. But I do not remember ever seeing any lessons on the construction of the piano—viz., a series of papers, with diagrams, and every other necessary information as to materials, &c., from first to last. Presuming on the kindness of "The Harmonious Blacksmith," I would beg to suggest to him that to contribute such a series of lessons, with diagrams showing the framing of struts, &c., and every important point, would be highly appreciated by very many of our readers, especially those who, like myself, are in the cabinet and wood-working trade, and who have long had an aching tooth for the piano, to purchase which would cost, with cabinet-work (which seems unseparable from a really good instrument), about £40—a sum which few working men would be able to spend.—B. R. B.

[12243.]—**Turpentine and Wood Naphtha.**—Can any of your readers inform me through the medium of your paper what spirits of turpentine and wood naphtha are principally used for, and also give me full particulars of how they are both made and what kind of timber they can be made from? What would be obtained by distilling fir or pine wood in a retort? Are there any books published that tell how, and what, can be obtained from different kinds of timber by distillation?—D. T. L. R.

[12244.]—**To Harden Lead or Zinc Type.**—Will some kind reader tell me how to harden lead or zinc type sufficient to resist the heat of gas about eight or nine hours per day? The lead type which I use melts in about half an hour after being in the gas. Brass type being so expensive, this is wanted as a substitute for brass type for printing metal leaf. The lead type is bought ready cast.—J. B. SHARPLEY.

[12245.]—**Chemical.**—Will Mr. Davis or Mr. Bottone be so kind as to give a method of separating olefiant gas from coal gas, or all the illuminating constituents leaving the marsh gas?—R. TERVET.

[12246.]—**Seven-Keyed Tuning Fork.**—Would any of your numerous correspondents inform me how I could make a seven-keyed tuning or pitch fork? I have tried one, but I could not get it to work at all, and I would like to know what key to set the fork on before I put on the slides.—A BARITONE SINGER.

[12247.]—**Sewing Machine.**—Could any reader of the ENGLISH MECHANIC tell me if a brake can be made for a Wheeler and Wilson sewing machine to stop the wheel from going backward; if there can, how is it made? Also, how can I attach a vertical engine to the machine; if attached, how can it be stopped or set going. Would a 2½in. stroke engine do to work it?—W. H. T.

[12248.]—**Sheet-Iron Fireproof Deed Box.**—Would any of your scientific readers inform me of a fire resisting material to fill up the space between outside and inside lining, to be of a light substance, such as sawdust?—TOM THE TINKER.

[12249.]—**High Pressure Fire-Box Boiler.**—I am in want of a boiler that will stand a working pressure of 80lb. to the square inch. It will be required to drive a 25 horse-power (nominal) compound engine turning (say) 100 horse-power. Also to warm a four-storied mill 40 yards long, and at some future time to feed a dye-house; 80lb. pressure of steam will be ample to heat the mill and feed dye-house. Any information from your able correspondents which will enable me to get out a specification will be esteemed, such as the length and diameter of shell and flues, thickness of plates, length of fire-grates, and how the boiler ought to be stayed, &c.—495.

[12250.]—**Chemical.**—Could any brother reader of "ours" tell me the original method of Gay Lussac and Thenard for making an alloy of potassium and sodium, which is liquid at ordinary temperatures? Also the chemical action between this alloy and water when brought into contact, and what is left behind after the action has taken place?—VULCANITE.

[12251.]—**Electrical.**—Supposing I had two plate glass electrical machines, one having only one-thirtieth part of rubbing surface of the other—could I by working the small one thirty times faster than the large one get the same amount of current out of each?—VULCANITE.

[12252.]—**Electrical Machine.**—Is there any machine invented that would give a stronger current with the same weight—that is, suppose a plate-glass electrical machine weighed 10lb. and gave a certain amount of current, is there any other electrical machine invented that weighs 10lb. and gives a current greater than that of the plate-glass machine?—VULCANITE.

[12253.]—**Organ Construction.**—Will some of the readers of this journal kindly inform me how to make the couplers, swell to great, swell to pedals, great to pedals? Also, which stops will be the best to use for an instrument of two manuals and pedals? The number of stops must not exceed eight.—AMATEUR.

[12254.]—**Aerostatics.**—Will some one of your correspondents give me the reasons why the weight of any steam engine so far exceeds its motive power as to render it incapable of raising itself (by means of suitable mechanism) in the atmosphere? Also state why, for the same reason, galvanic electricity is useless. Have any experiments ever been tried with a view of determining this point? if not, what are the theoretical proofs?—CYCLONE.

[12255.]—**Hair.**—Can any of your readers inform me of a cure for the following disease of the hair? The hair of my beard breaks off as soon as it is about half an inch long, and has always done so for the last ten years; that is, ever since it began to grow. On examining the hair, I find it bent, and covered with little white knots, like nits, and it breaks off at one of these white places during brushing or washing. I have tried several lotions, but nothing has hitherto done me any good.—C. WATSON.

CHESS.

ALL communications intended for this department to be addressed to J. W. ABBOTT, 7, Claremont-place, Loughborough-road, Brixton, S.W.

The arrangements in connection with the match by correspondence between the chess clubs of London and Vienna have been definitively concluded, and play will commence forthwith. This important match will cause some excitement in the "Chess World;" and, owing to the celebrity of the players engaged on either side, great interest is sure to be manifested as to the result.

TO CORRESPONDENTS.

R. A. P.—No. 1 is rather too easy, and the idea is old. No. 2 admits of another solution in two moves commencing with (1.) Q to Q B 8 (ch.). No. 3 is a neat little problem, and it shall appear on the conditions announced in your letter. We shall be glad to hear from you again.

G. V. G. (Gateshead).—Look again at your attempted solution to No. 1, and you will find that you have overlooked the interposition of the B P at the right moment. Thanks for your good wishes.

ARGO.—Your problem admits of the following solution: (1) B. to B. 6; (2) K. Kt. 2. Send us another specimen of your composition, &c.

T. J. MILLER (Fakenham) and W. COOK (Penge) are thanked for the interest they express in the welfare of our column.

F. OWDEN (Hoxton) and R. H. MACLEOD.—Re-examine Kling's problem attentively, and you will find you are mistaken. Don't take it for granted that the Black King has only one move.

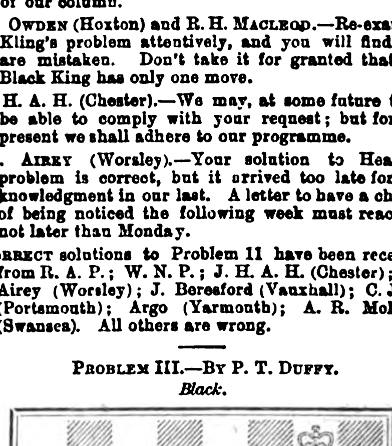
J. H. A. H. (Chester).—We may, at some future time, be able to comply with your request; but for the present we shall adhere to our programme.

W. AIREY (Worsley).—Your solution to Healey's problem is correct, but it arrived too late for acknowledgment in our last. A letter to have a chance of being noticed the following week must reach us not later than Monday.

CORRECT solutions to Problem 11 have been received from R. A. P.; W. N. P.; J. H. A. H. (Chester); W. Airey (Worsley); J. Beresford (Vauxhall); C. J. L. (Portsmouth); Argo (Yarmouth); A. R. Molison (Swansea). All others are wrong.

PROBLEM III.—BY P. T. DUFFY.

Black.



White.

White to play and mate in three moves.

SOLUTION TO PROBLEM II.

White.	*Black.*
1. R to Q B 3	1. K moves
2. B to K 6	2. K moves
3. R mates, acc.	

USEFUL AND SCIENTIFIC NOTES.

The ivy when viewed through the Nicol prism and a pink selenite, appears as if covered with blossom.

The cabbage moth has already made its appearance, and will visit the young cabbage and cauliflowers as soon as the plants are large enough to hold the eggs which produce the larvæ called cabbage worms. A capital remedy for these voracious fellows is that used by Quinn, of New Jersey. The mixture is:—1 part carbolic powder; 2 parts quicklime; 20 parts fine superphosphate. Dust the plants once or twice a week, when the dew is on the leaf.

Grease in Billiard Cloths. — Procure at the chemist's some powdered fuller's Earth (a very cheap article), form a paste by adding genuine spirits of turpentine. Rub the paste well in with tips of fingers and continue rubbing till the turpentine has evaporated and but a powder remains. This can be at once brushed off and all will be free from soil. Pitch, tar, or paint, shares the same fate as oil. The paste may be scented with essence of lemon if need be.

Abolition of Steamer Funnels.—According to the *Swiss Times*, two Austrian marine officers and a marine engineer have discovered by united experiments a method of conveying away under water the smoke from the steam-engine, instead of through a funnel into the air! They make use of double ventilators, which compress the smoke and force it overboard. For propelling these ventilators they employ, according to circumstances, either water-power—that is, the pressure of the water between the surface of the water and the place where this apparatus is fixed, or, for smaller vessels, steam power. A chief advantage of this discovery will be the greater security of ships of war, as, in armour-plated ships, the only vulnerable part, the funnel, will be taken away! For submarine and torpedo ships and monitors this discovery, it is said, will be of great value.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 81, *Tavistock-street, Covent Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, June 18, and unacknowledged elsewhere:—

Capt. A. Leslie Kaye.—Geo. Awford.—J. C. Crowther.—R. O. Berry.—A. P. Compton.—Gordon Douglas.—C. Townley.—Frances and Co.—Olley and Miller.—T. C. Rylands.—Evan Leigh.—Joseph Newton.—Isaac Sim.—Cunliffe and Croom.—H. Pallexfen.—John Bellows.—H. T. Casini.—Alfred Crofts.—T. Stanners.—Wm. Ibbetson. — J. Robinson.—Philo.—Sigma.—Plough.—Cometary.—Edward Watkins.—Capt. Hans Busk.—A. Wake.—Dr. A. McGregor Croft.—Lockwood and Co.—T. Fletcher.—Rev. W. W. Garrett.—J. D. Purvis.—John Murphy.—Jack of All Trades.—M. A. B.—C. J. B.—Youngster.—M. A.—T. W.—Excelsior.—A Constant Reader.—Charles Hopkinson.—John Wallace.—David Morris.—Trovatore.—E. S. T.—R. A. Proctor.—The Rev. T. B. Armistead.—E. G. H.—The Harmonious Blacksmith.—F. S. Beachey.—A. M. C. D.—M. Burns.—Scarborough.—Peerless.—J. H. Bushel.—J. W. Cook.—Henshaw and Son.—R. K. Blessley.—Old Ford.—H. J.—Artillery Captain.—E. L. G.—T. P. Lilly.—W. E. D.—Pinky Tone.—J. Marsden.—W. H. Skelton.—J. H. C.—Samuel Cook.—J. C. S.—J. E. Devlin.—Rat-Tat.—James Levesque.—A Leeds Subscriber.—Farmer.—A. D.—Edgar.—Devonshire.—Cornubiensis.—C. J. Recordon.—K.—Bron.—H. B. E.—Jno. Purday.—C. T. B.—Rev. H. C. Key.—S. D.—A Three Years' Subscriber.—M. G. C.—Houblon.—Ixion.—C. K. J.—M. Paris.—W. W. Still.—M. N.—A. T. C.—B. L. G.—Charles Corfield.—H. D. Plimsoll.—A. H.—F. F. C.—B. S.—L. M. F.—Derfla.—T. H. T.—An Apprentice.—Tablet.—Nottingham Sub.—W. M. Mitchell.—W. R. Birt.—Westward Ho!—J. B. Wilde.—Reporter.—Eye-piece.—Plumbago.—E. R. T.—T. W.—J. B. H.—C. C. R.—Musical.—W. H. Andrews.—T. W. Reynolds.—E. T. Greys.—T. S. Usborne.—Jonathan.—J. W. Fennell.—J. Pearson. — Suffolk Amateur. — Quercus. — T. H. Buffham.—Un Irlandais.—M. S. W.—Dundalk.—Afternoon.—King Cotton.—John B. Lindsay.—Sceptical.—Smithy Steying.—T. H. F.—J. G. W.—C. H. Wingfield.—Rev. J. Lukin.—A., Liverpool.—Inventor.—Saul Rymea. — Charles Lahee. — Sciolist. — A. Wake.—A. Williams.—W. H. Neal.—W. M. Parker.—B. Smith.—W. E. Hockling.—W. B., Lymington.—Mrs. Hodgson.—Edward.—J. C. J.—Vent Peg.—Beauty.—Caloric.—J. E. B.—E. Barker.—Finger Post.—Glasgowegian.—J. Roskell.—J. W. Morris.—Beginner.—R. B.—E. B. F.—A. G.—Wondering Willie.—Jacques Erick.—J. Eldridge.—J. W.—Francis & Co.—Wilson Irwin.—S. J. H.—W. F. W.

COMETS AND THE DELUGE.—E. K. says:—"In closing the discussion under this heading, you will consider it pertinent to the subject to remind your readers that, while 'E. L. G.' contends that the world was drowned by a comet, Sir Isaac Newton says comets are the fuel which supply the sun with heat and light, and that the comet of 1680 is approaching the sun, and will ultimately fall into it, and whenever that happens, the world will be burnt up and at an end."

ACHILLES.—1. If none of the methods of extracting glass stoppers given on pp. 48, 77, of the present volume are effectual, we are afraid you will have to give it up as a bad job. Every known plan is mentioned on those pages. 2. With regard to French polishing the paint box, you will find all the directions you require on pp. 444, 468, and 521 of Vol. XIII. 3. The village of Lexden, two miles from Colchester, is probably the site of the British Camulodunum, and, although Maldon was once regarded as the Roman Camulodunum, there is now but little doubt that Colchester is the true site of the Roman colony. 4. The book you mention is published at £7 8s. for the five volumes, and 31s. 6d. for the supplemental volume.

CONFIDENT is referred to "Hints to Correspondents."

"OLD RED CAP."—You are certainly entitled to the invention, but whether you can claim it after thousands of articles have been made on the plan, and without its being patented, is not so certain. Can't you arrange with your employers before you leave.

PH.D. — Means doctor of philosophy. The degree is obtained in Germany.

YOUNG HOPEFUL.—See "Hints to Correspondents."

PEACEFIELD.—Consult a medical man at once.

T. H. HOWE.—Apply to a racing paper.

FALSTAFF.—Your reply would give Messrs. Tangye and Co. an advertisement gratis.

FIDES.—See another query on the same subject.

GRAHAM HAMILTON. — Something like an advertisement. Inquire in Belfast.

A. W. L.—Consult a medical man.

A SHEFFIELD BLADE.—You must consult some local guide book. It is unreasonable to expect us to insert queries of such limited local interest.

SHEFFIELD, X. Y. (Birmingham), W. S., F. Chalk (Ipswich), T. R., J. Marsden, Rambling Tom, June Rose, W. O. K., are referred to indices to back vols.

Communications which can only appear as advertisements to hand from W. T. Wright, Bisnatus, Gaucho, J. Y., M. C., Manus, Midshipman, J. E. Bird.

W. H. SKELTON.—You have evidently a fair share of confidence as well as ignorance. Read and try to understand the discussion at present going on about "Time at our Antipodes." See also an article on the "Pathway of the Eclipse," of August 7, 1869, in the ENGLISH MECHANIC, of September 3, 1869, p. 521, Vol. IX. Your chess query is a very absurd one. Do you really require to be told that if black *could* avoid being checkmated in the given number of moves it would be no problem.

A FOREMAN. — Bourne's "Catechism of the Steam Engine" (Longmans).

JOHN HOPKINS.—We cannot insert your long reply to "F. R. A. S." It is little else than a repetition of your previous statements, and is characterised throughout by an evident inclination on your part for controversy for its own sake.

ANCIENT AND MODERN DURSTON.—It was a hoax; the same query was recently asked and answered in our pages.

YOUNG STUDENT.—Write the Secretary to the Council, and see indices to back vols.

A SUBSCRIBER.—Leroy's composition would suit you. See advertisement.

ASSOC. INST. C.E.—The information was obtained from a German source. You had better communicate with the inventor, whose address was given.

DANE AND WONDERING WILLY.—Inquire of any optician. We cannot spare space for such queries.

LEIBLICH.—We should be glad to receive the proferred working drawings—preferably in two parts as suggested.

OLD COINS.—Your rubbings are too indistinct to engrave.

GEORGE.—Write to the secretary of any insurance society, or ask any insurance agent.

A NOVICE.—Your query was an advertisement, and therefore not inserted. Why not read "Hints to Correspondents," and act accordingly.

P. SANTALINUS.—Yours in answer to "E. L. G." came too late, and the controversy is now closed.

RECENT READER.—Early rising, cold ablutions, regular but pretty good living, patience, and virtue. Those who sin *must* suffer. If you cannot repair the ravages of the past, you may assist in preserving tolerable health in future.

J. H. HALL, John Hopkins, and M. A.—The controversy on "Is Light Invisible" is closed.

J. T. SPRAGUE.—Second article on "Electro-metallurgy" next week.

T. B. S.—Consult last index.

S. LINWOOD.—The subject of Earthquakes and Volcanoes is, as you may see, continued this week.

E. L. W., Stopgap, Turner, J. M. Williams.—Your queries and replies are advertisements.

LENA BURRUT.—We don't remember hearing from you before, and from the tone of your letter do not wish to hear from you again.

HEWITT AND CO.—Your letter on Patent Laws contains nothing but what we have said again and again.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING JUNE 11, 1872.

1680 W. Stother and G. Milton, Manchester, for improvements in "folding desks" suitable to be employed in schools.

1681 A. McKenzie, Renfrewshire, N.B., for improvements in restoring heat to steam boilers or other furnaces.

1682 A. Dugdale, Paris, and J. Mingrat and A. Vansteenkiste, Brussels, for improvements in the manufacture of steam cocks, water cocks, and gas cocks.

1683 T. Hack, Hammersmith, for improvements in pipe connections.

1684 G. Thomas, Stoney Stratford, for improvements in portable cooking apparatus.

1685 G. Shaw and T. Shaw, Dukinfield, Chester, for improvements applicable to rotatory brushes and burnishers.

1686 J. Atkins, Birmingham, for improvements in metallic bedsteads and cots.

1687 R. Carey, Radcliffe-villas, Brixton, for improvements in rotary pumps, applicable also as fluid meters.

1688 J. Hayman, Poole, for improvements in brushes and in apparatus connected therewith.

1689 J. Sullivan, Boston, U.S., for hydrostatic safety apparatus for the rollers on rolling mills or other machinery.

1690 W. Riddell, Bishopsgate-street, City, for improvements in the manufacture of paper pulp from vegetable fibres and in apparatus therefor, which apparatus is also designed to be employed in making chloride of lime for bleaching pulp and in other similar processes.

1691 G. Westinghouse, jun., Southampton-buildings, for improvements in apparatus for working brakes and communicating signals on railway trains by compressed air, parts of which improvements are applicable generally for retarding locomotives.

1692 M. A. Clark, Chancery-lane, for improvements in ladies' bustles or tournures. A communication.

1693 J. H. Johnson, Lincoln's Inn-fields, for improvements in apparatus for applying colouring or mucilaginous solutions. A communication.

1694 G. S. Fleming, Oxford-street, for improvements in stoppers for bottles.

1695 J. Stevenson, T. Carlile, and J. Stevenson, Glasgow, for improvements in the manufacture of bicromates of soda and potash.

1696 I. A. Timmis, Manchester, for improvements in the manufacture of tarpaulin.

1697 E. Orr, Dublin, for improvements in the manufacture of gun cartridges.

1698 J. Hartley and Z. Sugden, Halifax, for improvements in boilers for heating or warming buildings.

1699 J. T. Dann, Cowley-road, North Brixton, for improvements in the manufacture of phosphorus. A communication.

1700 R. Faulkner, Kensington-gardens-square, for improvements in the production of photographic pictures from negatives, and in the means employed therefor.

1701 R. Hall and J. Hobson, Bury, Lancashire, for improvements in looms for weaving.

1702 G. B. Northcote, jun., Feniton, Devonshire, for showing the level of the liquid contained in a vessel, and for a proportional measurer.

1703 A. A. Bois, Paris, for improvements in the construction of ships or vessels, and in the means or apparatus for lading and unlading their cargo.

1704 J. H. Brown, Exeter Hall Hotel, Strand, for an improved principle and method of securing corks and stoppers in bottles, jars, and other receptacles for wine, spirits, beer, ale, aerated compounds, corrosive acids, and other liquids.

1705 J. Hinchcliff, Bromley, Middlesex, for improvements applicable to printing machinery.

1706 A. V. Newton, Chancery-lane, for an improved manufacture of bale tie or coupling. A communication.

1707 D. Vincent, Erith, for improvements in apparatus for distributing liquid, particularly applicable to gas scrubbers.

1708 C. W. Harrison and A. H. Harrison, High Holborn, for improvements in the manufacture of gas for lighting and heating purposes, and in the apparatus employed therein.

1709 L. Scala, Clerkenwell-green, for improvements in dyeing when indigo is employed.

1710 W. M. Brown, Southampton-buildings, for improvements in dyeing animal or vegetable textile fabrics or yarns aniline black, or other fast colours derived from coal tar. A communication.

1711 D. Hunt, Serle-street, Lincoln's Inn, for an improved motive power machine or apparatus. A communication.

1712 J. Hough, Manchester, for improvements in apparatus for coupling or connecting and disconnecting railway waggons.

1713 C. F. Clark and G. Bruerton, Wolverhampton, for improvements in coffee mills.

1714 W. R. Davis, Store-street, Middlesex, for improvements in graining wood and other surfaces.

1715 A. Greenwood, Leeds, for an improvement in the construction of screw gill machinery.

1716 A. Greenwood, Leeds, for an improvement in the construction of screw gill machinery. A communication.

1717 J. Conlong, Blackburn, and J. Smith, Clayton-le-Moors, Lancashire, for improvements in counting apparatus suitable for hank-winding machines and for other purposes.

1718 T. Telford, Newcastle-upon-Tyne, for improvements in the manufacture of bass and other brooms.

1719 W. S. Hodgson, Wortley, Leeds, for improvements in machinery or apparatus for dressing and finishing leather by the processes known as "levanting," "momelling," "glassing," "skiveing," and "whitening."

1720 P. Charpentier, Paris, for improvements in apparatus for heating by gas.

1721 W. C. McBride, Belfast, Ireland, for improvements in machinery for scutching flax.

1722 T. Gray, New Wandsworth, for improvements in the means of treating vegetable fibres for the manufacture of paper.

1723 J. J. Harrop, Manchester, and W. Corbett, Bradford, Lancashire, for improvements in puddling iron and in puddling furnaces.

1724 J. Cole, Great Portland-street, for improvements in breech loading arms.

1725 H. P. Holt, Leeds, for improvement in machinery and locomotive engines for driving tram cars and other road vehicles, parts of which improvements are applicable to other steam-engines.

1726 J. Dorrell, Westbourne-park, for an improved apparatus for containing coal, corn, or other commodities.

1727 J. N. Colby, Glasgow, for improvements in the glands of stuffing boxes for piston and other rods.

1728 J. Morris, Liverpool, for improvements in and connected with machines for finishing printed sheets of paper.

1729 W. E. Newton, Chancery-lane, for improvements in nocturnal telegraphic apparatus. A communication.

1730 A. Moseley, Newcastle-on-Tyne, for improvements in the construction of fire escapes.

1731 C. H. Russell, Regent-street, and J. Sax, Great Russell-street, Bloomsbury, for improvements in apparatus for marking or scoring at billiards, and for indicating the number of games played, and for other similar purposes.

1732 A. G. Speight, Spencer-street, Clerkenwell, for improvements in the manufacture of collars, cuffs, shirt fronts, and like articles for personal wear.

1733 C. J. Mercier, Paris, for improvements in the manufacture of indiarubber tissues for clothes and similar articles of a waterproof nature.

NEW EVIDENCE ABOUT STAR SYSTEMS AND STAR DRIFT.

By RICHD. A. PROCTOR, B.A., CAMBRIDGE,
Honorary Secretary of the Royal Astronomical Society,
AUTHOR OF "THE SUN," "OTHER WORLDS THAN OURS," "ESSAYS ON ASTRONOMY," &c., &c.

IT will be already known to those who read these columns, that on Thursday, June 13, Dr. Huggins announced to the Royal Society that among several other important discoveries he had found that there are systems of stars travelling bodily, or *drifting*, in definite directions through space. He had applied to these stars the spectroscopic method of determining stellar motions of approach or recession, and he had found (what no other method of determining stellar proper motions could have shown) that certain groups of stars are travelling with equal velocity towards or from the earth. Among such groups he mentioned one, the group formed by the stars, β, γ, δ, ϵ, and ζ Ursæ Majoris, respecting which I had announced more than two years ago not only that they form a drifting set, but that whenever Dr. Huggins applied the new method of research to them he would find that they were either all receding or all approaching at an equal rate. He has found that these five stars are actually all receding at the rate of about 30 miles per second. Moreover, he has found yet further evidence of their forming a single family or set of stars: for they all have similar spectra, with the lines of hydrogen strongly marked; whereas the stars Alpha and Eta Ursæ have spectra differing in character, the lines of hydrogen being scarcely discernible at all in the spectrum of Alpha, and not nearly so intense or broad in the spectrum of Eta as in the spectra of the other five stars.

I cannot but esteem myself most fortunate that within a few days only from the publication of my researches into the laws of stellar distribution and motion, such striking evidence in favour of one of the cometary theories should have been obtained by so skilful an observer and so eminent a physicist as Dr. Huggins. To say, indeed, that I am in a special manner gratified to find that my vaticinations respecting certain stars should turn out to be just, would be inexact. I had expressed no greater degree of confidence than I actually felt when I said that those stars would be found to move in a certain way, whenever the new method of research was applied to them; and I should have had abundant reason to be ashamed if so confident a prediction had been shown to be erroneous. For I hold that though every student of science must expect to fall into errors, and to have from time to time to withdraw or modify his published *opinions*, yet that it indicates a grave offence against scientific morality to be convicted of error where a theory has been announced as demonstrably true. It very seldom happens that a student of science is able to assert his *conviction* as distinguished from his *mere opinion* that a theory is sound. When he does so, he may be said to have staked his reputation on the result. If the theory is shown to be erroneous, it is demonstrated that either he spoke untruly in expressing conviction, or that he had yielded to an almost equally culpable fatuity. In either case he has lost thenceforth all claim on the confidence of other students of science.

Wherefore, in passing, I may lay down this general rule, that the student of science should rather fail on the side of caution than of confidence; that he should prefer to say "the evidence points to the belief" than "the evidence convinces me;" that he should be careful not to say "I have *shown* such and such a theory to be true," when in reality he has only gathered some evidence in its favour; and, lastly, that he should test a view in every possible way, and examine it in every possible light, before he announces it as a demonstrated theory. Or rather—in ninety-nine cases out of a hundred, he should attend to all these matters, and then *not* announce his theory (as demonstrated). As a rule, it will not lose by waiting. The exception is, when by so announcing it, the help of others may be gained for further inquiry in the same direction, or when the promulgation of some erroneous theory is injuriously affecting the progress of scientific inquiry. In either case it becomes the bounden duty of the student of science to speak plainly, if he really has deduced from sound evidence a demonstration of such and such facts.

The misfortune is that a line of reasoning which may afford a real demonstration may not be convincing save to a few. Michell proved, for instance, that certain stars lying close together must really be physically associated; and he very properly announced the discovery. A quarter of a century later Sir W. Herschel demonstrated the same fact by evidence which every one could understand. But Michell's demonstration, though more subtle, was as complete. If every person who read his paper had mastered certain branches of mathematical research, every one would have admitted Michell's reasoning as unanswerable. But because the majority could not appreciate Michell's reasoning, the world waited until Herschel had *watched* one star moving round another. This was a demonstration every one could understand; and thus the discovery is very naturally (though incorrectly) attributed to Herschel instead of Michell.

Hence the student of science may learn a second lesson. If he has demonstrated a certain fact and has occasion to announce it, he should take care to present it in an acceptable form. For instance, he should prefer pictures (when he can give them) to tabular evidence. The world has not time to examine tables of figures in order to see whether they really bear out such and such statements. He should remember, too, that though the world is not unwilling to be convinced,* a subject must be rendered to some degree attractive before it will gain general attention.

This, however, is a digression. Let us return to Dr. Huggins's discovery.

It can be shown that the spectroscopic method of research into stellar motions—if it can be extended to stars of the lower orders of magnitude (I mean the fainter stars), is likely to throw much light on the subject of real star magnitudes.

Thus we have seen that the stars included in the dotted line in the accompanying figure form two companions, are farther away than α and η, or the reverse? I conceive that we have, in the proper motions of these stars on the celestial vault. The direction and magnitude of these proper motions are indicated by the small arrow attached to each star, the point of the arrow showing the place on the heavens which will be occupied by the several stars at the end of 36,000 years.* Now, it will be admitted that the nearer a star is to us the more likely is it to be affected (apparently) by the proper motion of the sun, in such sort that a portion of its apparent proper motion would be due to the sun's real motion. We may, indeed, assume, without improbability, that that solar proper motion which causes a general prevalence of stellar proper motions in a certain direction, has reference to that portion of star-space which lies nearest to us. On this view we have only to inquire whether the stars β, γ, δ, ϵ, and ζ on the one hand, or α and η on the other, shift on the heavens more strictly in accordance with the effects due to the sun's proper motion in space, in order to ascertain whether the former or the latter are nearer to us. The answer comes in no doubtful terms. The stars α and η are moving in the star-vault almost exactly as they should if the sun's motion were alone in question, whereas β, γ, δ, ϵ, and ζ are moving in almost the exactly contrary direction. It can scarcely be questioned, then, that the latter are far the most remote.

Now, it is worthy of inquiry whether the direct spectroscopic analysis of these stars throws any light on this subject of distance.

Since β, ϵ, and ζ are not very unequal in apparent magnitude to α and η, it follows that if β, ϵ, and ζ are very much more remote they must in reality be very much larger than α and η.

Thus, suppose ϵ to be twice as far away as η (a very moderate assumption under the circumstances), then, since these stars are equally bright, or very nearly so, ϵ must really give out four times as much light as η. Hence, assuming equal intrinsic luminosity of the surfaces of these stars, it follows that the star ϵ is eight times as large as the star η. And similar reasoning applies to the other stars. As, however, it is altogether in better accordance with known analogies that the distance of the more distant drifting system should exceed many times the interval between the sun and the stars η and α, it would follow that the stars β, γ, δ, ϵ, and ζ are not eight or ten times, but *many* times larger (several hundred times larger, for example) than η and α.

Now, we might be led to the inference, as at least probable, that since the stars β, γ, δ, ϵ, and ζ

a single set or scheme. It follows as extremely probable that the stars α and η do not belong to the same region of space as the scheme formed by the other stars. In this case, they either lie very much nearer to us or very much farther away. It is true, indeed, that we might conceive the stars belonging to one drifting set to be carried into another set drifting in another direction. But it is altogether more probable that one set drifts one way because it has been exposed to such and such attractive influences, while the other stars, seemingly intermingled, have no such drift, because, being far removed from that region of space, they have been exposed to different influences.

Now, have we any evidence to show whether the five stars, β, γ, δ, ϵ, and ζ, as well as ζ's which thus exceed so largely the stars η and α (themselves certainly as large as our sun), the spectrum which is common to those five stars is in itself indicative of exceptional largeness. For it is manifest that when a star or sun is exceedingly massive, the gaseous envelopes which surround it must exist at a degree of pressure far exceeding that prevailing among the corresponding envelopes in the case of smaller orbs, like our own sun. And though it would by no means follow that the dark lines due to certain vapours would therefore be strengthened, yet there are some vapours whose lines we might expect to find broader and stronger. For instance, the vapours of the metallic elements would probably not produce stronger lines, or lines so strong, as in smaller suns, simply because a greater proportion of these vapours would occupy a position where their heat would be as great as

* Whenever a student of science asserts that he has been unfairly treated, and that the world is in a conspiracy against his views, it may be pretty generally taken for granted that the fault is not with the world at large. There is a considerable fund of generosity and kind-heartedness in human nature, and a man who works out his facts honestly and patiently will seldom have to complain of want of sympathy. Only he must not expect all men to give their attention solely to him. Some few may have other matters to think of.

* I adopt this arrangement here as in "Other Worlds," and elsewhere, as it gives a convenient scale for the arrows, and an easily remembered relation between the length of a degree on the sphere and the unit of measurement for these arrows. A star which would move over one degree of arc in 36,000 years would move over one second of arc in ten years, or a tenth of a second per annum.

that of the photosphere, and where, therefore, they would not cause absorption, or, rather, would radiate as much light as they absorbed. But the lighter gases, and particularly the gas hydrogen, might be expected to produce very strong and broad absorption lines, because a relatively greater portion of such gases would be in a position where it would act absorptively on the light from the photosphere. Now, it is the case, as we have seen, that the lines of hydrogen are remarkably strong in the spectra of the five stars β, γ, δ, ϵ, and ζ Ursæ, whereas in η the hydrogen lines are not nearly so strong, and in α they are somewhat remarkably weak.

Here, then, at any rate, is a suggestion of a certain view as to the significance of stellar spectra, which, should it be confirmed by future researches, could not fail to throw a considerable degree of light on the subject of the constitution of the heavens. Let us pause a moment to inquire how far it is confirmed by other known facts.

The star Sirius is one of those which has a spectrum with remarkably strong and broad hydrogen dark lines. Now, this star is certainly much larger than our sun, or, rather, it certainly gives out much more light. It is exceedingly probable that the intrinsic lustre of its photosphere is greater than that of the solar photosphere—yet not very greatly, we may suppose, since the researches of St. Claire Deville and others tend to show that there is a limit to the light and heat which matter can give out, under whatever circumstances. Now, assuming that the intrinsic luminosity of Sirius is equal to that of our sun, it is demonstrable that if we take the limiting determinations of the annual parallax of Sirius and of his absolute lustre as compared with the sun's, his orb is greater than the sun's in a proportion ranging from a minimum of 2,000 times to a maximum of 8,000 times. Taking the highest conceivable estimate of the inherent luminosity of Sirius, the lowest estimate of his absolute lustre, and the maximum value of his parallax (which, of course, gives the least value for his distance and for his magnitude, so far as its calculation depends on his distance), we cannot suppose that the volume of this star falls short of 1,000 times that of our sun. Here, then, is evidence strikingly in favour of the inference that a spectrum with strong hydrogen lines is indicative of relatively enormous magnitude.

Other stars which show this spectrum—as Altair, Vega, Rigel, and Regulus—are certainly very large stars, since we are certain that our sun, removed to a distance where, like these stars, he would have no measurable annual parallax,* would not shine nearly so brightly even as Regulus, the faintest of the four just named. It is a remarkable fact that Secchi has found this spectrum in the case of about one-half of the 600 stars he has examined. Unfortunately, Secchi's observations are somewhat rough, and have not always been confirmed by the more trustworthy researches of our great countryman, Dr. Huggins.

It will tend then greatly to throw light on the subject of the constitution of the heavens if it can be shown that, as Secchi asserts, the stars in certain regions exhibit similar spectra. We have seen that Dr. Huggins has confirmed this in one special instance. But if he can show that it is true in several cases, we shall have a means of, as it were, *placing* certain star groups. For when once we know that certain groups form a set (and can distinguish them from other stars seen in the same direction) we have only to inquire whether their average proper motions on the heavens imply relatively great distance or the reverse, whether their spectra imply great bulk or not, and so on, to gain an insight into their probable position, as a system, in the stellar universe.

The extension of the new method of determining motions of recess or approach to the fainter orders of stars, if it could ever be accomplished—and I conceive that at an elevated station, where the atmosphere was clear and pure, this might be done—would also afford an insight into the average *real* motions of the stars, which would cause the observed proper motions on the heavens to be much more significant as to stellar distances than at present.

* Vega is included among the stars whose parallax has been estimated. For my own part, I must admit that after noting the discrepancies in the estimates of the parallax of Sirius, and even of 61 Cygni, by the best observers, I find myself unable to place the slightest reliance in the actual measures of parallax, with the single exception of that of Alpha Centauri; and it is only in the cases of Sirius, 61 Cygni, and one or two other stars, that I can believe that an observable but not accurately measurable parallax exists.

It is very necessary, however, that we should have the heavens gauged with telescopes of different aperture, after the manner indicated in my "Essays on Astronomy." This is a work in which every possessor of a good telescope could take useful part, and it could not fail to throw important light on the subject of the constitution of the universe. Let it be remembered that Sir W. Herschel gave but a minute portion of his time to the work of star-gauging—that what he did was, as he said, "only an example to show the spirit of the method;" that Sir J. Herschel did only about as much work in obtaining certain gauge-fields in the southern heavens, and that Struve has pointed to the absolute necessity of systematic gauging, and with telescopes of different aperture. The work is by no means difficult, and it would "tell" quickly if the results of the gauging were duly (even though very roughly) charted.*

There is, indeed, an immense mass of work to be done towards advancing our knowledge of the stellar universe. Instead of being an explored field, as so many imagine, this field of research has scarcely been more than entered. What Dr. Huggins has just done proves that those peculiarities of structure on which I have so long insisted have a real existence. I venture to hope that the processes of research I have so long been advocating may now be entered upon. I have before me as I write the words of Sir John Herschel, the greatest astronomer of our age, and of the Astronomer Royal, the highest living authority on subjects astronomical, in confirmation of my opinion of their extreme importance.

* My star-gaugings with the telescope placed at my disposal for the purpose by the Royal Astronomical Society, have extended only to the region between Pleiades, Capella, and Betelgeux. (I propose next winter to renew them under slightly changed conditions.) This region is singularly interesting: it shows a very remarkable vacancy near the Bull's horns. This vacant space extends beyond my telescopic range: I should much like to know *how* deep (telescopically).

ASTRONOMICAL NOTES FOR JULY.

BY A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

THE right ascension of the Sun at Greenwich mean noon on July 1st is 6h. 42m. 57·46s., and his declination 23° 5′ 20·5″ north. Hence he will be found between the two stars ϵ and 36 Geminorum, at about two-thirds of the distance from the former. He rises in London on the 1st at 3h. 50m. a.m., and sets at 8h. 17m. p.m.; his rising and setting on the 31st taking place at 4h. 24m. a.m. and 7h. 48m. p.m. respectively, in the same locality. Twilight still persists from sunset to sunrise up to the 21st, on and after which there will be a very short (but, of course, gradually increasing) interval of real night. The equation of time is additive during the whole of July, increasing from 3m. 34·62s. on the 1st to 6m. 4·58s. on the 31st. The semi-diameter of the Sun at the instant of his Greenwich meridian transit on the 1st is 15′ 46″, this semi-diameter occupying 1m. 8·75s. of sidereal time (convertible into mean time by the subtraction of 0·19s.) in its passage over the meridian. On the 31st his apparent semi-diameter will have increased to 15′ 47·8″, and this will occupy 1m. 6.68s. of sidereal time (convertible, as above, into mean time) in its transit. The Sun will attain his minimum diameter on the 2nd, at noon, on which day he will be in apogee, or at his greatest distance from the earth. The sidereal time at mean noon is, on the 1st, 6h. 39m. 22·87s., and on the 31st is 8h. 37m. 39·59s.; the mean time at sidereal noon, or mean time of transit of the first point of Aries being 17h. 17m. 46·65s. and 15h. 19m. 49·31s. on those days respectively.

The Moon will be New at 6h. 24·9m. in the evening of July 5; enter her first quarter at 7h. 48·1m. on that of the 13th; be Full at 1h. 53·3m. in the afternoon of the 20th; and enter her last quarter at 7h. 18·7m. a.m. on the 27th. She is 25·4 days old at Greenwich mean noon on the 1st, and 29·4 at the same hour on the 5th. After this she will at noon on the 6th be 0·7 day old, and so on until the 31st, when her age will evidently be 25·7 days. At 11 a.m. on the 14th Libration will render more of her south-east quadrant visible, while at 3 p.m. on the 26th more of her south-west quadrant will be turned towards the earth from the same cause. The observer will, however, very evidently indeed, be unable to avail himself of either of these phenomena. The Moon will be in conjunction with Mars at 2h. 34m. in the afternoon on the 4th; with Venus at 11h. 30m. a.m. the next day; with Mercury at 11h. 20m. on the night of the 6th; with Uranus at 2h. 35m. in the early morning of the 7th; and with Jupiter afterwards, 11 minutes before noon. Lastly, she will be in conjunction with Saturn at 8h. 13m. in the evening of the 19th.

Six actual occultations of, and six close approaches of the Moon to, various fixed stars will take place during the month of July. Beginning with the evening of the 9th the moon will, as viewed from Greenwich, pass quite close to ι Leonis at 9h. 37m., and at 9h. 32m. on that of the 14th will also be almost in contact with 2 Libræ. The first real occultation will take place on the 16th, when BAC 5395 will disappear at the Moon's dark limb at 9h. 42m. p.m. to reappear from behind the bright one at 10h. 54m. At 11h. 28m. the next night (that of the 17th) the moon will almost touch 39 Ophiuchi, and at 1h. 5m. the next morning her dark limb will occult θ Ophiuchi; the star will, however, have set ere it reappears at the bright limb afterwards at 1h. 49m. During the early morning of the 21st at 4h. 6m., BAC 7197 will disappear at the Moon's bright limb, reappearing (below our horizon) at the dark limb at 4h. 42m. On the night of the same day, the 21st, BAC 7550 will disappear at the bright limb of the Moon at 11h. 38m., reappearing from behind the dark limb 37 minutes after midnight. On the 22nd, at 2h. 27m. a.m., τ^1 Aquarii will be occulted by the Moon's bright limb, and will emerge from behind her dark one at 3h. 37m. Subsequently, at 3h. 56m., τ^2 Aquarii will disappear at the bright limb, and reappear at the dark limb at 4h. 47m. Finally, the moon will make close approaches to 64 Ceti at 1h. 46m. a.m. on the 27th, and an hour afterwards to ξ^1 Ceti; as also to 121 Tauri at 4h. 14m. a.m. on the 31st.

Mercury sets after the Sun during the entire month, and during the latter part of it will be in a tolerably favourable position for observation. He will be on the meridian on the 1st 38·5m. after noon, and on the 31st at 1h. 50·7m. in the afternoon. During the middle third of the month he may be picked up near the west-north-west part of the horizon immediately after sunset. Mercury will be, as previously stated, in conjunction with the Moon at 11h. 20m. on the night of the 6th. He will further be in conjunction with Uranus at 8h. 34m. in the evening of the 7th; with Jupiter at 6h. 42m. in the afternoon of the 10th; and with Regulus (α Leonis) at 2h. 43m. on that of the 24th.

Venus is, for all practical purposes, invisible during the whole of July, from her proximity to the Sun; with which she is in superior conjunction at 5h. 47m. a.m. on the 16th. Her conjunction with the Moon at 11h. 30m. a.m. on the 5th has been before adverted to, and we may add that she will also be in conjunction with Uranus at 6h. 3m. a.m. on the 22nd, and with Jupiter at 2h. 22m. a.m. on the 29th. There are obvious reasons why none of these conjunctions will be observable.

Mars is a morning star, rising on the 1st at 2h. 52m. a.m. and southing at 11h. 12·2m., while on the 31st he rises at 2h. 25m. a.m., and is on the meridian at 10h. 41m., evidently setting in bright daylight. He is travelling through Gemini during the whole of July, but does not go near to any very conspicuous star. As his diameter is now only some 4″, and he is almost exactly circular, he possesses not the very slightest interest as a telescopic object. We have spoken above of his conjunction with the Moon at 2h. 34m. p.m. on the 4th.

Jupiter is now rapidly departing for the season, but during the earlier part of the month may be caught near the north-west horizon soon after sunset. He is on the meridian on the 1st at 1h. 46m. in the afternoon, and on the 31st only 14·7m. after noon. He is travelling through a portion of Cancer. His conjunction with the Moon at 11h. 49m. a.m. on the 7th; with Mercury at 6h. 42m. p.m. on the 10th; and with Venus at 2h. 22m. a.m. on the 29th, have been noticed under other heads.

It is just possible that the beginning of the transit of satellite 4 at 9h. 8m. in the evening of the 1st; that of satellite 2 at 9h. 18m. p.m. on the 2nd; and the reappearance from eclipse of satellite 1 at 9h. 23m. 20s. on the 3rd may be perceptible; but from July 3 to August 28 the satellites of Jupiter are invisible, from his proximity to the Sun.

Saturn is really the chief object of attraction in the night sky; but he continues in Sagittarius in the same deplorable position for observation which he has so long occupied. He rises on the night of the 1st at 8h. 37m., is on the meridian at 38·7m. after midnight, and sets at 4h. 40m. (after sunrise) the next morning. On the 31st he rises at 6h. 32m., souths at 10h. 31·6m., and sets at 2h. 32m. a.m. on August 1st. He is in opposition to the Sun at 11h. 13m. on the night of the 9th. His conjunction with the Moon at 8h. 13m. p.m. on the 19th has been previously spoken of.

Uranus is much too close to the Sun to be now observable.

Neptune rises some quarter of an hour after midnight at the beginning of the month, and about 12 or 13 minutes past 10 p.m. at the end of it; his southing and setting both taking place in brilliant daylight. He will be found *just* to the north-east of *o* Piscium. He is in so-called "square" with the Sun at 5h. 11m. in the afternoon of the 18th.

It may be interesting to note, in connection with this month, that on July 1st, 1770, Lexell's Comet came within 1,400,000 miles of the earth (the nearest approach of which any record exists). Perhaps it will tend to reassure some of those whose faith in the constancy of Nature may have been shaken by some recent very blatant assertion, if we add that (although we have the fullest details of the resignation of the Duke of Grafton, the succession of Lord North to the office of Prime Minister, the growing discontent in America, and the sensation created by the Letters of Junius) not one syllable has come down to us about a Deluge, universal or partial; nor were the most able trigonometricians of that day able to detect the slightest sign of an ark.

Watch should be kept for shooting stars between the 26th and 29th of July, as there would seem to be tolerably good evidence of the existence of a recurrent shower at this period.

THE CAUSE OF CONSUMPTION.*

SO long ago as 1855 Dr. Mac Cormac published the first public statement of the theory by which he seeks to account for the origin of consumption—tubercular disease of the lungs, the "fell destroyer," as the novelists term it, which decimates the populations of Europe. We say seeks to account, because although Dr. Mac Cormac considers the arguments he advances as "all cogent and conclusive," professional rejoinders have not been wanting, which show that many of those "learned in medicine" refuse to accept his hypothesis, while others, probably inclined to look favourably upon it, regard it as simply "not proven." It is abundantly evident from the book before us that our author has seen no reason to modify the theory first broached by him in his work on "Consumption as engendered by Rebreathed Air;" and while contenting ourselves by expressing the opinion that, in a common-sense point of view, there is much of truth in the argument put forth by Dr. Mac Cormac, we proceed to lay before our readers a brief résumé of its principal features. Stated in a few words, the theory is that tubercular disease of the lungs is caused solely by breathing air which has already passed through the lungs of either brutes or human beings, or air that is deficient in oxygen. If we assume the quantity of air in the chest at about 230 cubic inches, and that from twenty to thirty cubic inches are changed and removed during each respiration, about ten breathings will suffice to renew or exchange the gaseous contents of the chest cavity. At each inspiration from 4 to 5 per cent. of the oxygen inhaled is, or should be, replaced by about the same quantity of carbonic acid, an amount which in a few hours would be represented by an appreciable weight of solid carbon. If any portion of the inhaled air be pre-breathed air, says Dr. Mac Cormac, the dead metamorphic carbon will be retained *pro rata* unoxidised within the organism. This effete unoxidised carbon — this "detritus of degradation" being retained—speedily becomes "tubercle." It is not to be supposed that the unoxidised carbon left after two, twenty, or a hundred inspirations of pre-breathed air, or air in which there is insufficient oxygen, will result in the deposition of tubercle; but "one condition of things, to wit, the habitual respiration of already breathed air, having begun, the sequence of the other, namely the deposit of tubercle, follows as a matter of necessity." Such, in brief, is Dr. Mac Cormac's theory; the facts on which he bases it being ably gathered together, and brought to bear from his point of view. Our author, naturally enough, is opposed to the idea that consumption is hereditary. He holds that the same causes which produced it in the father may produce it in the son, but that those causes are avoidable and the disease preventible. In several places in his book he asks pertinently, What *is* tubercle? if not the dead carbon which has been left unoxidised by impure air; and as yet he has certainly not received a satisfactory answer.

Dr. Mac Cormac says that without adequate ventilation we cannot possibly get rid of the ten or twelve hundred cubic inches of carbonic acid which the lungs eliminate hourly. No air—at least no respired air—ought to contain a larger amount of this poisonous gas than the infinitesimal proportion of one or two parts per ten thousand. Now, as a matter of fact, it will be a difficult matter, we think, to find air so free from carbonic acid as Dr. Mac Cormac requires, for De Saussure found near the Lake of Geneva an average of five parts in 10,000, and Dr. Angus Smith found a mean of 332 parts in a million on the tops of such mountains as Ben Nevis and Ben Lomond. But this is a detail. Dr. Mac Cormac appears to have left no stone unturned to find facts to support his theory, as is evidenced by the opinions of eminent foreign medical men quoted by him. He has also been at some pains to obtain the average death rate from consumption in various parts of the world. We learn from him that in the Austrian capital phthisis prevails to such an extent as to have been named *morbus Viennensis;* but he traces the cause readily enough to close stoves in stuffy chambers, to doubly-glazed and padded windows, which are never opened, ventilation being entirely unthought of. A similar state of things he finds to exist nearly everywhere, the deaths being from 28 per cent. in some parts of America to 10 per cent. in Paris, while in S. Petersburg, out of 5,000 deaths, 1,900 are occasioned by phthisis! "Double doors and windows, every interstice being carefully closed with wadded cloth or *voilok*, exclude the current, and, along with the close stove or *petch*, render stagnant utterly the stinted breath-fouled atmosphere, effectively hindering its replacement from without, and, in fine, entailing the direful scourge of tubercle, from which no class or condition of the community finds escape." On the other hand the North American Indian and the Patagonian, who as frequently sleep in the open air as in their rude cabins, enjoy an immunity from consumption which in civilised quarters is only exhibited by the inhabitants of the West Highlands and the Hebrides, amongst whom tubercle is unknown. And yet Scotland as a whole is decimated by consumption. Every luxury that wealth can purchase, the most nutritious food, and the most careful nurture fail to keep it at bay; but in the Hebrides, where the scanty fare, the wretched huts, and the hard life would, popularly and medically, be considered productive of phthisis, "no scrofula, no consumption, in short, no tubercle-engendered malady whatever is to be seen." How account for these undoubted facts, save on the theory of Dr. Mac Cormac? He ridicules the idea which has been mooted that the West Highlanders obtain immunity from the disease by the inhalation of peat smoke, which, he points out, is abundant enough all over Scotland without awarding a like immunity elsewhere. The Hebrideans, in fact, live in ceilingless, partitionless hovels, each provided with a hearth on which a fire is continually burning. There a hole in the roof answers at once as a chimney and as a most efficient ventilator, and as the door of the hovel is rarely shut the air of the "room" is never stagnant and is never fouled. To imitate this state of things is the preventive means which Dr. Mac Cormac recommends to avoid creating the terrible disease; for if his theory is right it is certainly created. Therefore draughts and open windows are to be encouraged, especially at night, for if the body is well covered no harm will accrue; he speaks of entering his boy's bedroom and finding a fringe of snow on the coverlet, while the sleeper slept the sleep of health, all uninjured by the cold. The closely-curtained bedstead of our forefathers is a thing of the past; how long before it becomes the rule and not the exception to sleep with the windows open! "The respiration of unpolluted air by night will even go some way to neutralise," says Dr. Mac Cormac, "the evil influence of any vile pernicious atmospheric environment when we are constrained, as we too often are constrained, to breathe it by day." There is, however, one flaw in the doctor's theory which will occur to most of our readers, and that is that consumption does not come with "equal foot" to all our doors. True, it visits all *classes* tolerably equally, but of two men, working and living under exactly the same influences of "pre-breathed" air, one may fall an early victim while the other may live to the allotted span. It is true Dr. Mac Cormac acknowledges that, "once deposited, supposing only that there are no additions to it, tubercle may subsist long years latent; it may be eliminated speedily, or it may become cretaceous;" but this does not meet the case; for if the hypothesis is not baseless every one who continually breathes pre-breathed air for any length of time *must* contract tubercle. Is it so?

The subject of the present volume is one that is of more or less importance to every family in the kingdom, and readers of all classes will find much to interest them, even if they fail to profit by the teachings of a man so evidently in earnest as Dr. Mac Cormac. We regret to see the eccentricities of printing which, some will probably consider, disfigure the volume; because a man who exhibits crotchets in spelling and punctuation renders himself liable to be summed up as crotchety altogether. Of late years medical men have been great offenders in this respect.

* Consumption and the Breath Rebreathed. By Henry Mac Cormac, M.D. London: Longmans.

NOTES OF FRENCH SCIENCE.

DR. BEDOIN recently examined a lead Chassepot bullet taken from the body of a suicide. After passing through the softer parts it had been stopped by the vertebral column, and its *vis viva* changed into heat. As it showed signs of fusion, the temperature must have reached 315°.

M. Cailletet has investigated the influence of pressure on the spectra of gases. He fixed two platinum wires in the end of a thick glass tube, into which the gases were passed. The spark from an induction coil connected with three Bunsen elements passed between the wires. At ordinary pressure, the bright lines of the spectra of the gases appeared on a slightly illuminated ground; and as pressure was increased they grew brighter, but they by and by became merged in a continuous spectrum, whose brightness also increased with the pressure. At a certain pressure (between 40 and 50 atmospheres) the discharge suddenly ceased; and though the battery power was increased, and the distance between the platinum wires reduced to ½ millimetre it was not possible to obtain the spark beyond this point. It is thus seen that a spark which passes easily in the rarefied gas of Geissler tubes, or the electric egg, meets with considerable resistance in compressed gas. The brightness of the spark at the point beyond which the discharge is unobtainable is 200 times greater than at ordinary pressure.

Palmieri states, in a communication to the Paris Academy of Sciences, that on the night of April 26 a fissure opened on the south-west side of Vesuvius, the lava from which raised the scoriæ of previous years, and made a sort of hillock about 60 metres high. At the base of this the lava flowed with wonderful tranquillity, without noise or projections. None of the usual eccentric or adventitious cones were formed at the side of the fissure. Another curious fact is that the lava in the Fossa della Vetrana, flowing with a breadth of 800 millimetres, made successively three veritable eruptions, throwing out globes of vapour and incandescent scoriæ. The smoke from these was darker than that from the lava. Each of the eruptions lasted half an hour. The Professor made electrometric observations on the cloud of vapour, cinders, and lapilli which was carried over the Observatory. The vapour alone, without cinders, showed positive electricity; the cinders alone, negative; when mixed, they gave various results. Lightning flashes appear only when the vapour is largely mixed with cinders; and it is not true that the lightnings are without thunder, as some historians of Vesuvius relate.

M. Dufour has made observations as to the rate of growth of the nails. Here are some of his results: The nails of the little fingers grow more slowly than those of the other fingers and the thumbs. The difference is about one-ninth. The mean rate of these (excluding the little fingers) is about one millimetre (100th part of an inch) in ten days. The rate of growth on the thumbs is probably greater than that on the six longer fingers. There is little difference between the rates of growth in different animals. The nails grow at about the same rate on both hands. The rate of growth is not constant throughout the length of the nail; it is greater near the base. The rate of growth at the side parts is probably the same as in the middle part. The substance of the nail advances equally throughout its breadth. The rate of nail growth in an individual at intervals of several years shows sensible differences.

CRYSTALLISED IRON.

IN opposition to a commonly-received idea that wrought iron becomes crystalline and brittle when subjected to vibration, M. Caron recently brought before the Paris Academy the result of observations he had made on certain railways, which showed that the fracture of axles had in every case been occasioned either by the bad form of the pieces, or the faulty nature of the iron before it had been used. He contests the assertion that bar iron becomes crystalline and brittle under the influence of winter cold. This idea has arisen from the crystalline appearance of iron pieces that had been broken in such low temperatures. It is undoubted that there is more breakage of railway axles, and more breakage in the bones of men and beasts in winter than in summer, but the cause of such accidents is to be found in the greater hardness of the ground, the stiffness of joints, and the greater violence of knocks and shakes to which the pieces are subjected; and the fact of a crystallised appearance in the broken parts does not necessarily show that such crystallisation arises from the lowering of temperature. To prove this satisfactorily it would be necessary to show that a bar of iron which was crystalline at (say) — 20°, resumed its fibrous structure when the temperature was raised to + 20° C.

In order to test the influence of cold on iron, M. Caron experimented as follows:—Several pieces of good bar iron were exposed for four months in the ice factory of M. Tellier at Auteuil, to temperatures varying from 0° to — 18°. Others were allowed to remain throughout the cold of last winter at a temperature of about 20° in the open air. M. Caron then caused the pieces to be broken, both in their cold state, and after the temperature had been raised several degrees above zero. In no case was there any appearance of crystallisation. Of course, he had assured himself of the good quality of the iron beforehand. Iron of inferior quality acts differently; its brittleness is perceptibly increased through cold.

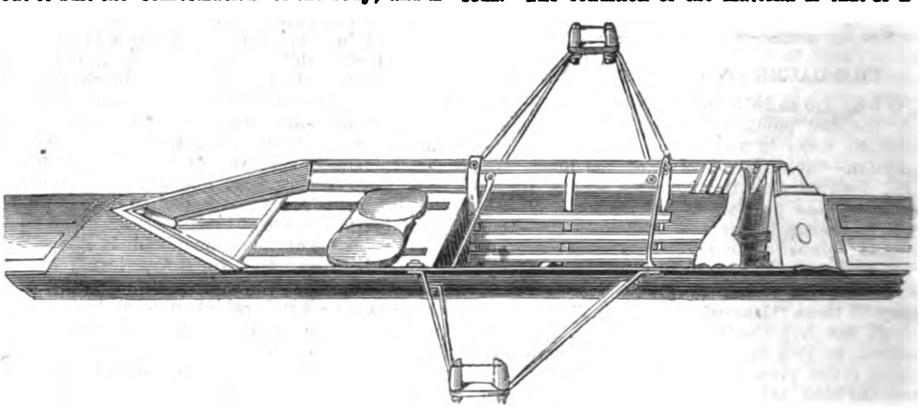
The experiments of M. Caron seem to prove that when a bar of iron breaks, through vibration or shocks, and the fracture presents a crystalline appearance, this crystallised state was that in which the iron was previously to its being used; and it is to be attributed to faulty manufacture, not to usage or cold after the piece was completed. From this it follows that the testing of *e.g.*, 4 or 5 per cent. of a large number of pieces of wrought iron does not supply a proper guarantee of the good quality of the remaining pieces, because of the varying care bestowed on the pieces, and various treatment of them as regards temperature and other points. A. B. M.

NEW MATERIAL FOR BRICKS.

DURING the last few years experiments have from time to time been made with the view to utilise in some way the mounds of shale (the refuse of the coal-mines) which cover an area of several thousands of acres in South Staffordshire, by converting them into bricks. Several enterprising firms have already embarked in this novel but profitable business. When properly pulverised the shale is found to be an excellent material for the purpose, the bricks produced being hard and durable, resembling in colour the fire-clay bricks of the Stourbridge district, although for furnace and such like purposes they are not so valuable. For ordinary building, however, they are found to be of equal practical value to the ordinary red bricks, the only possible objection to the former being their colour, which is somewhat too light for a smoky district like South Staffordshire. This objection, however, could only apply to their use for buildings of architectural pretensions ,and such buildings in the black country do not predominate. There is every reason to believe that this method of utilising the innumerable dusky hillocks which disfigure the South Staffordshire landscape will gradually develop into an industry of some importance. The material is to be had in any quantity for a mere nominal sum, and its exhaustion in those parts of the district where the collieries are worked out would be doubtless followed by a restoration of the landscape to a much nearer resemblance than it now bears to its former beauty.

NEW SLIDING SEAT FOR RACING BOATS.

THE principal features of the new sliding seat for outriggers and racing boats generally, which is believed to have contributed in no slight degree to the success of certain crews in recent matches on the Thames and elsewhere, will be readily understood from the accompanying illustration of the form recently registered by Messrs. Searle and Sons, the eminent boat-builders. This device has formed the subject of much discussion pro and con. amongst the "knowing ones" of the aquatic world, and the advantages which one side claims are fiercely disputed by the other side. Be this as it may, sliding seats have been used by many winning crews lately, and in the race between the Atalantas and the London Rowing Club, both boats were fitted with them. We believe that Elliott, the New York boatbuilder, was the first to make the suggestion of constructing the seat to slide, and he probably derived the idea from our North-country rowing men, who formerly constructed their boats with broad seats, which they liberally anointed with grease. By this means they considered that the weight of the body could be thrown into the stroke with more facility, and that the muscles of the legs could be brought into greater play and the stretcher utilised to the full extent. It is asserted for the new sliding seat, which is really only the mechanical adaptation of the principle underlying the Tynesiders' use of "grease," that it enables the rower to get further forward, and by utilising more effectively the muscles of the legs, equalises the effort from the beginning to the end of the stroke, at the same time relieving to a great extent the strain upon the arms. In the design registered by Messrs. Searle the seat is hollowed out to suit the conformation of the body, and is



attached to two hard-wood runners, which travel with a minimum of friction in grooves lined with brass or other metal in the under seat. The President of the Cambridge University Boat Club is said to have thoroughly tested the new contrivance, and to have highly approved of it, while many other noted scullers have also expressed the same opinion. The illustration, which shows the device applied to a sculler's outrigger, explains itself.

PAPER FROM WOOD.

IN a case placed in the section of the International Exhibition devoted to paper manufactures, Mr. Houghton displays the results of his processes for converting wood into pulp for paper. It appears that he has succeeded in overcoming the difficulties which have hitherto beset the employment of wood. We learn, from the *Paper Makers' Journal*, that the chief of these difficulties, hitherto regarded as little less than insuperable, has been the necessity for using such large quantities of alkali, in the progress of disintegration by boiling, as to make the cost too great to bring the material into the market in such quantities and of such quality as to satisfy the requirements of English makers. In other words, the evaporation and waste of the alkaline liquor, and the necessity for using such large quantities of caustic soda or soda ash for every fresh disintegration, made the cost of production of a high quality of half-stuff from wood too great to admit of its adoption as a cheap substitute for higher-priced material. This necessity Mr. Houghton has superseded, and that by a process which also removes the dreaded danger from the heat or pressure required in the preparation of the fibre by some other methods. Patents for the requisite machinery and processes have been taken out, and a company is, or will shortly be, formed for working them, or granting licenses for them, in England, Sweden, and Norway. They are now being placed in operation on a large scale in France, Austria, and Belgium; and with a view to explain and demonstrate the various operations Mr. Houghton himself has established a small working plant at No. 40, Borough-road, where we were invited to inspect the very simple machinery.

To begin with the wood itself—the pine wood of Norway, Sweden, America, and various parts of the world. It may be premised that the cuttings from the ends of planks, misshapen portions of trunks and limbs, misgrown timber, and what may be termed forestal waste, are completely adapted for the purpose. The cutting is effected by means of simple machinery, working a series of knives, which slice the timber in a diagonal direction, so that the fibre easily separates by the splitting of the grain. These slices are broken with the utmost facility into small pieces, and are then delivered to the factory as the material to be rapidly converted into paper pulp.

To this end they are first consigned to a patent boiler, so constructed as to endure great pressure, being composed entirely of welded rings upon welded rings double riveted together transversely. They are heated entirely by hot water circulating in pipes which traverse them in sections throughout their length, and in which the heat can be so regulated from the external apparatus as to raise or lower the temperature to a single degree. The pressure employed in the process of treating the fibre is 180lb., and the boilers are tested to 360lb. to the square inch. The wood is introduced into the boiler in wire cages running upon a set of rails, so that while one batch is being removed another is ready for disintegration. When the boiling is completed, the small pieces of wood—which may be called fasces of wood-fibre—are quite soft, and of a dingy colour, not dissimilar in appearance to a piece of rather coarse field rhubarb after it has been cut up and baked in a pie. The material is now ready for bleaching in a vat, where it is treated with chlorine, pumped into the liquor in such quantity as not to injure the fibre; and the operation is afterwards completed by the use of permanganate of soda. The condition of the material is that of a soft, pulpy, highly-fibrous mass, which having been subjected to the action of a hydro-extractor, or, more simply, a "wringer," comes forth in the shape of a damp, fleecy mass, in which only a microscopic eye could detect the pristine wood fibre.

In point of fact, one of the constituents which existed in the wood has been so completely removed that it affords a separate operation in the process of treating the alkaline liquor, a process which is, we understand, the achievement by which this system claims to inaugurate a new era for wood pulp.

When taken from the boiler, the liquor with which the fibre has been treated is of a dark colour, and somewhat resembles "double brown stout." In this state it is pumped into a vat, where it is subjected to the influence of carbonic acid gas, which has the effect of coagulating, or, to some extent solidifying, the resinous particles; so that it changes in appearance from brown stout to muddy coffee. In this state it is transferred to a copper, where it is heated exactly to boiling point, the result of this being a complete coagulation of the resin, which is at once precipitated, or, in plain English, falls to the bottom, in large masses, not unlike great flakes of peat. For this resin, doubtless, some commercial or manufacturing use will soon be found; and, at any rate, it cannot fail to be a source of profit.

The liquor is now of a clear brown colour, about the tint of moderately strong tea, and is destined not to be thrown away as waste, but to be used again, after the balance of the alkali absorbed by the fibre has been restored to it. This is effected by the use of sulphate of soda, so treated with coal as to produce a combined substance capable of restoring the necessary constituents. The material used for this purpose costs less than £5 per ton, and about 10 per cent. of it will restore the lost alkali, for which it is substituted weight for weight—a trifling cost when compared with that of making up the deficiency with either caustic or carbonate of soda at the present prices. By this process the liquor is made fit for re-introduction to the boiler, and on being removed is treated as before, so that it may be said to be constantly renewable.

ALLEN'S PATENT GOVERNOR.

ALLEN'S PATENT GOVERNOR.

THE improved form of governor shown in the accompanying engravings is the invention of Mr. R. K. Huntoon, of Boston, Massachusetts, and has been employed for the last three or four years in America, where, under different circumstances, it has given equally good results, and earned in actual practice the high encomiums passed upon it by the principal mechanicians of the United States. In this country it is known as the Allen governor, from the name of the proprietor of the English patent, and forms one of the exhibits in the International Exhibition of Whitley Partners, Leeds, who are the sole licensees and makers in Europe. Very few of these governors have been fixed in this country at present, but those that are in operation have given unqualified satisfaction. In the United States, however, the Allen (Huntoon) governor has had an extended trial on various descriptions of engines and in different kinds of work, and has been awarded a high character by firms so competent to judge as those of Messrs. Sellers and Co., of Philadelphia, and Messrs. Baird, of the Baldwin Locomotive Works, besides others too numerous to mention. The Allen governor, the construction of which will be tolerably well understood on inspecting the accompanying engravings, consists essentially in a revolving paddle-wheel working in a chamber partially filled with oil. The chamber is a corrugated cylinder with small projecting ribs on its interior periphery. Within this chamber is a paddle wheel carried on a spindle, to which a rapidly revolving movement is imparted by means of a belt on the fly-wheel shaft. The tendency of the revolving paddle-wheel throwing particles of oil against the internal ribs of the cylinder is to cause the latter to revolve in the same direction, a motion which is partially checked by means of a weighted lever attached to a trunnion on the cylinder spindle. Connected to the trunnion, but moving in an opposite direction to the weighted lever is a short lever which by means of connecting rods opens and closes the throttle-valve according to the load on the engine. The peculiar action of this governor enables a valve of large area to be used, by which means the greatest possible boiler pressure can be brought to bear on each stroke of the piston. The governor valve is also of peculiar construction, and is perfectly balanced. In Figs. 2, 3, 5, A is a cylindrical drum, having on its inner periphery a series of flanges or ribs *a a*, arranged at or about equal distances apart. This drum moves around the shaft *b*, which enters through the end *d d*, but is fixed to the shaft *c* at the end *e e*. Attached to shaft *b*, within the drum, are a number of paddles, or flat wings, *g g*. The two shafts are supported in bearings *h h* in a standard B, mounted on the valve-case, C. To the shaft *c*, which moves with the drum, a lever with an adjustable weight *l* is connected by the trunnion mentioned above, and the shaft is also connected by a short arm and the rod *m* to a lever fastened on the shaft *o*, which enters the valve-case C through stuffing-box *p* into the induct E. An arm *q* (shown in Fig. 6) carries an anti-friction wheel *r*, and projects from the portion of the shaft within the steam-passage E of the valve-case, entering a slot r^1, made in the shank *s*, connecting the two valves *t u*. These valves are arranged as shown, with the ports or openings *v v* made in opposite sides of the tubular induct E, which is closed at its inner end. F is the educt, leading out of the lower part of the case C.

The drum A being filled about two-thirds with best sperm oil, a driving-belt is passed from a pulley on the fly-wheel shaft to the pulley W on the shaft *b*, so as to insure a speed of the paddle-wheel of about 400 revolutions per minute, by which means the oil is thrown against the flanges or ribs *a*, causing the drum to turn in the same direction as the paddles. By this action the weighted lever is raised, and the shaft *o* turned through the action of the connecting-rod *m*, the valves being, consequently, held in a position governed by the amount of work or load on the engine; the rotary motion of the drum is, of course, resisted by the weighted lever *l*. By operating the valves by the arm *q* applied to the connecting piece there is no pressure on them like that experienced when a stem extends through a stuffing-box, and they are in reality "balanced" and easily moved by the governor.

Fig. 7 shows the application of the invention to engines with variable "cut off." Here the lever and weight are replaced by a fusee or scroll, 1, and a weight, 2, suspended from the periphery thereof by means of a chain, 3. A pinion, 6, fixed on the shaft C, works into a toothed sector, 7, moving freely on the stud, 4, but secured by the nut, 5. The stud, 4, is screwed tight into plate, 8, which is fastened to any convenient part of the engine by bolts, 9. In the arm, 10, of the sector, 7, is a slot, 11, for adjusting the connection of the valve gear. The weights suspended to the scroll have a tendency to roll the pinion, 6, to the right, actuating the sector, 7, from right to left, whilst the paddle-wheel in the drum A actuates it from left to right, causing thereby the arm, crank, or other device fixed to the slot-hole, 11, to move in these opposite directions, according to the prevalence of the power of the paddle-wheel upon the weights, or inversely; and giving the means of a self-acting motion on the cut-off valves, according to the variations of speed of the engine shaft. In this governor the resistance to the action of the revolving paddle increases with its speed in a manner calculated to open the partially closed valves as rapidly as possible when speed falls down, because of the scroll causing the weights to act upon increasing radii as they are lifted up.

The Allen governor is also adapted for marine engines, in which case, however, it is, of course, modified, as shown in Fig. 8; for it is necessary to dispense with all levers and weights liable to be moved by the motion of the vessel. These are replaced by a strong spiral spring, 1, one end of which is bolted at 2, to the arm B, and the other fixed to a loose socket provided with six wings, 3. One of the wings carries a catch piece, 4, which acts upon a pinion, 5, fixed to the shaft C. A smaller pinion, 6, also fixed to the shaft C, engages in a toothed sector 7, with an arm, 8, fixed by a friction socket to the spindle, 0, of the valve G, which it regulates. The spring, 1, having been tightened to the required speed by turning the wings, 3, from right to left, is secured tight by the catch piece, 4, its tendency being to roll the pinion, 6, up to the left end of the rack, 7, and keep the valve wide open. But as soon as the speed of the paddle wheel in the drum A becomes greater than required, its action upon the interior ribs of the drum A will overcome the resistance of the spring and cause the shaft C and pinion 6 to revolve from right to left, thereby causing the rack, 7, to move from left to right, and to close partially or totally the valve G, according to the greater or lesser speed of the engine. On the other hand, as soon as the number of revolutions of the paddle-wheel in the drum A, and consequently of the engine-shaft, becomes less than required, the action of the spring overcomes that of the paddle wheel, and the valve G opens wide. In this governor the resistance to the action of the revolving paddle increases with its speed in a manner calculated to open the partially closed valves as rapidly as possible when speed falls down, because of the greater resistance of the spring as it gets tightened.

Such is a description of a form of governor which is comparatively new to this country, only one or two having been fixed. All that need be said now is, that in no single instance has an Allen (or Huntoon) governor been removed from an engine, and no engine has yet been found which it cannot govern. Of the various forms shown in our engravings, it is probable that Fig. 7 will be found the one in greatest demand, as well as most useful; though of course that will not detract from the equal merits of the others in positions and circumstances to which they are suited and adapted.

WALL-PAPERS AND DISEASE.

A LETTER drawing renewed attention to the poison-dust given off by wall-papers appeared recently in the *Pall Mall Gazette*, from which we gather that, in the opinion of the writer, the evil is much more widely spread than is generally imagined. There is but little doubt that very many of the papers used for covering walls are coloured with pigments which contain considerable quantities of arsenic, which finds its way to the lungs in the shape of dust, it may be in infinitesimal amounts, but still sufficient to exercise unpleasant, if not dangerous, influences. The writer of the letter referred to, however, considers that arsenical wall-coverings are poisoning our population wholesale. The dangers of sewer gas have deservedly attracted much attention and inquiry in consequence of the alarming illness of the Prince of Wales, but the danger of arsenical wall-coverings remains unnoticed; although, if the truth were known, their ill effects would be found to rival those of sewer gas. There is a peculiarly close smell, rightly described as "fusty," from all papers containing arsenic; and the writer called attention especially to that very point in an article published in the *British Medical Journal* of September 30, 1871. This smell appears to be due to the evolution of arseniuretted hydrogen gas, and may be easily detected by most persons possessing sensitive olfactory nerves in nearly all rooms where the paper contains a trace of arsenic, but is more distinctly observable after the paper has been soaked previous to removal. As a rule, the workmen employed to put up or to remove arsenical wall-coverings suffer severely from doing so, but they often hesitate to own the fact, because their livelihood depends on their powers of endurance, and their employers endeavour to conceal the danger and make light of it for reasons of their own.

It is also said that in paper manufactories the sickness and mortality among the workmen is very great; but the truth in this matter appears to be studiously concealed from the public, because, as arsenic yields a great variety of brilliant colours, and is exceedingly cheap, it is the interest of the manufacturers to employ it. The correspondent says he has seen workmen in his house sick and faint from working a few hours at removing a single paper from the walls, and it is easy to understand how far more dangerous the work must be where papers piled one over the other have to be removed, and where consequently the amount of arsenic would be much greater; while, owing to the accumulation of papers on the walls, the usual precaution of soaking the papers cannot be effectually carried out.

If medical officers would exercise close observation as to the colouring of the papers removed in the various houses where there has been sickness, valuable information might be obtained; for although arsenic is used more or less in papers of all colours, those with green in the pattern generally contain larger quantities than other papers, and, the arsenic being combined with copper to produce green, the dust of copper as well as arsenic is inhaled, thus involving a double source of poisoning. Blue papers also appear to be especially injurious, whether they contain arsenic or not, some being covered with blue verditer and others with Prussian blue (also used very extensively in distemper wash for walls and cornices), both of which appear to have very injurious effects. There is also a blue pigment in use for such purposes, which contains a great deal of arsenic. As all unglazed papers and distemper washes give off more or less dust into the atmosphere, though often imperceptible to the naked eye, it requires no very great stretch of the imagination to realise that poisonous dust thus inhaled cannot fail to do harm; and physicians are well aware (though in this matter they have hitherto ignored it) that poisons are still more deleterious when inhaled than when swallowed, being more rapidly taken up by the blood. Consequently, as a variety of poisonous and medicinal ingredients are used for colouring wall-papers and washes, it would appear that our whole system of wall-coverings is probably one of the most gigantic errors in hygiene that has been committed in modern times.

The writer says that after several years' experience he is convinced that diseases of various types haunt those rooms and houses where the wall-coverings contain arsenic or other poisons; and he affirms, as the result of observation and inquiry, that arsenic when inhaled, either as dust or in a gaseous form, poisons the blood and seriously affects its circulation, weakening the action of the heart, and producing general and local congestions; that it produces inflammation of the entire mucous membrane (thereby affecting every organ of the body by degrees), and notably of the stomach and intestines, giving rise in many cases to gastric or enteric fever, but that its action is so subtle and uncertain that the effects may vary to an almost inconceivable extent according to constitution and temperament; that this mode of poisoning, which dates from the commencement of this century, may account for many of the mysterious ailments of the present day, especially among women, from which the past generation was exempt. Further, it is well known that arsenic produces eruptions of various kinds, and it appears to be the case that persons occupying rooms where there is arsenic are especially liable to attacks resembling diphtheria, and also to eruptive complaints which so closely resemble measles, scarlatina, and chicken-pox, that they are frequently called by the same names, and yet do not appear to be infectious, like the true types of those diseases. A severe spasmodic cough, hardly to be distinguished from whooping-cough, is also produced by the same cause. Is it not, then, highly probable that the apparently frequent recurrence nowadays in the same individual of disorders called by the above-mentioned names—a recurrence comparatively rare until the present century—may be, at least in some measure, attributable to the fact that our walls are reeking with poison? If we regard epidemic disease as the result of some poison in the blood, of which eruptions are but the outward token—the effort of nature to expel the poison—what can be more natural than that arsenic, a subtle blood-poisoner (and one, moreover, which is acknowledged to produce eruptions, while it also cures them in some cases), should have this effect? Every medical man in the kingdom is treating day after day numerous cases of disease originating in irritation of the mucous membrane, which simulate almost every morbid condition under the sun, the true diagnosis of which would be "arsenical poisoning."

ON EARTHQUAKES AND VOLCANOES.*

By Augustus Le Plongeon, M.D.

(*Concluded from p. 348.*)

6.—Cataclysms of the 13th and 16th of August, 1868.

THESE cataclysms are some of the most terrible known in the history of mankind, as much for the ravages they have occasioned as for their duration and the extent of country they have visited, spreading dismay and consternation, death and ruin among the inhabitants. Beautiful and densely populated cities have been levelled to the ground, flourishing seaports swallowed by the sea, whole towns, together with their dwellers, have disappeared into the bowels of the earth. In Peru the shock was felt over a radius of 1,670 miles. In Ecuador, 43,000 human lives were destroyed in a twinkling of the eye. The centre of the earthquake of the 13th appears to have been the volcanic zone comprised between Arequipa, Tacna, and Moquegua, where are situated six volcanoes—the Cailloma, the Misti, the Ubinas, the Huaina-putina, which made an eruption on the 13th of February, 1600; the Tutupaca and the Candarare. The focus of the second, that of the 16th, in Ecuador, was in the volcanic fields of Ocampo, surrounded by the three volcanoes, the Cotacachi, the Imbabura, the Pasto.

The prefect of Arequipa, Dr. Francisco Chocano, in his report to the Secretary of State, says:—That on the 13th of August, at 5.15 p.m., a very severe shock of earthquake was felt in Arequipa, when within five minutes the whole city was levelled to the ground. The oscillations, from S. to N.E., shook the soil with tremendous violence during seven minutes; they came accompanied by gushes of air charged with electricity; the motion of the earth was such as to make it next to impossible to keep a firm footing or remain standing. The soil heaved up and fell as the surface of the sea during a gale. A sudden obscurity spread over the city, adding to the horrors of the event. The waters became muddy in an instant. During the night of the 13th, thirty-five shocks were counted, but the soil was in continuous motion. Loud detonations were heard every instant and in rapid succession, like the rattling of musketry during a battle. Rents were opened in the earth; sources sprang forth through them so abundant as to inundate many places; others have sunk and disappeared. The shocks continued at intervals. The Misti sent forth enormous columns of smoke in the midst of horrid detonations. Such were the events of that memorable afternoon of August 13th, 1868, that were witnessed by the inhabitants of Arequipa. All these phenomena I have reviewed and tried to explain are effects of volcanic action. Arequipa is built on the slope, nay, at the very foot of the Misti, and has at periods nearly equidistant been destroyed. On the 2nd of January, 1582, an extremely severe earthquake shook that city to its very foundations; another, equally terrific, occurred in 1587; then another, in 1590, that laid to the ground the city of Camaria, an immense tide wave invading the ground, inundating the Peruvian shores; again, on the 18th of January, 1600, when the volcano Huayna-putina made an eruption; again, on the 25th of November, 1604; again, in 1605, when the city of Arica was destroyed; again, on the 13th of May, 1647—the shock was that time felt along the whole coast; again, on the 22nd of August, 1715; again, on the 6th of February, 1716—day of the destruction of the city of Torata; again, on the 27th of March, 1725—this earthquake shook the whole southern coast, and the port of Callao was submerged by the sea; again, on the 13th of May, 1784. I merely mention these earthquakes as they are the most important, passing in silence hundreds of others of minor intensity, that at short intervals have occurred, warning the inhabitants of these regions that under their feet was a focus of electro-chemical action, whose living activity continually threatened their existence.

Commandant Thomas Layseca, of the forces stationed at Torata, informs us that the earthquake was felt at 5 p.m., lasted twelve minutes; and that from the 13th to the 15th, date of his official report, 600 shocks had taken place.

In Tacna, on the 13th of August, a general oscillatory motion of the earth occurred at 5 p.m., lasting five minutes. At that place, for several days previous to the 13th, subterranean noises were heard, and some light shocks felt. When the earthquake occurred the day was cloudy, and shortly after it began to rain (a strange phenomenon in a country where it never rains), to the 16th of August, that is, during three days 64 vibrations, accompanied with subterranean noises, were felt; large and deep rents opened on the surface, and gushing through the openings. In Palea and La Portada, on the road to Bolivia, the shocks were most violent. Large portions of hills became detached, and rolled down the valleys—the mountains being split open with frightful noise.

I will call your attention to the fact, that in this place the motion of the earth was different from that at Arequipa, being oscillatory, instead of undulating, as it was at the latter place; notwithstanding its violence at both places, being such that men could scarcely keep their footing, the results were quite different. The strongly stone-built city of Arequipa was levelled to the ground, while in Tacna only 40 houses were destroyed. This fact would tend to show that the oscillatory motion causes less ravages than the undulating. Again, the premonitory symptoms of the impending castrophe were distinct, but passed unheeded. Electro-magnetic disturbances took place also in the atmosphere, causing rain to fall—an occurrence which seldom or ever takes place in this part of the country. In Chocorento, a village in the valley of Acari, the earthquake took place at 4.30, destroying all the houses in the valley. The shocks succeeded each other in rapid succession; the sea rose mountains high, and ran inland one and a half miles; all the watercourses became dry; the ground opened in many places, and water gushed up through the fissures in large bubbles; continuous noises, resembling the roaring of cannons in a battle-field, were heard incessantly. It would seem that the phenomenon manifested itself at this place thirty minutes in advance of the other localities; but this is evidently an error of computation of time on the part of the observer; for this valley is in close proximity to the other places.

In Moquequa, the earth began to shake at 4.45 p.m., five minutes in advance of Arequipa and Arica, about 90 miles to the south-west of the former city. There the vibrations were always preceded by electric discharges, louder than the heaviest cannonading; were from east to west, alternating with vertical shocks, and succeeded each other with frightful rapidity during five to six minutes. The hills of limestone were split, the rocks rent in small pieces. The soil opened, and through the openings issued streams of blackish and pestiferous water.

With Arequipa and Moquequa, the city of Arica is that which has suffered the most. Situated on

* From *Van Nostrand's Magazine*.

the sea-coast 40 miles to the south-west of Tacno, it is the most important port of Peru, next to Callao. At 5 p.m., a very severe earthquake was felt on shore, says the commandant of the ill-fated frigate *America*, which was stranded that day. "All the houses in the city surged, and with an ominous crash fell to pieces; then the earth was seen to open, a rolling, rumbling noise was heard, and gases, stifling gases, emanating from the fissures, soon filled the atmosphere, severely oppressing all living creatures, causing them a sensation of suffocation. The shocks lasted ten minutes, and succeeded each other at short intervals, and were accompanied with subterranean explosions. The hills themselves were seen to stagger like intoxicated beings. Large boulders, detached from their brews, rolled down their slopes, while their sides were seen to give up the dead bodies of the Aymarcis, that for centuries had been intrusted to their safe keeping, and had so long peacefully slept in their solitary resting-place, the slumber of death. These mummies seemed to have emerged from their graves, as if to witness the convulsions of mother earth; and their lifeless mouths appeared to laugh, exhibiting gumless rows of white teeth, at the terror of the living seeking refuge in open places, and flying to the top of the high lands for their lives. The shocks came from the south; the skies were stormy, a very light wind blew from a southerly direction. The whole soil of the country, as far as it could be seen, was moving; first like a wave, from north to south, then it trembled, and at last upheaved heavily.

During that time a very strong current from the south set in in the bay. The current was so strong as to set adrift the boat of the frigate *America*, sent to shore for the commandant, notwithstanding the efforts of the crew. It measured 5¼ miles an hour, lasting five minutes. Then came a second current from the opposite direction; this left the bay nearly dry. Currents, now from the north, then from the south, succeeded each other with great frequency, and became so rapid as to make it impossible to send boats to rescue the people who were seen floating on the palisade and imploring help. The frigate began to drag her chains and anchors. At 6.45 p.m. the currents increased to 9¼ miles, their duration being from five to ten minutes; at 7.5 p.m. a current came from the south, its rate 10¼ miles. Then the sea began to retire slowly from the shores, leaving the boats dry. It receded about to the line of extreme low tide, when at once it rose again and invaded the land. It reached a height of 34ft. above high-water mark, overflowed the town, and destroyed everything that the earthquake had left standing. The waters rushed back in the ocean, and rose again to the same height as before. Several times did the advancing waves wash over the doomed city; several times the force of the waters carried all the débris of the ruined habitations of men, until at last, retreating about two miles, it returned as an immense wave 50ft. high, carrying the frigate *America* more than a mile beyond the railway tract, in a place called Chinchero, and the American ship *Wateree* about a mile further up the beach.

Eleven tidal waves occurred; the intervening time between each invasive wave was three minutes, the third invasion having occurred soon after the first, and the last and largest twenty minutes after the first. At Iquique the earthquake lasted five minutes, the sea rose 30ft. above its ordinary high-water mark, and covered the town to the extension of 600ft. At Ilo, north of Arica, the sea retired, leaving the ships completely dry, and rising again in a wave 40ft. high washed away all the houses and everything else. At Islay the waves obtained also an altitude of 40ft. over their natural level, and covered three times the wharf without doing much injury. The town, being built on the summit of a very high cliff, escaped destruction. Caracas, a small landing place near Jisco, was swallowed by the sea, and the boats that were in the bay carried away and left two miles inland. In Callao the earthquake was felt at 4.48 p.m. It came with an oscillatory motion—a motion similar to that of a boat in calm weather; it lasted ten minutes; at 6.30 p.m. another shock was felt, of five minutes duration. A few minutes before seven high-water was to take place. The water, instead, began to recede; at 10.30, for the first time, the water reached a higher level than it was ever known to have attained before, within the memory of man; at eleven a tremendous wave, 18ft. high, invaded the land to upwards of 600ft. from the beach; currents set in from opposite directions at a velocity of three to four miles an hour; at the time a soft breeze from the south-west blew; the atmosphere was perfectly clear.

These are, in as few words as possible, the phenomena that were noticed during the terrible cataclysm of the 13th of August, 1868; the greatest, perhaps, on record, with that of the 16th of the same month, which visited the province of Imbabura during our historical period.

Following the great tidal wave which originated on the coast of Peru, on its way across the Pacific, and taking into account that the difference in longitude between Arica and New Zealand is approximatively 9 hours, we shall find that the wave having reached the New Zealand coast at 6 a.m. of the 15th has employed 29 hours to travel 6,120 miles. Its velocity may, therefore, be computed at 211 miles per hour. Its violence, even then, was extraordinary. The Island of Chatham to the eastward suffered greatly, for the wave that struck it was of such magnitude as to completely destroy the colony of Tupinga on the North.

The tidal wave reached Hokodadi (Japan) at 10 a.m. on the 15th, presenting itself by a series of waves that caused the sea to recede and be depressed until 3 p.m. under its level, and rise again above it with great velocity. During 10 minutes per watch a difference of 5ft. was measured; the constant elevation and depression of the tide at that place being only 2½ft. to 3ft. It reached the Sandwich Islands on the 14th at 8.46 p.m., and continued to manifest itself during the 14th, 15th, and 16th, by a series of waves, rising and receding 3ft. to 4ft. every 10 minutes.

From these data a comparative table showing the time employed by the tidal wave to reach the different places may be thus formed:

	Greenwich Time.		Local Time.	
Places.	Dates.	h. m.	Dates.	h. m.
Peru	13 ...	9 40 ...	13 ...	5 0 p.m.
Sandwich Islands	14 ...	2 6 ...	14 ...	3 46 a.m.
New Zealand......	14 ...	7 6 ...	15 ...	7 0 a.m.
	14 ...	13 6 ...	15 ...	10 30 a.m.

Fifty-six hours after the ruin of Arequipa and other cities of Peru, another terrible cataclysm visited the northern provinces of Ecuador. The volcanic fields of Ocampo seemed to have been the focus of the electro-chemical action whose effects culminated in the destruction of 40,000 human lives, and the ruin of the cities of Otabalo, Ibarra, Atmitaqui, Catacachi, Perucho, San Antonio, San Pablo, and many smaller towns and villages, besides part of the city of Quito, the ancient capital of the Seyris, or Kings that governed the Empire of Quito, before its conquest by Huayna-Capac, and the modern capital of the Republic of Ecuador. Quito, built on the slopes of the volcano Pichincha, is elevated 9,500ft. above the level of the ocean. Several times it has suffered from the eruptions of the Pichincha since the conquest, the most remarkable being those that occurred in 1575, 1587, and 1660. The cataclysm of the 16th of August seems, however, to have been the most disastrous that has afflicted these regions, the most volcanic known on the globe. Here are found grouped on a plateau about 200 miles long by 80 broad, a great many volcanoes, which, for the most part, at different epochs since the conquest, have given the most unmistakable proofs of activity. The Chimborazo, the Cotopaxi, the Pichincha, the Altar, the Illinaza, the Corazon, the Cayambó, the Riobamba, the Sangai, and many minor ones, are here gathered nearly within sight of each other. The earthquakes that visit Chili, Peru, Ecuador, and California, within the five days that elapsed between the 13th and 19th of August, notwithstanding their synchronism, did not originate from the same centre of action. Each had a distinct focus, to which a greater activity was communicated by coming in contact with some of the points of the voltaic arch formed, in those days, by the relative positions of the sun, moon, and earth. In Quito meteorologic disturbances occurred on the 15th: heavy showers of rain and hail, and heavy thunder; at 1.20 a.m. of the 16th a severe shock of earthquake was felt, then the earth continued to shake at intervals to the 19th. All the principal churches were levelled to the ground.

In the district of Catuchi two towns were totally destroyed without leaving a trace of having existed. The town of Atmitaqui was destroyed; in that of Ibarra, the capital of the province of Imbaburi, 13,000 persons perished; rents were opened and closed; huge pieces of rocks were seen tumbling down the sides of the mountains, hills sank, carrying with them sugar-cane plantations, houses, and everything on them. That where the city of Otalavo was built sank and was replaced by a lake. Where Cotacachi once stood is now a swamp; large quantities of stone were hurled from the Cotacachi; from the Imbabaru issued a torrent of mud, the flow of which was followed by that of water; from the crater of the Ocampo were ejected large quantities of butiminous matter. The Sangai was seen in a state of constant eruption. Dark clouds of dust and a heavy rain of fine powdered earthy matters fell; a total darkness prevailed and covered the country as a pall, the obscurity of which was illuminated at intervals by flashes of light from the volcanoes, amidst continuous detonations that resembled the roaring of a distant cannonading.

Resuming all these data, I came to the conclusion that the production of these phenomena had its origin in four different centres of action. Those felt in Peru had for centre the country between Moquequa, Arequipa, and Arica, encircled by the four volcanoes—the Misti, at the foot of which is situated Ariquipa; the Huayna-putina, the Ubinas, and the Tutapaca, forming part of the chain of Cordilleras immediately behind Moquequa.

The earthquake that shook the greatest part of Chili seems to have originated in the volcano of Leullallco, situated 240 miles from Copiapo. It was reported to have broken out in a violent eruption, its crater vomiting lava, ejecting large stones; the ground at the base of the mountain opened in numerous places, and through the rents spouted forth currents of water impregnated with sulphuretted hydrogen gas; these occurred on the 14th and 15th of August.

The earthquakes that destroyed the northern parts of Ecuador had their centres of action in the fields of Ocampo, and in some of the numerous active volcanoes that are strewed all over the great plateau of Quito. They took place on the 16th of August.

The earthquakes that occurred the 16th of August in San Francisco and various other places in California had probably their origin among the numerous volcanic fields that are so frequently met with in that country; and their centre of action may have been the same that has produced lately the earthquakes of Sacramento, Inyo, and other places.

MECHANISM.*

IN the spring of the year 1869, a course of Cantor lectures was delivered by John Anderson, Esq., of Woolwich. The subject was "Applied Mechanics," and the complete course will be found in Vols. IX. and X. of the ENGLISH MECHANIC. Mr. Anderson closed those lectures with the following sentence:—"It will be found that so long as any of Nature's secret laws remain unexplored, well-directed irrepressible thought will alight on new discoveries one after another; and to the endless variations of mechanical combinations there is practically no limit." To some of the elementary forms of "these endless variations of mechanical combinations" our attention in the present course of Cantor lectures is to be directed. It may appear disheartening to enter upon an inquiry which at the outset is said to consist of "endless variations;" but by classification and division, not only all the inhabitants of the world, but all of which the world itself is made, and even the very universe, has been brought under careful and minute examination. The words—animal, vegetable, and mineral—comprehend the world and its inhabitants. Division and sub-division have so placed these that those with similar distinctive features are soon classified side by side.

A digression upon these words for a few minutes, even thus early, will not be out of place. To Aristotle, who was born about 384 years before the Christian era (he died 322 B.C.), we owe much in respect of a development of the system of classification and division. When Aristotle was classifying natural history, and seeking for some distinctive feature by which to distinguish men from every other animal placed in the same class, he selected for him a name appropriate at this day—he called man "a tool-making animal;" for man was the only animal in the creation that made tools for his own special purposes. Had Aristotle lived now, how much more appropriately would this characteristic have applied, and yet our surroundings might have deprived us of the man; for Aristotle was appointed tutor to a youth then fourteen years of age—that youth is afterwards known in history as Alexander the Great; but Lord Bacon, in his "Advancement of Learning," writing of Alexander the Great, says "that he does not choose to consider him Alexander the Great, but prefers to call him 'Aristotle's pupil.'" In these days, and in this country, more indebted as it is than any other in the old hemisphere to the scientific development of the tool-producing faculty, and to many other science faculties, we may look in vain for such encouragement. Alexander did not forget his science tutor, for history records that he allowed Aristotle 800 talents per annum (a large sum, however the talent may be estimated) with which to prosecute his studies in natural history. May it not be that in England in the present generation there are no Aristotles because there are no Alexanders?

By a like law of broad classification we may say of our present subject there are two marked groups, under one or other of which may be arranged all our mechanistic contrivances. These groupings are comprehended in the words structures and machines. The considerations which present themselves vary considerably, according as one or other of these divisions is under notice, and unfortunately for the science and practice of mechanics in the full acceptation of the term mechanics, modern usage has disjoined what should always have been united. The class of men whose business requires that they should attend to the branch called structures disregard the branch called machines. The compliment is repaid. The mind of the man who thinks of structures is ever dwelling upon contrivances for securing stability and perpetual rest, whereas the thoughts of the mechanical engineer dwell upon contrivances for securing motion, and he sometimes dreams of making motion, and not rest, perpetual. Although each of these men look to mechanical aids for accomplishing his purpose, they look at them from two very different

* By the Rev. ARTHUR RIGG, M.A., being the Cantor Lectures delivered before the Society of Arts.

standpoints, and in very different coloured lights. The man who deals with structures is always thinking of struts, tensions, pressures, and frictions, and he adopts those means which seem most likely to secure what he calls stability and immobility. The other man considers that to put the machine in a state of rest, to so proportion the powers as that each elementary part of that machine shall be in equilibrium, is to put a machine in a state of absolute idleness. Now, idle machines, like idle people, do us no good; they destroy themselves, they rust, they in fact decay, and, to borrow the phrase from the workshop, we may say of idle machines that they really "eat their heads off." The true state of a machine, as those who are concerned with them know well, is a state of motion. So completely is this idea of motion impressed upon mechanists, that rest as accomplished by struts, and stays, and rods, forms no part of the mental employment of the mechanician. A mechanician has no faith in the machine requiring rest. If a mechanician wants a piece of machinery to pause in its work, in order that another part of that machine may go through some operation or other, he accomplishes it by establishing such a relation between and amongst the motions of the respective parts as shall produce the result he requires. As two waves of light or of sound in opposite phases produce, by coalescing, darkness or silence, so two motions can be so mechanically combined as to produce absolute rest. The owner of a machine considers a machine worthy of room on the floor of his factory only so long as it can move and is moving; and, indeed, nowadays, that is hardly sufficient for manufacturers and owners of machinery. Machines are expected to be not only diligent when they are at work, but to go back, when they have done their work, with a speed which no employer has ever yet considered too great. There is no law upon a labourer to return an empty spade to the ground at twice or three times the speed with which he lifts a full one. A machine, however, is expected to do this. It is expected when it has done one stroke of work, literally without turning round, to run backwards at twice or thrice the velocity at which it does its work in order to start and do another stroke. Nor is it in readiness to return to its work at an increased speed that any great triumph of mechanistic skill is noticed. There is hardly a plan or device for the saving of bodily labour, nay, there is hardly a scheme for saving mental thought, that mechanism is not both expected and requested to undertake. Mechanism burrows in the earth, it builds our houses, it conveys us by land and by water, it clothes us, it supplies us with teeth, it will even do a large portion of the work of digestion if we wish, it counts for us, it determines the weight of our gold and silver coins, accepting or rejecting those coins, as, in its mechanical judgment, it deems best; and, to crown all, it thinks for us; it calculates, it sets up its own type, it prints its own calculations, and and if by any accident it makes a mistake, it rings a bell and tells us it has done so.

Thus, not only English society, but all society depends upon mechanism, and it is, therefore, singular that educational books, and even treatises upon mechanics, lay the foundation of all the information and instruction that they give, not in states of motion, but in states of rest. To put levers, pullies, inclined planes, wedges, and screws in states of perfect equilibrium, to demonstrate by tedious and complicated reasoning what is called the parallelogram of forces, to be poring over problems for establishing equalities by both geometric and analytical formulæ—these constitute a large portion of the so-called scientific mechanical knowledge contained in our treatises upon machinery for students—at least for those who are beginning to study. If a few advance beyond elementary knowledge, they are generally confronted by still more complicated and uninviting discussions upon the laws which have much to do with motions in the universe, but little or nothing to do with motions on the earth or in our machines.

In 1788, when Lagrange published a great and fine example of analysis, he wrote in the preface of the book (it was upon machinery):—"The reader will find no figures in this work; the methods which I deliver do not require either instruments or geometrical or mechanical reasoning, but only algebraical operations." Lagrange herein made mechanics subservient to analysis. Analysis ought to have been made subservient to mechanics. Our books of mechanical science deal with questions chiefly of rest or of celestial motion only; hence the man who wants a machine for a given purpose, who wants to combine certain motions, turns in disappointment from volumes that he considers are delusions and snares. So far as power, and so far as strength of materials are concerned, he is satisfied that these are ample for all his requirements. Until he can obtain such a combination as shall secure a special end, questions of construction and equilibrium are not felt by him as matters really of even momentary consideration. He knows that if the motions he needs are won, he will have no difficulty whatever in producing the rest. To modify control, and regulate the motions of connected materials, constitutes the chief object of study with those who hope, by machinery, to improve upon manual labour. This study is clearly independent of the building of the machine; it is clearly independent of all those parts of the machine that are comprehended under the word "structure." It is also equally independent of the source whence the machine derives its power; and, further, it is quite independent of the work to be done by that power, after it has passed through the machine. What it does involve, however, are any mechanistic contrivances by which motions may be changed, or constrained, or diverted, and that, appearing in one form, existing for a specific purpose, they may be transformed into another exactly adapted to the purpose required. Thus it will be for a pre-arranged object, and to follow a predetermined law. This is that which is comprehended under the word mechanism, and it is in consequence of the development of this aptitude in the few minds given to the special study—and they have been but few—that England owes all her present manufacturing industries.

Having thus explained what is comprehended under the word mechanism, it may be well to regard what it is that is excluded. All our experience tells us that motion is a consequence of force. So sure are we of this, that we say that whenever force acts motion ensues. If, however, it is wished to arrest an ensuing motion, it is usually done by the introduction of an opposing force. Thus, even in this aspect, rest, observe, is the result of a combination of motions.

The branch of mechanical studies which thus considers force as compelling rest, or preventing a change of motion, is called statics; and states of rest produced by opposing forces, except when the mechanism is called upon in the interval to perform some special operation, do not concern us, and further allusions to questions of statics may be put aside.

But force may produce change, either in the amount or direction of motion, and the branch of mechanical studies which comprehends this is called dynamics. The term dynamics is a marvellously comprehensive one. To say of an operation that it is a dynamical one, gives just about as much information of the operation as to say of a substance that it belongs either to the animal or vegetable kingdom. Division and sub-division must enter, in order to an accurate and instructive investigation of questions of a dynamical character. Two of these divisions are so intimately related in the branch of dynamics to be treated of in this course of lectures that a distinction must be drawn between names much alike. M. Ampere, in the year 1834 (for that is about the time when this subject first began to attain special consideration), wrote:—"Long before I employed myself upon the present work, I had remarked that it is usual to omit, in the beginning of all books treating of sciences which regard motion and force, certain considerations, which, duly developed, must constitute a special science." He then proceeds to describe the science, and calls it kinematics, from a Greek word, κινημα, which signifies motion. Further, he makes a proposal which was taken up by others, and the progress of the idea is interesting. He (M. Ampere) defined a machine, not as it had hitherto been considered—an instrument "by means of which we may change the intensity and direction of a given force," but as an instrument "by means of which we may change the direction and velocity of a given motion," hereby excluding force from all considerations of mechanism. Mr. Willis, to whom I shall have occasion to refer again, proposes another definition, namely, to consider a machine as an instrument "by which to produce, not motion simply, but relations of motion between parts, thus setting aside M. Ampere's definition that a machine is an instrument to change the direction and velocity of a given motion. Dr. Whewell, in his "Philosophy of the Inductive Sciences," in the first volume, page 144, has a very short chapter indeed on "Motion," and he was well competent to write a long one on the subject. He wrote in that chapter, in 1840:—"Motion should be considered quite independent of its cause—force. The science might be termed 'pure mechanism,' in contradistinction to 'mechanics proper,' or 'machinery,' in which force is taken into consideration. Such a science is the science of mechanism independent of force, and I consider it to be the solution of a problem which may be expressed in these words:—'To communicate any given motion from a first mover to a given body.' The necessity of this separation (says Dr. Whewell) has been seen by those who have taken a philosophical view of the sciences." Dr. Whewell, it will be observed, excluded force, and in this respect he follows M. Ampère's views, expressed just six years previously.

Thus has arisen the distinction between two very similar terms, kinetics and kinematics. Each term involves considerations of motion, but in two very different aspects. In kinetics it is not mere motion which is considered, but the relations that motions bear to forces. Hence questions in which the expenditure and nature of force, and the motions produced, are considered belong to kinetics. Kinetics comprehend the laws of energies, and the modes by which men may best avail themselves of these laws. We are too prone as a people to generalise laws; and what we find to be true under one set of energies, we assume to hold good under another set. Such is not the case. The energies of gravity, electricity, vitality, affinity, light and heat, require different treatments, in order that each may be most advantageously utilised.

An example or two may make clear the distinction now insisted on.

The velocity and penetrative or destructive effects of a cannon ball, in relation to the character and explosive consequences of the energies of guncotton, gunpowder, nitro-glycerine, dynamite, or whatever other elements are used, would be a question in kinetics.

Again, that singular calculation, that if a man were engaged in producing a certain motion, as, for example, drawing water from a well, by the expenditure of his muscular energies through the period of his manhood, he would raise by the mechanism of his bodily frame no more water than could be raised by one load of the best Wallsend coal, hence completing the parallelism, and reducing it to the form of money value—and it is wonderful how much more we appreciate these things when they are put in a money value—the life energy of a man acting through the mechanism of his muscular system does not exceed the energy of a load of coals employed through the mechanism of a scientifically-made engine. In other words, given the two mechanisms, the life of a man is not worth more than about 60s. Had man been created for no higher destination than this, we may depend upon it he would have been put together as a piece of mechanism very different from that on which he is now constituted.

In kinematics these elements of force occupy no attention whatever. Neither the force that produces the motion, nor the forces impending the motion, nor the forces that these two motions call into action, none of these belong to the division of the subject with which these Cantor lectures have to deal. Kinematics, therefore, is a science of mere motion; even elements of strength are not considered in it. The galloping tortoise which we see advertised in the windows in the streets of London, and that tricky little mouse that you see creeping up the hands of men in Oxford-street or Lombard-street, claim from mechanicians quite as much attention, and involve questions of mechanism perhaps quite as curious as Babbage's calculating machine, or those singular things, the orreries of the last century. It is, therefore, the division of the subject called kinematics with which the present course of Cantor lectures is chiefly concerned.

(To be continued.)

HEATING STEEL.

WE believe that overheating has condemned splendid steel more frequently than anything else. "Make it well hot that it will work easier" is a common saying, and sounds well in the shop; but when heating steel, don't follow the advice, for although it may seem to work easier when overheated, the error committed thereby will soon become apparent. All cast steel (excepting the comparatively new article, "chrome cast steel," which has properties entirely its own) requires the most careful heating. The fire must be regulated by the size of the work; and in heating the steel, beat the coals around the outside of the fire as soon as the flames begin to break out in order to prevent the heat from escaping. To save fuel, damp the coal and throw water on the fire if it extends beyond its proper limits.

To ascertain the heat of the steel, says *The Hub* (U.S.), draw it out of the fire, and that often; for it requires to be well watched to heat it properly, and if not hot enough, thrust it in quickly again; but be careful not to use a higher degree of heat than is absolutely necessary to effect the desired purpose, and to use as few heats as possible. Steel is essentially iron with a larger ingredient of carbon; therefore, too frequent heating or overheating burns out the carbon, and thus spoils its valuable character. Many smiths have the idea that so long as the steel does not fly to pieces when they strike it with the hammer it is not too hot; but this is an erroneous idea, and easily proved when it comes to be hardened, and when it is brought into use. We therefore say again, that no forger can be too careful in the heating process, and when he takes the heats. The practical eye will soon learn when it is heated properly for forging. But few forgers will admit that they spoiled the work by overheating, and yet this is unfortunately most frequently the case.

For welding cast steel, a flux is required in order to prevent oxidation of the surfaces to be joined. For this purpose, use a composition consisting of sixteen parts of borax and one of sal ammoniac, which has been boiled together over a slow fire for an hour, and when cold, ground into a powder. The steel is first heated a little, then dipped in the flux, and the heating continued until the metal has attained the proper heat. The flux is then fused over the surfaces, and has dissolved any oxide of iron which may have formed. The two surfaces to be joined are laid together and struck continuously, working toward the edges in order to expel the flux and insure a perfect union of the metal. Shear steel is joined to wrought iron without difficulty; but when cast steel is to be welded to wrought iron, the greatest care is required, or else no sound welding will be effected. By using the above mentioned flux, it can be done; but in all cases where steel is to be joined to iron, the steel—no matter what kind—should never be heated to so high a degree of temperature as the iron.

IMPROVED SCREWS FOR WOODWORK.

THERE are but few persons who have not experienced the difficulty of driving home a screw into hard wood. This difficulty is overcome by an improved form of screw recently patented in the United States by Mr. E. S. Willis, of Philadelphia. The first part of his invention relates to a spoon-shaped point to the screw for forming a boring and tapping device, so as to dispense with the necessity of boring soft wood previous to the insertion of the screw. The second part relates to a central bore in the screw from the concavity of the point throughout its whole length for the passage of the borings. The accompanying engraving fully explains the device. This screw will not split the wood, as the spoon point cuts through the fibres, and the central bore allows ample space for the chips. Machine screws made on this principle are found to operate well. They are made with a square head instead of the slotted head represented in the illustration. In putting ordinary screws into hard wood, the friction attendant upon the thread crowding the fibres out of place is very great, and it is hard work to drive the screw. With the improved screw, the fibres are cut through by the tapping point sufficiently to remove a portion of the friction and to secure easy driving, but not enough to prevent the screw retaining a tight hold on the wood.

USEFUL AND SCIENTIFIC NOTES.

Preserving the Polish of Steel Instruments.—For this purpose the *Lancet* confidently recommends a mixture of equal parts of carbolic acid and olive oil, smeared over the surface of the instruments. The plan is much used by medical officers in the navy, and is found to preserve the polish and brightness of the steel, however moist and warm the climate may be.

Washing out Locomotive Boilers.—The "Report of the Committee on Boilers and Boiler Materials," on page 17, of Fourth Annual Report American Railway M. M. Association, contains the objections to blowing off boilers, and allowing them to cool before washing out. As the heat retained in the boiler after blowing out bakes or hardens the mud or other deposit, a proper method is to blow off steam, and, after the pressure is off the boiler, to run in cold water, while hot and impure water is run off, thus gradually cooling the boiler until it is cold, after which time washing out with cold water will not injure it.

Improvement in Fractional Distillation.—Linnemann has successfully applied to laboratory purposes the principles of a method largely used in the arts, in the construction of the so-called dephlegmators. This principle consists in partially condensing locally the vapour which rises from a boiling liquid, in such a manner that the vapours which subsequently rise shall pass through the condensed liquid, and thus in a certain measure be washed. The apparatus employed consists simply of a vertical tube, attached to the flask in which the liquid boils, and containing six or eight little caps of platinum wire gauze separated from each other by small intervals.

Liquid Lenses.—A lecture experiment adopted by Professor Henry Morton illustrates very forcibly the action of refraction. A magic lantern is arranged vertically in connection with suitable mirrors to throw the image upon the screen. An empty watch glass is substituted for the usual objective lens. If now we introduce an object, as, for example, a photograph on glass, of course, no image will be produced on the screen, but only a nebulous patch of light. On pouring water into the watch glass, however, a well defined image is produced. On replacing the water by alcohol, muriate of tin, or other more highly refracting liquid, a lens of higher power is obtained.

Submarine Railway.—The railroad bridge which has been planned to extend across San Francisco Bay, from the mainland to Goat Island, is of a submarine character. It is an immense iron tube intended to be sunk from 28ft. to 30ft. below the surface, and held in its place] by its own buoyancy and by cables and mushroom anchors. The tube is to be 20ft. in diameter, and made of boiler iron, strengthened by an internal framework of iron beams. The invention is based upon the idea that the buoyancy of the tube will be equal to the weight of a train of cars. Anchors are to hold the tube in place.

SCIENTIFIC SOCIETIES.

ROYAL ASTRONOMICAL SOCIETY.

THE last meeting of the Session was held on Friday, June 14, the President, Professor Cayley, in the chair. The meeting was well attended, and there was a considerable influx of valuable papers. That on

Photographic Irradiation,

by Lord Lindsay, attracted much attention. His lordship—after having remarked that in the photographs taken on the occasions of the late eclipses the dark limb of the moon is *eaten into*, and that the image of a luminous object is surrounded by a border of light which it is difficult to separate from the edge of the image, and beyond which there is an outer fringe of light, the separation between the two fringes being more definite—described at some length the experiments which he had instituted for illustrating the phenomena, principally with a view of eliminating the effects on the apparent diameters of the heavenly bodies produced by irradiation. A plate of zinc having been prepared of about a foot square, with an aperture of a triangular form in the centre, across which a wire was stretched from the apex to the base, and a gas flame being placed behind it so as to entirely fill the aperture with light, the triangle of light thus produced was photographed in the usual way. A large number of photographs were taken, the normal time of exposure being *one* minute, but extending, for comparison, in some cases to twenty minutes. After an exposure of one minute, the image on plain white glass was sharp and well defined, but with an exposure of ten minutes, Lord Lindsay found the image to be surrounded by a halo—in fact, the appearance was that of a round spot of light, and not a triangular spot. Experiments were made with a great variety of surfaces, glass ground on one or both sides, or backed so that the image could be seen by reflected light only, and some photographic impressions were taken on slate. The best substance, that which gave the least extension of the image with the longest time of exposure, was found to be the yellow glass ordinarily used for glazing dark rooms. The greatest extension of the image occurred when and where the light was strongest. It thus appears that, by taking certain precautions, these effects of irradiation may, to a great extent, be eliminated.

Dr. De La Rue, in commenting on Lord Lindsay's experiments, said that it would be difficult to overrate the value of them: they were of the greatest importance, especially at the present time.

Planetary Markings.

JUPITER.—Mr. Browning exhibited drawings of Jupiter selected from a collection which he had made during the late apparition of the planet. The specimens selected represented the most striking intensifications of colour.

VENUS.—A very interesting communication relative to the markings on the planet Venus was read by Mr. Langdon, a "station-master" on one of our lines of railway. It appeared that the author, wishing to devote some portion of his leisure to astronomy, became possessed of a 6in. silvered glass reflector with which he observed the planet Venus from May to November, 1871. At first he had some difficulty in obtaining good views of the planet, but by inserting a diaphragm of card perforated with a fine hole by means of a red-hot needle, in the eyepiece, and thus shutting off all extraneous light, he brought the planet into perfect subjection, and pursued his observations with ease and comfort. Having read some time last spring that doubts had been cast on the existence of markings on the planet, he referred to his notes and sketches, and compiled from them the paper now communicated. In May, 1871, he noticed a dull cloudy mark on Venus, which was seen by some men to whom he showed the planet. One of them, a mason, declared that the object he was looking at was the "moon," and he knew it to be so, because of the dark mark upon it. On one occasion Mr. Langdon saw the southern horn rounded off, the northern horn being quite sharp, and ending in a fine needle-like point. On another occasion both horns were sharp and pointed, and once the northern horn appeared *bent*, and turned inwards towards the centre of the disc of the planet. The appearance of the terminator is described as being jagged, very like the moon, but sometimes hazy; the author comparing the moon's terminator to net-work, he said that of Venus appears like fine lace. Near the time of inferior conjunction the dark body of the planet was well seen. In concluding his paper, Mr. Langdon returned his thanks to Messrs. Proctor, Norman Lockyer, Browning, and others, for having sown the seeds of knowledge broadcast, some of which he had picked up, and endeavoured to turn to account.

Tables of Uranus.

Mr. Dunkin announced that Professor Newcomb had nearly completed his "Theory of Uranus." There were but a few Greenwich observations to add. It is expected that the observations will be well represented by the theory, and that the errors will be very small.

New Planet.

The discovery of a new minor planet (121) by Professor Watson, on May 12, was announced.

Jupiter's Satellites.

The Rev. R. Main, Radcliffe Observer, Oxford, communicated observations of the eclipses of Jupiter's satellites. As compared with the times given in the *Nautical Almanac*, the errors were as follows:—1st Satellite *nil*; 2nd satellite *twenty seconds*; 3rd satellite *one minute*; 4th satellite *three minutes*.

Meteors.

Italian astronomers having succeeded in observing several meteors last November, on the 14th and 15th, Mr. Proctor considered it desirable that a careful watch should be maintained in November of the present year.

A paper was communicated by Mr. Greg, in which he had collected and arranged all the existing observations of radiant points of meteors, and found the arrangement very satisfactory and instructive. This paper was characterised by Mr. Glaisher as a "very valuable and important paper." The details were so numerous, and the table so extensive, that the paper was not read, and we are consequently unable to give that analysis of it which we could wish.

Orbit of the Double Star Castor.

An interesting and valuable paper on the orbit of Castor was read by Mr. Wilson, from which it appeared that the orbit of the companion star is hyperbolic, and not elliptic. In the year 1845, Mr. Hind computed the orbit, and found that the elements differed entirely from those previously computed by Sir John Herschel and Dr. Mädler, and attributed the difference to the effect of the then recent measures by Mr. Dawes, made at Mr. Bishop's observatory. Mr. Hind's period came out 632·27 years. Herschel having found a period of 253 years, and Smyth one of 240 years. In 1846 Capt. Jacob computed the orbit, his period being 658·1 years. By the assistance of Mr. Gledhill, Mr. Wilson became possessed of a list of measures from 1740 to the present time, from which he obtained eleven points of the orbit, ranging from 1740 to 1866. These points lie nearly on a hyperbola of eccentricity of 2·2. This result is exceedingly interesting. The component stars are nearly of the same magnitude (3 and 3·5), and the companion star appears to have approached the primary from the depths of space in a hyperbolic path, and will recede further and further from it in a similar path, never again to revisit it. Castor is the only star known to have a companion moving in such a path; the components cannot, therefore, be regarded as forming a binary system. [Instances of hyperbolic motion are very rare, two comets only—those of 1771 and 1824—are known to have moved in hyperbolas, and we believe the last to be doubtful.—REPORTER.]

Stellar Motions.

Dr. Huggins gave a *vivâ voce* account of the subjects treated in his paper lately communicated to the Royal Society. In one portion of the paper the Doctor gave the results of his researches with his large instrument, bearing on the motions of certain stars. He had re-examined spectroscopically the motion of Sirius, and found reasons for reducing its rate of recess from the sun of 25 miles per second to 18, or, at most, 22 miles per second. Dr. Huggins mentioned the names of several other stars, the motions of which he had examined; some were receding from the sun and others were approaching him. The velocities mostly quoted of the receding stars were about 18 or 22 miles per second; and amongst the approaching stars, Arcturus, with a velocity of 55 miles per second, and α Lyræ moving at the rate of 54 miles per second were specified. In explaining these motions, the Doctor called attention to three circumstances capable of modifying them. A portion of the motion results from the transference of the Solar system in space, this occasions an apparent proper motion of each star; the motion of groups of stars in given directions as set forth by Mr. Proctor; and the actual motion of each star in space. In referring to the motions of groups of stars, Dr. Huggins took occasion to notice the confirmation of Mr. Proctor's views by means of spectroscopic observations, and mentioned that he had found five of the seven principal stars of Ursa Major exhibiting motions precisely as indicated by Mr. Proctor. In illustration of these remarks of Dr. Huggins, Mr. Proctor exhibited a map on which he had drawn arrows, by the directions and extents of which the direction and extent of the proper motions were indicated, and he hoped that Dr. Huggins would honour him by using the map in selecting his stars for observation. We believe there is a great probability of the map being published. Dr. Huggins's paper appears to be opening out to us a most interesting field of stellar astronomy of equal, if not of greater, importance in the study of the physics of the heavens than that of binary stars so intimately connected with the name of Herschel.

Constitution and Distribution of Nebulæ.

A portion of Dr. Huggins's paper before alluded to treats of the further spectroscopic examination of Nebulæ, particularly the Nebula of Orion. In adapting his large instrument to these special observations, the Doctor found it necessary to produce the light, giving the comparison lines, within the tube, and by an ingenious contrivance he succeeded in obtaining it in the axis of the telescope, so that the light from the Nebula under examination and that from the gaseous element with which it was compared traversed the tube. The three bright lines of the Nebula were referred to the hydrogen lines, of which the brightest is well known to be double; but Dr. Huggins could not succeed in doubling the brightest line of the Nebula, so that the real character of the brightest line of the Nebula is still uncertain.

Mr. Proctor read a paper on the distribution of the Nebulæ in the rich region of Virgo and Coma Berenices, in which he directed attention to relations that appeared to exist between the gathering of stars and the scarcity, or otherwise of Nebulæ in their neighbourhood, indicating the existence of a connection between the stars and the Nebulæ.

Improvement of Tripod Stands.

Mr. Lecky exhibited and explained an improved tripod, to which, by the addition of certain cross braces forming ties and a brace in front of the nature of a strut, a remarkable firmness was given. It could be used for a variety of purposes. Before explaining the principles of his improvement, Mr. Lecky exhibited the first double tripod made in England.

The large number and important character of the communications read contributed to render this, the last meeting, one of the most interesting of the Session.

THE CHEMICAL SOCIETY.

The Faraday Lecture.

THE Faraday lecture founded by the Chemical Society was recently delivered by Professor Cannizzaro, of Palermo, who chose for his subject the form which the theory of chemistry should take at the present time. Whilst giving a broad sketch of the progress of modern chemistry, he showed that the atomic theory had become more and more intimately interlaced with the fabric of chemistry, so that it is no longer possible to separate them without rending the tissue, as it were, of the science, and that up to the present time we have been unable to enunciate even the empirical laws of chemical proportion independently of that theory; for those who employ the term "equivalent" in the sense that Wollaston did, commit an anachronism. Consequently, in the exposition of the value and use of symbols, formulæ, and chemical equations, not only are we unable to do without the atomic and molecular theory, but it is inconvenient to follow the long and fatiguing path of induction which leads up to it. By one of those bold flights of the human mind we can at once reach the height whence we discern at a glance the relations between facts.

He then went on to show that the solid basis, the corner-stone of the modern molecular and atomic theory—the crown of the edifice of which Dalton laid the foundations—is the theory of Avogadro and Ampère, Koenig, and Clausius, on the constitution of perfect gases, to which chemists, unknown to themselves, have been led in the progress of their science. He thought the time had arrived for reversing the order which had hitherto been followed in teaching chemistry, that instead of setting out from the criteria for determining the weight of the molecules, and then to show their ratio to the vapour densities, they ought, on the contrary, to commence with the latter, with the theory of Avogadro and Clausius, demonstrating it from physical considerations; to found upon that the proof of the divisibility of simple bodies—that is to say, the existence of atoms; and to show, as occasion presented itself, that the weight of the molecules and the numbers of the atoms deduced by the application of this theory are in accordance with those which are deduced from chemical criteria. By this means we can measure the degree of confidence to be placed in the latter criteria, since so-called compound equivalents do not suffice to determine the weight of molecules, or even to prove their existence, although they may be deduced from a single principle—the theory of the constitution of gases: this is the natural transition from physics to chemistry.

The Professor then stated how he applied in detail the principles he had laid before them. He introduced his pupils to the study of chemistry, in endeavouring to place them on the same level as the contemporaries of Lavoisier, and to teach them to appreciate the importance of the principle of the conservation of the weight of matter, showing them that this is quite independent of any idea of its nature or constitution; they are thus led to examine the ponderable composition of substances, so that the student passes rapidly from the epoch of Lavoisier to that of Proust, and then to that of Berzelius, at the time when he commenced his researches on proportions. At this stage the same impulse is given to the pupil as Berzelius received on becoming acquainted with the hypothesis of Dalton. The latter is laid before him without any accessory, the use of symbols and formulæ being introduced dogmatically. There will now arise in his mind the same doubts and difficulties that assailed Berthollet, Sir Humphry Davy, and Wollaston in the application of Dalton's theory, and at the same time a desire for an explanation of the simple relation which exists between the vapour volumes of bodies which react on one another, and of the products which are obtained. Now is the moment to state or recall to mind the physical theory of the constitution of the perfect gases, commencing with a rapid glance at their general and special characters. He insisted that in this part of the instruction the mind of the student should not be diverted from the numbers expressing their relations, by consideration of the variations caused by changes of temperature and pressure. In applying the theory of the constitution of gases, it will be perceived that the molecules of simple bodies are not always the atoms of Dalton, and a certain confusion will thus be produced in the mind of the beginner in the conception of the ideas of atoms and molecules. The hypothesis of Dalton can now be laid aside, substituting, as a starting point, the theory of the relation of molecular weights to the vapour densities. A table must be prepared of the vapour density compared with that of hydrogen as 2—that is to say, the weights of their molecules compared with the weight of the semi-molecule of hydrogen taken as unity. We must then compare the composition of the molecules containing the same element—including, or not, the molecule of the element itself—and thence deduce the law of the existence of atoms, that is to say, the amount of each element which always enters by whole multiples into the molecules which contains them. We here have the atoms of Dalton, which in the present state of the science, express not only all that Dalton discovered, but also the composition of equal volumes of their vapours, and in the choice of which those doubts can no longer arise which embarrassed Davy and Wollaston. The ideas of molecules and atoms suggested to the student by this law are devoid of all considerations of form, size, continuity, or discontinuity; the only property indissolubly connected with them is that of ponderability, the very definition of matter.

Recollecting that no physical theory of the constitution of matter had yet been advanced which thoroughly conformed to chemical ideas, he insisted upon the advisability in teaching the molecular and atomic theory to keep it free from all that is not absolutely essential, so that it may preserve sufficient plasticity to adapt itself to the progress of our physical and mathematical knowledge. For this purpose he thought it useful to allow the student, in the first place, to glance at the changes in the hypothesis of the constitution of matter, and then to cause him to estimate the degree of confidence they merit in the actual state of our knowledge. Having thus placed upon a solid basis the fundamental notions of atoms and molecules by the comparison of the composition of equal volumes of the bodies in the gaseous state, it becomes necessary to consider the difficulties which arise in the application of these notions when the vapour densities are wanting. He explained and justified the use of various auxiliary criteria to which we have recourse in these cases, proving them, in the first instance, by the touchstone of the theory of Avogadis and Clausius by showing that they gave results in accordance with that theory whenever the two methods can be employed simultaneously.

He believed that we should never lose sight of the starting point, nor give the formulæ of all compounds as of equal probability. "It is not by concealing the obscurity of these questions that we shall enlighten the student; on the contrary, we should estimate each fact at its true value by showing him that our science does not merit an equal degree of confidence on all points." This forms the introduction, the preparation for the study of the transformations which matter undergoes—the real object and aim of our science.

The comparison of the atomic composition of molecules has led chemists to the law of substitution, to the theory of types of Dumas, then to that of Williamson and Gerhardt, and, lastly, to the theory of the different mobility of atoms and their modes of union, or the so-called theory of atomicity, which includes the former. Although at present it is impossible in teaching chemistry entirely to eliminate this latter theory, which gives a summary of several laws, and guides us ordinarily in the co-ordination and even prevision of a large number of facts, yet it is difficult to keep it within just bounds, so as to avoid infusing into the mind of the beginner illusions which are dangerous for their intelligent education. In order to avoid this, it is advisable to bear in mind the progress of this doctrine, and the actual phase of development which it has at present reached. It is still far from being a complete and well established theory, but it is in a state of transition, for although doubtless, it embraces a large number of facts, as yet it does not embrace them all. It is only a partial representation of the reality, and that from a restricted point of view, showing but little relation to our views of the constitution of matter, for it is the result of a comparison of diverse facts expressed by means of the atomic and molecular theory. It is convenient, therefore, to consider each point of this doctrine exclusively in relation to the group of facts which has suggested it.

It is unadvisable to define the valency of atoms as a property inherent in them, and then to deduce as a corollary their different modes of union; on the contrary, it is preferable to regard each portion of this doctrine as a deduction from the observation and comparison of a determinate group of facts, until an opportunity offers to unite these fragments into one whole, not forgetting, however, to notice the gaps which exist; never going beyond what the facts themselves suggest, and never applying to all bodies indiscriminately the laws which suit only a single group. For instance, we must not pass over in silence the fact that whilst certain elements are bi-tetra or even hexa-valent, others are tri and penta-valent; but the pupil should be prevented from acquiring mechanical and geometrical ideas from the cause and effect of the valency of atoms by frequently reminding him that chemical facts show nothing about the size, form, continuity, or relative disposition of atoms. If we are sometimes obliged to employ the expression "relative position of atoms in the molecules," and even to represent them graphically, we must warn the student that these are only artifices to express certain transformations, and that we are really ignorant of the relative position of the atoms either in space or in the mutual action of different portions of matter. With these reservations, it is possible in teaching to derive considerable advantage from the theory of atomicity, and at the same time avoid its inconveniences.

In the study of the transformations which matter undergoes we should direct the pupil's attention, not only to the ponderable changes in the composition of molecules, but also to the electrical and calorific phenomena which accompany these transformations. Even from Lavoisier's time it has been recognised that we cannot separate the study of matter from thermic considerations, and every day the connection which exists between chemical and thermic phenomena becomes more apparent. As in the study of ponderable changes we were guided by the law of the conservation of weight, so in the connection between chemical and dynamical phenomena we are guided by the law of the conservation of force; the two studies mutually supplementing and illustrating one another; and not only will the atomic and molecular theory and that of atomicity help us to compare dynamical phenomena, but the study of dynamical phenomena will show us analogies and differences between chemical actions which would not be observed in the ponderable equations. We should, therefore, instruct the student in the little definite knowledge which we at present possess concerning thermic and electric phenomena, and especially fix in his mind the fundamental notion of a mechanical equivalent, and the manner of comparing it with chemical action, as expressed by the atomic theory. In this we should be aided by the previous or simultaneous instruction of the student in physics, under the form and language of the thermo-dynamic theory.

The lecturer concluded by observing, that in the choice of methods and of matter for a course of chemistry, it should always be borne in mind that it was eminently a progressive science, and that even at the time of its most rapid development. The student should start not only with a knowledge of certain definite and fixed principles, but with an aptitude and sufficient preparation to enable him to follow the science in its unceasing transformation and progress; whether he intends to expressly cultivate chemistry, or has only learnt the elements of the science as an auxiliary to other studies or professions; moreover, the end of chemical instruction for both these classes of students is not only to fix in their memory a certain amount of knowledge, but to assist in their intellectual education. For this, chemistry, of all sciences is one of the best, offering, both in verbal and practical instruction, excellent occasions for the exercise and harmonious development of all the faculties of the human mind.

Dr. Williamson said that there was scarcely anything of greater moment in the scientific education of youth than the rightly setting before them those wonderful transformations of matter which it is the province of chemistry to explain. These great and growing truths—for, as the lecturer had said, they were growing truths—should be set before youth in such a manner as to form a coherent whole.

Professor Tyndall said he had heard the discourse with deep interest, for it showed that the lecturer knew the importance of a teacher's vocation, and that his province was not merely to communicate knowledge, but to do it in such a manner as to arouse an interest in and love of the subject in the pupil, by presenting it in its proper relations. He would have welcomed the lecturer to that institution even had he come to tear in pieces the notions which he cherished regarding atoms and molecules. How pleasant it was, then, to find such a broad agreement between their views. The chemist cannot halt at equivalent proportions, he *must* ask himself whence they arise, and the inevitable answer is some form of the atomic theory. This theory, however, cannot be confined to chemical phenomena. The motions of those atoms and molecules underlie all our explanations of the physical cause of light and heat, and it is already taking up the field of magnetism and electricity. Consider, for example the heat of gases, both as regards the motion of translation of the molecules which produce temperature, and the motions of rotation and vibration of their constituent atoms, which, though they do not express themselves as temperature, constitute a portion of the heat. The lecturer had also referred to atoms of the same kind combining together, so that free oxygen and free hydrogen being considered as composed of molecules, each containing a pair of atoms, has certainly simplified the results. But it must not be forgotten that this combination of like atoms is generally different from that of unlike atoms. The union of oxygen with oxygen or nitrogen with nitrogen produces no such effects upon the luminiferous ether as the union of oxygen with nitrogen. With the same quantity of matter the amount of *vis viva* sent forth as radiant heat may be augmented a thousandfold—perhaps a millionfold—by the act of diverse combination. This act seems to carry with it a condensation of the ether to a dense atmosphere around the atoms. In the same way the diverse atoms vibrating in the denser atmosphere formed on combination, show their vast superiority as radiators over like atoms, which, except in such special cases as ozone, &c., are incompetent to produce similar condensation.

THE METEOROLOGICAL SOCIETY.

AT the ordinary meeting, the last of the Session, held on Wednesday, June 19, the President, Dr. Tripe, in the chair, Captain Toynbee, Marine Superintendent of the Meteorological Office, explained the system of procedure in constructing the series of oceanic wind and weather charts now in progress in his department of the office. Four monthly charts were exhibited, January to April, of which the January chart is lithographed. It is intended to circulate this chart among meteorologists with the view of eliciting expressions of opinion previous to the publication of the portion of the series now ready. The geographical extent of the four charts exhibited embraces 10° of latitude and longitude so chosen as to illustrate the best longitude for crossing the equator. Each chart contains 100 2in. sub-squares of 1° of latitude and longitude, in which are arranged the *results* of all the records in each sub-square of wind, direction and force; barometric heights; temperature of air, dry and damp thermometers, also the temperature of the surface of the sea; direction and rates of currents and specific gravity of sea water. In each sub-square concentric circles are drawn, within which certain results are recorded, the central space containing arrows indicating the winds met with in the particular latitude and longitude to which the sub-square relates. The arrow, representing the largest number of wind observations, extending to the *centre*, shows the prevailing wind in the sub-square. The ratio of calms to winds is pointed out by a shaded segment of the same ratio to the whole circle. In addition to the sub-squares are marginal squares which contain the sums of ten sub-squares running in the same degree of latitude or longitude. They also contain the percentage of *wind* and its mean force for each quarter of the compass—N.W., N.E., S.E., and S.W., the percentages of *variables* and *calms*, and the percentage and mean rate of *currents*, and also the percentage of *no current*. In addition to this information the marginal squares include the summings-up of *weather* and *cloud* for ten sub-squares.

The explanation of Captain Toynbee was very lucid. Having sailed over the locality, he very ably pointed out the best route for sailing vessels, specifying with great distinctness the sub-squares they should avoid—those in which they would meet with the largest number of calms—and he showed on the chart for April that on the most easterly strip of longitude calms were much more frequent than on the most westerly; also that the wind gradually increased in force in proceeding from east to west, so that a ship in the more westerly longitudes would meet with greater wind propulsion than one further east. The Captain also pointed out the differences existing between the January and April charts. In connection with the air and surface temperatures, upon laying down the isotherms it was found that the surface of the sea was invariably 1° warmer than the air above it.

Mr. Glaisher spoke in very high terms of the great value of the charts now in progress, and congratulated the country generally, and the maritime community in particular, not only on the establishment of the Meteorological Office, but on the highly important character of the results which it had produced—results enabling the seaman to choose his route, for with such charts in his possession, extending over the twelve months of the year, he had no difficulty in selecting his course so as to avoid detention on the one hand, and avail himself of advantageous winds on the other. If the Meteorological Office had produced nothing beyond the four charts now before the meeting, it had fulfilled its mission and had fully answered the expectations of its promoters.

Towards the conclusion of the meeting, the residential address was read; it was ordered to be printed and circulated among the members. We may probably return to it on a future occasion. This being the annual meeting, the Fellows present balloted for officers and council to serve during the ensuing year. Upon the report of the scrutineers, the following gentlemen were declared to be elected:—

PRESIDENT.—John W. Tripe, M.D.

VICE-PRESIDENTS.—Arthur Brewin, F.R.A.S.; Robert H. Scott, M.A., F.R.S.; George James Symons; Charles Vincent Walker, F.R.S.

TREASURER.—Henry Perigal, F.R.A.S.

TRUSTEES.—Sir Antonio Brady, F.G.S.; Stephen William Silver.

SECRETARIES.—Charles Brooke, M.A., F.R.S., F.R.C.S.; James Glaisher, F.R.S.

FOREIGN SECRETARY.—Lieut.-Col. Alexander Strange, F.R.S.

COUNCIL.—Charles O. F. Cator, M.A.; George Dines; Henry Storks Eaton, M.A.; *Rogers Field, B.A., Assoc. Inst. C.E.*; Frederic Gaster; Robert James Mann, M.D., F.R.A.S.; *William Carpenter Nash*; Thomas Sopwith, M.A., F.R.S., M. Inst. C.E.; *Rev. Fenwick W. Stow, M.A.*; *Captain Henry Toynbee, F.R.A.S.*; Samuel C. Whitbread, F.R.S.; E. O. Wildman Whitehouse, Assoc. Inst. C.E.

The names given in italics are those of new members of the Council.

USEFUL AND SCIENTIFIC NOTES.

Improved Method of Laying Footwalks.—A new process of laying footwalks is being tested on a portion of the footway in front of the Municipal Offices, Dale-street, Liverpool. On a foundation of gravel, grouted with composition cement, is laid, by means of self-acting machine (having a roller with a pressure of about 40lb. to the square inch), a layer of cement, which forms the footwalk. The roller has projecting ridges, and these produce a number of grooves, which carry off the rain, thus insuring the footwalk being always dry. The composition gradually dries, and in a few days after being laid becomes, it is said, a hard, solid mass, more durable than stone, and not in the least liable to chip or break up. There is another advantage, that if a portion of the footwalk has to be temporarily removed it can be taken up in sections. The process can be applied to roadways, but in that case the material requires to be laid in sets, to prevent horses slipping. The cost is stated to be considerably less than that of flags or stone sets.

Reminiscences of Paper Making.—It is said that William East, an English paper-maker, once upon a time set his men to work, and went away on business. While the men were at dinner, Mrs. East accidentally let a blue-bag fall into one of the vats of pulp. Alarmed at the occurrence, she determined to say nothing about it. Great was the astonishment of the workmen when they saw the peculiar colour of the paper, and great the anger of Mr. East when he returned and found that a whole vat of pulp had been spoiled. After giving the paper made from it warehouse room for many years, Mr. East sent it up to his agent in London, to be sold "for what it would fetch." "For what it will fetch!" said the agent, misunderstanding the meaning; "well, it certainly is a novelty, but he must not expect too much." So he sold the whole at a considerable advance upon the market price, and wrote to the mills for as much more as he could get. The surprise of Mr. East may be imagined. He hastened to tell his wife, who found courage to confess her share in the fortunate accident, and to claim a reward, which she received in the shape of a new cloak. Mr. East kept his secret, and for a short time supplied the market with the novel tint, until the demand far exceeded the supply, and other makers, discovering the means used, competed with him.

The Deepest Well in the World.—Twenty miles from Berlin is situated the village of Sperenberg, noted for the deepest well that has ever been sunk. Owing to the presence of gypsum in the locality it occurred to the Government authorities in charge of the mines to attempt to obtain a supply of rock salt. With this end in view the sinking of a shaft or well 16ft. in diameter was commenced some five years ago, and at a depth of 280ft. the salt was reached. The boring was continued to a further depth of 960ft., the diameter of this bore being reduced to about 13in. The operations were subsequently prosecuted by the aid of steam until a depth of 4,194ft. was attained. At this point the boring was discontinued, the borer or bit being still in the salt deposit, which thus exhibits the enormous thickness of 3,907ft. The boring would have been continued in order to discover what description of deposit lay under the salt but for the mechanical difficulties connected with the further prosecution of the operations. During the progress of this interesting work repeated and careful observations were made of the temperature at various depths. The results confirm very closely those which have been already arrived at under similar circumstances.

How to Destroy Thistles.—While giving botanical evidence in some thistle prosecutions, Dr. Daniel Bunce, curator of the Geelong Botanical Gardens, stated that an infallible way to destroy thistles was, just before the bud began to form, to cut the roots through with a spade about 2in. below the surface; also, that the practice of cutting them above the surface was an utter waste of both money and labour, as the thistles thus treated invariably sprang up again with a greater number of heads than before.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

**** In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

LIGHT SCIENCE—α DRACONIS AND PRECESSION.—TESTING A TELESCOPE—CEMENTED OBJECT-GLASSES.—AXES OF THE PLANETS—AND PURCHASE OF A REFLECTOR.

[4404.]—I AM sure that "W. H. S." (query 12120) can only want a candid answer to his question; and will not, therefore, be offended with me if I say that there is not even the ghost of "a shadow of probability" in his "theory." Before replying to the concluding part of the query which he puts, it would be necessary to have his definition of a "vacuum." Perhaps what is called the "Torricellian vacuum" (or space above the mercury in a barometer) is as perfect a one as we can obtain; and I certainly see the light through *that* twice every day myself when I read off the height of the barometer.

Will "J. X. T." (query 12126, p. 340) permit me to point out that he is now putting a very, very, different question to that which he asked on p. 159. If he will refer to his original query there (11716) and re-read it, I think that he will find that, upon the face of it, it is an inquiry whether α Draconis, having been at its nearest to the North Pole (and so our Pole Star) at a certain epoch, returned to the same position 600 years afterwards. My answer to that was (let. 4047, p. 171) that 25,800 years must elapse from the date of its occupation of the position of the Pole Star—when, bear in mind, *it was only some* 10′ *from the North Pole of the Heavens*—until its return to the same place. Now, however, he is asking about a wholly different matter. He has, apparently, been exercising himself severely with some of Professor Piazzi Smyth's pyramid vagaries, and wishes, seemingly, to know how, assuming α Draconis to have been at a distance of 8° 42′ from the Pole, it should, after the lapse of 1200 years, have been found at the same elongation from it? The best answer I can give to this is that the phenomenon of precession is produced by the revolution of the pole of the earth round the pole of the ecliptic (a revolution occupying, as I have said, 25,800 years) at a distance of some 23½° from such ecliptic pole. It must, then, be pretty evident that in the case of a star not actually *in* the pole of the ecliptic, the pole of the equator must approach it, get to its nearest, and then recede from it; and that at equal times before and after it is at its greatest proximity to our supposed star, must be at equal distances. I should strongly recommend "J. X. T." to obtain Proctor's large "Star Atlas"—or, failing that, he might make shift with the smaller one—and study the arrangement of the precessional arrows in Map 1 in connection with the very star about which he is inquiring. He will get a better idea of what he wishes to know from this map than he could derive from almost any amount of verbal description, unaccompanied by Diagrams. He will, of course, find the pole of the ecliptic marked on the Solstitial Colure. Into the physical reasons of precession, and into its complication by nutation, it is as impossible as it is needless here to enter, for are not these things written in the famous "Ipswich Lectures" of the Astronomer Royal?

In reply to Dr. Blacklock (let 4387, p. 357) I would observe that the formula which he quotes for ascertaining the separating power of a telescope of any given aperture, is the one given by Dallmeyer; but that, with a not very limited experience, I have never yet met with an instrument with regard to which its *rigid* applicability could be predicated. Moreover, in testing an object-glass or mirror to the limit of its theoretical separating power, we presuppose a combination of the most favourable circumstances; and, therefore, we should examine the star to be divorced on a calm evening in twilight, with a power not much less than that of 100 to every inch of aperture, and to give the telescope the best possible chance, the components of the pair we are viewing should be almost, or quite, equal, and of a magnitude not exceeding the fourth. I think it extremely likely that Dr. Blacklock did see the companion to δ Cygni on the occasion to which he refers, and for this reason, that the chief difficulty with this very delicate test arises from the fact that the 9th magnitude companion is just *on* a diffraction ring, a ring which would be obliterated by such a haze as your correspondent speaks of. Dr. Blacklock's ideas as to the probable, or possible, cause of the disappearance of very faint stars under increased amplification seem to me to be very suggestive ones, and I think that it might be desirable to institute some experiments for the purpose of determining, or attempting to determine, one or two of the points mooted in his interesting letter.

I may tell "C. B." (let. 4366, p. 353) that object-glasses are *not* balsamed to shorten the focus, but to prevent internal reflections, and to preserve the inner surfaces of the lenses from decomposition. I confess my inability to understand how, if the lenses of "C. B.'s" 48in. object-glass were—as they ought to have been—in contact, he shortened its focus one-third (!) by interposing balsam. This, by the way, induces me to remark that this method of cementing lenses is only applicable when the radii of the two internal surfaces are identical, and that, consequently, it is quite unsuitable in a large proportion of astronomical telescopes.

And, while on the subject of cemented object-glasses, I may inform "Albireo" (query 12224, p. 366) that I believe that the cracking of the balsam to which he refers almost always has its origin in a blow or jar of some sort; at least I know that the tumble of a pocket telescope of my own was incontinently followed by this result. With reference to the second part of his query, I should certainly say that a cemented object-glass was the more durable of the two, and I may answer his concluding question by advising him to have nothing to do with a pancratic eyepiece for delicate celestial purposes. What with the great loss of light, and the annoying visibility of the dirt and dust on its component lenses, it is about as worrying a piece of apparatus as the observer can employ. Nothing equals the Huyghenian eyepiece for astronomical purposes.

"Countryman" (query 12227, p. 367) asks a question with reference to a subject on which our information is by no means perfect, no determination being much more difficult than that of the exact inclination of the axis of a planet to its orbit. With the reservation then, that the data I am about to give are only approximate, I may tell your querist that Bessel put the inclination of Mercury's axis from a perpendicular to its orbit at 26°, that de Vico imagined the inclination of the axis of Venus to be no less than 53° 11′ 26″ (!) that Sir William Herschel conceived the axis of Mars to have an inclination of 28° 42′, and that Jupiter's axis is almost perpendicular to the plane of its orbit, or, at all events, inclined to it less than 2°.

If the object of "Canis Minor" (query 12229, p. 367) be (as it ostensibly is) to examine the physical aspect of the objects about which he reads in books on astronomy; or, should he wish to devote himself—as he would further seem to indicate—to selenography, he could in no other way get so much for his money, as in the purchase of the instrument to which he refers. I should however, strongly recommend him to spend a little more money and have an *equatorial* mounting. An altazimuth movement with a high power is enough to drive anybody mad.

A Fellow of the Royal Astronomical Society.

CONCERNING CERTAIN (OR UNCERTAIN) CRITICS.

[4405.]—Mr. J. M. G. Brookwood (let. 4357, p. 352) is kind enough to attempt to set me right; but, perhaps, it might have been as well if, *in limine*, he had made himself acquainted with what I said, before attempting to criticise it.

I am wholly unaware that I ever penned any such nonsense as an assertion that "the semi-barbarous Hebrews '*wrote*' the account of the Deluge." Admitting, for argument's sake (for we have nothing approaching to proof of it), that Moses did write the account which we possess, I assume that he only gave what lawyers call secondary evidence on the point (as I can scarcely conceive even Mr. Brookwood contending for his bodily presence in the ark); and, such being the case, he must have been indebted to the floating legends of his time for his data. Furthermore, I demur wholly to the dictum of my critic, that "whether the Hebrews themselves can be properly styled semi-barbarous is doubtful, *if we compare them with the other nations of their time*"! Just so. "Inter indoctos etiam corydus sonat;" but the question here is not their relative, but their absolute, knowledge.

The concluding paragraph of the letter under discussion is delicious. How would it read paraphrased thus: "But if 'P. Santalinus' disbelieves, as he seems to ignore, the existence of King Arthur, what reason has he to believe in the existence of George the Third, or of any one else in particular"?

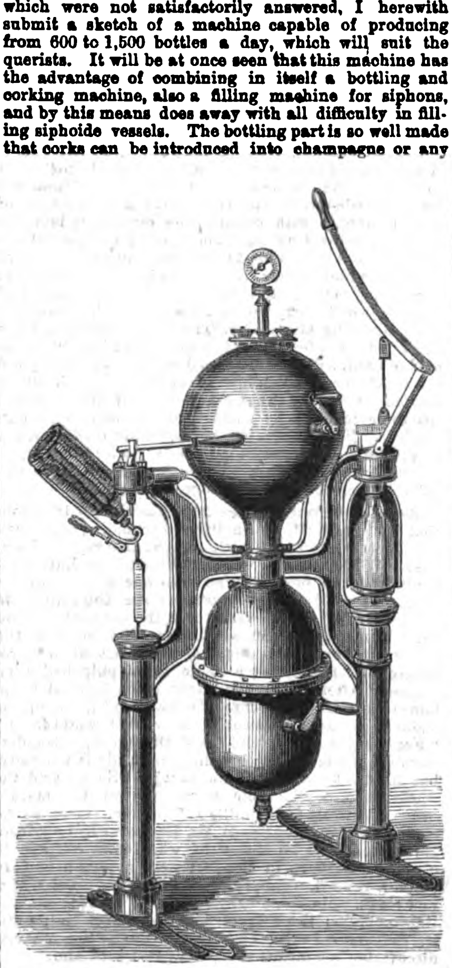
I am exceedingly curious to know on whose authority Mr. Brookwood, in his preceding letter (4456, p. 352), limits the antiquity of the Cave Men to 7,000 years; and I fail utterly to see what he means by the "testimonies adduced by Lyell," inasmuch as that great philosopher assigns 100,000 years as a moderate estimate. It might be worth your correspondent's while to re-examine the evidence on this point, and to make a theory to fit the facts, instead of trying to force the facts to fit his theory.

I should not have condescended to notice the reply to query 11991, on p. 362, coming as it does from a person who, apparently knowing nothing, seems so burningly anxious to impart it to his brother readers, but for the fact that in his floundering attempts to correct me he has himself blundered hopelessly. He never penned a truer sentence in his life than that in which he disclaims all knowledge of fourpenny catechisms, or he would never have made this last successful essay to justify his enrolment in the category adverted to in Romans i., 22. I repeat to "Anon." that the plate *is* placed in the focus of a camera lens, since in everything worthy of that name the chemical and visual foci are made absolutely coincident. I yield to "Philo" the full credit of the assertion, or insinuation, that it is a *fixture* there.) Moreover, if we were to employ a single lens, the plate holder would *not* have to be placed "at a considerably *greater* (!) distance" from such lens than its optical image was formed at, but at a *less* one—the actinic rays residing at the violet, and consequently more refrangible, end of the spectrum. What the "congregate focus of diverging rays" means "Philo" knows best. I fancy that this would bother the Astronomer Royal and Professor Stokes (our two first living authorities on light) a little. With the utmost deference to "Philo" I think that the study of a fourpenny catechism would have obviated this solecism, at all events.

A Fellow of the Royal Astronomical Society.

IMPROVED MACHINE FOR MAKING AERATED DRINKS.

[4406.]—Having seen from time to time inquiries in "ours" as to the best machine for this purpose, which were not satisfactorily answered, I herewith submit a sketch of a machine capable of producing from 600 to 1,500 bottles a day, which will suit the querists. It will be at once seen that this machine has the advantage of combining in itself a bottling and corking machine, also a filling machine for siphons, and by this means does away with all difficulty in filling siphoide vessels. The bottling part is so well made that corks can be introduced into champagne or any



other bottles without the least danger of breakage. It can be used for any aerated drinks, soda water, lemonade, ginger beer, champagne, &c.; it takes up but little space, about a yard and a half square being amply enough. It is remarkably well constructed—with great strength and solidity, can be worked with ease, and not at all liable to get out of order. The gas is produced by means of sulphuric acid and common whiting; the gas compresses itself, becoming perfectly washed and pure before saturating the water. The saturation is made in 25 minutes' time by turning an agitator. It has a manometer to indicate the pressure of gas. I would recommend this to the notice of "D. W. L." or "L. W. D.," who, I believe, asked the question. Anything further I shall be most happy to explain, and I can give the price. H. B. E.

A SEARCHER AFTER TRUTH.

[4407.]—What a strange thing it is that people so generally lose all sense of common justice, civility, and good feeling, to their opponents in any matter which has a theological or ecclesiastical tinge—either will do, though they are very different matters. That being so with people who are usually fair and reasonable, and the weather having taken so warm a turn, with considerable electrical disturbance, I am not disposed to be too hard upon "E. L. G.," who appears to be a subject rather for sympathy under the attack of rabies, which has set him snapping and biting (letter 4360, p. 352).

Permit me to say that "E. L. G." states "the thing which is not," and bears false witness against his neighbour. As to his good taste in making a direct personal attack upon me because I think differently from him, I say nothing, because I care nothing; but I will not allow him to set forth what is absolutely false, and further to deduce from that false premise equally false consequences.

I am not going to discuss either the Bible or my own theological opinions, which concern no one; I would do so faithfully and fearlessly, as I have often done in other pages. This is no place for such topics. It was impossible to discuss the Deluge without some such reference as I slightly made on two occasions, but I ask any one of common sense if there is a shadow of truth in the remark, "What single paragraph thereon has 'Sigma' written without naming or referring to the Bible?" I further ask whether even that limited honesty which disputants of "E. L. G.'s" calibre usually feel binding on them is exercised when, without a shadow of information as to me or my opinions, he ingeniously but indirectly contrives to class me with Voltaire and Bradlaugh.

I have not read any of the works of either of those writers, except Voltaire's poem, "The Henriade," which I thought wretchedly dull stuff. Of Bradlaugh's opinions I know nothing but the probably false statements sometimes given in the papers; if they are true, I entirely dissent from them. In fact, I have formed this sort of picture of him:—A tolerably wide reader, with an intensely bigoted and narrow-minded way of looking at things; an absolute incapacity for seeing anything which does not suit his ideas; a considerable amount of ability, with a vastly excessive estimate of it; a firm conviction that any one who thinks differently from him is certainly a fool, and probably a rogue or a hypocrite; immeasurable presumption, and therefore a belief that, coming from him, assertion is evidence, and abuse argument. That is the sort of conception I have of Mr. Bradlaugh; it may be entirely wrong, as it is based on the reports mainly of his opponents, but if correct, what fun it would be to hear a discussion between him and "E. L. G." That would be a case of when Greek meets Greek,* &c.

It was certainly my impression that my remarks were aimed at the purely physical question of whether there had ever been a universal Deluge, and even that only in the second place, the first being given to "E. L. G.'s" absurd comet as the cause of the supposed Deluge; at all events, I distinctly deny "E. L. G.'s" assertion that my chief object was the Bible, or that I endeavoured to single out two popular errors about it and thrust them forth as facts. To use "E. L. G.'s" words (he furnishes one with a complete armoury), "I flatly deny that any 'sincere searcher after truth' of any kind" would so gratuitously falsify the object, nay, the actual words of his opponent. Why, I did exactly the same thing as "E. L. G." does in the letter I am discussing; he says they are errors, that they are misconceptions of the real meaning of the writers, only it pleases him to except the Deluge from the list. That is what I said and say: they *are* errors, misconceptions, and popular delusions; and I further said and say that it is a mischievous error to insist on our accepting them, or to link them up in any way with religious ideas. It is a gross calumny, and I can scarcely believe an unintentional one, to say that I used them "exactly as Voltaire and Bradlaugh;" on the contrary, I say they are dangerous points incapable of defence, and ought to be recognised as such, instead of being bitterly defended as Sacred truths. (Please give the big S which "E. L. G." so values.) "E. L. G.'s" talk about the account of the sun and moon standing still is pure twaddle, as any one may see who will read the account itself; in fact, he utterly falsifies it, for the battle was actually fought in defence of the Gibeonites, who had surrendered themselves as serfs: the Israelites had *not* bound themselves not to destroy the Gibeonite *religion* in any way, and the writer does *not* tell us that the "superstitious legends are from no Sacred book." There is a sort of parenthesis or marginal note by some later copyist, remarking that there is a similar account in the book of Jasher, which may be a novel, as "E. L. G." says, for all I know about it, but which, I believe, the Jewish Targum calls "The Books of the Lord," and which a greater G. than "E. L. G."—viz., Grotius, considers was a sort of metrical tradition handed down from the period of the events, and such as are repeated to this day among the Arab tribes.

Sigma.

[After "E. L. G.'s" attack on "Sigma" we feel bound to insert the above letter. We are, however, so heartily sick of the subject, and the manner in which it has been discussed, that we will not insert another line on it, come from what quarter it may.—Ed.]

THE ANCIENT CONSTELLATIONS.

[4408.]—The steam-comet is dropped by consent, and your readers breathe again. Without wishing to approach that subject, I must touch on an astronomical matter raised by "E. L. G." He gives an interpretation (letter 4354, pp. 351, 352) of the origin of Aquarius, Capricornus, Argo, and Sagittarius. Now, I think there is very strong evidence to show that every one of these constellations got its name from its aspect. But setting that on one side, I would ask on what evidence "E. L. G." asserts that "only we westerns have enlarged the Bow of Promise into Sagittarius." In the zodiac of Dendera, Sagittarius is a bow-armed Centaur, as in modern maps. That is the most ancient known representation of the constellation.

Richard A. Proctor.

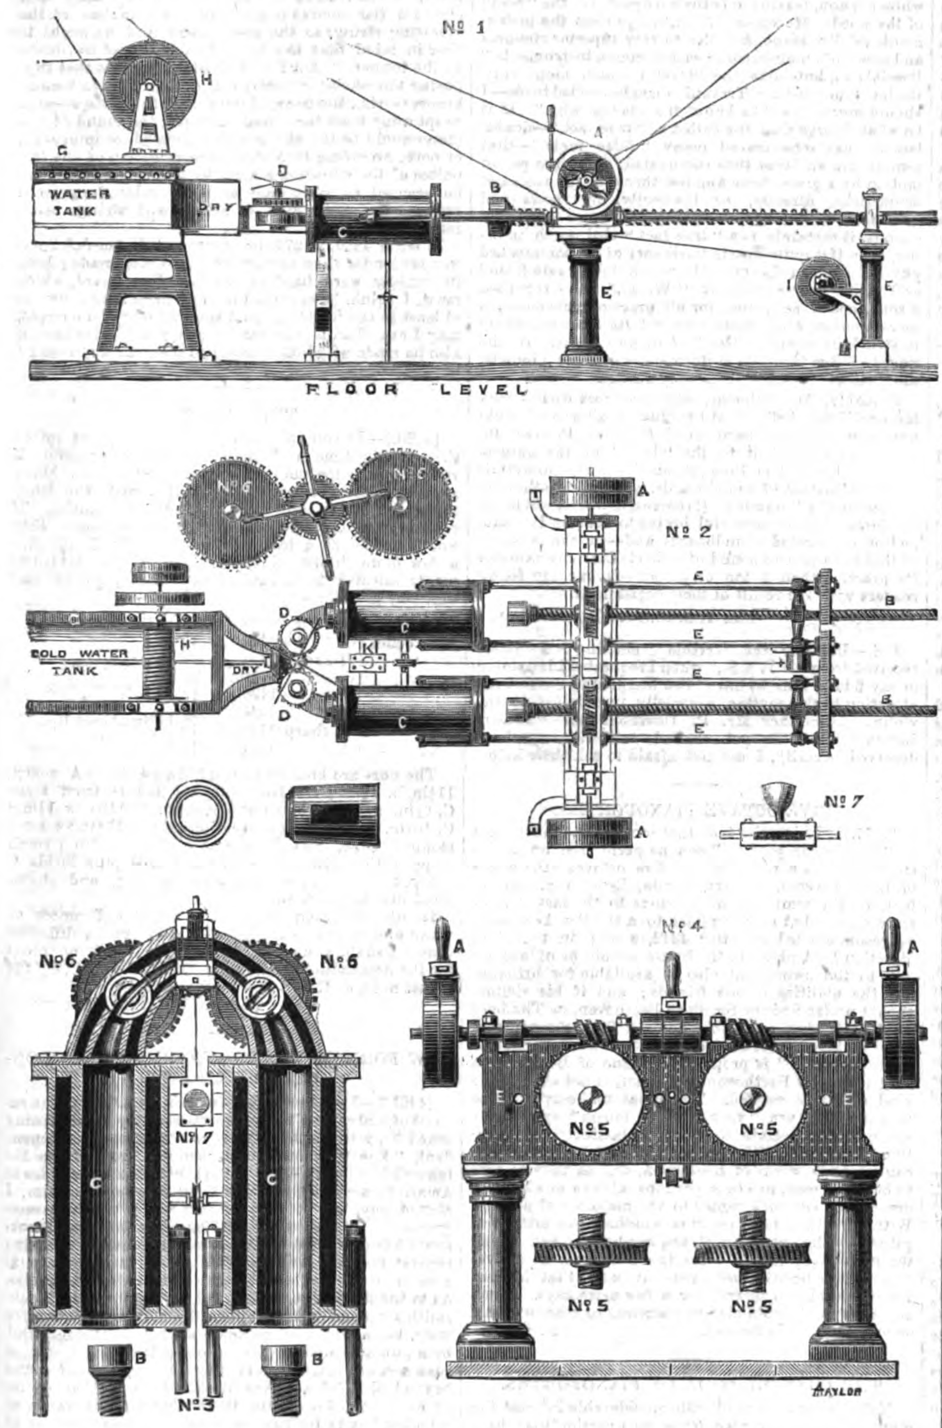
* The original is when Greek *joins* Greek, &c.—F

SYCOSIS.

[4409.]—VARIOUS sufferers have asked at different times advice on this subject. After ten years' suffering from this disease, I adopted, with the most complete success, the practice recommended by Dr. Erasmus Wilson, of plucking out the hairs, which can be easily done with a pair of tweezers, when the pimples are about one or two days past their height. I have well satisfied myself that the removal of the disease is effected by removing the roots of the hairs. M. N.

WIRE-COVERING MACHINES.

[4410.]—I INCLOSE diagrams of machines for covering copper wire with guttapercha or insulating materials, the machines being identical in motive



power with those which furnished the great Atlantic and Red Sea cables. I do not think a description of these machines has ever appeared, and therefore, probably, it may interest many of your readers. I shall not enter into lengthy details, as the diagrams will explain themselves:—A, the driving power; B, the plunger; C, the double steam cylinders; D, the stop-cocks for turning off or on the guttapercha; E, the slide bearings; F, the die; G, the water-tank; H, the creel of covered wire; I, creel of copper wire; K, naphtha pad. No. 1, side section; No. 2, top section; No. 3, enlarged section of cylinders; No. 4, enlarged section of die; No. 5, cog-wheels for screw plunger; No. 6, enlarged section of stop-cocks; No. 7, naphtha pad. It will be easily perceived that the cog-wheels screw on the plunger. Only half or mid section of bearings is shown, the cog-wheels being inclosed.

JOSEPH WILLIAM FENNELL.

SPINNING TOPS AND GYROSCOPES.

[4411.]—"E. H.'s" surprise (let. 4363, p. 353) at my language is due partly to his misunderstanding me, and partly to his misapprehending his subject. He writes, "I say the weight of the top is always sufficient to change, and is in reality always changing the direction of the particles' motion." But the question is, *at what rate?* Moreover, we want rather to have reasoning than to hear what "E. H." or any one else may *say* without showing cause why. He confounds A.'s incorrect reasoning on one subject with my totally distinct line of reasoning on another. It is, of course, perfectly true that gravity draws down the most swiftly travelling bullet—fired horizontally—so that it reaches the ground as quickly as a ball dropped from rest at same height. But it is not true that gravity changes the direction of a bullet fired horizontally as quickly as it would change the direction of a ball thrown horizontally by hand. The velocity of a moving body set travelling horizontally has no effect whatever in preventing the body from being brought to the ground; but it *has* effect in giving the body greater or less power to resist change in the direction of its motion. In the case of a rapidly rotating body, whether the axis be vertical or inclined, the question of the effect of velocity is all important. But "E. H." has utterly misunderstood me if he supposes I intended (as he says) to give a popular explanation of the subject of spinning bodies. I only took one case and one feature of that case. The subject is one for the mathematician. I have never seen a popular explanation that was worth reading.

I would remark that nutation is *not* an action, but the modification of an action. Lunar precession is the action; and this action proceeds more or less rapidly according as the moon's path is more or less inclined to the earth's equator. Solar precession is subject to a similar variation, having a year for its period. The resulting variation in the rate of the lunisolar precession is called *nutation*. ("E. H." speaks as though the matter were a *vexata questio*, asking what is *at present* the explanation accepted; but the whole matter has long since been disposed of. "It is hardly necessary to state," says Sir J. Herschel, "that a rigorous analysis of this great problem, by an exact estimation of all the acting forces and summation of their dynamical effects, leads to the precise value of the coefficient of precession and nutation which observation assigns to them.") The explanation given in Airy's "Popular Astronomy" is the best popular account I know of. It is reproduced (somewhat maltreated) in Mr. Lockyer's "Elementary Lessons," where Mr. Airy's woodcuts reappear, though (through some unfortunate accident) reference to Mr. Airy has been omitted. RICHARD A. PROCTOR.

THUNDERSTORM OF JUNE 18, 1872.

[4412.]—ON the 18th June, 1872, between the hours of 4 and 7 p.m., an interesting phenomenon presented itself. The early part of this period was bright and clear, the sun shining strongly. Suddenly the sun became obscured by a dense mass of cumulus, which filled the north-west portion of the sky. The cumulus, the edges of which was exceedingly well defined, gradually and slowly advanced eastward, but scarcely passed the zenith of this place (Walthamstow) the sky to the east remaining clear. About 5 p.m. distant thunder was heard, increasing in intensity and rapidity, accompanied with every appearance of a severe thunderstorm coming up from the north-west. This, however, did not take place. Towards 6 p.m., or, perhaps, earlier, the thunder ceased, and the dense clouds, instead of passing on eastward, gradually retreated westward so that the sky became clear about 7 p.m., except that shortly after masses of cirro-cumulus formed, which at 7.15 p.m. were finely polarised nearly in the direction of the magnetic meridian. Was this an instance of condensation and evaporation of a stationary cloud? No lightning was seen, nor did rain fall. The above remarks may assist in determining the area of the storm. From the numerous instances of severe thunderstorms on the 18th and 19th, reported in the daily papers from the provinces, it would appear that the atmosphere, being strongly charged with electricity, the *towns* were so many points which determined the disruptive discharge. W. R. BIRT.

LUNAR OBJECTS FOR OBSERVATION, JULY, 1872.

[4413.]—JULY 8, Oriani, Apollonius, Firmicus; July 9, Cepheus, Franklin, Oersted; July 10, Piccolomini, Riccius, Stiborius; July 11, Littrow, Vitruvius, Jansen; July 12, Theophilus, Cyrillus, Catharina; July 13, Rhœticus, Stöffler, Alfraganus; July 14, The Apennines, Aristillus, Autolycus; July 15, Hell, Maginus, Moretus; July 16, Helicon, Leverrier, Euler; July 17, Gassendi, Mersenius, and the *Percy Mountains* between them; July 18, Sirsalis, Crüger, Fontana.

A correspondent of a cotemporary calls attention to the colour of the shadows which covered up the level plain of the Sinus Iridum, on March 19, 11h. 17m., Greenwich mean time. He described it as unlike the ordinary lunar shadow, being of a light gray, through which he saw dimly the surface below, indicating the existence of some ethereal matter overshadowing it.

W. R. BIRT.

ARTIFICIAL MANURES.

[4414.]—PROBABLY at some future time I may have something to say on the subject of artificial manures generally. In the mean time I beg to lay a trifle of information before your readers, and put one or two queries, which some of your correspondents may be able to answer at once, or after experiment. In the first place, I want to know what it is that is understood by the term "stone" coal? In a specification of a patented manure recently published, the inventor states that his discovery consists in the employment of from one to five parts of "stone" coal and one part of sulphate of iron. This mixture is reduced to very fine powder, and may be applied in either the dry or liquid state. When I read this I imagined that "stone" coal might be a printer's mistake for "bone" coal—animal charcoal—but I have found the same term in a communication to the *Revue Horticole*. In this the writer gives some information which may be useful to many of your readers, and I have, therefore, sent it for what it may be worth. He says that he purchased a very fine rosebush, full of buds, and, after anxiously awaiting their maturing, was greatly disappointed, when this took place, to find the flowers small, insignificant in appearance, and of a dull, faded colour. Incited by the suggestion of a friend, he then tried the experiment of filling in the top of the pot, around the bush, to a depth of half an inch with finely pulverised stone coal. In the course of a few days, he was astonished to see the roses assume a beautiful red hue, as brilliant and lively as he could desire. He tried the same experiment upon a pot of petunias, and soon after all the pale and indefinite coloured ones became of a bright red or lilac, and the white petunias were variegated with beautiful red stripes. Some of the lilac petunias became a fine dark blue. Other flowers experienced similar alterations; those of a yellow colour alone remained insensible to the influence of the coal. Now, will any one tell me what is "stone coal"?

Sulphate of ammonia is strongly recommended as an artificial manure, to be applied in a liquid form to plants, especially in pots; and I can quite understand that it may be of very great service in the conservatory, the stove, or the greenhouse, where necessarily the plants do not obtain any ammonia from rain. But I am very doubtful if it is at all necessary for flowers and vegetables in the "open." It is very certain that by some means or other plants do obtain the requisite amount of nitrogen, and it appears to me that sulphate of ammonia can do no more than encourage the "growth" of the plant: it cannot, I take it, increase the quantity or improve the quality of the produce. I think, on the contrary, that the great necessity of plant life—that which it cannot obtain for itself—is phosphoric acid, and I am under the impression that if this is supplied we need not go any further in the direction of artificial manures—except, of course, for crops which require special substances, such as the potato, which cannot be grown without potash. If I am right, the one manure in greatest demand would be "superphosphate," mingled with the chemical ingredient which the constituents of the proposed crop indicate, and of which the soil is found deficient. Farmers are threatened with a great scarcity of guano—one of the most profitable manures used, containing as it does phosphoric acid and ammonia; but the price has risen rapidly of late years, and is now £16 per ton for the best quality. If the price continues to rise it will be impossible to employ guano as a manure with an economical and profitable result; and consequently some other material must be employed to supply the necessary ingredients to the soil. A little discussion may help to throw light on the subject, and I have, therefore, started it with the proposition that sulphate of ammonia and guano at £24 and £16 a ton are not so profitable as nitrate of soda at £17, and "superphosphate" at £6.

SAUL RYMEA.

THE LAW OF VIBRATION AND ATTRACTION THROUGHOUT THE UNIVERSE.

[4415.]—I HAVE no doubt that you, Mr. Editor, will kindly allow me to say a few words on this subject, especially after "The Harmonious Blacksmith" has been kind enough to mention it in his letter 4375, p. 355; and also because I have referred to it several times, and promised to answer several questions, provided I was allowed to explain it first. What I mean by the law of vibration is, that everything in nature, when set in vibration, arranges itself in the same relative proportions between its two ends and its centre of gravity or inertia; that some parts are comparatively quiet to others, and that there are only some parts on a body on which we can set the whole in vibration effectually.

My experiments include almost everything I could lay my hands on; and I found that a strip of wood vibrates in exactly the same relative proportions as a log of a tree, a piece of wire as a block of metal, the air in a pipe as the air in a concert-room, and lastly, I believe it is reasonable to conclude that the earth follows the same, as a stone or a piece of slate does. I could not believe, at first, that this discovery was new, because it is so simple. Then I began reading almost all those books treating on vibration, &c., but found that all those experiments and discoveries were only details, while the law for all is still undiscovered. I am certain these few words sufficiently explain at least what I mean I have discovered.

In my letter to "Fiddler" (4308, p. 307) there is one word left out, and two misprinted, which was, no doubt, my own fault. The sentence commencing, "Whether the law of vibration," and ending at "except the strings," requires the word *is* to be inserted between "instrument" and "constructed;" and the words "prevent the sound parts from 'paulking'" should read "prevent the side parts from 'baulking.'" When the strings are put on a violin it expands sideways, and consequently rarefies the breast in that direction.

J. H. SCHUCHT.

ON THE EFFECTS OF INCREASING THE SUPERFICIES OF SOUNDBOARDS WITHOUT EXTENDING THEIR EXTERNAL DIMENSIONS, AS CARRIED OUT IN VIOLINS, PIANOS, &c.

[4416.]—IT has been proposed to do what the title of this paper expresses for the purpose of increasing the loudness and improving the quality of the sounds obtained from stringed musical instruments, and it is obvious if the corrugation of a soundboard's surface can affect this, doing it will have this advantage over increasing its external dimensions—unless the strings be radiated, and the bridge made longer—because the extent of surface near the string will be greater than it would be if the soundboard's external dimensions be increased, and supposing corrugation does affect what is claimed for it, I think it would in many instances, especially in the harp and violin, be preferable to the employment of two or more soundboards under each other.

Two methods of carrying out corrugation have been published. In one M. Pape places each string or set of strings for one note on what he terms an "harmonic bar," whatever those words may mean. This bar, as represented in the illustrations of his patent, seems to me to be nothing else than a wooden bracing bar of small section. He places the strings very close—*i.e.*, within about ½in. of it, so that the tendency of their tensile force to arch it is well resisted. Each of these so-called harmonic bars is glued on the soundboard proper, and as the strings must, through their bridges, communicate their vibrations to the bar, and the latter (being glued on it) to the soundboard we cannot doubt audible sounds will be generated, although we may doubt if their loudness will exceed those generated in pianofortes strung in the ordinary manner, because each bar being glued *on* the soundboard must become in relation to it a "belly bar," imparting its stiffness or rigidity *to* the soundboard. Now, excessive stiffness in a soundboard is not found to conduce to the production of loud sounds—"quite the contrary," and we may reasonably doubt if the additional extent of surface in vibration—to wit, that of the harmonic bar—can compensate for the rigidity it must induce in the soundboard. I fear the vibrations of the latter will be deficient of amplitude and its sounds of power.

Mr. Robertson, in his patent of November, 1858, No. 2587, price 4d., proposes to augment the surfaces of soundboards by making them of thicker wood, and removing, or as he expresses it, "grooving out" the soft white portion, leaving only the hard part, *i.e.*, the "beat" of the wood. He states "from this process the instruments (violin, piano, &c.) derive very superior richness and power of tone compared with common instruments." Possibly so, but—like the 20,000 Cornish men when the late lamented Mr. Trevanion condescended to die—I should much like "to know the reason why." If it be what George Canning called a "true fact"—doubtless he has experienced many "false facts"—that soundboard surfaces thus corrugated do (when put in motion by a given force applied through the media of drumsticks, directly, or indirectly, by bows and hammers actuating strings) yield more powerful sounds, it certainly is a "true fact" well worth knowing, even if it quite upsets the theory of the soundboard put forth in the ENGLISH MECHANIC by my late friend and fellow correspondent "W. T.," who regarded a soundboard as being, for all practical purposes, a mere wooden drum head (without its tension), which is struck by strings instead of (drum) sticks. By the way, to judge from the performances of some pianists, the "sticks" are not invariably absent.

Probably, Mr. Schucht, who produces what I may term artificial belly wood by glueing alternate thicknesses of soft and hard wood together, thereby insuring an equivalent to the "beet" of the natural belly wood, and has thought much on the materials and construction of soundboards, also some others of our eminently "practical" (?) correspondents, will bring the force of their powerful brains to bear on the subject of corrugated soundboards and—in the absence of that experience a pound of which is far more valuable for practice than a ton of theory—favour my fellow readers with the result of their cogitations.

THE HARMONIOUS BLACKSMITH.

P.S.—But for the terrible "chaffing" I lately received from "F.R.A.S.," when I requested his opinion on my fiddle, I might have been tempted to request his attention to this matter, especially in relation to the violin. As neither Mr. P. Davidson nor "Beacon Lough" have as yet chaffed me with, perhaps deserved, severity, I am not afraid to ask their help.

FIVE-OCTAVE PIANOFORTES.

[4417.]—IT is quite true that most of the music that is "best worth playing" can be performed on an instrument with a range of only five octaves—the works of Bach, Handel, Mozart, Haydn, Beethoven, and, in fact, all the compositions previous to the last fifty or sixty years; but is going back to a smaller keyboard, as recommended in letter 4342, a step in the right direction? A piano in the house should be of use not only to the owner, but also be available for bringing out the abilities of his friends; and if his visitors should prefer Sydney Smith to Beethoven, or Thalberg to Mozart, what could they do on a five-octave instrument? When a few friends meet of an evening, and a "little music" is proposed, a fugue of Bach's, or a long sonata by Beethoven or Mozart, is not exactly the kind of music wanted. The great majority of those who say they are "very fond of music" are utterly unable to appreciate so-called "classical" compositions; and, in addition, it may be said that those who can play the works of Beethoven, &c., as they require to be performed, are (and perhaps always will be) in a great minority with regard to the majority of players. With myself, it is a question whether true music has gained by the extension of the key-board; but, taking things as they are, I think the purchaser of a five-octave instrument would speedily wish that he had given a few more pounds for a few more keys. Such an instrument would also be valueless in case of a sale or exchange being desired.

F. E. C.

THE CONSTRUCTION OF PIANOFORTES.

[4418.]—HAVING read with considerable interest the many articles upon pianoforte construction that have appeared in your valuable periodical for some time past, and having seen nothing referring to Rüst and Co.'s Patent Tubular Upright Pianos, "cottage grands" as they are called, I should like to ask "The Harmonious Blacksmith" if he has ever seen any of them, and if so, whether he would kindly give your readers the benefit of his thoughts about them. Rüst's soundboards are strengthened by means of hollow bars of wood (called "tubes") in place of the solid pieces in general use, and the soundboard is bored through in several places to admit the air into these tubes. The effects of this arrangement are (so the makers say): 1, to more effectually strengthen the soundboard itself; 2, and principally, to produce a greater volume of tone than any pianos made on the old plan. The tone is also of a more mellow and brilliant quality, and much better sustained. I have examined a few of them myself, and consider the method a decided improvement in pianoforte construction, the tone resulting from them being clearer, deeper, and more expansive than anything I have ever heard. The amplitude of vibration is greater than anything I have ever met with, but I would like to have the superior judgment of our friend as above stated. I believe this method of making soundboards involves a scientific or acoustic principle, and there is nothing like working on principle.

H. J.

THE PIANOFORTE.

[4419.]—ALLOW me to put one or two questions to "The Harmonious Blacksmith" with reference to some observations in his letters on the piano. In letter 4351, p. 335, last number, he says, "It would seem that every augmentation of the mass of the bridge must, like increasing the thickness of the belly-bars, obstruct the communication of the impulses of the vibrating strings to the soundboard, and we ought to bear in mind that the latter is only caused to vibrate by the former." Am I to understand by this that supposing the whole, or nearly the whole, of these incumbrances—viz., the heavy bridge and thick bars—were swept away from the sounding-board, the sound of the piano would be thereby greatly increased, or improved, or both, providing that the communication of the impulses of the vibrating strings to the soundboard can be secured as intimately as it is under the present system, the same kind of action and strings being retained?

In letter 4230, p. 275, he observes, "It (the dulcimer) was far louder than any grand piano then made; both its bridges were fixed on its sounding board, which must, I think, have caused it to produce louder sounds at least in the bass." Should such a theory be current, may I ask what is the reason why pianofortes cannot also be made with both bridges on the sounding-board?

SCIOLIST.

THE ORGAN.

[4420.]—IF you have money, buy your pipes rather than waste time and materials in making them; if you have patience and perseverance, make them. Many seem to make themselves acquainted with the fancy names of stops, and build up ludicrous fancies. If readers would search the last seven volumes, they would not be at a loss how to proceed. I will give a few more hints. Subjoined are a few measurements selected from several sets made, voiced, and tuned by myself:—

SQUARE PIPES (WOOD) OPEN.

Tenor (C)	20in.	× $2\frac{1}{4}$	From one set, measuring from the chamfered lip.
(C) sharp	19in.	× $2\frac{1}{8}$	
(D) ,,	$17\frac{3}{8}$in.	× $2\frac{3}{8}$	
(G)	14in.	× $1\frac{3}{4}$	
(A)	$12\frac{1}{2}$in.	× $1\frac{7}{8}$	
(A) sharp	$11\frac{1}{4}$in.	× $1\frac{5}{8}$	
(B)	$10\frac{7}{8}$in.	× $1\frac{1}{2}$	

The next are broader in front than sides:—A sharp, $11\frac{3}{4}$in. × $1\frac{5}{8}$in.; B, 11in. × $1\frac{3}{8}$in; 2nd G from tenor C, $6\frac{3}{4}$in. × $1\frac{1}{4}$in. From another set: B, 11in. × $1\frac{1}{8}$in.; C, $10\frac{1}{4}$in. × $1\frac{1}{8}$in. From another set: B, $11\frac{1}{8}$in. × 1in.; stopped pipe, 2nd D in treble, 5in. × 1in.; small stopped CC, $5\frac{1}{4}$in × $\frac{5}{8}$in.; chamfered pipe inside C sharp, $9\frac{3}{4}$ × $1\frac{3}{8}$in.; semicircular opening, and chamfered inside, 2nd G sharp, $6\frac{1}{4}$in. × 1in.

It will be seen there are slight differences of width and length; each pipe has a somewhat different tone. I shall, at an early opportunity, touch on reeds for the descending scale, from tenor C to CCCC, the lowest note, as the result of my experience.

JOSEPH WILLIAM BRUNELL.

NEW FORM OF VIOLIN—VIOLIN AND VIOLONCELLO COMBINED.

[4421.]—I HAVE much pleasure in attending to the request of, and cannot but feel flattered at my opinion being asked by, your facetious and good-humoured correspondent, "The Harmonious Blacksmith," relative to his funny fiddle (letter 4201, p. 254). Whether the shades of Amati, Guarnerius, and Strad., will rise against him, I cannot say, but on his devoted head be the consequences. Joking apart, "The Harmonious Blacksmith has combined two ideas which I would examine separately—(1) a wholly new form of instrument; (2) a union of the fiddle tribe, from violin to violoncello. As to the first point, taking "The Harmonious Blacksmith's" figure not to represent a section of a box or body, but a series of six open soundboards connected by a jointed sound-post, I conceive that the result of such a construction would afford little force of sound beyond that of a string stretched as is that of an archery bow, for I must think that the resonance of a hollow box or body is necessary to produce power of tone. Witness the effect of a musical box when placed upon a table, particularly if the same table has a hollow drawer. Compare a tambourine with a drum. Also the fact that old Lindley usually mounted himself upon a hollow box (not that I mean to insinuate that he was a sounding-post), to increase his power.

I must agree with "The Harmonious Blacksmith" that soundboards vibrate synchronously (and simultaneously also) with the string which starts them playing second fiddle thereto. If every bit of wood of which a fiddle is built, and which glued together form the body, sounded its own note, what a "jolly row" there would be. It is often laid down in theoretical instructions for fiddle making that the back should vibrate so many times to another number of vibrations for the belly; but this only indicates a certain thickness or test of such thickness of wood as will tend to give a good tone, and neither back nor belly dream of sounding their own independent note, nor does the glued-up body, which possesses a note of its own, act otherwise. It may be laid down as a rule that if two or more pieces of wood are glued together, their pitch will be the same (allowing for non-vibration of glue) as if they were originally one piece of same dimensions. Another remark I would make. If the soundboards are (as it would seem by "The Harmonious Blacksmith's" figure) fastened to the thick outer frame, the thickness of such frame would be likely to deaden the vibration.

Now, as to the second point—the union of the violin tribe in one instrument. I am unable to see how the strings can be fingered. The mastery of double notes on the violin alone is sufficiently difficult, and nothing short of a Briareus (a mythic gentleman, with one hundred hands and fifty eyes) would apparently be sufficient to play a concerto on the proposed instrument. Neither do I think that soundboards fit for a violin string would do for the string of a violoncello.

Suppose our worthy friend "The Harmonious Blacksmith" were first to construct the violin part of his instrument and try its action. This he might chin and save his wooden leg. I see no apparent reason why the vibratory action of a string should not be "returned with interest," whatever may be its position (distance excepted) to the resonant body.

SUFFOLK AMATEUR.

THE BELL PIANETTE.—To MR. BOTTONE.

[4422.]—I AM greatly obliged to Mr. Bottone for recalling my attention to Dr. Cleggatt's patent, and thereby convincing me yet more strongly the wisdom of our law courts' practice of refusing secondary when primary evidence is obtainable. Although I possessed Dr. Cleggatt's patent, I was unable to refer to it at the time I wrote the article on the bell pianette and the lyrichord (printed in No. 378), so I was tempted to trust to the "Abridgment of Specifications Relating to Music and Musical Instruments from A.D. 1694 to A.D. 1866"—one of the cheapest books, containing over 500 pages, in existence, sold for what Jeremy Diddler, Esq., termed the "ridiculously small sum of 1s. 10d.," by her Majesty's Commissioners of Patents at "ye office of ye said Commissioners, over against ye Birkbeck Institution in Southampton Buildings, nere unto Holborne." The aforesaid work is generally pretty accurate, although some of the said abridgments might have been better drafted; but in this they fail in common with certain and sundry Acts of Parliament, not to mention our last treaty with Uncle Sam concerning his Alabama claims. Being, however, but an abridgment, it occasionally is guilty of sins of omission, amongst which are Dr. Cleggatt's proposals to employ "hammers or jacks as in the pianoforte or harpsichord" for vibrating his tuning-forks when arranged to form a musical instrument. I again thank Mr. Bottone for enabling me to correct the error I inadvertently committed, from which some experience ought to have saved me—to wit, excessive faith in official accuracy.

THE HARMONIOUS BLACKSMITH.

AURORA.

[4423.]—Mr. W. HATFIELD, of Bell's Hill, Stoke, near Slough, a reader of the ENGLISH MECHANIC, observed the Aurora of June 3, 1872, and noticed streamers from the magnetic to the true north of a a white silvery colour, sometimes slightly tinged with red, features that I missed.

W. R. BIRT.

COLOURED SUNS—BALSAMED OBJECT-GLASS.

[4424.]—THANKS to "Linea" (let. 4394, p. 358). The erratum he points out very finely illustrates the whole subject of such errors. Not only had I, as he mentions, given the magnitudes of the components of ε Bootis rightly in my "Half Hours with the Telescope;" not only have I a distinct mental conception of their aspect; but positively at the very time the sheet containing the erratum was going through the press, I was publishing in the *Mechanics' Magazine* a picture of the pair, rightly drawn and properly described. How on earth such mistakes creep in, and escape getting turned out, passes me. My reviewer too. How did he fail to notice the error? His remarks show that he is a practised observer.

It may interest "C. B." (let. 4366, p. 353) to know that Dr. Huggins's 15in. object-glass, now being used for spectroscopic work, is balsamed. Dr. Huggins considers that the saving of light is about equal to the effect of an increase of aperture-area by the area of a 5-in. object-glass. Balsaming *ought* not to have shortened focus, if the two glasses were properly shaped. They cannot have fitted, and the balsam became as it were a third lens.

RICHARD A. PROCTOR.

COLOURED SUNS.

[4425.]—IN connection with the excellent essay by Mr. Proctor, inserted on p. 296, perhaps your readers might be interested in a list of the terms employed by several of our best observers, who have endeavoured to convey their impressions of tints in the words which follow. The majority are from Smyth's "Cycle," but eleven other observers have contributed to the list (which I have had in private use for some time), whose names are indicated by the attached numerals. [1] Sir J. Herschel, [2] Struve, [3] Webb, [4] Dawes, [5] C. P. Smyth, Hind, [7] Dembowski, [8] Knott, [9] Talmage, [10] Slack, [11] Miller. The principal authority for these is that invaluable work for all telescopists, "Celestial Objects."

Pale fawn.	[4] Brownish.

CREAMY.

Pale cream coloured.	Pale plum coloured.
Dusky.	Livid.
[3] Tawny.	Lurid.
Plum coloured.	

In the foregoing list only a rough classification has been attempted, and that more one of terms than exact chromatic significance. Descriptions are frequently of equivalent meaning, though differing in words; and of others it can only be said that a general idea is conveyed, the terms being too indefinite. Notwithstanding the difficulty where colour is concerned, the majority of them indicate pretty clearly the impression made on the observer.

T. H. BUFFHAM.

COLOURS OF THE CLOUDS.

[4426.]—WILL some of our meteorological friends kindly favour me with their opinion as to what condition of the atmosphere or of its vapours do the various colours of the clouds arise from? I have not met with any meteorological work that furnishes such information. Why are the clouds at various times of the following colours—dark gray, ruddy brown, bluish brown, brown gray, intense white, yellow white, blue gray, and other colours? The subject is important meteorologically, and one to which I have devoted careful attention during many years, and, by the experience thus acquired, I can readily, and I say without hesitation, successfully, describe for months beforehand the colours which the clouds will display at certain times. I know that the idea or possibility of doing this will be met by profound scepticism by thousands; it is not, however, my object to excite controversy, which would prove nothing, but to put the matter to the test at once by submitting it to direct observation. Before attempting this I should like to learn something of what other persons know of the subject, as it would evidently be useless for me to attempt to explain or describe a law of nature which, after all, might be quite as well known to others.

T. W.

DR. CARPENTER AND PERSPECTIVE.

[4427.]—(LET. 4320, p. 328.)—I wish merely to add that the pane of glass will not exhibit the horizontal and vertical lines which are required in a perspective drawing. I have tried it, and fact seems to agree with theory. It may be necessary for artistic purposes to ignore this convergency, but why, then, should all books upon perspective teach that the drawing should be similar to what would be seen by tracing on a sheet of glass?

M. PARIS.

PERSPECTIVE.

[4428.]—WE cannot, I think, lay down the laws of pictorial perspective by mathematical demonstration, and Mr. Proctor's remark that the perspective of a picture (by which I understand the linear perspective) ought to be mathematically exact must be received with so much modification that I am rather inclined to agree with M. Paris that pictures are, as to perspective, a compromise. By pictorial perspective I mean that representation on a flat surface which truthfully represents to the mind the object sought to be delineated. Form and colour, including shade, are the means by which the picture is produced. The question is, must one or both of these be identical with the form and colour of the object? It is agreed that the colour need not be the same. Mr. Proctor admits that as to colour, shade, and so on, there must always be some degree of compromise. This being the case, there would seem no necessity, *à priori*, for the forms of the object and picture to be identical. The object of the painter is to give a representation of a coloured object existing in space of three dimensions by means of pigments and a flat surface. If he does not seek to copy the colour with pigments of the identical hue, in order to obtain the effect he desires, much less is he bound to make an exact copy on his flat surface of the projection of the solid object. The different points or lines which the eye is accustomed to view stereoscopically are seen under different conditions, and produce different impressions, to that of their projection on the picture; and it may be, therefore, that these latter have to be modified in the same way that the colour was designedly varied by the painter. It is for this reason, I believe, that positions of what I may call "violent perspective" have to be avoided by an artist, or, if necessary to the picture, the sudden convergences of lines have to be tempered or modified in order to obviate an unreal effect. Distant mountains, also, which (if drawn in perspective) would look diminutive and insignificant, have in a picture to be drawn two or three times that height in order to give a natural idea of their elevation. For the mountains, though their height subtends at the retina a smaller angle than does their more elevated outline in the picture, are, through the stereoscopic functions of the organ of sight, which suggest to the mind their distance and consequent magnitude, magnified in comparison to the picture of these objects on a flat surface, which, not being viewed stereoscopically, is not subject to this effect. However this may be, there exists an apparent disproportion between distant and near objects (as may be seen in photographs and in the coloured pictures on the focussing screen of a camera), which renders it necessary in some cases to modify the perspective, or, in the words of M. Paris, calls for a compromise in the picture.

There is no doubt that the nearer objects are the darker they are, and hence arises the blackness observable in the foreground of photographs; but if a painter were to make his foreground always dark, the effect would be unreal, for the broad lights and the detail of near objects give them apparently a greater brilliancy than the greater amount of light, which actually comes from the direction of distant objects produces. Here, also, [illegible] a compromise between fact and ficti[illegible]

A GIANT PLANET.

[4429.]—In the article (p. 244) bearing the above title, which you have republished from the *Cornhill Magazine*, there appears so much loose reasoning that I think it will not be amiss to call the attention of your readers to it. Near the end of the article, the writer says: "As Jupiter and Saturn hold an intermediate position between the sun and the minor planets in respect of size, so those giant orbs hold a corresponding position in respect of inherent heat. Roughly speaking, the earth is 8,000 miles, the sun 840,000 miles, in diameter, and Jupiter, with his diameter of 82,000 miles, comes midway between these orbs." Coming, as it does, from an astronomer, this is a remarkable statement, for most people suppose astronomers to be very exact in the use of numbers, and nothing could well be more reckless than the assertion that 82,000 miles is midway between 8,000 and 840,000 miles. If we multiply Jupiter's diameter by 5, it will then be very nearly midway between that of the sun's and the earth's. But it is not the diameter, it is the "size" that the writer asserts to be "midway," and when we remember the sun's bulk is more than a thousand times greater than Jupiter's, we shall easily see how little he is entitled to hold the place the writer assigns to him. In continuation, he says, "Now the sun is at a white heat, and the earth gives out only what is called obscure heat; and if Jupiter's globe is at a red heat, he again comes midway between the sun and the earth." White heat is a very elastic term, embracing every degree of temperature, from that of a candle flame upwards; admitting, however, that radiant heat decreases in the proportion of the square of the increased distance from the radiating body, then the white heat of the sun must be some thousands of times hotter than red heat. Let us admit, for the sake of argument, Jupiter to be red hot, then the difference between his heat and the sun's will be still greater than the enormous disparity in their bulk. When the writer of the article thinks fit, with insufficient regard to facts, to place Jupiter midway between the sun and earth, in respect of bulk and temperature, it looks very much like struggling to find the materials with which to build a theory at any price.

If Jupiter has masses of clouds so great as to require his surface to be at a red heat to produce them, how could the light and heat of a red-hot body penetrate through these dense and voluminous clouds. According to Dr. Tyndall, a small amount of aqueous vapour will very materially retard the passage of radiant heat, and in this country we get evidence, almost every day, that a moderate thickness of cloud will shut out the sun from our view, and intercept a large part of his light and heat. Now, if Jupiter is at a red heat, his clouds must be as dense and impervious as a Newfoundland fog bank; in fact, they must partake more of the nature of semi-condensed steam than of terrestrial clouds, for if clouds are generated by this red-hot surface rain must fall on it, and directly rain fell it would be sent hissing back in the form of steam. If we even suppose the whole of Jupiter's surface to be red hot, and the clouds to have no effect whatever in retarding the transmission of heat and light, thus giving to the writer's arguments a tenfold greater force than they naturally possess in this direction, then the planet would be totally incapable of materially adding, from his own inherent heat, to the light and heat of his satellites, or to the light of his own surface beyond that which he receives from the sun. The amount by which Jupiter, under these supposititious circumstances, could augment the temperature of his satellites admits of strict calculation. Putting his temperature as high as that of iron red hot in daylight, it will be 1200° F., and his furthest moon must receive less than 2° from such a source; so, as far as heat is concerned, Jupiter would cut a very sorry figure when playing the part of secondary sun to his moons. In the matter of radiant light, calculation shews him to be a still more inefficient performer; for if not illumined by the sun, and shining only as a red-hot planet, he would be invisible to any dwellers in his most distant satellite, if they did not possess any optical power greater than our unassisted vision.

According to Dr. Zöllner, whom the writer refers to, Jupiter shines three or four times as brightly as a globe of his size should, if reflecting the sun's light only. If such is really the case it certainly is not owing to the planet being red-hot. The light of the sun at Jupiter is about $^1/_{27}$th of what it is on the earth, and sunshine here is hundreds of times brighter than the light emitted from a body heated to redness. Now, if Jupiter absorbs two-thirds of the sun's light, and reflects only one-third, he will then shine as brilliantly as if he reflected the whole of a light equal to the $^1/_{81}$st part of sunshine; therefore, if his brilliancy is increased threefold by his globe being red hot, then light emitted from a substance at red-heat must be equal to the $^1/_{27}$th part of bright sunshine.

I have not in these calculations taken into account the effect of absorption due to the dense aqueous vapour surrounding Jupiter; but if we do, how hopelessly weak does the theory of his being a secondary sun appear! Hyrab Scen.

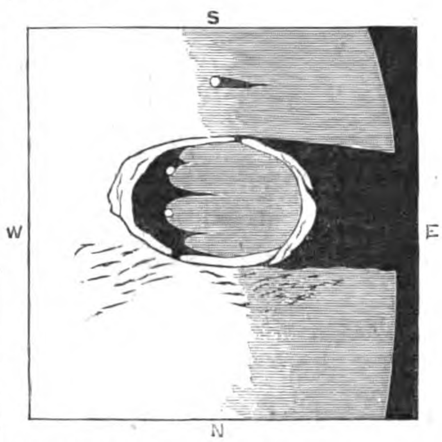
SELENOGRAPHY.

[4430.]—Letter 4381, p. 356, No. 378, by "E.B.F.," calls for a remark or two from me. "E. B. F." is quite right in considering that selenographical sketches, *neatly shaded*, are of general interest provided they are perfectly accurate, and convey to the mind an *exact representation* of the object sketched. They must also be accompanied with the following data:—The day elapsed with the hour and *minute* Greenwich mean time of the Julian period; the selenographic latitude and longitude of the points on the moon's surface which have the earth's and the sun's centres in the zenith and the position of the terminator at 60 north latitude, the equator, and 60 south latitude. These quantities are given monthly in the *Astronomical Register* for Greenwich midnight. The value of the supplement of the angle ☾ − ☉, or the difference of longitudes of the moon and sun at midnight are also necessary as giving the angle of reflection of the sun's light from the moon. In nine cases out of ten shaded sketches are far from being accurate in those details which are really of importance, especially when the objects are near the terminator, as then the shadows change rapidly. We have had from some of our correspondents very valuable shaded delineations of parts of the moon's surface, and such, as they appear now and again in our columns, give a pleasing and useful idea of the objects represented. If "E. B. F." be the possessor of a small telescope he does not require carefully and elaborately drawn selenographs to acquaint him with the appearance of lunar objects as seen in the larger instruments. The fine crater "Copernicus" is a magnificent object in a three-inch telescope. Of course it appears a still finer object when viewed through a larger aperture; but the real value of increased aperture in the object-glass or increased magnification by means of eyepieces consists in the increased perception of minute detail. Without exception, the English Mechanic is, so far as I am aware, the only serial which notices to any extent selenographical matters, and it contains the two kinds of selenographs, the shaded sketch, giving "appearance," and the diagrammatic sketch, giving relative, and in some cases absolute, "positions." If "E. B. F." uses a small telescope frequently, he will often find diagrammatic sketches useful in identifying objects more readily than shaded sketches, as he is confined in using such to the epochs at which they were drawn.

In reference to query 12229, "Canis Minor" will find for general lunar scenery 3in. or 4in. aperture ample. For clefts, minute spots, and streaks not less than 6in. should be used. W. R. Birt.

PLATO.

[4431.]—I beg to inclose a sketch of the lunar crater, Plato, taken June 14, 1872, 10h. p.m., Greenwich mean time, with an excellent two-inch achromatic, power 90.



Can Mr. Birt inform me whether there is a heap of débris near the centre of the floor of the crater, because I failed to perceive any trace of any whatever? T. H. F.

ANCIENT MUSICAL INSTRUMENTS AT SOUTH KENSINGTON MUSEUM.

[4432.]—In his interesting paper on the above subject, printed in No. 377 of "our" journal, Mr. Charles Reade, who, however clever a special correspondent he may be, is, I fear, not quite "read up" on the subject of ancient musical instruments (by the way, he says he is specially "well up" in fiddles), mentions what he terms a keyed dulcimer (query, what can it be) which he classes with the virginal, clavichord, spinet, harpischord, and pianoforte, under the general title of children and grandchildren of that rather "ancyente instrumente of mvsick," the dulcimer.

In his (query, illegitimate) family he confounds two essentially different classes of musical instruments—viz., those struck by hammers, and those whose strings are pulled. He could hardly have done this had he previously "read up" more diligently. The harp, lute, mandolin, guitar, the modern zither, virginal, spinet, and harpsichord are all treated just as Mr. Reade would be were he to "came up" for his "exam." before instructed judges. They belong to the latter class—in other words, their strings are "plucked," and no amount of "pluck" Mr. Reade possesses could save him from the same fate with that conspicuous absence of knowledge he exhibits. On the contrary, the drum, gong, harmonicon, and bells, the dulcimer, and its legitimate child the pianoforte, belong to the former class—*i.e.*, they are more or less forcibly "struck," as in truth the writer was also by Mr. Reade confounding them with the harp class, which are not "instruments of percussion." What Mr. Reade means by a "keyed dulcimer," unless it be the pianoforte, I have yet to learn.

Mr. Reade laments that the complex Welsh harp, with its very practically inconvenient three rows of strings, has survived all the executants. I see but little in this to regret, because I am not aware of anything worth doing which can be done on this I think deservedly obsolete instrument which can't be done at least as well—if not better, certainly with far more ease—on Sebastian Erard's double action instrument, the somewhat complex mechanism of which greatly facilitates performance.

Mr. Reade also mentions certain harpsichords, especially the Rucker, said to have belonged to Handel, the statements concerning which much be taken *cum grano salis*, for its history is rather "fishy," also one bearing the honoured names of "Abraham et Josephus Kirkman, fecit," and the very unusually modern date 1798. The tones of the latter he says are "full of sweetness and tenderness," which may be quite true on the same principle that it was logically proved that a very unkindly man must be full of sweet and tender feelings because he never suffered any outward manifestation thereof to escape him. My fellow readers must long since have perceived the writer has an old fashioned "tenderness" for his favourite harpsichords, but he avers that his—perhaps not very musical—ears have never yet been regaled by "sweet" sounds obtained from any harpsichord furnished either with hard leather or quill plectra, whatever the timbre of those which he obtained by the employment of plectra coated with soft leather on their upper surfaces. The tones of a quilled harpsichord may, to Mr. Reade, be "full of sweetness and tenderness." *De gustibus*, &c. Probably—as it is my intention to visit the collection as soon as I am able to procure the forthcoming enlarged edition of the catalogue—when I hear this instrument both "sweetness and light" may be vouchsafed unto me, for which I hope to be duly thankful, but until I do hear it I may be permitted to christen its sounds—and most of those of its brethren—after my old dog "Snap."

The Harmonious Blacksmith.

THE USE OF COMPRESSED AIR FOR STORING AND TRANSMITTING FORCE.

[4433.]—Being desirous of collecting information on the above subject I should be greatly obliged by new information thereon, also instructions where to obtain what has been printed concerning the perhaps unavoidable waste of force which results from the conversion into heat of a portion of that employed to compress air, especially when its compression is carried as far as from 50 to 100 atmospheres.

I should also be glad to learn if there has been any economical application of compressed air for propelling small boats or private land carriages in which steam boilers and coal are decided nuisances. For this purpose a fellow correspondent once suggested coiled springs—query, a legion thereof—which you may (if you can) wind up "just as you do your watch," and run up Highgate-hill at the rate of ten miles per hour. Now, as steel springs whose reaction would be sufficient for such "up-hill" work as this would be rather costly to make, "let alone" the winding them up "like your watch"—a thing, perhaps, possible by a Brobdignagian horologist for a Liliputian bicyclist—it might be rather more economical to employ compressed air, even if it did cost something more than the fuel of a steam boiler in a boat or railway locomotive. I suspect compressed air would cost considerably less than horse keep, for the fuel—I mean food—those animals consume is rather more costly than coal; indeed, horses are animals of such extravagant habits that I have known instances of their continuing to eat their provender even when they did no work. Perhaps, however, considering the sad (query, jolly) examples we humans set them in the matter of eating and drinking, too (without working), it will be wiser for us not to complain within their hearing, for possibly they might retort "small blame to us equines for that same," or even say to their drivers "You're another." Now, *tu quoque* (especially when true) is not exactly gratifying to our feelings.

The Harmonious Blacksmith.

P.S.—The above—or rather another letter on the same subject—was written about a fortnight ago, and I believe sent about June 9. I presume it and the article on the choice and best methods of working steel for cutting tools and screw-drivers are lost.

THE BEARING REIN.

[4434.]—Perhaps if you print these remarks it will be thought (by some of our readers) that the subject is out of place in a publication professedly devoted to the advancement of science. I know, however, that you for one are on my side. Your words on one occasion were: "We shudder as we write the word" (vivisection). I do the same, and dismiss the last-named practice to call attention to something less horrible—viz., to a most unnecessary cruelty daily and hourly practised on thousands of noble and, notwithstanding their sufferings, affectionate animals. This special act appears to be without the pale of the law; and when I remonstrate with a man (?), I am generally told to mind my own business. If I venture to address my rude ungracious self to a lady, she thinks it may be wrong, but likes to see it.

How many would shudder at such an announcement as this placarded on walls of our towns—"Gratis! Under distinguished patronage. An invention for the punishment of animals has now been perfected, and may be seen in operation daily. Sundays 11 to 1," &c.

Those who shuddered may, perhaps, smile when I state my belief that what is known as the bearing rein used on horses is one of the most diabolical engines ever invented by demons in human form. If careful attention is given to the fact I contend that it is indisputably what I have stated; and who is to blame? I cannot think that those delicate ladies who lounge in the open barouche caressing their pet dogs, have the least idea of what the magnificent animals in front of them are at that moment enduring. Look at the position of the ears, the abortive effort to throw out the chin, the lather on the mouth and breast, the patch of sweat on the satin neck, the quivering under lip, and other expressions of suffering known only to the initiated. What powerful wielder of the pen will undertake to write down the insane use of this horrible instrument of torture? I can supply some materials if "The Harmonious Blacksmith" or any other talented friend to dumb animals (by-the-by some animals make a sad use of the faculty of speech) will put them into shape. OLD PLOUGHMAN.

OUR COAL STORES AND THE ATMOSPHERE.

[4435.]—I SHOULD like to make a few observations on letter 4349 with the above title. Take the atmospheric pressure as 15lb. on the inch we have a pressure of 144 × 15 = 2,160lb., nearly a ton on the square foot, or about 27,000,000 tons on the square mile; since a square mile contains 5,280² square feet, assuming England and Scotland to contain, say, 80,000 square miles, we get 2,160,000,000,000 tons as the weight of the atmosphere. Now, if 2 per cent. of this were converted into carbonic acid, it would be unfit for respiration; 2 per cent. of the last amount is 43,200,000,000 tons.

I think there is a misprint or error in the letter. In the 15th line it is said that "England alone is raising to the surface one hundred and twelve million tons of coal annually, and further on that we have "one hundred and forty million tons of obtainable coal." If this were so our coal supply would not last much over a year.

Now, 3 tons of carbon produce 11 tons of carbonic acid, therefore it would require nearly 12,600,000,000 tons of coals, if we had them, to render our atmosphere poisonous with carbonic acid, even supposing it not to diffuse itself over the world; of course a much smaller quantity of carbonic acid in the atmosphere would make it very unhealthy; but I am of opinion that our atmosphere will last longer than our coal, besides, if 2 per cent. by volume is meant, the weight of the carbonic acid would be half as much again, its specific gravity being 1·5236, or so. PHILANTHROPIST.

BOOT AND SHOEMAKING.

[4436.]—NEVER did one man express the experience of another more pithily than does "Irish Mechanic" express mine in letter 4350, p. 335, on this subject. We differ only in this, he has not mastered the difficulty. I have, and shall rejoice if he benefits, as I have done, from the following experiment. I drew plans of my feet on a sheet of paper, purchased lasts, a good size too large, and a rasp from an ironware shop, and in half an hour succeeded in reducing the lasts to the size and form required, with nothing but the rasp. No technical knowledge of the last-making or shoemaking trades is required for such a very simple operation. I gave them to a bootmaker, whom I engaged to work my boots according to these lasts in every way. The result is entirely satisfactory.

M. N.
