Fig. 2 shows a portion of a very large wheel of many teeth (to wit, 2,000) geared with a pinion of 6 trundles, the teeth being shown large and the trundles small for distinctness. The black dots show the trundles of a pinion of 6in. diameter, and, therefore, what I call 3·14 pitch. The teeth are true cycloids, also 3·14 pitch. Now, having shown by the black dots what I call the right way of doing it, I proceed to set out a pinion on "Tubal-Kain's" plan. He says, make the pinion a polygon, each side being equal to the pitch of the large wheel. I have done so—viz., taken *a b* as a radius, and drawn the arc *b c d*, which gives us *d*, the centre of "Tubal-Kain's" enlarged pinion, and then from that centre *d* drawn the pitch line of the pinion *a c e f*, and set off *a c*, *c e*, *e f*, the pitch (as he calls it) of the trundles which are shown by circles. I need now only call attention to the position of *c* and *h* relatively to the sides of the teeth to make any one used to a drawing appreciate the amount of backlash the gearing would have as made thus.

I know I am not likely to convince a practically experienced man like "Tubal-Kain," so I have only written the above to prevent learners and young hands running a-muck.

J. K. P.

SUN'S DECLINATION.

[4003.]—If Henry Woods (q. 11578) will turn to the pages in the *Nautical Almanac* for 1872 headed "Phenomena"—pp. 510-512—he will find that the summer solstice occurs at June 20d. 15h. 32m., and this will be the time at which the sun has attained his greatest declination north. At p. 241 he will see that the apparent obliquity of the ecliptic for this time is 23° 27′ 23·6″, which would be the sun's declination, assuming that at this time he had no latitude. On reference to p. iii. of June he will find that his latitude at this time is − 0·4″, which, applied to the obliquity, will give 23° 27′ 23·2″ for the sun's declination at the summer solstice. It may also be obtained approximately from pp. i. and ii. by interpolation, thus from p. ii. the daily differences of declination commencing from June 19 are + 28·2″, + 3·4″, and − 21·2″, giving a mean second difference of 24·7″, which divided into 3·4″ gives 3h. 18m. This quantity must be added to June 20d. 12h. (because + 3·4″ is the sun's daily motion at this time), and will give June 20d. 15h. 18m., differing only a few minutes from the time previously stated. If the declination be computed for this time, and corrected for second difference, it will produce 23° 27′ 23·1″. Or it can be computed from the declinations at apparent noon thus:—The difference of the hourly motions (not *second* differences, as stated by Henry Woods) is 1·03″, which, divided into 0·66″, gives 0·641 of a day, or 15h. 23m. from apparent noon of June 20, which is June 20d. 15h. 25m., mean time. If the sun's mean hourly variation (0·33″) for a time midway between noon and the apparent time required be multiplied by 15·42h. it will give 5·2″ to be added to the declination at apparent noon, and will produce 23° 27′ 23·2″, and with which I trust Henry Woods will be satisfied.

With regard to indicating the change in signs, the cases stated are not analogous—the equation of time being a primary quantity, and the variation merely the hourly motion of the declination. If Henry Woods turns to p. 122 he will see no line placed to indicate that the equation of time has attained its maximum, and is then getting less. The line is placed to read with the precept at the head of the column, and changes of motion must be recognised by the augmentation or diminution of the quantities themselves. I may here remark that our nautical friends up to the present time have been averse to the introduction of algebraical signs, which only tend to confuse them, and pp. i. and ii. are essentially sailors' pages.

If Henry Woods knows anything of computation, he must be aware that it would be utterly impossible, with the present staff of the *Nautical Almanac*, to give lists of occultations for any other place than Greenwich. A list as long as that there given would be required for *every place on the face of the globe*. It is, therefore, left to those interested with these phenomena to work out for themselves a list specially adapted to any given place, and the elements of occultations are given with this view.

With respect to the query about the transit of the moon's upper limb, I presume he means the moon's upper transit. The time of transit (upper or lower) at any place can be readily obtained by the usual method of interpolation. ALTAIR.

SIMPLE WEATHER-GLASS, BURSTING OF AIR CHAMBERS, ELECTRICAL, & SPIRITUALISTIC.

[4004.]—INSTANTLY I saw the not very picturesque engraving accompanying letter 3901, page 69, it recalled to memory the severe strictures passed upon Squire Baxter's papers in one of our earlier volumes, although, like a real genius, he gave us not only the "crude notion" which had appeared before the public long before, but he improved upon it, and when he last addressed us upon the subject left details of a weather-glass which would not cost more than eighteenpence if the work was done out, and one, too, from my experience of the past five years (for of course I made one) far more reliable as a mere weather indicator than a 30s. mercurial barometer. I have not time just now to refer W. Bright to Mr. Baxter's last, as it appeared in "ours," but I trust he will refer himself to back numbers, and then try his hand at something equally "simple," and, I must say, far more beautiful.

(3904.)—PSYCHIC FORCE PEOPLE, &c.—"M. S. A." should read "Spiritualism Answered by Science," by Ed. W. Cox, S L., F.R.G.S., and then develop himself for a medium for a few months; he will then probably write less lightly upon so serious a subject. We do not purify gold by submerging it in iced water, since the means are inadequate to the end, so if darkness is insuperable for spiritual manifestations, why should we judge those who can and have produced the phenomena satisfactorily by a standard in direct opposition to that required for the test? Probably one of the severest tests of a true diamond would be a darkened room, although it may require light to determine its full value. I might also instance the circumstance that probably not the most sensitive subject of Reichenbach could discern the phosphorescent Od emanating from his person while he was exposed in the full glory of sunlight. True, more than eighteen hundred years ago One said that "men loved darkness rather than light," and assigned a not very complimentary reason therefor, but then that was only directed against a certain class of men, and could not be intended for the mediums or psychics of our time, as they did not exist in those days. "M. S. A." is evidently too nearly a kin to Thomas Didymus ever to become a medium, and I therefore venture to advise him not to attempt to develop further than learning to sing "Home, Home, Sweet Home."

(11294.)—DIVIDING METAL DISC.—"G. F. H." has reproduced a very neat solution (geometrically) to this query which appeared in the *Mechanic's Magazine* about the year 1848, but then as now, without demonstration. Will "G. F. H." kindly supply this desideratum? I for one think it well worth the trouble and space it would occupy.

(11442.)—OLD WIVES' SCIENCE.—If "A., Liverpool," will make up his fire with the same care, and pay the same attention to it as he would on a day when the sun is under a cloud, he will get just as much heat from the fuel consumed, and cook a joint just as rapidly when the sun's rays fall full upon the fire; he will not have the perception by means of his eyes that the fire is as bright, but the heat will be there, and the coals will burn just as long in the one case as the other. Supply oxygen, and the fire will "never say die" even under the direct gaze of Phœbus while any carbon is left.

(11444.)—BURSTING OF COMPRESSED AIR CHAMBERS—I apprehend that no comparison can be formed between the bursting of a compressed air chamber and that of a steam boiler. True, they are both elastic gases, and if nothing else was present there is every probability that *cæteris paribus* the results would be equal, but in the steam boiler there is another element—viz., water, and that overheated beyond the point necessary for the formation of steam, and only prevented from doing so by the pressure of the steam already generated, and the strength of the containing vessel. Now if a given volume of the steam is removed by any outlet, its place is instantly supplied by fresh evaporation, and with a scarcely perceptible diminution of temperature in the whole mass, but if the retaining vessel gives way at a weak point then there is not only the sudden rush of imprisoned gases, but the instantaneous conversion of a great portion of the overheated water into steam, and that not merely endeavours to escape through the weak spot, but brings with it the particles of water not yet converted into the gaseous state; then (if the other portions of the boiler are not sufficiently strong to resist it) comes the crash a larger orifice is formed, and the whole, or nearly the whole of the water, flashes into steam, at a lower pressure, granted, than that it sustained in its confined state, but sufficiently great to account for any boiler explosion yet recorded.

Some people can "read sermons in stones," and as the subject is one of a rather momentous nature, allow me to lay before your readers one of the many calculæ whereby I have thought myself worthy occasionally to give an opinion upon the matter of "boiler explosions." Nearly twenty years ago a labouring man, who was employed under me, was in the habit of warming his coffee for breakfast in a tin can by placing the can on a piece of red hot iron previously prepared for the purpose. On one occasion, to which I now advert, he had forgotten to remove the cork from the mouth of the tin. All of a sudden we had a miniature boiler explosion; the cork was violently ejected, like a bad paying tenant, there was a tolerable volume of steam, and on the ceiling, which was at least 15ft. high, there was a nearly circular patch about 5in. diameter, the sole relic of nearly a quart of coffee infusion, for nowhere around or about was the slightest trace of a single drop having fallen or been dispersed, and yet the can was perfectly dry and empty, but no longer on the hot iron plate: it was capsized, but not burst.

Leaving the study of this curious instance of the effects of vaporisation to our friend "Lyons," and believing that he must have witnessed somewhat analogous effects produced on opening indiscreetly a bottle of lemonade or soda-water, I will proceed to

(11445.)—ELECTRICAL.—Don't do it, "J. H." If you have not enough of No. 22 to complete your coil, sell what you have and buy No. 32 to use with "the further length you possess," how much further you do not state. But even then you will not have a medical coil. These things are not made for the purpose of "affecting three persons at the same time," any more than is electricity suited to become a universal nostrum under all conditions or idiosyncrasies of a patient. "J. H." may not know why, but he may, in the exuberance of his philanthropy in displaying his electrical attainments, be actually killing one of his patients while he is curing the other two; and the proposition equally admits of the obverse hypothesis: he may kill two in trying to cure one. Electricity, so far as we know it, is not a panacea for all ills, but, judiciously applied, is one of the great boons Heaven has granted to its creatures; but it must be used with intelligence and the skill that a master mind, properly directed by experience, can alone use to render it available. To any one who can show that he possesses these primordial requisites I am always "at home," and only too happy to give any information, in my poor way, in the constructive department, and now and then the theoretical, but in the wholesale destructive department of kill or cure three patients at a time I respectfully beg to withdraw until "J. H." can assure me that he really understands the full nature and extent of what he asks for.

(11446.)—SMALL COIL.—This query is so directly the antithesis of the preceding, that it merits a line if only for its foppishness. "An Anxious Mechanic" wishes for an induction coil that he can deposit in the same receptacle as he usually places his toothpick! Now, some over-ardent electricians might come out with Pio Nono's "Non possumus" in replying to this query, but I cannot do so, since I have seen a working model of a steam-engine, with boiler complete, exhibited in the window of one Bramah, an optician, &c., of Bristol, the whole of which was contained in half a walnut shell, and I have read of an ingenious blacksmith making a chain of thirty links which was fastened with a lock consisting of eleven parts round the leg of a flea which drew the whole with marvellous rapidity, the chain, key, lock, and flea, weighing eleven grains. I have further heard of things even more wonderful, but as I have never done any such feats nor even attempted them, "An Anxious Mechanic" will readily pardon me for my want of ability to help him out of his present difficulty when I assure him that if he asks for any information that is worthy of occupying your space and my time, he will find no one more ready to assist him to the full extent of my power.

(11465.)—PROBLEM.—"Puzzled" may well be in a quandary if he attempts to read this query as it is written. The first hypothesis assumes that the trains, unequal in length, "move with uniform velocities," and, in the second case, that they move with the same (that is, uniform) velocities, and yet one is a faster train and outstrips the other in six seconds! Surely there is a want of uniformity and coherence of thought in the propounder of such a problem, and small reason to wonder that "Puzzled" is puzzled.

(11472.)—PLASTER OF PARIS.—"C. B. B." must have been imposed upon by the person who sold him, under the guise of plaster of Paris, some old ill-used, or it may be originally worthless, material. It is not suited for continuous exposure in the Daniell's cell; but if originally good of its kind, it answers admirably as a substitute for the ordinary porous cell, being very cheap, always to be obtained, and, though not lasting long, will give good results, and it is also so easy to make the cells at home. Some of the finest medallions I have yet been able to make I achieved with a little battery of six cells, with plaster of Paris porous cells; but they require great care in handling when thoroughly saturated, and hence when I could obtain biscuit ware I discontinued the use of plaster. I have even used porous cells of this material for Grove's when I wanted "effect" for a limited period, but I had to pay for brilliancy in zinc coin.

WM. TONKES.

INFLUENCE OF COLD ON VEGETABLE GRAINS.

[4005.]—I was pleased to see our friend "Sigma" put his foot down on "L. C. E.'s" rather "unwise" letter; but I hope he will not misunderstand me if I inquire what is the use of the experiments of M. Duclaux detailed by "A. B. M." in letter 3928, p. 94? The conclusions arrived at by M. Duclaux are not very clearly stated by "A. B. M.," for in the first place it is said that "the cold of winter has a real influence on the germination;" secondly, that "grains kept all winter in a heated chamber germinate *none the less* in their season;" and thirdly, that "the discovered (?) influence of the winter's cold on some [grains] is a presumption that the others do not entirely escape it." I cannot hope to point out what is really meant, and must, therefore, appeal to "A. B. M." There are, however, one or two things in this letter which attract my attention, and appear to show that the experiments of M. Duclaux have not been conducted in a very scientific manner. For instance, if his object is to show that an exposure to a very cold temperature is absolutely necessary to the germination of seeds, why select those of marvel of Peru and convolvulus? the first a native of the West Indies and the second, I believe, of the warmer parts of America. I submit that, growing in their native habitats, *Mirabilis jalapa* and *Ipomœa purpurea* are never subjected to the intense cold of a glacier, nor their seeds either; therefore, all that can be truly said of the experiments of M. Duclaux is that cold has no effect on these seeds. The reason that none of the grains unexposed to the influence of cold germinated requires explanation, and I have a suspicion that that explanation must be found in the method of carrying out the experiment. I perceive that of six grains of *M. jalapa* which had endured two months' cold, five germinated; of six exposed one month, only three; while of six not exposed at all *none* germinated. A somewhat contradictory result attended the experiment with the seeds of *I. purpurea*. Of twelve seeds exposed two months, *none* germinated; of a similar number exposed one month, two germinated; while of those not exposed, *none* germinated. But these seeds were all sown in pots and placed side by side in a *heated* chamber on Nov. 10, and germination did not commence till Jan 25, 76 days afterwards! This fact, I think, nullifies the whole experiment, and points to improper sowing or treatment of the seeds. We all know that many seeds germinate almost as soon as they fall from the pod; others will remain exposed to the winter and germinate in the spring, though thousands of the same species are destroyed. But seeds of the same plants may be taken when ripe, kept on a shelf in the hot-house, or stored away in the drawer of a seedsman's shop where they are exposed to air heated by gas, and yet, properly sown (no matter when, so that the requisite heat is applied), never fail to germinate. If further experiments are made I would suggest that seeds of the Antirrhinum and the poppy should be tried.

SAUL RYMEA.

EXTRACTS FROM CORRESPONDENCE.

Australian Meat.—I have seen various communications, some approving, and some disapproving, of the preserved meat. I have used it for a length of time, and I must say I consider it a great boon. It is not much more than half the expense of butchers' meat, and as to the nonsense some talk about the nourishment being abstracted, it is quite absurd. It is cooked in almost a close vessel, and not boiled in a quantity of water, which does abstract a deal of goodness from meat; and then, look at the mottled appearance of the beef. Where, in England, except at Christmas time, do you get meat like it? It is pure grass fed, natural meat, which cannot be said of butchers' meat with all the artificial food with which animals here are obliged to be fed. True, they become very fat, but I have great doubts whether it is altogether healthy fat or lean either. When we look at the diseases prevalent, I often think this wants consideration.—E. T. S.

The Oxyhydric Light.—The oxyhydric light has not proved a success in Paris, and it has been discontinued in the public lamps on the Boulevard des Italiens. It is not generally known that a carburating apparatus is always employed in conjunction with oxygen, which adds to the complication of the apparatus as well as the cost of the light. There are but few, remarks *Le Gaz*, who will consent to have installed in their houses two meters, two regulators, a carburator, and two distinct systems of pipes. For this reason alone, the system was certain to fail, even if the alleged economy were proved, which has never been the case.

Adulteration of Aniline Colours.—The intense tinctorial power of the aniline dye seems to offer irresistible temptation to dishonest dealers to imitate or adulterate them with worthless ingredients. A sample of fuchsine (an aniline red) lately placed in our hands by Dr. Genth was composed entirely of sugar crystals saturated with the colouring matter. To any one familiar with the peculiar arborescent appearance of the pure fuchsine particles, the sugar crystals, with their rhombic prisms, would betray the imposition at a glance; but without this knowledge the detection would be attended with some difficulty, since the colour of both genuine and counterfeit samples is equally intense. One of the simplest methods to detect this and similar impositions is simply to digest a sample of the suspected substance in ether or absolute alcohol, when the colouring matter will be dissolved with ease, and the sugar, crystals, or wood fibre (which is also used for dishonest purposes) will remain undissolved.—*Journal of Franklin Institute.*

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[10414.]—**Retrievers (U. Q.).**—As sportsmen do not seem to patronise (?) the ENGLISH MECHANIC AND WORLD OF SCIENCE, I should advise your correspondent to train thus:—First, they must learn to obey implicitly: that done, with such dogs everything is easy. I should teach a dog first to carry and then to fetch a stick, half a dozen lessons will teach that much; the lesson once learnt every act of disobedience must be punished; take him by the ear, scold him, then give three or four cuts with a light switch, no more; no act of disobedience must be overlooked, and the dog will soon cease to disobey. Most gamekeepers for the first season chain the dog to their belt, for a young dog when he sees a hare always bolts after it; but if during the next four months "A Subscriber" can take his dogs where game is, he will soon teach them not to move when they see game; they will at first, but punish each time. Retrievers ought to be fed on oatmeal and bran made into cakes, and then made into a sort of rough mash with milk; but I feed mine on the scraps of the house; she is perfectly healthy, only rather too fat. These dogs are as intelligent as most children, and think more of a scolding than a flogging apparently.—HEDERA.

[10609.]—**Separating Iron from Brass (U.Q.).**—We generally melt it, not very hot, skim it off clean and ingot it, and when it is used skim it off again. I heard of a machine like a grindstone-box, with magnets fixed on radiating arms in place of the grindstone, the filings being removed by coming in contact with a brush.—ANGLO-AMERICA.

[10617.]—**Watchmaking (U. Q.).**—Isochronism is meant when the watch is truly balanced and beats precisely equal.—ANGLO-AMERICA.

[10830.]—**Fern Printing on White Wood (U. Q.)**—One method of doing this is to fasten, with gum or fine pins, fern fronds, or other suitable leaves, on the surface to be ornamented, which is then "spotted" over with Indian ink or sepia, rubbed thick from a tooth-brush or a small nail-brush. The spotting must be done evenly, and gradually shaded off to the outside. A good effect is produced by taking off some of the larger leaves before the completion of the operation, and slightly spotting over thin places, which makes them appear in the background.—Q. Q. R.

[10873.]—**Tooth Stopping.**—With respect to this I do not agree with H. G. Young. No sensible dentist would use more silver than tin; if so, the stopping is almost sure to discolour. I certainly erred in not mentioning chemically pure mercury.—DENTISTE.

[10882.]—**Damp Walls.**—Not knowing all the circumstances, and failing to elicit any detailed statement, it is somewhat difficult to give a direct reply. But taking for granted circumstances are otherwise equal in both gables, the inference is that aspect has something to do with it, for although a driving rain may not be sufficient to saturate a 9in. brick wall, it may be of considerable assistance to that which falls vertically, the wet being absorbed by two faces at the same time, for the same reason exposed angles are liable to damp. Another place especially liable to damp is under windows, where there is no projecting cill, as is generally the case in "R. J.'s" class of house. In a driving rain all that which falls on windows is sent on to bricks beneath, increasing the liability to saturation twentyfold.—T. H. SAUNDERS.

[10913.]—**Screw Cutting (U.Q.).**—If "Persevering Screw-Cutter" will adhere to the following plan he will not fail to accomplish what he requires. Having run back his saddle close to the poppet head, and fixed his tool about a quarter of an inch from end of work, he must turn the lathe round until the saddle is in gear with the leading screw, then take a piece of chalk and mark top of faceplate and top of leading screw; now set your lathe in motion, then having run the required distance, ungear the saddle, run her back, and then turn the lathe round as before until the marks appear on the top.—F. HUME.

[10917.]—**Power (U.Q.).**—It is difficult to say what would be the exact gain by simplifying the driving gear; but the friction of so many wheels, pinions, and bevel-wheels, to say nothing of straps and journals, would be considerable, and if they are large might amount to one horse-power.—Q. Q. R.

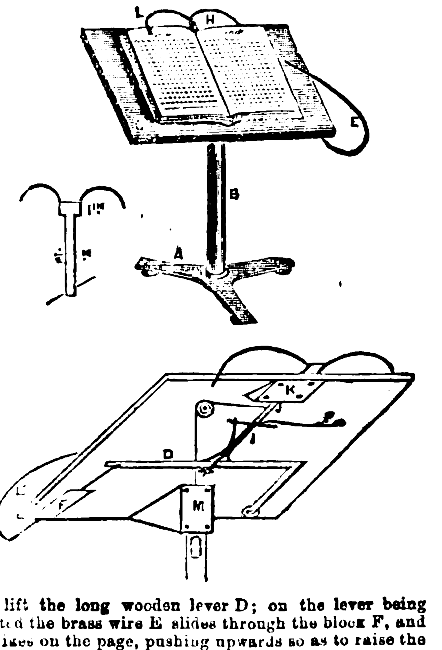
[10922.]—**Engine Query.**—I should read the indicator diagrams thus: Front end has ample lead on the steam side, steam cut off about ·5 of stroke, steam expanded to less than atmospheric pressure. The exhaust is too slow, or has too much lap on the exhaust ports, therefore bad. The vacuum (as it is termed) is very inferior at the commencement of the stroke, whereas, from the reduced pressure of the steam at the end of the stroke it should be very much better. It would appear to me, without the data relating to the slide valve or valves, that the motion is very sluggish, and the exhaust ports too small to give good results. Back end—lead too small, the steam cut off about ·20 of stroke, the same remarks as to the exhaust here also apply. It would appear that a misprint is in the formulæ, 1-20in. = 1 horse-power. It is intended, I presume, 1-20in. = 1lb. pressure. If that is the correct scale for the pressures, the gross steam pressure at the commencement of the front side of stroke would be 7¼lb. expanded to 1·5lb. below the atmosphere at the end of the stroke, and the commencement of the vacuum only 2½lb. below the atmosphere, ending at 5lb. at completion of stroke. The back end, 6¼lb. steam pressure at beginning of stroke, and is expanded to 1·75lb. below the atmosphere at end of stroke, the vacuum commencing at 3lb. pressure below the atmosphere, and ending at 4¾lb. at completion of stroke. Now, if the boiler pressure is 34lb., surely 7¼lb. on the piston at commencement seems a great contrast. The lead of the valve should be equal at both ends, and the exhaust ports opened out larger to give a freer passage to the condenser. You can do so by narrowing the bars between the steam and exhaust ports on valve face. The velocity of piston being 324ft. per minute, the lead of slide valve on the steam sides at ends of stroke should be ·103 of the width of the port.—TUBAL-KAIN.

[10941.]—**Spontaneous Combustion.**—This question seems to me to have met with an amount of discredit which is scarcely consistent with known phenomena. I have never had an opportunity of witnessing the fact myself, probably through the precautions I have always taken in order to avoid such an accident, for I thought it was generally admitted that such might happen. Nor are we unaware of its rationale. I should have thought that most of the objectors were acquainted with certain substances which go under the name of pyrophorus, which inflame upon mere exposure to the air. Notably among these is iron when reduced to a state of very minute division, and which, on being thrown into oxygen gas, immediately ignites, and, if my memory serves me rightly, manifests the same action on being scattered in the air. I do not suppose there are many regular courses of lectures on chemistry where this is not exhibited; at any rate, I witnessed it in those I attended—namely, of Professors Thénard and Gay Lussac in Paris, and of Professors Turner and Graham at University College, London. The minute division of the substance is the cause of the action as favouring its rapid oxygenation, and herein, essentially, combustion consists. Now, I suppose we all know that some oils have an aptitude for oxygenation; perhaps, for aught I know to the contrary, linseed oil more than others, since this is the one selected for the manufacture of boiled oil and dryers, as known in commerce. We know, further, that when we wish to burn oil in a lamp we do so through the intermedium of a wick, which effects the segregation of the separate particles of the oil, and thus conduces to their more rapid oxygenation (combustion). But if the oil is taken up by loose cotton it will diffuse itself into a much more minute state of division along each hair of the cotton, and I see no reason why it should not become, like other substances so situated, an effective pyrophorus, especially if aided by some other and extraneous source of heat.—F. R. C. S.

[10954.]—**Circulation of the Blood.**—My answer on this subject, at page 18, was intended for the requirements of "Corien," as expressed on p. 597, of Vol. XIV., where he wished to know how respiration aids circulation. There had been several replies, but none of them were calculated to afford the querist satisfaction, for most of them denied that any such aid exists, and some diverged altogether from the matter in hand. I, therefore, ventured to step in, strictly confining myself to answering the question, and in as few words as possible. I mentioned that there are many forces that contribute to the circulation of the blood, but the majority of these were left on one side as being irrelevant to the question before us. I was, indeed, so reticent as to speak of what we will, for convenience, call "the suction power of the chest" as being exercised at only the very last stage of the circulation—viz., when the two currents of blood had met from the junction of the ascending and descending *venæ cavæ*, and I adduced the instance of a wound in the chest to show that such a power really exists. I now find myself met by "M. R. C. S.," at page 74, who invites me "to reconsider the case," in order "to give up the old and still prevalent opinion," &c. I doubt not that "M. R. C. S." will feel that I have already well considered the case, when I inform him that I have been for many years a licensed teacher of anatomy and physiology, whose lectures are recognised by the examining boards, and that it is, therefore, my duty to keep myself acquainted with the most recent discoveries, and to test their accuracy. It often happens, in scientific research, that a theory that has subsisted for some time, finds an opponent who brings forward a plausible experiment, which secures to him a decent following of converts, till a flaw is found in the argument, when all are content to resume the original creed. Now this is just what has happened in the case mentioned by "M. R. C. S." There was a general belief in a suction-power in the chest during inspiration, which was thought to favour the return of the blood to the heart. But an objector was found who based his opposition on the following experiment. If we take the jugular vein of a horse, or a portion of the intestine of a fowl, and connect one end with an exhausting syringe, and then place the other end in water, we shall find that on drawing up the piston the air in the tube will be withdrawn, when the atmospheric pressure without will cause collapse of its sides, and no fluid will pass through it. It was, therefore, argued that the chest could exercise no suction action on the veins. But there was grave oversight in this proceeding, for the tube was inert, dead, and empty, while the veins are living and constantly full, so that the conditions not being identical, the experiment was worthless. There is no necessity for rings to keep the veins patent, because they are not only always full, but the current through them is always in the same direction: these conditions do not obtain in the windpipe, and hence the difference in structure. The whole vascular system is so full, in fact, that we cannot prick the skin with the finest needle without blood flowing from the puncture, and there would be no circulation at all were there no gap in the circuit, but such is furnished by the diastole of the heart, or the right side from the systemic to the pulmonary circle, and, on the left, from the pulmonary to the systemic. I trust this will be deemed a sufficient justification of what I have advanced; at any rate, I decline any further controversy, as this would, most probably, only lead us further and further away from the consideration of the function in question, and necessitate the bringing forward of esoteric matters which are scarcely calculated to edify the general reader. Should, however, any such desire a purely mechanical illustration, the following may be adopted:—Having procured a pair of bellows, remove the nozzle and screw into the larger end of this nozzle a tube of two or three inches in length, to the free end of which attach a flaccid bladder. Now introduce the bladder and tube through the nose of the bellows, and fit the nozzle in its place as before. The valve in the under leaf of the bellows being stopped, we have a representation of the lungs in the chest, the bladder standing in lieu of the aggregate of the air-cells, and the pipe as the windpipe. The bellows being worked the air will be admitted to and expelled from the bladder through the bellows pipe, but has no access to the walls of the bellows. If we now make a hole in the lower leaf of the bellows and fix a glass tube in it, and then place the lower extremity of the glass tube in water, we shall find that on continuing the action of the bellows the water will ascend into them. The analogy would be more perfect if the upper end of the glass tube communicated with a hollow indiarubber ball within the bellows.—F. R. C. S.

[10993.]—**Mildew in Old Engravings (U. Q.).**—The plan I find answer best is to put dried salt on the engraving, and with a thick slice of bread (not too stale) to scour it well, and then to place it between blotting paper, after having shaken off the salt and bread crumbs.—ESMEY.

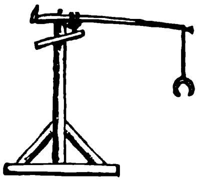
[10996.]—**How to Use a Book Without Hands.**—I believe there are contrivances for this purpose, but I don't know what they are. The following will answer the purpose. A stand, B stem, made of gas-pipe, C desk. The movement is as follows:—Connect a pedal



to lift the long wooden lever D; on the lever being lifted the brass wire E slides through the block F, and strikes on the page, pushing upwards so as to raise the leaf at H, and the point I pushes up the wooden spindle J, which slides through the block K, so that the brass wire arm L is pushed back off the other page, and is instantly turned round by the string, which passes over two small sheaves (one of which is in the block M), and is tied to a 6lb. sashweight moving in the stem B. The two stops now come into contact, one of which is adjustable by a thumb screw, so that the arm is just opposite the pushed up leaf. The pedal is now released, the spring P then brings the wire arm under the page, the stops are disconnected and the string pulls round the spindle, turning over the page. Each revolution of the spindle turns over two leaves. The weight may be wound up by the arms L, it may run through the stand to get a good fall. The wire E should be about fifteen degrees angle with the face of book, and the point must be very obtuse so as not to bite through into the next leaf; try this part of the dodge with a dry pen. The mechanism may be covered with a board.—ANGLO-AMERICA.

[11058.]—**Red Stain and Polish for Kitchen Chairs (U. Q.).**—I find the best thing is to paint with Indian red, and varnish if necessary. But John Moore will find they look very well not varnished.—H. B. E.

[11059.]—**Spinal Complaint.**—A boy of my acquaintance was cured of curvature of the spine in the following way, and he is now a "crack" oarsman:—Procure a round wooden (or iron) rod about eight or nine feet long, and support it vertically, as sketch—Drive a smooth iron pin in at the top, and over it put a tapering horizontal piece, so as to revolve freely. It will require a small washer and some grease under it. To the outer end attach a short strap and padded collar of leather to fix round the boy's neck comfortably; the strap behind.

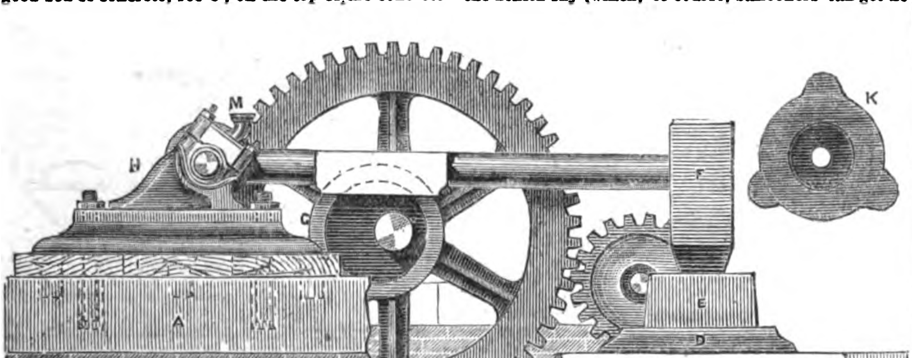


To the under side of the inner end, about six inches from the upright pole, screw any kind of a chair or sofa caster, so that its wheel may run on a round piece of wood like a little table fastened under it. This round piece has a hole in the centre of it, through which the upright rod passes, and it must be firmly fixed in a slightly sloping direction, as shown. The machine acts as follows:—When the collar is tied round the patient's neck (strap behind) he is made to walk round the pole, of course bringing the horizontal bar round with him. Whenever the caster is treading the lower side of the sloping disc the strap is only just kept straight by the flexibility of the bar to which it is attached (all wood is flexible enough) but on the opposite side it will be raised up so as almost to lift the boy off his feet—thereby giving a regular intermitting stretch and release to the spine. Care must be taken that the vertical pole does not move, but, above all, the boy must keep his arms and legs down straight whilst walking, and not be allowed to get tired.—W. J. HOWARD.

[11095.]—**Microscopic Deposits on Bricks (U. Q.).**—Eggs of stone mite (*Trombidium lapidum*).—G. W. R.

[11101.]—**Mortices in Hard Woods.**—I am pleased to find "Jack of All Trades'" kind reply to my query as above. May I beg for fuller explanation? It will not be wasted. I really cannot make anything out of the sketch and description. I wish to apply the application to a lathe, for which the writer, "Jack of All Trades," says it is applicable. I do not see how, or where, to fasten it to face plate, nor how the chisel is held; in short, I fail to recognise or understand either the application or mode of working the apparatus. Could a mortice be cut with it? To what does the letter F on Figs. 1 and 2 refer, and C on Fig. 1? I have benefited very much by one of "Jack of All Trades'" kind replies, and I hope he will overlook my ignorance in this matter, and favour me with a more explicit description.—LEANDER.

[11108.]—**Tilt Hammer (U. Q.).**—The diagram sent, I think, will explain itself, but as I have set them out after my own fashion, and am no engineer or mechanical draughtsman, any little imperfection must be excused. My idea would be first to make a good bed of concrete, see C; on the top of the concrete I should build brickwork in separate layers or cells, crossing and re-crossing in party divisions, each division to be well rammed down with sand, or filled in with concrete; on this I should bed my stone blocks (see A), the screw sockets I should run in with molten lead. Between the oblique pedestal or plummer blocks I have introduced 8in. timber; the whole, with the plummer blocks, is firmly screwed down to A (see H). The hammer F is worked by an eccentric motion with flanges on each side (other motion might be substituted) by a boss with 8 cams (see K). The anvil is marked E; the bed plate, D; L, is sand well bedded around block for anvil; M, lubricator to bearings.—JOSH. WM. FENNELL.



[11120.]—**A Question of Sight.**—"Touchstone" is right. Sound travels through air at velocity of 1180ft. per second, a speed but the one hundred and seventieth part of that of light. Sound travels through cast iron at 11,090ft. per sec., and through glass at 18,000ft. per sec. "E. L. G." says we know nothing about the comparative nearness of atoms; and says the velocity is the same irrespective of their distance. Such assertions are easy, and may save him trouble of opening his eyes; but let him suppose a single needle to extend from his eye to the source of light, would not, I ask, the impulse at one end be instantly carried to the other, and the transmission of force be thus instantaneous? But cut half the needle off and divide the other half into ten parts spread over equal distances in the former line, thus—

1 2 3 4 5 6 7 8 9 10

The impulse imparted to No. 1 has to travel over nine gaps, which, if occupying but a second each, will occupy nine seconds before they reach No. 10. So is the transmission of light and sound quicker or slower, or, rather, of longer or shorter period, according to the total amount of space or vacuum that exists between the total of the atoms in the whole line. What other reason can possibly be given? Though through the pores of glass the luminiferous ether vibrates with as much ease as the late Daniel O'Connell could drive a coach through any Act of Parliament, yet so close are its atoms or molecules that sound travels through it sixteen or seventeen times more quickly than it does through atmospheric air; through steel sound travels 17,000ft. per second, its atoms or molecules being slightly further apart. And this point of distance of atoms or particles apart being measurable by the degrees of transit speed of the sound or the sight they convey is what I wish to impress on "E. L. G." and all students of science, for I have not found it noticed by any one but myself; and it is ridiculous of "E. L. G." to reply to me that the velocity is just the same if the atoms be twice as near or twice as distant; discoverers despise no rational theory. Why are we in total darkness the moment flame is extinguished if light ceases not instantly that combustion stops? Of course I speak not of the light from stars, which to reach us occupies a thousand years; but if a flame exists just a minute the light from it exists just a minute likewise, neither more nor less. "E. L. G." says our shadow is longest on July 1st and shortest on January 1st. Can he prove this? The nearer we are to the light the more rays we intercept, and shadow is nothing more than the absence of intercepted rays; and whatever hinders us from seeing the flame or any part of it is the intervening object that intercepts the rays, and in whose shadow we are; and I take it a shadow in space has no precise boundary, but pales gradually till, to our feeble sight, it becomes imperceptible, but rays once cut off I take it cannot reappear; and if a shadow has no focus or diminution of size it darkens an extent of space in length immeasurable, if not illimitable. I may ask "E. L. G." how he proves the earth's shadow to extend to but four times the moon's distance. Its size will not diminish with the square of the distance whatever its intensity may.—J. BARWICK.

[11120.]—**A Question of Sight.**—"Fiddler" may be quite sure that what he calls "illuminated space" and "infinite" is only the denser bottom layer of air; that the main sky-light all comes from within four miles of the ground, or rather of the sea level. Humboldt and all climbers who have approached 4 miles, or even the 3½ that comprise the lower half of the aërial mass, have spoken of the indigo or black darkness of the zenith sky (which, of course, balloonera can get no sight of), and if "Fiddler" could be corked up in a big soda-water bottle of oxygen, and raised 30 miles, he would doubtless find it at all hours equally black and equally starry as on a moonless midnight. If sky-light came from aught beyond the shallow, watch-glass-like lens of air above us, why should the zenith at any time be any less bright than the horizontal layer? Would not a photograph of sky be all of even tint, and the day sky give, like the nocturnal, the idea of a hemisphere or cupola, rather than the wide, slightly-raised watch-glass ceiling that it does?—E. L. G.

[11122.]—**Strength of Boiler.**—"Data" not sufficient to answer this query. What is the thickness of plates—¼in. or ⅜in.? Surely the strength depends a little on the thickness and condition of the material of which the boiler is made.—E. M.

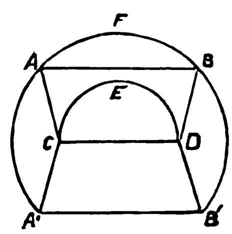
[11123.]—**Lantern Pinions.**—See "J. K. P.'s" letter.

[11129.]—**Greek "Upsilon."**—"A Harrow Fellow" (p. 75) is clearly wrong, when he states that the English *u* is the Greek upsilon; and "E. L. G." appears also to be in error, when he writes *y* for upsilon. The Romans not having the Greek *u*, which is u French, or *ü* German, adopted the letter *y* to represent its sound when they Latinised Greek works; but our *y* has quite a different sound, and it would be just as absurd to write "Müller" as Miller or Myller, as tupto typto, or drus drys; the *y* in these cases being no nearer the *u* than *i*. "E. L. G." seems to be confusing Latinised Greek words with transliteration. If we really wish to represent the Greek sound, we must do what the Romans did, use a new character, and we might, therefore, write *tüpto* without offence.—M. PARIS.

[11137.]—**Repairing Concertina.**—There is no difficulty in tuning the reeds of concertina notes; file the free end to sharpen, and near the rivet to flatten. Different metal may be made to give a note of the proper pitch, but the timbre of the tone will not be the same exactly as the notes of another metal. A different quality of the same metal can be rectified by filing.—E. M.

[11146.]—**Lamp for Forcing Pan.**—I never tried anything of this kind, but as no one has answered the query, I may say that the best lamp of all is a Bunsen burner; but that means gas also. If "Seedsman" has not the gas laid on, a paraffin lamp with a squat chimney will probably answer. Colza oil would be better, but rather expensive. I find no difficulty in germinating tender seeds by placing the pots near the kitchen fire, sometimes on the oven itself.—SAUL RYMEA.

[11166.]—**Area of Segment of Circular Ring.**—I cannot help acknowledging that the word "segment" was loosely or even incorrectly used by "Thankful," and that I did not notice the mistake. I do agree, however, with "E. L. G.," Vol. XV., p. 76, that any one reading the question could misunderstand the meaning, or that the sketch, Vol. XIV., p. 650, fails to indicate what was desired. Following "E. L. G.," p. 675, let us make the inner arc C D a semi-circle of 25 radius, and see what A B or A' B' comes out like; see Fig. Now, by "E. L. G." A C BD being supposed a segment AC, CD, and BD, must be in one straight line, as they are all parts of the chord, or in this case of the diameter, which they do not appear to be, to any serious extent. In fact, work it how you will, I do not see any other conclusion to arrive at than that "Thankful" meant, and fairly represented a portion of an annulus bounded by lines AC, BD, pointing to the centre, or that although he said "segment," anything but "sector" could be understood.—J. K. P.



[11168.]—**Area of Segment of Circular Ring.**—I gave my solution (p. 675) believing, from the figure given by "Thankful," that A E B was a tangent, and I afterwards saw in that case the conditions were incompatible; I employed the term apothegm for radius of the circle inscribed to a regular polygon. The apothegm of the hexagon cannot be expressed exactly.—BERNARDIN.

[11202.]—**Transfer of Prints to Wood.**—The only varnish I have used in transferring has been the white or brown hard spirit varnish of commerce. The pictures were printed on transfer paper, and what I did was for the purpose of furniture ornamentation before French polish was introduced, which I notice is now becoming very common in the trade, with the difference that it is now done with polish instead of varnish. Great care must be taken to have well seasoned wood. Give two coats of the varnish and let the second coat be nearly set before placing the picture in position; slightly damp the picture with methylated spirit, do not rub it down too hard, or you will rub some of the varnish into the fibre of the paper, which will make it difficult to remove the back. When it has all set hard, after which, and the picture having been well developed by careful rubbing off the back with damp cloth, give two or three coats of the varnish, each coat being allowed to well dry before the other is applied. As a last process we would sometimes rub the surface of varnish down with the palm of the hand, or, for a large surface, with a smooth cabinet-maker's cork with chamois leather over it, rough side out, and finish off with sweet oil and flour, which, when done, was equal to French polish. Why should not the most beautiful ornaments be transferred to wood in the same manner or by a similar process as the willow pattern is given to our common plates, and even others of a better quality and appearance by the picture being printed on prepared skins, and afterwards immediately transferred?—SQUARE.

[11206.]—**Defective Plating Solution.**—It is only for needles and similar goods I wish to silver. Watts says it can be done (see p. 118, fourth edition) by simply dipping a sponge in the solution, and rubbing it over the steel. As "J. A." has kindly offered help, I beg to say that it is only small steel goods I cannot silver or gild and copper. I make all the solutions by battery process. I have tried both Gore and Watts.—COBBLER.

[11276.]—**Extracting Glass Stopper.**—A very refractory case of the above complaint was once brought to me. The stopper of a handsome decanter was broken short off at the plug, and resisted all attempts at its extrication, though oil was used, the neck warmed and rapped to jar it, a handle having been cemented on the broken part. All being in vain, I drilled a hole $\frac{1}{8}$in. diameter through the bottom of the decanter in the centre on an ornamental engraved star. A straight steel wire was introduced through the hole, and a few taps on it with a hammer soon drove out the stopper. The hole was plugged up with a small piece of vulcanised indiarubber, and by cementing together the broken parts of the stopper the decanter was made perfectly usable, and has been in constant use for twelve years since the operation.—Q. Q. R.

[11313.]—**Setting Lathe.** — I beg to thank "J. K. P." for the notice he took, on p. 48, of my query, but I am afraid I did not render myself sufficiently explicit; if not, I will now endeavour to do so. The lathe which I work is somewhat similar, both in shape and size, to the one advertised in "our" journal by Blackett, and the mandril head is cast with a narrow piece in the centre, for a set screw, made just the length of the width of gap in the centre of lathe bed, so that if you turn the screw it will shift the head either way; there is one at either end of the head. Now, you will perceive the inconvenience I am put to; after turning anything conical, I am obliged to take a cut down the next article I have to turn for the purpose of knowing whether I have got the lathe parallel or not. Would "J. K. P." give a design of his little contrivance for turning taper screws as offered? for I quite agree with him with regard to the work being drunk, but I do not see how it would act on a large lathe for such work as engine connecting rods.—F. Hume.

[11314.]—**Polishing Oak Floors.**—The French, who indulge in polished floors, whether of oak or red tiles, more than we do, have an easy method of effecting their object. They use beeswax, and brushes attached to the soles of their feet, by a simple strap over the back of the brush, through which the foot is passed. This not only gives facility of motion, but the weight of the operator adds to the effect. In fact he skates about the room. Some use but one foot, women especially, but this is but a limping sort of affair. When a man servant is engaged in a good establishment he is always asked if he is a good *frotteur* (rubber). In more modest houses a man is hired, the same as we do for beating carpets. I shall never forget the surprise I experienced, as a youngster, shortly after my first arrival in France, on beholding a man in an empty room on the opposite side of the street, tearing about with the wildest gesticulations imaginable. I, of course, drew the attention of those in the house in which I was residing, to the strange sight, when I learned that my supposed madman was merely polishing the floor. Persons may dance for a whole night on a floor which has been so prepared, with much more comfort and less fatigue than on one that has been chalked, or is covered with a carpet, but beware, ye novices, for you have to buy your experience at the cost of some mortification, whether you be young lady or young gentlemen, as you will, on setting out, in all probability perform that sudden transition from the perpendicular to the horizontal which is not considered a meet or acceptable sacrifice to Aglaia, Thalia, and Euphrosyne.—F.R.C.S.

[11359.]—**Casting Brass Solid.**—The metal should not be run any hotter than is necessary to insure sharp castings, which practice will show. The probable cause of the honeycombing of the castings is that the air cannot get out of the way, and should have proper vents made for it from the highest part of the mould. The metal should run in near or at the bottom of the mould. By attention to these points good castings may be obtained, but a little practical teaching is very necessary in such a case, and would save much after trouble and disappointment.—Q. Q. R.

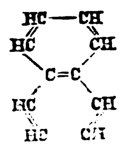
[11366.]—**To Mr Tonkes.**—It is not my opinion, nor is it my belief, that $\frac{1}{0} = \infty$. For if $\frac{1}{0} = \infty$, then is $\frac{1}{\infty} = 0$, and hence we have $0 \times \infty = \infty \times 0 = 1$—a most truly absurd conclusion to arrive at. You may probably desire to know what $\frac{1}{0}$ is equal to. Permit me to assert and to prove that $\frac{1}{0} = \frac{1}{0}$. For as $1 : 0 :: 1 : 0$, and $1 : 1 :: 0 : 0$, $\therefore \frac{1}{0} = \frac{1}{0}$ the which was to be shown. Neither Liebnitz's nor De Morgan's "Differential Calculus" do I desire to look at in relation to the arithmetical subject under consideration. In addition to E. A. Poe's poetical effusions, "Fear not the Raven," &c., I have some slight recollection of a few words in one of P. B. Shelley's published works, even after forty years' neglect of such "metaphysical" stuffing, as per example: "Thou canst not find one —— on earth whereon," &c. To your adherents I have only to remark that I decline to be drawn by W. L. Giles into the differential maze; and as to "Excelsior's" equational pun, I fear that he has not yet so carefully studied as he may now be led to do the mathematician's trinity, formed of 1, 0, and ∞.—S. J.

[11371.]—**Steel for Tools.**—I really must point out an erratum or two in my answer on p. 102. I am not so shaky in my grammar as to say that Stubs's steel or Vickers's "*are* first-class," however funny it may sound to say "Stubs's *is*." Also, "Buck keeps Sanderson's *small* (not *all*) sizes."—J. K. P.

[11378.]—**Killing Beetles.**—When "Sempervivo" has constructed a "suffocating" box, with its tin-foil, cotton-wool, and chloroform, which complication will doubtless effect its purpose, he will find that the easiest way to kill beetles, especially the larger kinds, is to immerse them, legs downwards, for an instant in boiling (212° F.) water. This simple method is founded on the knowledge that the nervous system is located on the underside of beetles, and it has at the same time the advantage of being the least painful mode of death, the heat of the water destroying sensation and life at the same instant. See that the water is boiling: a little practice will soon show the fraction of a second necessary to immerse to kill. I believe it varies a little with different kinds of beetles—a simple dip being sufficient for most.—Saul Rymea.

[11382.]—**Parrot.**—I should advise "Cygnus" to discontinue milk for a time, as this is heating to the blood, and makes the parrot pull its feathers off.—Menelaus.

[11386.]—**Crystals in Gas Tar.**—These were, in all probability, crystals of naphthaline. This body is contained in large quantity in some samples of tar, and crystallises out when the tar loses its more volatile constituents, which dissolve the naphthaline. Napthaline is a hydrocarbon of the composition of $C_{10}H_8$, probably linked together in the following mode:—



It is now used in the manufacture of artificial alizarine.—S. Bottone.

[11393.]—**Scent from Violets and Roses.**—The scent of these and other flowers is obtained by placing thin layers of butter in closed boxes or drawers, together with shallow trays full of the fresh leaves of the flowers, which are renewed when their scent is gone. The butter absorbs the scent, which is then extracted by treating the butter with spirit, or in some similar manner.—Q. Q. R.

[11398.]—**Stinging of Bees, Hornets, and Wasps.**—The sting of a bee is generally more virulent than that of a wasp, and with some people attended with very violent effects. The bee sting is barbed at the end, and, consequently, always left in the wound. That of a wasp and hornet is pointed, so that they sting more than once, which a bee cannot do. When a person is stung by a bee let the sting be immediately pulled out. The longer it remains the deeper it will pierce, and emit more poison. The pulling out of the sting should be done carefully, with a steady hand, for if any part of it breaks in, all remedies will be, in a great measure, ineffectual. When the sting is extracted, suck the wounded part, if possible, and very little inflammation, if any, will ensue. If drops of hartshorn are immediately rubbed in, the cure will be complete. Sweet oil, bruised parsley, &c., appear, on various trials, to be of no use or benefit.—H. B. E.

[11409.]—**Canine.**—If the pup has lost all its hair, and its body is covered with dark patches and large pustules, commence by freely puncturing the dark patches to allow the venous blood to escape. This produces no pain, and the punctures soon heal; also, open the pustules. This done, tenderly wash the bare skin with warm water and a soft sponge; then smear the body with an ointment composed of equal parts of camphor powdered, mercurial ointment, and elder ointment. Repeat this daily. This kind of mange requires some months' good nursing. Don't allow the pup to lie on barley straw, or to subsist entirely on flesh food.—Monte Cristo.

[11434.]—**Salmon Spawn as Bait.**—First, let me state that it is now illegal in this country to have it in your possession. But if "Kingfisher" wishes to use it in some country where it is legal, he may. The broken roe is the best, and must first be well washed in several waters (cold) until all greasiness disappears, then spread upon a cloth, or placed in a bag, and hung up for a day or two to drain all water away; then rubbed with salt until it feels tough in the teeth, when it may be put into jars for use, and will keep for years in a cool place.—Goat.

[11435.]—**Bootmaking.**—When leather is soaked in water, and "beat" well, it is more durable than if worked dry. To work leather dry, means wet feet to the wearer.—Cobbler.

[11438.]—**Lemon Marmalade.**—Pumpkin marmalade is thus made:—Take vegetable marrow or pumpkin, young or old, rather old preferred. Boil till quite tender, and peel or scoop the pulp from the rind with a spoon; put the pulp into a cloth and wring it to remove the excess of water; put the pulp into a preserving pan; to each pound of pulp add 4oz. preserved lemon peel, cut thin, or fresh lemon peel boiled till quite tender and cut in shreds; to each pound of pulp add $\frac{3}{4}$lb. sugar, boil and stir until a sufficiently firm consistence is obtained; stir the whole time if you wish to be quick over it and have the preserve keep well; this rule holds good in all soft fruit preserving. If the flavour of orange is preferred, preserved orange peel or well boiled Seville orange peel with the unboiled juice may be added; a drachm or $\frac{1}{2}$oz. citric acid to the pound will improve both.—Dixi.

[11438.]—**Lemon Marmalade.**—To each pound of lemons allow 18oz. of fine loaf sugar. Pare the thin yellow rind off all the lemons except four, which are to be grated. Cut the parings into as thin chips as possible, and put them into a muslin bag. Cut the lemons in four, take off the white skins and remove the seeds. Put the pulp in the pan, and break it thoroughly with the hand or a potato beater. To each pound of lemons add half a pint of cold water, put in the bag of chips, and let all boil for half an hour. Pour a little boiling water over the gratings, and let it stand until the other is boiled; then pour the pulp through a hair-sieve into a basin. Wash the pan and the sieve, and pour the juice back again through the sieve into the pan; remove the chips from the bag, and put them into the pan also, add the sugar and let all boil together; the gratings are also now added. Boil for half an hour or until it jellies, which may be known by putting a spoonful into a saucer, and setting it in a cool place. Pot it, then eat it.—Champagne Charlie.

[11442.]—**Old Wives' Science.**—Mr. Tomlinsen's experiments referred to are very inconclusive. The weights of candle consumed in equal times, in sunshine and in "a dark cupboard" were compared, the cupboard having, of course, a flat horizontal ceiling, that is, an air-mixer adapted to send down all the carbonic acid, and as rapidly deoxygenate the store of air, and keep it as unchanged as possible with the given inlets! In fact, an English builder's indoor atmosphere was compared with an out-of-doors one! I have always held, with the "Old Wives," that the sun puts out flame, because I used to try, as a boy, to make paper, wood, or linen blaze with a burning-glass, always in vain; and though the lens or mirror be capable of melting iron, never have I found this possible. The wood or rag may burn with incandescence quite visible in the sun, and if there be a current of air, burst into flame the instant the focus is off it. But never can I make it do so in the concentrated rays. I mean to attempt it again, however, with yellow glass, filtering back the chemical blue rays.—E. L. G.

[11444.]—**Bursting of Compressed Air Receivers.**—The effect depends very much on the material; cast iron is usually broken in fragments. Boiler-plate, I think, would be affected pretty much the same as by an explosion caused by steam. Copper is not so brittle, and is more likely to open. In the case of a steam-boiler exploding (say) at 60lb. to the inch, the temperature corresponding to this pressure being about 300°, when the pressure is removed by the bursting of the boiler, the water in the boiler, which was at 300°, cools down almost immediately to 212°, the boiling point at atmospheric pressure, and thus about one-thirteenth of it is suddenly flashed into steam, the sum of the latent and sensible heats of steam being about 1,200°. Of course, scalding with steam or hot water in the case of an air reservoir is avoided.—Philanthropist.

[11448.]—**Chronometer Balance Spring.**—"O. M." has got an inferior article, as the low price might have told him, for £6 5s. is a low price for such an article. He is rightly informed that a good watch with chronometer balance cannot be had unless he gives a good price for it. I, myself, a short time back inquired the price of a first-rate silver watch of this class, having its balance scientifically adjusted (without which they are almost worthless), and was informed that the cost would be £15 or £16. I have no doubt, however, that "O. M." may procure a good timekeeper of this class for (say) £12.—Excelsior.

[11450.]—**Adjusting Equatorial.**—Declination being reckoned from the equator does not require any correction for difference of latitude. It is only the altitude which increases or decreases by going north or south.—O. M. 94021.

[11451.]—**Weight for Safety-Valve.**—The lever seems to me to be very weak, only 12$\frac{1}{2}$oz. weight. The weight to be placed at the extremity for the steam to blow off, at 40lb. pressure, will be 8lb. 6oz., and the ball shifted 2in. in each case towards the fulcrum for the other pressures.—Bob J.

[11456.] — **Saw Sharpening and Gulleting Machine.**—I believe the saw sharpening machine is a patent; but if "F. T. S. S. D." requires one for his use, he could manufacture a rough one that would answer his purpose. The working gear, he will, no doubt, understand, that is, if he is a working sawyer or engineer. The wheels are made of wood, and covered with emery and glue. One or two things have to be considered in these machines. First, is the sharpening required sufficient to eventually repay the outlay; second, the saws require touching up after leaving the machine; thirdly, the use of the machine on the saws hardens them, so that an old file will not touch them. On the other hand, if a number of saws are in use, it will repay the cost very soon, also the regular depth of the gullet enables the saw to perform its work in a superior manner. What I have here stated is from hearsay, not having given the machine a trial. I know of a mill proprietor, in my immediate neighbourhood, who purchased one, but did not find it answer either for circular saws or frame saws, nevertheless, if I could procure a machine to sharpen band saws, if found to answer, I would readily purchase the same.—Samuel Smither.

[11457.]—**Motive Power for Amateurs.**—I have seen lately a machine which, I think, con[illegible] serviceable for that purpose. It consists of [illegible] connected springs, inclosed in dent barrels with each other, the last of those acting by [illegible] dent wheels and pinions on a pulley with [illegible] strap. The springs are wound up very [illegible] handle, and their elasticity is moderated by a fly. The motor I saw is applied to a sewing machine, and, indeed, many readers of the English Mechanic may have seen it also, since there were two of the said machines at the International Exhibition, 1871 (French section). But, that motive power can, of course, be applied to a great many machines which are now worked by the hand or the foot, I am aware—for instance, those connected springs have been of late adapted to the "Hughes' Printing Telegraph," as a substitute for the heavy weights which the telegraph clerk had to lift up with his foot at every moment.—Novi, Amiens.

[11457.]—**Motive Power for Amateurs.**—Is "Zoo Andra" poking fun at "our" readers? The lever—*i. e.*, his weighted pendulum—will, no doubt, give a certain amount of power to his saw; but this I know from practice (not theory), that I will produce more power from a fly-wheel than he can with the pendulum; that is to say, for the same person to exert his strength in turning a fly-wheel as will swing the pendulum; as for ratchet-wheels it would be a great mistake. The best motive power for amateurs is the treadle, unless they can incur the cost of a fly-wheel, horse-mill, or steam-engine. If "Zoo Andra" is actually fitting up a bench in the style sent, when complete, will he use it for a week together, and let the readers of the Mechanic then know as to its practibility?—Samuel Smither.

[11459.]—**Printer's Ink.**—Red Brasil wood four ounces, diluted acetic acid one pint, alum half an ounce; boil for one hour, strain, and add an ounce of gum.—H. B. E.

[11459.]—**Printer's Ink.**—Linseed oil boiled to a thick varnish, and a sufficient quantity of vermilion or Prussian blue ground with it to give the required depth of colour.—William H. Hey.

[11459.]—**Printer's Ink.**—"W. J. H." can buy what he wants cheaper than he can make it. The finest dark blues are Prussian, Chinese, and Antwerp; they are very hard to grind, and when used too thin have a greenish hue. Vermilion (pure) is, of course, the best "red," but a little bright drop lake improves it, where richness of tone is wanted. These require to be ground on a clean slab with a clean muller and clean varnish—the very best. I hope "W. J. H." is a modern Hercules, for he will find it a tough job; but they may be ground in turpentine first, and mixed with the varnish afterwards. This saves a little labour. If only a small quantity is required, and very fine, use Canada balsam as the varnish. I have seen excellent work produced by taking an impression with gold size and dusting on the colour required in a very fine powder—specially prepared, I think. This latter method is by far the quickest for a small quantity, and the pigments retain their colour well.—Saul Rymea.

[11462.]—**Steel Hardening Paste.**—The red paste must have been "J. Fielden's Rouge Steel Paste," which is used to improve cutting tools and to restore burnt cast steel, or for case hardening small iron castings. We have given five shillings per pound for it. We dip all our cutting tools, and find that a few pounds will serve a long time if the dust cover is kept upon case supplied with "rouge paste." If "A. B. C." will advertise his address in these columns I shall be pleased to let him know where the "rouge steel paste" may be purchased.—Halifax.

[11464.]—**Spring Beds.**—It would be a trade advertisement if I sent the address of a maker, but if "Associate" will look at the London Directory, or apply at some large bedding manufacturer he will procure what he wants, I have no doubt.—Samuel Smither.

[11469.]—**Air and Warmth.**—From 700 to 1000 cubic feet per head; from 55° to 60° Fahrenheit.—Excelsior.

[11471.]—**Bow.**—Yew is the wood used to make the best bows. Should "Archer" not be able to procure it apply at a respectable coach builder's for a piece of lance wood, let it be quite sound and dry; one inch by three quarters of an inch will be about the size; taper at each end to five eighths of an inch by one half inch, rounded on the outside. A sharp steel scraper is very useful to an amateur for the manufacture of the same.—Samuel Smither.

[11471.]—**Bow.**—Bows of Yew-wood won Cressy and Agincourt; why should they not win at archery matches now?—Hedera.

[11472.]—**Plaster of Paris.**—"C. B. B." has evidently been using the common plaster used by builders. He should get either fine or superfine plaster and keep it in a dry place, it will soften when left in water for a long time, but does not fall to pieces. Porous pots are sometimes made of it, but only as a temporary appliance.—Dentiste.

[11478.]—**Silver Bath.**—"F. C. C." should get a good manual of photography. In reply to his question no definite number of plates can be given, it is quite possible to continue preparing plates with the 8oz. silver bath until there is not sufficient left to cover the plates in the bath. This, however, is not very likely to be the case, as "F. C. C." will doubtless find he cannot get good photographs after having used his nitrate of silver bath till about a third of it has been wasted. By this time he will find it has got somewhat out of order. The best way to set it right again will be as follows:—1. Pour the solution into a clean dish and set it in the oven, or on the stove, till it has nearly all evaporated, having first made it slightly alkaline by adding a drop or two of strong liquor ammonia. 2. Add sufficient distilled water to make up to 8oz. once more. 3. Set it in the sun for a few hours, or even a few days. 4. Filter, and then add sufficient pure nitrate of silver to make the strength up to 35 grains to the ounce. 5. Try a plate; if it does not work well add a drop or two of dilute nitric acid.—G. Avery.

[11482.]—**Algebra**:—

$$x : y :: z : t$$
$$x + t = 14$$
$$y + z = 11$$
$$x^4 + y^4 + z^4 + t^4 = 24929$$

Let $x = a$; $y = a + d$; $z = n(a)$; $t = n(a + d)$. We have—$a : a + d :: n(a) : n(a + d)$. By addition—$a + n(a + d) + (a + d) + n(a) = 25 = (n + 1)\cdot(2a + d)$. By subtraction—$a + n(a + d) - (a + d) - n(a) = 3 = (n - 1)d$. As $5 \times 5 = 25$ ∴ $n + 1 = 2a + d = 5$, and $n = 5 - 1 = 4$, $d = \frac{3}{n-1} = \frac{3}{3} = 1$, and $2a + d = 4 + 1$. That is, $2a = 4$, and $a = 2$.

$$\therefore \text{the analogy is } 2 : 3 :: 8 : 12$$
$$2 + 12 = 14$$
$$3 + 8 = 11$$
$$16 + 81 + 4096 + 20736 = 24929$$

—Thetamu (Horsham).

[W. R. Kemp, William Hughes, and "A New Subscriber," have also answered this question.—Ed.]

[11483.]—**Dyeing Parchment.**—Dye it blue by brushing over with a solution of pearlash, two ounces to the pint. For dyeing red, boil a pound of Brazil wood and an ounce of pearlash in a gallon of water, and while hot brush over the parchment until of a good red colour.—H. B. E.

[11484.]—**Manures and their Values.**—If Mr. Richardson is within carting distance of sea-weed, he will find it a rich and stimulating manure when dried, burnt, and the ashes, mixed with sand, wood or coal ashes, hand-spread over his land.—Manus.

[11486.]—**Arithmetical Question.**—This is most easily accomplished. For the

length, 4 lengths of each	$4 \times 5 + 4 \times 7$	$= 48$
breadth, 6 of the 5 less 1 of the 7	$6 \times 5 \quad - 7$	$= 23$
heighth, 3 of the 7 less 2 of the 5	$3 \times 7 - 2 \times 5$	$= 11$

—William Hughes.

[T. P. Lucas, "H. H. C.," "Excelsior," and "Philanthropist," have also answered this query.—Ed.]

[11486.]—**Arithmetical.**—Surely any man in such a position would first measure off 2ft. on the 7ft. rod, by the assistance of the 5ft. rod (7 − 5 = 2), and then divide the 2ft. into two parts; or, having got the 2ft. length, he would mark off from each end of the 5ft. rod, 2ft.; the interval between these marks would, of course, be 1ft. What more would he want?—Hedera.

[11487.]—**Preventing Rust.**—One part white-lead to two of tallow will answer the purpose, and rub off easily with a little turps.—Manus.

[11487.]—**Preventing Rust.**—Bright work is generally covered with a compound of tallow and white-lead.—Excelsior.

[11489.] — **Weight of Cattle.**—(Shepherd's "Problem").—As it is not likely that all his heifers would live to breed for twenty years, what would he allow for deaths?—T. P. Lucas.

[11493.]—**Indiarubber Overcoat.**—"W. P." can repair his overcoat with indiarubber solution; clean the seams with a little coal naphtha; then with the finger put a thin coat of solution; let stand for two hours; make warm a smoothing iron, with which iron down the seams; cut up 1oz. bottle rubber; put into 4oz. coal naphtha. A wide mouthed bottle is best to make the solution in. When dissolved, use it.—Cobbler.

[11499.]—**Zymotic Diseases.**—It seems to me that M. Paris has answered his own question by the very designation he has given to the diseases. Zumé (Greek) fermentum, leaven. If I take a mass of dough, to which I add a portion of leaven, I shall cause the whole mass to ferment. I may now remove successive portions, and add others of unfermented dough in their stead, and the process will still go on, though the aggregate of portions removed may embrace the whole of the original mass. So much for diseases that are zymotic; if there be any such. I give no opinion.—F. R. C. S.

[11503.]—**Stair Noses.**—Nail a little oil canvass on the edges, or if you have canvass on the stairs make it double at the edges; this is if you have carpet down; if not, nail lead on, but don't on any account put lead under the carpet.—H. B. E.

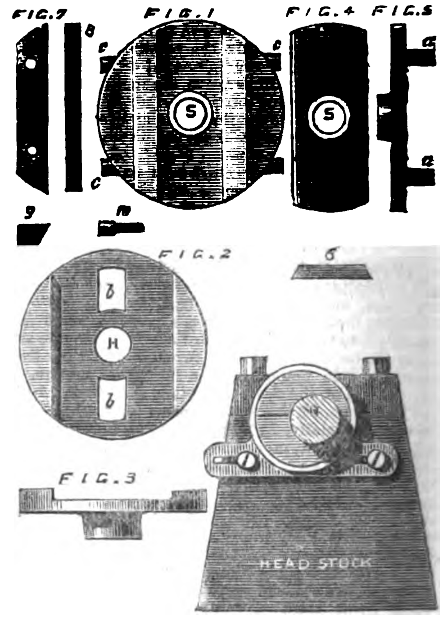
[11504.]—**Photographic.**—I would suggest to "Cornubiensis" the use of cocoa fibre matting for the covering of the floor of his studio. He will find it durable, of nice appearance, noiseless, and should he work with a tripod stand, there is no fear of the legs moving on the floor.—W. Phelps.

[11505.]—**A Wooden Pump.**—"Cornubiensis'" friend may set his pump in good order by either of the following methods:—First (if not already done) shorten the spear or rod that is connected to the top bucket, so as to allow the bucket to work higher up. Or he may get a large gauge with a long handle and open the mouth of the pump sufficient to allow a new bucket to be substituted. The chips will come out with the bucket.—H. D.

[11511.]—**Rubber Tires.**—I cannot conceive any "suction," but, perhaps, there may be a little more adhesion with the rubber than with the iron tire, but the result is that with the rubber tires scarcely half the fatigue is experienced as with the iron—indeed, there is no comparison.—T. P. Lucas.

[11511.]—**Rubber Tires.**—If the roads are very smooth there is little advantage to be gained with rubber tires. The case is different, however, on most of common roads, where the iron tire is always grinding away among the dust and small stones; the difference being equal to the amount of power wasted in grinding said stones. Soft roads and rubber tires bear no resemblance to one another, inasmuch as soft roads are not elastic; and as regards suction, it is only in wet fields and mossy ground that it impedes locomotion, places where few velocipedists will think of straying.—G. Smith.

[11512.]—**Lathe Chuck.**—As a further description of my oval chuck seems wanted by some of "our" readers I give details:—Fig. 1 shows the face of the chuck, S being a hole tapped to screw in any kind of poppet required; Fig. 2 shows the chuck plate before slide, and justing bars are added; H hole tapped to screw upon the spindle of lathe, *b b* slot holes, through which two pins or gabs work, marked *a a*; Fig. 5, Fig. 3, cross section of chuck without slide-bars; Fig. 4



shows slide-bar face side; Figs. 5 and 6 sections of slide-bar; Figs. 7 and 8 are justing bars fixed from back with two screws, each same as Fig. 10; C C C C are justing screws to make slide-bar to work right. The headstock shows how the ring is fixed to it, with two screws, outside of which the two pins marked *a a* revolve. The other end of the shaft works upon the dead centre, and of course round, which is an advantage when making sprig bit handles to get the ferrule on. The drawing is made to scale quarter size of mine.—Goat.

[11514.]—**Brunswick Black.**—Recipes for this, under the names of Berlin black, japan, &c., have been frequently given. See No. 367, reply 11357.—S. Bottone.

[11517.]—**Lathe Queries.**—"H. E." will find a description of index pegs for counting in Vol. XII, p. 180.—J. K. P.

[11524.]—**Pitch of Roof.**—The only "measure" of the pitch is the number of degrees of a roof's inclination. Certain pitches in fashion at different times have doubtless had names, and I believe, among English workmen, "old" or "common pitch" has, for ages, meant that of Westminster Hall, the great typical old English roof, whose internal span is 4 standard perches, and corresponding rafter-slope 3 perches. This gives the inclination about 48° 13', and the lowest of "high" or "gable" pitches, that is, of those above 45° or the "square pitch;" for so unsightly has this latter seemed to all races that nowhere have roofs of this pitch, or within several degrees thereof, above or below, been either common or tolerated in buildings of any pretension to dignity. Though there may be even cathedrals (as Langres) with a square-pitched roof, yet, as Ruskin says, men have everywhere made a great gulf between the two kinds of roofs—the "low-pitched" (*i.e.*, below 37°), and the "high" (*i.e.*, above 53°). The above Westminster pitch, beside being too near the "square," is inconvenient from having the height incommensurable with the base and slope. Carpenters would always have saved themselves much trouble (or the architects for them) by keeping, like the ancients, to angles whose functions are all commensurable (as slope 13 to bases 12 and 5, or slope 25 to bases 24 and 7). The simplest of all, known as "Plato's triangle" (of 3, 4, and 5), turned one way, makes what is rightly the lowest high pitch (or lowest tolerable on Gothic buildings), approximately 58° 7' 48" 38''', or, as I would write sexagintals compactly, $5_8{}^\circ 0_7 4_8 3_8$; and the other way, the highest low pitch (or highest tolerated on non-Gothic buildings), $3_6{}^\circ 5_2 1_1 2_2$. This latter (which is hardly low enough to be called a "pediment" pitch) seems to have been universal from the decline of Rome till the grand twelfth-century movement that originated "Gothic" architecture, and which Viollet le Duc attributes to the anti-clerical spirit of the "Communes" and other lay guilds then arising. It certainly was a Radical or anti-traditional, and therefore anti-churchmenly movement; and the new cathedrals were a protest against the abbeys. This movement was weakest in England, and our Gothic building the most timid; and it seems never noted that the high roofs distinctive thereof were from the beginning higher in all Continental countries than here. I do not know of a single Old English roof so steep as 60°; while all over Germany and France, even south of the Loire, it is doubtful if they were not oftener above that pitch than below it. Another point overlooked is that the builders of the great times, instead of regulating their roofs by particular pitches (or proportions of height to width), aimed at some simple ratio of their vertical height to that of the walls they crowned—either making heights of wall and roof equal, or as 2 : 1, or as 3 : 1, in their grandest erections. As examples of their equality, we have the two noblest secular buildings remaining of old England and France—Westminster Hall, and the exquisite Palais de Justice of Rouen. Of course, plenty of humble churches also illustrated this, especially in England (they having probably noted, from the Book of Exodus, that the Mosaic Tabernacle did so); but I doubt if more than one cathedral is thus roofy (to coin a much-needed adjective)—that of Vienna. Then, of the next degree of roofiness—the roofs half the height of whatever bears them—you have the noblest of all civic buildings, the Stadthouse of Brussels; and of cathedrals, that of Rheims, and, perhaps, other first-rate (but many second-rate) on the Continent; though in England, I think, only Lincoln. The general proportion for grand churches, both French and English, was the roof a third of its supports. In the decline of building, the first architects, by some centuries, to return to low roofs were our English, who depressed them first on side aisles (as at Westminster, 1300; Winchester, 1400); and the first nave, again, made low-pitched (as in pre-Gothic times) was York, about the latter date. From low they came to make them invisible, to mimic, I suppose, the effect of the platforms of castles; and at length, for the three centuries preceding the present, no English building could be held respectable that did not appear roofless. In no other land did this idea gain absolute sway, even in the maddest swing of Classicism; and though St. Peter's, at Rome, set the example, Louis XIV., indeed, seems to have held that only sacred buildings ought to show any roof, as appears by the wondrous contrast between the Versailles Palace and its chapel.—E. L. G.

[11530.]—**Violin Construction.**—"Reed Maker" has touched upon the principal point to be considered in the construction of the violin—viz., the divergence of tone to be produced by making the breast and back dissimilar. The last article in "ours" did not state that Savart's fiddle had a maple back in opposition to the deal breast, and I am in doubt whether he has satisfied himself so as to have two deal resonants opposite to each other. The old box fiddles were all made with hard backs, mine (to inflict punishment on some and create joy in others) had a soft back. I found no difficulty in tuning my pieces of wood, for I made them all a different thickness. Now, if I am not understood, I beg to say that everything has a sound or tone of its own, and many of us have heard music hammered out of pieces of hard wood of different sizes and thickness, and was it not Lulli who, while a scullion, knocked airs out of the cook's stewpans? I have also heard that Handel broke Corelli's violin over his head because the latter did not understand the French style of playing. There is a great difference in producing tones by bowing (that's polite) or hammering. Percussion is easy in comparison with bowing, but I have reason to believe does not affect the senses so enjoyably. I think I am right when I state that two strings of the same calibre, on the same bridge, soundboard, and of the same tone, do not increase the power but produce a whirr, also heard in the organ accordion, when the two rows of vibrators are sounding together. These are all distinct, and so add to the power. I cannot say what the effect would be if two vibrators were placed close together in the same pan, probably no increase of power, but if I am wrong here, could not the flageolet be made more powerful by blowing through two reeds into the same tube? I do not think so. We have the tone increased in the piano by doubling and trebling the wire, but beyond four I think we should miss any further extension of power without more soundboards, or a more violent method of bringing out the tone, viz., moving the soundboard. Now, in the violin we hear tones produced by the weakest method of moving a soundboard—therefore, the various parts must be made of different sizes and thickness, so as to form a variety of centres or tones (or rather they become places for tones to sound on or in). I wish some of "our" contributors would kindly inform us about the harp, especially the construction of the soundboard, whether the strings would sound as well if they were strung at right angles with or to the soundboard, and what kind of tone would bowing produce? I fancy very poor. I fear the harp is not so fashionable as it used to be, more's the pity. If we make the breast of the violin larger we require a thicker string to move it, and the thicker the string the lower the tone must be; if we make the breast smaller we reduce the plane in which the tones can be produced, thus we have only one size for the violin proper, and so only one amount of power. This is true with all instruments, they have their limits, although, of course, all are open to improvements—for instance, the drum could be made a formidable if, instead of strained skin, a vibrating sheet or face of metal was substituted. It may be said, but this would not be a drum—true, and if we alter the violin ever so little we lose the violin tone. Then the question will always remain, how can a bowed instrument be made to sound louder than the violin, yet having the same notes? In a back number the "Harmonious Blacksmith" has presented to our notice a fiddle without a back, a great curiosity, and perhaps a shadow of good things to come. As it has no back it could easily be joined to a series of breasts, one under the other, but here is the difficulty, a gut string would not move more than one breast, no matter how the string was placed or fixed, with a bridge, or, weaker still, harp fashion. A steel wire would sound well, but only by pulling and not by bowing. I have noticed in the toy harps (all wires are used) that when played in a box suited to its size the tone is considerably increased, yet when the violin is substituted in its place no increase ensued. Then it comes to this, can one performer play on many violins at once and so command an increase of tone? Shall we ever get a practical method of playing a series of violins, &c., by means of a keyboard?—FIDDLER.

[11535.]—**Small Wheel Cutting Machine.**—"A Horological Mechanic" will find full description of dividing apparatus for lathe in Vol. XII., p. 277, and of the cutter-frame, for use with slide-rest, in Vol. X., No. 245, p. 281. To answer q. 10859 would require a treatise, and at least half what you want you will find dispersed through the last four volumes. You cannot get a "recipe" to make cutters, like a dose to cure a bellyache, and it requires as much knowledge, of a sort, to do it properly, as a medical man would require for his purpose. Moreover, "simple" working drawings can only be made by those who thoroughly understand the job, and know how to draw thoroughly well too. If you want cut wheels you can get them in Clerkenwell better cut than you can do them, and if you want cutters you can buy them, I believe, for less than 21s. each at Holtzapffel's.—J. K. P.

[11547.]—**Bass's Beer.**—Some years ago Mr. Cooper, of London, analysed some water taken from a well at the brewery of Messrs. Bass & Co., in which he found—

	Amount of ingredients in imperial gallon represented in grains.
Carbonate of lime	9·93
Sulphate of lime	54·40
Chloride of calcium	18·28
Sulphate of magnesia	0·83
	78·44

—YOIZA.

[11579.]—**Blue Billy.**—It was owing chiefly to the presence of arsenic that I expected hard iron to be produced. I imagine that it is prevented from escaping by being picked up in the upper parts of the furnace by the lime, and thus continually brought back. At all events it does not escape. The copper is in great part volatilised, and colours the flame of the furnace. By hard iron, I did not mean the technical term for "strong forge" iron, but a brittle nature. The iron produced was very small grained, whitish in colour (not white iron), and brittle. I tried reducing some by itself in a cupola furnace, and produced a pig, the fracture of which was more like bad steel than pig iron, so much so that I had it tried for forging, but it broke up at the first blow. I am informed that it is used a good deal by some furnace owners, and that they get a fair iron from it. But, in my case it was not worth while trying to do anything with it, as the carriage made the material as dear as others at command, and the make of iron being one of the best in England, it was not worth while to run any risk of damaging it.—SIGMA.

[11585.]—**Chemical.**—To prepare chlorine from chloride of sodium, in such a manner as to obtain at one operation sodium also, is a most expensive affair, as it necessitates the employment of a powerful battery. But it is easy to proceed in such a manner as to prepare hydrochloric acid from the sodium chloride (see second process, paragraph 54, of the Lessons), and from the hydrochloric acid chlorine may be easily obtained, as explained at paragraph 51. The residue obtained by acting on sodium chloride with sulphuric acid is a sodium sulphate. From this sodium sulphate sodium carbonate is prepared by heating it strongly with a mixture of chalk and slack, and dissolving and crystallising. The carbonate, when dried, may be mixed with finely-powdered charcoal, and strongly heated in a cast-iron retort, when it is resolved into sodium and carbonic anhydride. The changes, results, &c., of these operations are briefly expressed in the following equations:—1. Separation of chlorine and sodium from sodium chloride by means of electricity—

$$NaCl = Cl + Na.$$

The results of this mode of procedure are, therefore, nothing but chlorine on the one hand, and sodium on the other. 2. Separation of chlorine and sodium from sodium chloride by chemical means. (a) Separation of the chlorine from the sodium by the action of sulphuric acid—

$$NaCl + H_2SO_4 = NaHSO_4 + HCl.$$

Here we obtain hydrochloric acid and hydrogen sodium sulphate. (b) Separation of the chlorine from the hydrochloric acid by means of manganese dioxide—

$$4HCl + MnO_2 = 2H_2O + MnCl_2 + 2Cl.$$

Here we obtain free chlorine on the one hand, and a solution of manganese chloride on the other. (c) Preparation of sodium carbonate from the residue of the preparation of hydrochloric acid—see (a)—by the action of carbon (slack) and calcic carbonate (chalk)—

$$2NaHSO_4 + 4C = 4CO_2 + H_2S + Na_2S, \text{ then}$$
$$Na_2S + CaCO_3 = CaS + Na_2CO_3.$$

From this mixture of calcium sulphide the sodium carbonate is separated by lixiviation with water, and crystallisation. (d) Separation of the sodium from its carbonate—

$$Na_2CO_3 + 2C = 3CO + Na_2.$$

—S. BOTTONE.

[11587.]—**Cleaning Scarlet Cloth.**—Take 8oz. of sal ammoniac, 1½lb. of nitric acid, and heat the mixture slightly. Then add, little by little, 8oz. of pure tin. When the tin is entirely dissolved, add 6oz. of water. This constitutes the famous "eau écarlate," so much used for revivifying faded colours. It may require further dilution with water.—S. BOTTONE.

[11592.]—**Medical.**—The protosulphate, the protonitrate, and the acetate.—S. BOTTONE.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "Hedera" has answered 10414; "Anglo-America," 10609, 10617; "Q. Q. R.," 10830, 10917; F. Hume, 10913; "Esmey," 10993; "H. B. E.," 11058 "G. W. K.," 11095; J. W. Fennell, 11103.

11190 Copying Ink, 650

QUERIES.

[11595.]—**Starlings.**—Acting upon "Joe's" advice, although not "a young lady," I have resolved to try the experiment of rearing one of these magnificent birds, and, if possible, teach it to talk. Will "Joe" kindly give his valuable opinions on the following queries:—(1) What kind of cage is the best? (2) At what age should the bird be caged? (3) Ought the cloth to be kept over the cage all day and until the bird will talk? (4) Should food be given at fixed periods, or left in the cage? Other hints will be gladly received by—RARA AVIS.

[11596.]—**Photographing Engravings.**—Would some one inform me the easiest method of photographing an engraving the same size as the original (which is 5in. by 3in.), and what sized camera will it require?—VERITAS.

[11597.]—**Mean Longitude of the Sun, &c.**—Will any kind reader inform me (1) What is the mean longitude of the sun? (2) Its variation in 100 years? (3) The longitude of the perigee, and its variation in 100 years? (4) The obliquity of the ecliptic, and its variation at any epoch in the latest astronomical tables (say, Leverrier's)? (5) Also those of the moon? I am possessed of the tables of Delamtre and Burg, but they are not sufficiently accurate for modern astronomical calculations.—W. H.

[11598.]—**Long and Short Rifles.**—I have a rifle 28½in. long. I want to cut it at 26in.; if I did so would it shoot as well after being cut as it does now? If I put higher sights on, (the sights are 2in. from the back end of the barrel), what height would they require to be to shoot well at 100, 200, and 300 yards after being cut?—A. G. MILLER.

[11599.]—**Lint.**—How can it be most easily made, and what is the best material?—LOAN GOCH.

[11600.]—**Analysis of Water.**—Can some correspondents give me a method of estimating the comparative wholesomeness of different waters for domestic purposes, or tell me in what work I can find the subject satisfactorily treated? I am used to making analyses, but the books I have say very little on this subject. I want a process that shall be both quick and accurate, if any such process exists.—ANALYST.

[11601.]—**Cracked Oven.**—My oven is cracked down the side and across the bottom, is it possible to mend it, and how?—DENTISTE.

[11602.]—**Ligurian Bees.**—I should be . . . of my fellow readers would be kind en . . . me from their own experience, whethe . . . the Ligurian bees superior to the E . . . Also how to unite a queen (Ligurian) t . . . rock. I have thought it would be a . . . after the first swarm has just left, as . . . be no difficulty in getting rid of the . . . old hive would be greatly helped in . . . soon as it swarmed. I know this is . . . common black queens with late great advantage. I should also like to know how it is that these Ligurian swarms are so very dear. £3 2s. seems to be the lowest, and 12s. 6d. for queens.—G. M.

[11603.]—**Dinas Firebrick.**—The Dinas firebrick is made out of coarse ground stone. Can any of your readers recommend me a machine for making these bricks? Much pressure is not required, but owing to the silicious nature of the stone, the wear and tear in any elaborately constructed machine would be very great. At present they are made in hand presses—a slow and expensive process.—Dinas.

[11604.]—**A Task for Chemists.**—To "Busy Bee."—In reply to query 10510, "Busy Bee," in speaking of getting the resinous and silicious matter from wood, thinks to accomplish it by boiling in caustic of 18° Tw., for three or four hours. If he has succeeded in getting the resin out this way, will he tell me how to proceed, for I have been working at this subject for upwards of six months, and I have been unable to get the resin out except that which was superficial, by such a method? I could also show "Busy Bee" a piece of wood which has been soaking in a bleaching-liquor cistern for upwards of eight months, and when the outer layer of ½in. is shaved off, the wood is just as tough and resinous as ever underneath.—George E. Davis.

[11605.]—**The Organ Built.**—Will "J. D." please to further explain Fig. 7, p. 638, Vol. XIV., as I have got into a fog at this point? What is that part of the leather (Fig. 7) for that projects inside? By so doing he will oblige.—W. C. Mannin.

[11606.]—**Organ Pipes.**—Will some correspondent inform me what should be the diameter of the foot-hole for a pipe 4ft. in length, measuring 4in. by 3½in. internally, and for one half that size? and what should be the height of the mouth of each pipe?—C. F. S.

[11607.]—**Ebonising Wood.**—Can any one describe the process and materials required for ebonising furniture in the best manner, to be polished afterwards in the usual way? I have tried the logwood and copperas solution, but cannot succeed in obtaining a good black, such as seen on ebonised articles.—W. C. W.

[11608.]—**Boiling by Steam.**—Can any reader inform me how to boil by steam? The contents to be boiled would be 50 gallons, and the mixture must be kept stirred all the time, so that a steam coil passing through would not answer.—A. W. B.

[11609.]—**Screw Cutting.**—Will some practical screw cutter give me a little advice? I want a rule for getting five or six change wheels, for cutting 14, 16, 18, or 20 threads per inch, left hand. I can get plenty of wheels for cutting right hand, but the quadrant is so small it will not allow for another stud with the ordinary wheels for cutting right-hand threads. The leading screw is 3 per inch. I have cut many left-hand screws with wheels in single train; also I can get 4, 6, or 8 wheels to cut coarse pitches, but the wheels have to be very small.—Young Hand.

[11610.]—**Defective Battery.**—I have a Smee's six-celled battery with coil, which I use as an invalid. Recently it became unworkable, and the coil was taken to a maker and repairer, who supposed something must be wrong with the battery. The silver plates have been replatinised, and the zinc ones re-amalgamated. When the connections were completed, the vibrator immediately acted, but when the two handles were held, there was only a sensation felt two or three seconds, and, occasionally, none at all. A few days ago, on trying it, the sensation continued for about five minutes, when the vibration ceased, since which time there is no action whatever. Has the insulation been destroyed, or may the cause be polarisation? and how should I proceed to discover and remedy the evil? If "Sigma," or Mr. Tonkes, or any competent fellow reader, would kindly direct me, I would feel greatly obliged. The distance (40 miles) from a repairer, and the expense are serious obstacles.—G. F. L.

[11611.]—**Opaline Photographs.**—Will any subscriber help me out of my present difficulty? Having coated the albumenised plate with chloridised collodion when dry, I find it has settled in rings, presenting a very ugly surface. Will any one explain the cause?—is my collodion at fault? A formula will oblige.—Opaline.

[11612.]—**Injury to Vacuum Tubes.**—I have two vacuum tubes, which have the platinum wires broken off at one end. The wire is broken off close up to the glass, but the tubes are not damaged in any other way. Will some one please tell me how I can remedy it? I have passed the current through them by placing the broken wire in mercury—is there any better plan?—Zeta.

[11613.]—**Stuffing and Preserving Animals.**—Would any one of your numerous subscribers give me some information as to the stuffing and preservation of dead animals?—H. S.

[11614.]—**Gums.**—Will some correspondent give me a list of those gums which are soluble in methylated spirits of wine?—Menelaus.

[11615.]—**Teeth.**—Will taking tincture of iron and quinine for strengthening purposes, as recommended in the Mechanic, tend to loosen the teeth if persevered in for some time? What will set them fast again when loosened?—Menelaus.

[11616.]—**Engraving.**—What is the liquid used in aqua tinting?—Menelaus.

[11617.]—**Numismatical.**—I should be glad to know something about the value and origin of the following coins:—1. Copper coin.—Obverse, elephant and castle; legend, "Coventry Halfpenny;" reverse, horseman, legend, "Pro bono Publico, 1792." 2. Copper coin.—Obverse, shaft of a mine; legend, "Cornish Penny, 1811;" reverse, fish; legend, "For the Accommodation of the County." 3. Brass coin, very small.—Obverse, head of king; legend, "Carolus Rex;" reverse, a crown, "X. S."—C. Colman.

[11618.]—**Deadening Sound.**—Will any one tell me the least inexpensive method of deadening sound between two rooms, which are divided only by a boarded partition?—Wickliff.

[11619.]—**Electrical.**—Will some correspondent kindly inform me why I can only get exceedingly faint shocks from my Leyden phial, when it is charged with 90 or 100 sparks from an electric machine which generates well? The phial is a pint jar, and is coated with tinfoil two-thirds of its height inside and out; the coating is gummed on; the connection between brass and interior coating is perfect; the stopper is of baked wood, covered with shellac varnish. I may add the glass is free from crack or break of any kind. The shock it gives is about equal to that of a good spark from prime conductor.—F. T. Z.

[11620.]—**Capturing Moths.**—I have heard that entomologists attract and capture moths with a composition they call sugar. Will any one kindly tell me how it is made? Also how, when, and where, to use it for that purpose?—Entomologist.

[11621.]—**Killing Roots of Trees.**—What acid or other stuff will kill trees if emptied into a hole bored into them? I am troubled by large willow tree roots closing up drains and making mischief.—A Gardener.

[11622.]—**Chaldron.**—What is the exact value of a chaldron?—Merci.

[11623.]—**Bell Pianette.**—I should be much obliged to S. Bottone (11393) for details of the Bell Pianette.—J. R.

[11624.]—**Photography.**—I live in the country where rain-water may be had purer, probably, than in many places, as I can collect it in the fields, and I wish to know whether in such a case, filtered rain-water may not be used for the same purposes as distilled water is prescribed, and, if not, whether there is anything short of a distilling apparatus, by which it can be made pure enough, and, if so, how? The experience of some practical photographer or chemist on this subject would be valuable, I have no doubt, to others besides—A Constant Reader.

[11625.]—**Deaf Dog.**—We have a dog that is almost totally deaf (nine months old). His ears are not cropped; I can see nothing peculiar about them; he can hear a loud whistle if close to him. Could any reader give a remedy?—Spot.

[11626.]—**Electric Bells.**—I would be much obliged to some kind reader of the English Mechanic, who would give me a little information upon the construction of electric bells and their mode of working. I have made various electric machines from information received in these columns, for which I am thankful, and I have no doubt that with the information I shall receive upon the above subject I shall accomplish my object.—Thomas Whalley.

[11627.]—**Gilding Strips of Wood.**—Whenever I am in a difficulty of a certain nature, I fly to the pages of "our" Mechanic, with the certainty that if I state my difficulty or question with moderate clearness I shall find some one of the many kind contributors to its columns who will help me to a solution. Well, I want some help now. I wish to gild some flat strips of wood about 1in. broad, and ½in. thick, so as to give them a dead gold look, all but one edge, which must be burnished. How am I to prepare the wood for gilding? and how am I to gild it?—Ironsides.

[11628.]—**Violin.**—Would Mr. Davidson (the author of "The Violin") oblige by telling me if an old violin, made by Ursula Collier, at the sign of the Correlli's Head, on old London Bridge, is of much value?—T. R. Willis.

[11629.]—**Skeletons.**—How can the skeletons of small animals (up to, say, a cat) be obtained, without a knowledge of anatomy, or without a very great deal of trouble?—Hedera.

[11630.]—**Compendious Perpetual Calendar.**—Would any of your correspondents tell me the best way of making a compendious perpetual calender?—James South.

[11631.]—**Income-Tax.**—A maiden lady formerly had an annual income of about sixty pounds. Two-thirds came from the "Albert" Insurance Office, and one-third from money in the funds. The first is apparently lost, and upon paying the other, income-tax has been invariably deducted by the Bank of England. How must a third party proceed to claim exemption, and can he recover any of the former deductions?—Helpless.

[11632.]—**Debility.**—I have been unable to follow my employment as a blacksmith for five years, from giddiness, singing in the head, indigestion, and general debility. Would any homœopathic doctor kindly give me a prescription to meet my case? I have tried allopathy and hydropathy without any benefit.—Westmoreland.

[11633.]—**Fever Tree.**—The fever tree of Tasmania has been cultivated in the south of France, and seems very prosperous there. I wish to know the scientific name of that tree, and if it is adopted in the pharmacopœia?—Quinquina.

[11634.]—**Tudibi Gum.**—Is the tudibi or black boy gum of Australia a kind of kino? What are the uses of that gum?—T. G

[11635.]—**Davis's Refrigerator Car.**—A few particulars about that car will oblige the querist? It is employed in the United States for conveying light perishable victuals.—D. R. C.

[11636.]—**Desert of Sahara.**—Many authors say the Desert of Sahara is under the level of the sea. A Frenchman, at a recent meeting, pretended the average height was 400ft. or 500ft. above that level, and that there were no shells nor any other marine remains found there. A few particulars about such statements will oblige many readers, and—W. W.

[11637.]—**Cormona Wood.**—I read in Payen's "Traité de Chinise," that cormona wood contains 55 per cent. of carbon. What kind of wood is this? and where is it obtained?—Guillaume.

[11638.]—**Silkworm Disease.**—Is there a credible cause assigned to the plague which affects silkworms in several countries?—Bombyx.

[11639.]—**The Rock Inscriptions.**—Will "E. L. G." or others explain how it is that the Sinaitic cuneiform inscriptions remain so neglected? Ever since my first acquaintance with the reports concerning them, it has been a matter of wonder and disappointment that they have not been energetically explored and transcribed. If there is only a colourable probability that they were the work of the Israelites in their exodus, why are they not eagerly deciphered? If they are veritably coeval and autographic records, how insignificant are discoveries in Nineveh, Babylon, Moab, or Palestine, scripturally considered, compared with the flood of light which might be extracted from these, either corroborative or corrective of the Mosaic accounts, and illustrative of language and letters. A tithe of the money and time spent in triangulating Palestine or groping the sewers of Jerusalem, would secure photographic transcripts, upon which linguists and archæologists might operate. If the lawless nomads of the desert cannot be reached by firmans or edicts, why should not a strong covering force be organised? Such a crusade would find plenty of volunteers. Excursions to Sinai are not uncommon now that the Red Sea is a highway. But whence the apathy about them? Are there doubts about their reputed genuineness, or are there apprehensions lest their revelations may interfere with the Mosaic traditions?—H. E. H.

[11640.]—**Photographing Sun.**—Is it possible to photograph the sun with a 3in. achromatic telescope mounted on pillar and claw stand without slow motions of any kind?—X.

[11641.]—**Observatory Clock.**—How can I make use of an ordinary clock as a sidereal clock for astronomical purposes?—X.

[11642.]—**Romsey Observatory.**—Has any one ever built an observatory on the Romsey principle, using sheet iron for the walls? Can it be recommended for cheapness and effectiveness?—X.

[11643.]—**Estate Agency.**—I shall be glad to have any information on the subject of estate agency. What are the duties of the profession, &c.?—L.

[11644.]—**Mending Copper.**—Will any subscriber inform me how to put a patch on a copper and make it watertight, without common solder?—M. B.

[11645.]—**Bees (Managing Old Stocks).**—I have kept bees in a small way for some years, but don't know how to manage my old stocks. Soon after they have swarmed they get very weak, and do not get enough food to keep them through the winter. I feed them, but all to no purpose, for they generally die the early part of the next summer. I have a stock now in a Woodbury hive in just such a condition. I am trying to feed them but they will not take the food. I have been told that bees will not stay in a hive more than three years, but I can't think that is true. If Mr. Abbott or any kind reader will tell me the reason and remedy, I should be much obliged.—J. O. Y.

[11646.]—**Electrical Apparatus Wanted.**—Will "Sigma," Mr. Tonkes, or some other contributor on electricity, kindly help a non-electrician in a fix? I want to obtain an electric spark ⅜in. long, by bringing the ends of two copper wires together, to the distance above named (⅜in.), the wires to be brought together and separated again, four times in a second, and the spark not to pass between them when at a greater distance than ⅜in. What will be the cheapest and most effective apparatus to produce the above result for the space of (say) six hours? I have a rotating shaft at my disposal, this can be taken into consideration when comparing cost. What will be the cost of such apparatus, and cost of working per hour? How long would it keep in good order?—J. Hicks.

[11647.]—**Cabbage Plants.**—Will some brother reader tell me how to prevent cabbage plants from running to seed?—Anon.

[11648.]—**Bee Management.**—I commenced bee-keeping near London last year, and as I am away from home during the day I have no one to attend to my bees in my absence. I am anxious to overcome the difficulty of the swarming season by artificial swarming. I shall, therefore, be obliged to some of your astute correspondents, for information as to the best mode of procedure to obtain a swarm from a common hive—the bees being a second May swarm of last year in a healthy and prosperous condition. I intended to try the plan of placing the present hive of bees over an empty hive, and, reversing the positions of the hives, driving the bees into the empty hive, leaving the nurse bees and brood in the old hive. The instructions I have had from bee books are not sufficiently clear. I wish to know whether I am to wait for appearances of swarming, before I commence operations—whether I should raise the hive of bees from the foot-board in the same night as I attempt to drive them? How long the hives should be left together after the bees are driven into the upper one, before they are separated for removal—the old hive to a new place, and the new hive to the old stand? Whether it is advisable or necessary to wear a bee dress? and any other information suitable to the approaching time that may be kindly given. Is it necessary that any stupefying material should be used, as when I formerly kept bees I have not been successful in the application, a great many bees dying from the effects of it, and the stocks never thriving after.—Apis.

[11649.]—**Astronomical Formula.**—Will some astronomer show practically the method of working out the following formula from the *Nautical Almanac* for 1873? Latitude 53° 48′ north, longitude 1° 50′ west. For any place not far distant from Liverpool, the Greenwich mean time of the beginning of the solar eclipse, May 25th, 1873, may be computed by the formula cos. ϖ = 2·0892 − [0·18987] sin. l × [9·98326] cos. l cos. (λ − 114° 0·1′) t = 20h. 58m. 18s. − [3·59312] sin. ϖ · [3·42434] sin. l − [3·82088] cos. l cos. (λ × 16° 26·0′) contact on the sun's limb, ϖ × 23° 38·9′ from the north towards the west.—G. Lennox.

[11650.]—**Annealing Steel.**—I shall be glad to learn from any of your numerous contributors a good process for annealing steel so as to insure free and easy turning with a fine cutter. My present process sometimes results in failure, and gives much trouble in wear and tear of cutters, and greatly retards the work in its progress.—J. A.

[11651.]—**Analysing Ash of Cane Sugar.**—I wish to ascertain the quantity of ash left by burning a sample of cane sugar, but I find great difficulty in burning the sugar away. If, however, I add a small quantity of SO_3, all goes well, and the operation is easily and quickly performed. I do not know what allowance to make in the resulting ash for the SO_3 added. Can Mr. G. E. Davis help me?—Uncertain.

[11652.]—**Tasmania.**—Will any of the numerous readers of the Mechanic inform me of the prospects of an emigrant to Tasmania? What clothing, &c., would be necessary for one who intends to start farming? and would it be advisable to take a gun or rifle to the colony? Any information regarding the above, will trust, be acceptable to more of your readers than to— TASMAN.

[11653.]—**Carving.** — Will some experienced wood carver inform me how long it takes to learn carving? I mean to say, to get a good start in the art. I am very fond of carpentering and turning, and fancy I should like to try carving. On what wood, and with what sort of designs should I commence? Any hints on the subject will be gratefully received.—A. H. COOKE.

[11654.]—**Cleaning Violoncello.**—What is the best way of improving the appearance, without injuring the tone, of a violoncello that has long lain by and become grimy? I was thinking of removing the dirt by turpentine, and then polishing, but having just heard of a violin that has been made "tubby" in sound by polishing (with furniture restorer, and not previously cleaned!) I would rather have some advice before putting my idea into practice.—SCRAPER.

[11655.]—**Making Gold and Silver Leaf Adhere to Fabric.**—Would some reader tell me how to make metal and silver leaf adhere to silk and cotton fabrics. The methods given in No. 359, page 542, do not act very well, and are too expensive.—J. B. SHARPLY.

[11656.]—**Boiler for Small Steamboat.**—Having an iron boat 21ft. long, 4ft. 6in. beam, I am desirous of fitting it with about 1½ horse-power steam-engine, and shall be glad if some of "our" brethren will kindly give me the benefit of their experience in advising as to the best form of boiler to make. It must be rather low, as the stability of the boat is not good.—L. M. F.

[11657.]—**Thorough Bass.**—I was very much rejoiced when you commenced publishing the treatise on music by Mr. Evans, having a desire to become acquainted with the rules of harmony, but I have been disappointed (owing to my obtuseness) in not being able to comprehend much that is therein written. My object in writing this is to ask whether any of our gifted correspondents can point out a work of a more elementary nature that will prepare me for the more effectual study of your treatise, which is "a little before my time." Any hints for my guidance will be most thankfully received.—L. M. F.

[11658.]—**Power to Drive Crown Printing Machine.**—Will some kind correspondent please inform me whether a quarter horse-power engine will drive a crown printing machine? The machine is turned easily by a boy of fourteen. The engine could possibly be arranged so as to work direct with a band from the engine to the machine (thereby saving shafting). If quarter horse would not do, what size would be sufficient? Also, the best form of engine and boiler. Could I raise steam by gas, and what description of boiler (dimensions, &c.) would be required for gas. Also, the amount of gas required per hour. Also, whether using a gas boiler would increase the insurance on the whole house? Any information with regard to above will be gratefully received.—AMPERSAND.

[11659.] — **Black Varnish for Microscopic Objects.**—I have been trying to put a rim of black varnish about my microscopic objects, and failed to come up to those that are done by other preparers. Would any readers furnish me with their method of doing the same?—J. T. A.

[11660.]—**Lead Pipes.**—I purpose laying on the gas in my greenhouse, which is 120ft. from the meter. Will some one kindly inform me if I can convey it through leaden pipes underground (by far the cheaper way), or must I have iron? If so, what is the cost per foot for a small tube?—FLACTEM.

[11661.]—**Photography (Background).**—I wish to make a background of canvas, I should like it a dark slate or lead colour. Will any able reader kindly inform me the best way to commence?—A BEGINNER.

[11662.]—**Colouring Walls.**—I live in the Peabody dwellings, and we have permission to colour or stencil the walls, which are at present a very light cream colour, almost white. I coloured mine last September with a colour in powder, mixed with ordinary size and whiting, but I find after six months' wear it soon rubs off in patches. I should feel obliged if some correspondent will tell me how to colour the walls with a hard or glazed surface, if possible, so that they can be dusted without rubbing off the colour. The surface of wall is Roman or Portland cement, very hard, and tolerably smooth. Will soluble glass do? and if so, how is it to be mixed with colour?—STENCIL.

ERRATUM.—On reading my query (11578, p. 107) over, I find that I have asked "why it is that the meridian passage on p. 4 is only given for the upper limb of the moon." It should have been the meridian passage for the upper transit. I trust that you will insert this correction in your next issue.—HENRY WOODS.

USEFUL AND SCIENTIFIC NOTES.

Formation of Ozone.—Dr. Pincus states that ozone is formed during the burning of hydrogen; and that if a flame of this gas is allowed to burn from a fine point, the smell of ozone can be distinctly recognised. This statement recalls to mind the announcement made some time since by Loew, of New York, that ozone might be obtained in sufficient quantity for purposes of lecture demonstration, by simply blowing the heated air on the edge of an ordinary Bunsen flame, with the aid of a glass tube, into a glass receiver, containing the ordinary reagent for testing an oxidising agent—iodide of potassium, acetic acid and starch—when the blue colouration of the iodide of starch almost instantly makes its appearance. At the time, Loew's announcement met with some objectors, who sought to explain the phenomenon by assuming that the oxidising process originated with certain oxidised nitrogen compounds formed by the heat of the flame. From the fact, however, which is well-known to chemists, that it is impossible to unite nitrogen and oxygen directly, by any means short of the electric spark, the explanation of Loew would seem to appeal correct one.—*Journal of Franklin Institute.*

Waterproof Leather.—An ingenious patent is now being worked, by which leather for the soles of boots and shoes is rendered impervious to wet and damp by exhausting the air from the pores of the leather, and filling them up with a substance which unites with and adheres to the fibre, thereby strengthening without impairing the elasticity of the material. It is stated that the patent, known as "Fanshawe's Waterproof Leather," is not only likely to be largely employed for the purpose to which we have referred, but that when asphalte pavement becomes more general, it will be possible to shoe horses with a material as hard as the asphalte itself, and which will prevent them slipping.

Road Locomotives.—We believe that Lord Dunmore intends to introduce his Road Locomotive Bill into the House of Lords this session. Some unfortunate non-compliance with standing orders prevented its introduction last year; but as no difficulties stand in the way this session, we may hope for at least a discussion on the advisability of relieving road locomotives from the, as we think, absurd regulations which at present hamper their use, and tend to retard their development and improvement. The bill will seek to abolish the regulation which prescribes the use of the red flag in advance of the locomotive, and will allow of a speed of four miles while passing through towns, and eight when on country roads.

Abyssinian or Talmi Gold.—According to Dr. Winkler, writing in *Dingler's Journal*, this is a brass composed of about 91 parts of copper to 8 of zinc. The appearance of gold is obtained by causing a very thin sheet of that metal to adhere by passing the compound through rollers. This gilded sheet is then cut and formed into ornamental articles by means of ingeniously-constructed steel tools.

Conductivity of Copper Wire.—It appears that a very inferior kind of copper wire is finding its way into the market, and has been used extensively in the construction of the coils for use with electric bells. Sir William Thomson has recently tested a large quantity of cotton-covered wire of this character, and found its resistance per metergramme to be ·439 of a B.A. unit, good wire being about ·16 of a B.A. unit.

V. C. A., or Velut Cera Adhaerescens.—Under this rather fantastical name we have received a preparation which will doubtless be found of use by many of our readers in various ways. It consists of sheets of paper gummed on one or both sides and perforated in squares or strips so as to be readily torn up to the desired size. It will be found useful by those who do not keep a gum bottle, or keeping that article have so little occasion to employ it that the gum becomes thick and dirty, and is often not to be found when wanted. For fixing scraps in albums, cuttings from newspapers, and periodicals in an "Index rerum," for mending torn leaves in books, and in many other ways, this prepared paper must be handy, as it can be carried in the pocket-book or kept in the writing desk, and is always ready when wanted. The inventor has also prepared a "glue muslin" and a "glue paper," which merely requires dipping in boiling water to render it as serviceable as the ordinary glue-pot for numerous little "odd jobs," such as mending the binding of books or securing the corners of cardboard boxes, fixing handles on umbrellas, or knobs on drawers. According to the inventor the glue-paper when thoroughly wetted forms a kind of "pulp" that is even stronger than glue when dry. Mr. G. P. Hill, of Redhill, the inventor, says he has no desire to keep the process of preparation secret, but will communicate it to any of our subscribers—the best way of doing which would be to publish it in these columns.

Destroying Aphides.—The black-fly is the greatest enemy to cherries. We append two recipes for its destruction, which, it is said, are effectual in ridding plants of the aphis pest. The first is a mixture of pitch, with one-sixteenth part of powdered orpiment and one-sixteenth part of sulphur, dissolved over a slow fire in an earthern pipkin, until they are well incorporated; when cold, divide it into small pieces about the size of a hen's egg, and burn it under the trees with damp straw, directing the smoke, as much as possible, where the insects are most numerous. A spare piece of sheeting, suspended from the top of the wall, will keep the smoke in position; or if the trees be in the open air quarters, draw on the caps on a moist, mild, quiet, evening, which will keep the smoke a little under. A good syringing or two afterwards will bring down the dead or dying aphides. Mr. Rivers's recipe is a more simple one. He says:—The best remedy is a mixture made by boiling 4oz. of quassia chips in a gallon of soft water ten minutes, and dissolving in it as it cools, 4oz. of soft soap. It should be stirred, and the trees syringed with it twice or thrice. The day following they should be syringed with pure water.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, April 16, and unacknowledged elsewhere:—

Odgen and Gibbs.—J. Gillingham.—Wm. Hill.—Wm. Brown.—John Walton.—Fletcher and Sinclair.—G. R. Prole.—W. F. Healey.—W. H. Cnell.—E. S. Hunter.—Alex. Gilles.—Alex. B. Macdowall.—Soui-Hong.—Geo. Parson.—W. Marden.—C. N. Abbott.—F. C. Richardson.—C. B. Bostock.—Major J. N. Beasley.—Rob. Allen.—A Housekeeper.—Charles Fletcher.—R. A. Proctor.—A Horological Mechanic. — Ginger Beer. — C. S. — Aceticum.—Hector.—F. N.—Apiarian.—A Yorkshire Pivot.—R. S. H.—A. Tabraham.—Comet.—S. Bottone.—Atlas.—R. T.—Loach.—Para.—Farmer.—E. W. J.—F. A. R.—Hydraulican.—Linum.—C. W. M.—P. W. H. J.—Ignoramus.—Joe.—J. X. T.—Gymnast.—Jannifred.—Proudfoot.—Youngster.—Sulphur.— S. B.—J. S.—W. Nicholson.—Bed of Stone.—E. H.—Rev. E. L. Berthon.—Jack of All Trades.—Musa.—Khoda Bux.—Tubal-Kain.—J. D. H.—J. M. Taylor.—C. P. E.—F. L.—Samuel Smither.—M. Paris.—J. L.—J. Kilpax.—C. P.—F. Gray.—W. R. Birt.—Fantail.—E. Barber.—J. H. B.—Journeyman Painter.—Science.—Charles George Payne.—J. F. E.—G. E. H.—Brightonian.—A., Liverpool.—Sorius.—M. A. B.—F. R. Rohn.—Mrs. F.—D. W.—H. T. C.—Inquiring Mind.—S. W.—C. T. B.—F. C. S.—T. A.—An Engine Driver.—J. D.—J. J. Knight.—Hy. Franklin.—Z. A.—S. T.—Neville.—York.—Linea.— C. J. R.— Thetamu.— A Reader.— John Pearson.—A. P. S.—Cincinnatus.—Tinsmith.—A Young Beginner.—Milled.—G. S.—Jasper.—J. H. Graham.—Philo.—Saul Rymea.—P. E. M.—A. M.—E. Parker.—J. S.—A. Macdowell.—W. H. Lockwood.—C. Williams.—James Slater.—W. P.—James Northorp.—Wee Pet.—A Novice.—An Old Subscriber.—Paper Maker.—J. K. P.—An English Mechanic.

? ?—We have not heard of the spiritualistic wonder, and don't believe in it.

ANXIOUS, S. BOTTONE, G. S.—See "Hints to Correspondents," No. 4.

C. G. P.—You would oblige by sending us the letters and post cards referred to in your letter.

NUMISMATIST.—Just seriously ask yourself the question why you should endeavour to injure men who would not injure you?

A SUFFERER.—Ask a chemist and druggist.

J. FOSTER.—We don't know, but you might ascertain by advertisement.

E. G.—We have certainly caught one, and shall administer such punishment as may be deemed advisable.

GEO. HY. SHIEK.—You inclosed no postage stamps.

MUSICAL MONEY-BOX hopes Henry Newman or some one else will give the proffered information on Model of Church, query 11031, p. 672.

UN FABRICANT.—There is no review in England devoted to paper-making.

W. H. PENNY.—See "Hints to Correspondents," Nos. 4 and 6.

R. E. SMITHSON.—No P. O. O. inclosed.

YOIZA.—Optional on the part of writer.

W. KIRKMAN (Nottingham).—Mr. Wallace's pamphlet was printed for private circulation. His address is A. R. Wallace, Holly House, Barking, E. John Beardsley's pamphlet came to hand, but it was simply unworthy of a passing thought. What would you think of a man offering himself as a professor of mathematics, who had never mastered the first rudiments of arithmetic? You might laugh at him, certainly. But might he not be more worthy of pity?

T. BUCK, Jun.—The agent is trying to impose upon you. Cases for any volumes can be had at 1s. 6d. each.

A CRIPPLE.—We cannot assist you. You could only obtain the information by personal inquiry of the proprietors of such establishments.

A COUNTRY PLUMBER.—We do not recommend manufacturers.

Communications which can only appear as advertisements to hand from J. Franklin, Paul Gill, A Joiner, Cincinnatus.

WHITAKER.—A printer's error.

JACK FACE.—Your reply is an advertisement.

J. W. H.—See replies 10696, in last number.

TREBOR.—We do not see how you can dye them white. For other colours use Judson's dyes.

ROBERTUS REEKUS.—Make and try your model engine yourself first.

LEGATO.—Buy the indices to our last five volumes, and you will not again send such a simple question.

MOXLEY.—The Agent-General for New Zealand is J. Morrison, 3, Adelaide-place, London-bridge.

A LEEDS MAN.—Write to the makers, or employ a patent agent to make a search.

J. UNWIN.—Such private communications can only be effected by means of an advertisement.

ANGLO-SAXON.—We have given in back volumes all the recipes for copying ink we have space for.

J. O. J.—Yes; buy the indices. Pianoforte keys will do.

BOOKWORM.—No.

A. M. FESTING.—The letter appears, but it is too late to review the book.

WOODSTOCK.—The queries you refer to are all of a homely but very useful nature; yours is only of use to few.

E. W. S. says he hopes Mr. Denning will commence these problems soon.

W. L.—Yes; please send.

W. C.—We do not remember your reply; probably the others that appeared were already in type. Anything sent on the subject must be sent as all other contributions are, *unconditionally*. We do not encourage you to expect the insertion of any *lengthy* contribution on phrenology.

B. H. H.—Various methods of destroying bugs were given in Vol. XIII. See pp. 394, 423, 445, 468, 647. We cannot repeat a query that has been so recently answered.

"PRIAM" is "glad to see the remarks of 'Manus' concerning the habitual tone assumed by Mr. Tonkes in addressing his fellow contributors." Priam says:—"Humility is the best test of wisdom," and "he who is wise is cautious of his own opinion, and tender to that of others."

A POOR MAN.—Consult a medical man.

M. L. L.—No doubt something will be done in the way of forming a piano alliance before long.

A. O. and R. SPENCER.—Your queries are advertisements.

W. A. WHITE.—Advertise.

KHODA BUX expresses his sorrow that so many personalities have crept into the ENGLISH MECHANIC recently through "Philo," Wm. Tonkes, and "E. L. G.," and hopes that correspondents will constantly remember two things: first, that they are writing on scientific questions; and, secondly, the space of the ENGLISH MECHANIC is precious.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING APRIL 9, 1872.

963 J. J. F. Manent, Paris, for improvements in the principal organs of pumps of all kinds, allowing to apply them to purposes to which the pumps in actual use would be unfit.

964 W. E. Gedge, Wellington-street, Strand, for a new or improved system of hygienic elastic spring bed or mattress. A communication.

965 T. Lowe, Brampton, Derby, for improvements in the manufacture of paper pulp or half stuff.

966 J. B. Croskey, Portsdown-road, Maida-hill, for an improved system or process for making asphaltic or bituminous pavements.

967 C. Delattre, Roubaix, France, for applying potatoe starch or its derivates for the sizing of woollen or worsted warps or yarn.

968 W. R. Lake, Southampton-buildings, for improvements in paper rag engines. A communication.

969 B. Platt, Widnes, Lancashire, for improvements in purifying turpentine and resin or resinous substances and obtaining the the spirit therefrom, and in apparatus employed therein.

970 T. Don, Redhill, Surrey, and R. A. Wright, Homerton, for improvements in treating fibrous, ligneous, and textile substances and fabrics for the production of substitutes for leather, gutta-percha, papier-maché, and other manufacturing materials, and for other useful purposes; also in manufacturing articles from such substitutes, and in preparing agents used in the said treatment, and in apparatus employed in the said manufacture.

971 J. H. Johnson, Lincoln's Inn-fields, for improvements in liqueurs or cordials and other beverages, and in apparatus to be employed in their manufacture. A communication.

972 W. Benson and J. J. Hetherington, Northumberland, for improvements in machinery or apparatus for washing and dressing ores.

973 J. H. Johnson, Lincoln's Inn-fields, for improvements in the treatment of hair bristles and feathers. A communication.

974 J. Ashbury, Sussex-place, Hyde-park, for improvements in apparatus for propelling and steering vessels for inland navigation. A communication.

975 F. Prudencio and J. F. Cotterell, Bath, for an improved apparatus for stoppering bottles.

976 W. E. Hodgson, Kennington-park-road, for improvements in the manufacture of bread and other farinaceous food.

977 W. R. Lake, Southampton-buildings, for improvements in apparatus to be used in combination with a gas burner for concentrating the light of the same. A communication.

978 J. Gowans, Edinburgh, for improvements in machinery used in the construction of tramways and railways and applicable to other purposes.

979 W. R. Lake, Southampton-buildings, for an improved compound for cleansing carpets and other woven fabrics. A communication.

980 A. R. D. Mackenzie, St. James's-square, for an improved construction of iron steam-ships for trading purposes.

981 H. Young and A. Kitt, Horseferry-road, Westminster, for improvements in the purification of illuminating gas, and in apparatus to be used therefor.

982 B. Boby, Bury St. Edmunds, for an improved construction of cultivator or scarifier.

983 J. F. M. Rigod, Paris, for an improved apparatus for carburetting air.

984 J. L. Casartelli, Manchester, for improvements in pyrometers.

985 R. H. Huch, Brunswick, Germany, for improvements in coffee machine.

986 C. G. Hill, Nottingham, for improvements in machinery for goffering, fluting, and crimping fabrics.

987 J. O. Hanctin, Paris, for improvements in machinery for pounding, grinding, and mixing moulding sand and other substances.

988 J. G. Pembery, Carlisle-street, Lambeth, for a new or improved application of machinery or apparatus for propelling canoes and small boats generally.

989 J. C. Sellars, Chester, for improvements in obtaining hydro-carbon liquids, gas for illuminating and heating purposes, and coke.

990 A. A. Rossignol, Paris, for an improved apparatus for reporting music played on the pianoforte, organ, harmonium, and other analogous musical instruments.

991 F. C. B. Robinson, Teddington, for detaching both tackles simultaneously from ships' quarter or other boats when being lowered, by means of disengaging tumblers.

992 W. R. Lake, Southampton-buildings, for an improved subsoil implement chiefly designed for making trenches or ditches for drainage and other purposes. A communication.

993 W. Whittle, Harborne, Staffordshire, for improvements in the manufacture of nails and spikes, and in machinery to be employed in the said manufacture.

994 J. F. Lafrogne, Paris, for improvements in the manufacture of gas for lighting and heating, and in apparatus employed therein.

995 W. E. Newton, Chancery-lane, for improvements in packings for the working parts of steam engines and other machinery and apparatus. A communication.

996 J. H. Johnson, Lincoln's Inn-fields, for improvements in machinery or apparatus for sewing boots and shoes. A communication.

997 C. Delattre, Roubaix, France, for improvements in cotton-sizing machines for the purpose of rendering them applicable for the sizing of woollen or worsted warps.

998 J. Baynes, Manchester, for improvements in headings and borderings for woven fabrics.

999 J. F. Warbrick and J. Clegg, Bolton, for an improved apparatus for ascertaining and registering the number of persons entering in or upon a vehicle or into any place of public entertainment.

1000 S. E. Asquith, Leeds, and F. A. Greenwood, Bradford, for improvements in machinery for spinning silk, cotton, wool, and other fibrous substances.

1001 J. Reynolds, Belfast, Ireland, for improvements in roving or slubbing frames, partly applicable for imparting motion in other machinery.

1002 W. R. Lake, Southampton-buildings, for an improved method of and machinery for utilising the butts and other parts of railway rails. A communication.

1003 C. Stevenson, Milngavie, N.B., for improvements in apparatus employed in converting esparto, straw, wood, and other similar substances into pulp.

1004 B. Hunt, Serle-street, Lincoln's Inn, for an improved speed indicator for railway and other similar purposes. A communication.

1005 W. Wright, Sheffield, for improvements in valves and apparatus for flushing water-closets and other purposes.

1006 J. Ormerod and D. Speirs, Waterfoot, Manchester, for improvements in the mode or manufacture of a certain colouring matter.

1007 G. Tidcombe, jun., Watford, Herts, for improvements in apparatus for the cutting of paper, which improvements are also applicable to other apparatus requiring changes of speed.

1008 W. Walton and J. T. Fallows, Denton, Manchester, for improvements in and machinery for rolling wire for making wire cards and for other purposes.

1009 J. Cochran, New Barnet, for improvements in valves, applicable to use on the overflow pipes of water and other cisterns or vessels.

1010 H. Reeves, Bratton, Wiltshire, for improvements in the construction of elevators for stacking hay, corn, and straw.

1011 E. G. Brewer, Chancery-lane, for improvements in the construction of railways, in rolling stock for same, and in other apparatus connected therewith. A communication.

1012 A. V. Newton, Chancery-lane, for an improvement in the mode of and apparatus for obtaining and metallicising electrotype moulds. A communication.

1013 F. Coales, Chicheley, Bucks, for an improvement in the manufacture of beer.

1014 W. Clay, Birkenhead, for improvements in tools for cutting and shaping metals, and in the means of keeping the same cool while in use.

1015 J. R. Wigham, Monkstown, Dublin, for improvements in illuminating lighthouses, beacons, harbour lights, and light ships.

1016 G. T. Bousfield, Brixton, for sewing and other machine treadles. A communication.

1017 R. S. Wright, Inner Temple, London, for improvements in obtaining motive power, and in the apparatus or means employed therefor.

1018 J. H. Johnson, Lincoln's Inn-fields, for improvements in heating and in apparatus employed therefor. A communication.

1019 W. R. Lake, Southampton-buildings, for improvements in theodolites. A communication.

1020 E. Feldtmann, Mark-lane, City, for a new or improved universal mandril. A communication.

1021 W. N. Nicholson, Newark-upon-Trent, for improvements in horse rakes, part of such invention being applicable to other machines.

1022 J. W. Smith, Oxton, Cheshire, for an improvement in the ventilation of sewers and drains.

1023 A. B. Wimpenny, Hayfield, Derbyshire, for improvements in the construction of smoothing irons.

1024 J. Worrall, Manchester, for improvements in the process of scouring, dyeing, washing, and drying piece goods, and in apparatus to be employed therein.

1025 W. E. Newton, Chancery-lane, for improvements in governors or apparatus for regulating the speed of steam or other motive-power engines. A communication.

1026 A. Pilling, Rochdale, for improvements in ventilating mines.

1027 J. Webster, Birmingham, for improvements in the manufacture of iron and steel, and in the recovery of certain gases resulting from the operation.

1028 M. Tildesley, Wolverhampton, for an improved oven for annealing cast iron.

1029 M. Tildesley and M. Barnard, Wolverhampton, for improvements in the manufacture of door fasteners and like articles.

1030 J. A. Telfer, Campbell-terrace, Bow, for improvements in the construction of borders, edgings, or moulding for tables and other similar articles of furniture.

1031 S. Norris, Lombard-street, City, for an improved pavement.

1032 A. M. Clark, Chancery-lane, for improvements in the manufacture of illuminating gas and in apparatus for the same. A communication.

1033 H. A. Laurence and L. A. Laurence, Lower Clapton, for improvements in the manufacture of hats, bonnets, and shapes, and in apparatus for such manufacture.

1034 A. Friedmann, Vienna, for a new method of collecting sediments of tubular steam boilers and apparatus employed therein.

1035 T. Nutting, Rhode Island, U.S., for improvements in machinery for spinning wool or various other fibrous matters.

1036 F. Hurd, Wakefield, and S. Firth, Leeds, for improvements in machinery for excavating coal and other minerals and in the permanent way for the rails of the same.

1037 F. E. Saxby and J. Winnington, Lorn-street, Hulme, for improvements in machinery or apparatus to be used for the purpose of regulating the supply of cotton and other fibrous material to machinery used in the preparing, manufacturing, or finishing of the same.

1038 J. H. Mills, College-street, City, for improvements in apparatus for generating heat by the combustion of gas.

1039 J. H. Mills, College-street, City, for improvements in steam boilers.

1040 J. B. Muschamp, Kensington, for a new or improved aërating egg beater and mixer.

1041 L. Herrmann and A. Laurent, Belgium, for improvements in the manufacture of lamp shades made of porcelain, ceramic, or other plastic materials.

1042 T. Mitchell, Cullingworth, Yorkshire, for improvements in machinery for doubling and twisting two or more yarns or threads of fibrous substances.

1043 A. M. Clark, Chancery-lane, for an improved loom for weaving. A communication.

1044 W. R. Lake, Southampton-buildings, for improvements in the manufacture of pulp from vegetable fibres for making paper and other materials. A communication.

PATENTS SEALED.

2618 E. V. Neale, for improvements in apparatus or appliances for stopping and regulating the extent of angular motion, and intended, though not exclusively so, to be adapted to doors and French and other windows.

2633 N. Wilson, for improvements in sewing machines.

2641 J. P. Furness, for an improved mode of fixing teeth or knives to the rod or back of reaping and mowing machines.

2646 J. Ball, for improvements in the manufacture of reaping hooks and sickles, and in the means or apparatus to be employed therein.

2647 G. L. Scott, for improvements in ventilating mines and tunnels.

2651 W. R. Lake, for improvements in grain elevators, chiefly designed for the loading and unloading of ships and similar vessels.

2654 G. Stevenson, for improvements in apparatus for the preparation and manufacture of iron and steel.

2657 J. Darlington, for improvements in steam and pneumatic engines.

2661 M. Tossell, for an improved mode or means of ventilation.

2666 J. Stockley and M. Stainton, for improvements in and applicable to steam engines and boilers.

2674 T. Walker, for improvements in the construction and working of lithographic and letter-press printing machines.

2675 H. Hughes, for improvements in apparatus for attachment to windows, doors, and steps of buildings.

2694 J. Flower, for improvements in or connected with "smiths'" forges.

2706 J. E. Holmes, for improvements in teeth for saws and in devices for securing the same, partly applicable to saws for cutting stone.

2709 J. S. Templeton, for improvements in apparatus to be used in weaving looped-pile fabrics.

2726 W. Leatham, for improvements in ambulance carriages and other vehicles for the removal of the sick or wounded, being also applicable for field hospitals and other purposes.

2728 H. Williams, for improvements in tents and other weather protectors.

2741 G. Loughton, for improvements in balances or weighing machines.

2745 R. Pinkney, for improvements in the production of colours from aniline in dyeing and printing.

2749 J. S. Crosland, for improvements in steam boilers or generators.

2812 H. Jackson, for improvements in apparatus for heating water by means of steam or for condensing vapour.

2821 W. Haworth, for improvements in machinery for rolling tea leaf.

2857 G. Camp, for improvements in the construction of harmoniums.

2868 W. Gossage and F. H. Gossage, for improvements in the manufacture of sulphate of soda by the decomposition of chloride of sodium, and of sulphate of potassa by the decomposition of chloride of potassium.

2875 W. R. Lake, for an improved method of preserving wood.

2943 A. V. Newton, for an improved construction of twine cutter.

2979 C. Fairbairn, for improvements in bolt-making machinery.

2993 J. Macintosh, for improvements in waterproof compounds for covering roadways, footpaths, floors, or other surfaces.

3169 D. Stewart, for improvements in sugar-cane mills.

3317 E. H. Bentall, for improvements in machinery for manufacturing screw bolts and nuts, part of which improvements is applicable to the working of other automatic machinery.

3415 H. Ashworth, for improvements in the construction of shuttles.

3477 J. W. W. Shaw, for an improved depilatory composition for hides and skins.

3494 J. C. Mewburn, for improvements in the manufacture of dolls and other like figures for the amusement or instruction of children, or for artistical purposes.

50 J. H. Johnson, for improvements in the regeneration of heat for furnaces, and in the apparatus or means to be employed therein.

59 J. H. Johnson, for improvements in melting furnaces.

80 J. H. Johnson, for improvements in discharging or tapping molten metal from furnaces or crucibles, and in casting the same into moulds.

419 J. H. Johnson, for improvements in steam generators, and in the mode of applying heat thereto.

420 J. H. Johnson, for improvements in refrigerating apparatus.

491 W. R. Lake, for improvements in mowing and reaping machines.

447 J. A. Hodgson, for an improved apparatus or gear for driving a screw propeller when the engines are broken down at sea.

463 T. Bear, for the adaptation of mica or talc to water gauges to steam and other boilers.

500 W. R. Lake, for improvements in the manufacture of boots and shoes, and in machinery therefor.

530 D. G. Low, for an improved sail hank.

538 W. R. Lake, for an improved lawn mowing machine.

2677 W. Yates, for improvements in miners' lamps.

2681 J. Tagell, for an improved automatic nut-screwing machines.

2683 J. M. Joannides and L. M. Adutt, for a new or improved apparatus for ventilating and protecting or preserving goods when packed.

2683 W. Clark, for improvements in steam boilers and in cleaning apparatus for the same.

2680 W. Simmons, G. W. Simmons, and G. Smith, for improvements in the means, method, and apparatus for printing zincographic and other impressions.

2692 W. Bowker, for improvements in drilling machines for drilling the holes in guide plates, card cylinders, and other parts in connection with Jacquard machines, part of the improvements being also applicable for punching metal plates.

2695 W. H. Ronald, for improvements in umbrellas, sunshades, and parasols.

2708 G. A. C. Bremme, for an improved construction of wheel for traction engines and other vehicles.

2720 E. Heywood, for improvements in washing machines, part of which is also applicable to other squeezing rollers.

2721 G. Zanni, for improvements in magnetic bells and signals to render the same more simple and economical for telegraphic and domestic purposes.

2727 S. Moorhouse and W. J. Kendall, for improvements in mechanism or apparatus to be employed for signalling on railways.

2733 J. Horrocks, for improvements in pickers used in looms for weaving.

2734 J. R. Macfarlane, for improvements in apparatus for charging and drawing gas retorts and for other purposes.

2737 C. Randolph, for improvements in common road steam carriages, and in part applicable to railway locomotives.

2775 J. R. Napier, for improvements in water-pressure speed indicators.

2793 W. R. Lake, for improvements in the pistons and slides valves of steam engines, and in apparatus connected therewith.

2797 A. Guattari, for improvements in pneumatic telegraph apparatus.

2805 L. M. Casella, for improvements in maximum registering thermometers.

2810 J. Webster, for the manufacture of metallic lead paint.

2890 A. M. Clark, for improvements in electric telegraph apparatus.

2904 G. W. B. Edwards, for improvements in drills or machines for setting corn and seeds.

2910 A. M. Clark, for improvements in rollers used in spinning machinery.

3008 H. Wells, for improvements in railway permanent way applicable to the passing of drainage and irrigation waters.

3033 C. G. Johnson, for improvements in apparatus for drying and burning bricks and other similar articles.

3125 J. Castle and C. Turton, for improvements in the manufacture of aickles.

3234 J. Oldroyd and M. Oldroyd, for a new or improved carpet

3298 R. Booth, for improvements in apparatus employed in manufacture of British gum and other artificial gums.

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

FRIDAY, APRIL 26, 1872.

ARTICLES.

METALLURGY OF IRON AND STEEL.*

(*Continued from p.* 111.)

PIG-IRON is essentially iron and carbon; when these two things are heated together strongly they combine, and if the temperature be high enough to fuse the product we get pig or cast iron. There are some remarkable properties about this pig-iron, essentially it is iron and carbon combined in certain proportions; with other proportions of carbon we get various kinds of steel. If we take pig-iron containing a large proportion of carbon, say some four or five per cent., and melt it in mass, and then allow it to cool very slowly, on examining the product we shall find it to be gray pig, having a granular, dark-grayish, white appearance. The carbon in the mass after melting, if allowed to cool slowly, separates throughout the entire substance, in the form of graphite (crystallised in cubical system); acids do not attack it. Gray pig-iron is, therefore, essentially metallic iron with graphite diffused through it, and we may make it so that nearly the whole of the carbon is separated as graphite by the act of slow cooling.

If we take a mass of gray pig-iron, melt it, and instead of allowing it to cool slowly, cool it rapidly, then it is possible to get a product so entirely different in appearance from gray pig-iron that we can hardly believe that one may be transformed into the other. This is white pig-iron. In some cases we can get a product partly white and partly gray. The fracture of white pig iron is very different from that of gray, so also is the colour, being a uniform white; it is likewise much harder and highly crystalline. If the white pig be acted on by an acid, as common muriatic, &c., we get a brown residue quite different in appearance and chemical composition from that which is left in the other case, with no graphite or no sensible portion of it. Yet it consists chiefly of carbon in a totally different state from graphite. If graphite be treated with caustic potash or soda no action occurs, but this residue is dissolved if so treated. In the white pig the carbon is in a state of combination. If gray pig-iron is cooled very rapidly we get a particular kind of pig-iron called Spiegeleisen (from the German word spiegel, meaning a mirror), now in great demand for the Bessemer process, and imported in large quantities from Germany, and some from Sweden, and we also make a small quantity ourselves, but we have only a limited quantity of suitable ore. It contains a large proportion of manganese, in some cases as much as 10 per cent. It contains also 5 per cent. carbon, and although other matters are generally present, about 85 per cent. of iron. When manganese is present it is found that the whole, or nearly the whole of the carbon, is retained in combination. This variety is exceedingly hard, and when freshly broken is very bright. Perfectly pure iron would not be acted on by acids. If we take white pig and act on it by acid, and cool the gas evolved, it is possible to get some remarkable products from it, or at least one product from which others can be obtained. If, for example, the hydrogen evolved when iron is acted on by oil of vitriol be produced by iron containing carbon in combination, then union between the hydrogen and carbon takes place, and the result is a volatile oil. The lecturer exhibited a quantity of liquid hydrocarbon obtained from Spiegeleisen in the metallurgical laboratory connected with the institution.

Conversion of Pig-Iron into Malleable Iron.

In former times the process adopted was very simple, and charcoal was always the fuel employed. Usually a square forge-like hearth was employed for that object, with one jet of blast s in a blacksmith's forge. A given quantity of pig-iron was put into the furnace along with the charcoal, and by means of a powerful blast the r was enabled to reach the surface of the metal. e iron was burnt immediately into the oxide, and so was the carbon in that portion of the iron. The result was the formation of the oxide of iron, and the workmen then used to stir up the whole mass and mix it up thoroughly with the molten pig-iron, and finally bring out of the furnace a lump weighing about three hundredweight, exactly similar to the lump produced in the Catalan forge. All the malleable iron in this and other countries was, until recently, produced in this manner.

In the above case there was direct contact between the charcoal and the molten iron. Now, charcoal is devoid of one impurity which exists in all coal and coke—namely, sulphide of iron. This ancient mode is still carried on in South Wales, and extensively in some parts of Staffordshire. The best kind of iron known for tinning is called charcoal plate, and is manufactured by this process, being the only stage of the process in which charcoal is used at all.

If we take some pig-iron and pound it, or otherwise finely divide it, and then mix with it oxide of iron (the scale of iron seen on the surface of iron after a red heat is oxide of iron), and heat the mass so as to melt it, we should get a vigorous action between the carbon and the oxygen. If we took a given weight of pig-iron and reduced it to coarse powder, and knew the exact quantity of carbon it contained, then if we added a proper quantity of oxide of iron to supply the oxygen requisite to burn the carbon into carbonic oxide, we should get wrought iron. So that by intermixing the oxide with it in the right proportion and exposing to a high temperature we could burn up the whole of the carbon. The same principle is employed in the process of "puddling;" in both cases the oxide of iron is used, being either added or generated.

The question is how to accomplish the conversion of pig into wrought iron economically on a large scale. It would incur a great expense to reduce the iron to powder, &c. When wood became dear, and consequently charcoal scarce, attempts would be made to substitute coal or coke for the charcoal. If coke were applied in the former process in the same manner as charcoal a very bad article would be the result. It became essential to devise some means of using coal so as to prevent contact between the solid fuel and the pig-iron operated on. That was accomplished in the so-called reverberatory furnace where the two are kept completely apart. A reverberatory furnace is one where the flame is reflected or reverberated down on to the material to be heated. If we make the flame from one of these furnaces to act upon the pig-iron, the latter may be satisfactorily and economically converted into malleable iron. That is done in puddling.

Puddling.

This process is ascribed to a Mr. Cort, who took out a patent for it in 1784. The process is known as Cort's puddling process; the history of it is very interesting and somewhat painful. Cort spent his private fortune, about £20,000, in carrying out these investigations. After this a gentleman employed in the Admiralty advanced him money, which subsequently was found to be not his own, but the nation's. Thereupon the Government came down upon Cort. The other unfortunate individual died, and the Government, instead of allowing Cort to work his way and pay off the money, which he would soon have done, stopped the whole thing, and gave what advantage there was to certain ironmasters, whereas they might have recouped themselves a hundredfold. Cort died a ruined man, depending for subsistence upon a small bounty from the public purse. Here was a man who systematically developed this process by which not only private individuals, but the nation at large, has been immensely benefited, yet that man was allowed to die only just out of the workhouse.

Other persons had puddled iron by much the same process as Cort shortly before him, but it is perfectly certain that these persons did not appear to be aware of the value of that process, and Cort was the first to develop it on systematic ground. Remember, the principle is the removal of carbon from pig-iron in a reverberatory furnace so as to prevent contact with the solid fuel

A reverberatory furnace consists essentially of three parts—the fireplace, the bed, and the "stack" or high chimney. The fireplace is separated from the bed by a wall of fire-bricks—the "bridge"—reaching up some distance towards the roof, and often a little wall separates the bed from the flue, where it is much contracted. All these must be made of good fire-brick, or other highly refractory material. Underneath, the wall rests upon an iron girder. About the bridge the temperature is very high, and must consequently be kept down. This is done by placing a cast-iron girder, anchor-shaped, and protected from the fire by fire-brick, opposite it is another girder, and over the top another piece of cast iron, the whole encased in fire-brick, somewhat overhanging, and thus affording means for a free circulation of the air.

In former times, when Cort lived, the bed was made of sand, agglutinated together by oxide of iron, but this did not answer well. In 1819 Mr. Rogers substituted the use of iron bottoms, which has proved to be a very important improvement. Like Cort, he died in great poverty a few years ago. Since then these bottoms have been everywhere adopted. They consist of two parts, one called the frame, of cast iron, and laid between the fire-bridge and the flue wall; the other portion consists of four flat plates of iron dropped into the frame. These latter are supported by girders of wrought iron running along and resting on standards of cast iron. All underneath this bottom is left perfectly clear, so as to allow of a free contact with the air, and thus the intense temperature is kept down, which would of course otherwise be sufficient to fuse the bottom itself as well as the materials laid on it. The walls of the furnace somewhat overhang the bed, and also certain stops are put so as to make a border running round, except facing the door.

The bottom of the furnace is covered with "fettling," and for this purpose we cannot do better than take some kinds of iron ore, or of slag, the latter well calcined—"bull dog;" take the fettling right under where the walls overhang. The door is an iron frame, filled in with fire-brick, and suspended on a lever worked between two projecting ribs. The door may be wedged up, leaving a draughtway between the chimney and the edge of the door; there is also a small hole in the bottom of the door. The door drops upon a piece or bar of iron, called a fore plate, and the puddler has to work a long iron rod resting upon this fore plate. The action of this rod soon wears away the fore plate where it acts, and this is to some extent provided against by cutting out a piece of the iron from the plate at this place and putting in a piece of much harder iron, which can be renewed from time to time. The fore plate rests on a vertical plate of cast iron containing a hole with a plug, through which the slag is from time to time tapped out. The whole of the furnace is cased in plates of cast iron, supported on standards, tied at the top by tie rods. It may be observed how large the fireplace is in comparison with the bed. The roof of the furnace dips down towards the flue.

Now, let us suppose the furnace in working order, being heated ready, the last charge having just been drawn off. The puddler is there—it takes a good strong man to be a puddler. Now take a charge of pig-iron, weighing (say) about 4cwt., the iron to which the common name of forge pig is applied. Put in the furnace along with this, or rather previous to the iron, on an average about 1cwt. of smithy scales—in fact, oxide of iron. The iron is melted, and after a time we are struck by the appearance of boiling in the metal, and it rises up considerably and swells up so as sometimes to come out at the hole in the door. This phenomenon is called pig boiling, and the process is comparatively modern. The boiling is caused by the generation of carbonic oxide gas and its escaping through the molten metal. After a time the boiling subsides, and in proportion as the cast iron loses carbon it becomes less and less fusible, and wrought iron is produced in bright grains, multiplying very rapidly, and by-and-by the puddler will collect all those small portions into a series of balls, each weighing about 80lb., and in one hour and twenty minutes these balls are drawn from the furnace in succession, and subjected to mechanical treatment, and made into bar iron. There is also produced a very infusible silicate of iron, being the combination of the silicon in the pig-iron and iron, every one part of silicon carrying off not less than four of iron.

What is known as "puddle-bar" is nothing more than a spongy mass of malleable iron, containing slag in its pores; when the balls are taken out of the furnace at an exceedingly high temperature they are pressed in a squeezing apparatus at a welding temperature, the slag is squeezed out, and we get a bloom or metallic mass. It is next passed under grooved rollers and drawn out, into puddle bar, which is a comparatively impure bar iron.

(*To be continued.*)

* An abstract report of a course of lectures by Dr. ...cy at the London Theatre of the Geological Museum.

CAPILLARITY.

When the end of a capillary tube is thrust into a liquid, such as pure water (the tube having been previously moistened with water), the liquid rises in it, quickly at first, and the rate of rise is gradually diminished as the liquid approaches its ultimate limit, which it is very slow of reaching in tubes of small diameter. M. Decharme is investigating this spontaneous upward movement, and he proposes the following points for inquiry :—Is the motion retarded uniformly or irregularly? What is the nature of it? How do the rate of ascent and the space vary, by the end of a determinate time, with the diameter and inclination of the tube, the nature and temperature of the liquid, and with such physical and chemical properties as density, specific heat, boiling point, equivalent, &c.? What liquids rise most rapidly? and do these reach the greatest height, or is the opposite the case? What relation does this kind of rise bear to that of liquids moving in a tube under constant pressure? What is the relation between this capillary motion and the endosmotic motion of the same liquid?

With regard to the nature of the motion, he finds from experiment that it is not uniformly retarded. If a curve be drawn to represent the numerical results connecting the space with the time, each liquid being under identical conditions of experiment, it appears that while the curve has for some liquids some analogy to a parabola in the first part of its development, it departs from this more and more in proportion to the time, its latter part approaching to a hyperbola. It belongs to the category of logarithmic curves, and M. Decharme has not yet satisfied himself as to its formula.

He gives the following general results from his experiments :—

1. Each liquid has its own rate of motion in a capillary tube (say) one millimetre in diameter, the liquid and tube being kept at a fixed temperature—zero (*e.g.*).

2. For the same tube, kept at the same inclination, and for different liquids taken at the same temperature, the rates of rise are not in direct proportion to the ultimate lengths of the tube occupied. Viscous liquids, such as sulphuric acid, glycerine, or oils, have a slower initial and continued motion than very fluid liquids like alcohol, sulphuret of carbon, or ether, and yet the former rise higher than the latter. The rate of rise is, moreover, neither in an exactly inverse proportion to the entire time occupied, nor to the density of the liquids. The law appears to be somewhat complex.

3. Of the liquids submitted to experiment (more than 150, chosen principally from the chlorides, iodides, bromides, and the salts of ammonia, potash, lithia, glucina), the aqueous solution of hydrochlorate of ammonia had the quickest rate of rise—a rate which increased in proportion to the salt dissolved, and which exceeded that of water in proportion as the temperature was raised. Chloride of lithium in aqueous solution, the only liquid which, after the solution of sal-ammoniac, rises higher than pure water, has a rate of rise considerably less than that of water, which is surpassed by those of a large number of liquids. It is to be remarked that an alcoholic solution of sal-ammoniac, in conditions identically similar, always rises less rapidly than anhydrous alcohol, while at the same time it reaches a greater height ultimately. Chloride of lithium diminishes similarly the rate of rise of its solvent, but the alcoholic solution does not rise so high as the pure alcohol.

4. For all liquids, rate of rise in a capillary tube increases with the temperature. Even water, when near its maximum density, is not an exception to this law. It may be stated, however, that if the rate increases in a continuous manner, between zero and 10° or so, it increases much more rapidly if the temperature is further raised. The increase in rate of rise due to temperature varies besides with the rate of rise peculiar to the liquid. This rate, in some cases, is even doubled for an elevation of temperature 50°.

5. For each liquid, and the same inclination of the tube, the motion by the end of a unit of time, or, more simply, the space passed in a second, increases in proportion to the diameter of the tube.

6. For the same liquid, and the same tube, the rate of motion increases with the inclination of the tube. In proportion to the time, these differences in rate of motion successively diminish, then disappear, then show themselves in the contrary direction, and the heights ultimately reached are inversely as the diameters. So that the curves relating to one tube and one liquid do not cut each other, while the curves relating to one liquid and to tubes of different diameters, placed at the same inclination, cut each other at points which are nearer the initial point, in proportion as the difference of diameters is greater.

A. B. M.

ASTRONOMICAL NOTES FOR MAY.

By a Fellow of the Royal Astronomical Society.

The right ascension of the Sun at Greenwich mean noon on May 1st is 2h. 35m. 46·82s., and his declination north is 15° 15′ 21·6″. He will consequently form a roughly equilateral triangle with the two small stars, π and σ Arietis. He rises in London on the 1st at 4h. 33m. a.m., and sets at 7h. 21m. p.m.: while on the 31st his rising and setting will take place at 3h. 51m. a.m., and 8h. 4m. p.m. respectively. On and after the 22nd there will be no real night, inasmuch as, even at midnight, the Sun will never descend more than 18° below the horizon, and twilight does not cease until his angular distance from it exceeds that quantity. The equation of time is subtractive during the whole of May. On the 1st 3m. 6·03s. must be taken from the instant of apparent noon to obtain the time which a properly-regulated clock ought to show; while on the 31st, 2m. 34·28s. must be subtracted from the time shown by a transit or sundial to get true mean time. The semi-diameter of the Sun at his Greenwich transit is, on the 1st, 15′ 53·8″, and this occupies 1m. 6·09s. of sidereal time (convertible into mean time by the subtraction of 0·18s.) in its transit. On the 31st the Sun's semi-diameter will have diminished to 15′ 48·2″, and the meridian passage of such semi-diameter will take 1m. 8·37s. of sidereal time (or 1m. 8·19s. of mean time, to complete. The sidereal time at mean noon on the 1st is 2h. 38m. 52·87s., and on the 31st, 4h. 37m. 9·57s.: the mean time at sidereal noon—or mean time of transit of the first point of Aries being 21h. 17m. 37·25s., and 19h. 19m. 39·93s. on those days respectively. The absence of Solar activity, as indicated by the paucity and small size of spots, &c., continues.

The Moon will be New on the afternoon of the 7th at 1h. 18·7m.; enter her first quarter at 4h. 5·6m. on that of the 15th; be Full at 11h. 8·3m. on the night of the 22nd; and enter her last quarter on the 29th at 2h. 12·4m. in the afternoon. She is 23·5 days old at noon on the 1st, and so on until the same hour on the 7th, when her age will obviously be 29·5 days. Then on the 8th at noon her age will be 0·9 day, and, increasing *de die in diem*, 23·9 days on the noon of the 31st. Libration will, at 7 in the morning of the 5th, render more of her S. W. quadrant visible; and at 3 a.m. on the 19th it will cause additional surface in her S. E. quadrant to come into view; while again on the 31st, at 9 at night, the same cause will operate in once more bringing an extra portion of her S. W. limb into view. The Moon will be in conjunction with Venus at 8h. 48m. in the evening on the 5th; with Mercury at 2h. 44m. a.m. on the 6th; with Mars at 5h. 9m. in the afternoon of the 7th; with Jupiter at 1h. 54m. a.m. on the 13th; afterwards with Uranus at 7h. 58m. a.m.; and, lastly, with Saturn at 5h. 34m. a.m. on the 26th.

There will be a small partial eclipse of the Moon, visible at Greenwich, on the night of May 22nd; but even at the time of greatest obscuration, the magnitude of the eclipse will only amount to 0·116, the Moon's diameter being taken as = 1. The first contact with the shadow will happen at 177° from the north point of the Moon's limb, towards the east (*i.e.*, in point of fact, almost at the southern part of the lunar limb), the last contact at 143° towards the west. In each of these cases we assume the Moon to be viewed with the naked eye, or with an ordinary terrestrial telescope.

		h.	m.
First contact with penumbra, May 22	...	9	9·8
First contact with shadow	„ ...	10	40·9
Middle of the eclipse	„ ...	11	18·2
Last contact with shadow	„ ...	11	55·5
Last contact with penumbra	„ ...	13	26·6

The Moon will occult no less than twelve fixed stars during May, and come almost into contact with three others, as viewed from Greenwich :—First, on the evening of the 12th, B.A.C. 2514 will disappear at her dark limb at 6h. 59m.; reappearing at her bright limb at 8h. 10m. Then on the 16th, just as 42 Leonis is setting, at 2h. 1m. a.m., it will disappear at the Moon's dark limb; it will emerge (below the horizon) at 2h. 36m. from behind the bright limb; but will, as a matter of course, be invisible here. On the evening of the 17th, at 8h. 5m., ν Virginis will disappear at the dark limb; reappearing at the bright one at 9h. 20m. At 9h. 15m. on the night of the 19th 65 Virginis will disappear at the dark limb of the Moon; as will 66 Virginis at 10h. 8m. 65 Virginis will reappear at the dark limb at 10h. 25m., and 66 at 11h. 20m. Then, at 2h. 44m. the next morning, l^2 Virginis will be occulted by the dark limb, but will set ere its reappearance at the bright one at 3h. 41m. On the evening of the 20th, at 8h. 28m., κ Virginis will disappear at the dark limb, reappearing at the bright limb at 9h. 8m; while at 2h. 54m. the next morning 2 Libræ will be similarly occulted, setting, however, ere its reappearance, at 3h. 36m. At 9h. 15m. in the evening on the 21st the Moon will pass quite close to ν^1 Libræ. On the night of the 22nd ω^1 Scorpii will be occulted at 9h. 26m., and ω^2 Scorpii at 9h. 52m.; in each case at the Moon's dark limb —which, however, in this case, will be very close to the enlightened part. ω^1 will reappear at 10h. 34m., and ω^2 at 10h. 59m., both, of course, at the bright limb. At 1h. 13m. in the early morning of the next day (the 23rd) B.A.C. 5395 will disappear at the Moon's bright limb; reappearing from behind her dark limb at 2h. 24m. The moon will pass quite close to 39 Ophiuchi at 2h. 26m. a.m. on the 23rd. Afterwards at 4h. 10m. θ Ophiuchi will disappear at her bright limb. Its reappearance from behind the dark one will take place at 4h. 49m. after it has set. Lastly, at 2h. 49m. a.m. on the 28th the Moon will be almost in contact with 37 Capricorni.

So unfavourable a month for the observation of planetary phenomena as May, 1872, is hardly within our recollection.

Mercury, having passed his inferior conjunction on the 24th of April, is now travelling towards the west again; but his proximity to the Sun during the earlier part of May, and his consequent rising, southing, and setting in the glare of bright twilight and daylight, will render him invisible. On the 22nd at 9h. 5m. a.m. he will attain his greatest elongation west (25°) from the Sun; but, inasmuch as his declination north will be considerably less than that of that luminary, he will even then rise in twilight too bright for him to be discernible save by the aid of an equatoreal. He will be, as before, observed in conjunction with the Moon at 2h. 44m. a.m. on the 6th, and with Venus at 10h. 52m. a.m. on the 8th.

Venus is moving towards her superior conjunction. Her diameter diminishes slightly during May; being about 11″ at the beginning and about 10″ at the end of the month. *Mutatis mutandis*, all our remarks with reference to the bad position of Mercury in the sky apply with equal force to this planet too. She will, as just remarked, be in conjunction with Mercury at 10h. 52m. a.m. on the 8th, and with the Moon at 8h. 48m. on the evening of the 5th.

Mars is invisible during the whole of this month; being in conjunction with the Sun at 3h. 50m. on the afternoon of the 17th. He will be in conjunction with the Moon, as previously intimated, at 5h. 9m. on that of the 7th.

Jupiter is the single conspicuous object in the sky during the earlier part of the night, and may be seen in the west and north-west part of the heavens up to about 1 a.m. at the beginning of the month, and until a little after 11 o'clock at the end of it. He rises on the 1st at 8h. 55m. a.m., souths at 5h. 0·6m. in the afternoon, and sets at 1h. 7m. the next morning; while on the 31st his rising, southing, and setting takes place at 7h. 23m. a.m., 3h. 22·5m. p.m., and 11h. 23m. p.m. respectively. He is now travelling slowly from Gemini into the confines of Cancer, and the crooked line which he forms with Castor and Pollux during the early part of the month approaches to a straight one towards the end of it. He will be within a degree of μ^2 Cancri on the night of the 31st, and almost exactly south of that star; and will, further, be in the immediate neighbourhood of Uranus, which will be very slightly to the west of him at this date.

As a matter of course, the phenomena exhibited by Jupiter's satellites are becoming fewer and less perceptible. Beginning with the 1st evening of May. Perhaps the ingress of the shadow of satellite 2 at 7h. 43m., and the egress of that satellite itself at 8h. 13m. may be caught in the twilight. When it gets darker, the ingress of satellite 1 will begin at 9h. 52m., the egress of the shadow of satellite 2 will take place at 10h. 40m., and the ingress of the shadow of satellite 1 at 11h. 5m. If Jupiter be not too near the horizon satellite 1 may be seen to leave his disc 11 minutes after midnight. On the night of the 2nd satellite 2 will reappear from eclipse at 10h. 35m. The egress of the shadow of satellite 1 at 7h. 34m. in the evening of the 3rd, and the occultation of satellite 4 at 12h. 28m. the same night, may perchance be perceptible. On the night of the 6th the egress of satellite 3 will take place at 9h. 13m., its shadow not entering on to Jupiter's opposite limb until 10h. 30m. Perhaps the beginning of the transit of satellite 2 may be discerned at 8h. 1m. p.m. on the 8th. Its shadow will afterwards enter on to the planet's face at 10h. 21m., and the satellite itself pass off at 10h. 57m. Afterwards at 11h. 50m. the ingress of satellite 1 may possibly be detected. This same satellite 1 will disappear in occultation at 9h. 2m. on the night of the 9th, to reappear from eclipse under very unfavourable circumstances for observation 30m. 28s. after midnight. It is possible that satellite 2 may be seen to reappear from eclipse at 8h. 3m. 42s. on the evening of the 10th. Afterwards the egress of satellite 1 will take place at 8h. 39m., and that of its shadow at 9h. 49m. If it be not too light, the ingress of the shadow of satellite 4 may be seen at 7h. 54m. in the evening of the 12th. On the night of the 13th satellite 3 will begin its transit at 9h. 55m. The ingress of satellite 2, on Jupiter's disc, will occur at 10h. 46m. on the night of the 15th. On that of the 16th satellite 1 will be occulted at 11h. 1m. During the evening twilight of the 17th satellite 3 will reappear from eclipse at 8h. 6m. 38s.; and the transit of satellite 1 begin at 8h. 18m. Subsequently at 9h. 24m. the ingress of the shadow of satellite 1 will occur; while the egress of the satellite casting it will happen at 10h. 37m. Immediately afterwards at 10h. 38m. 30s. satellite 2 will reappear from eclipse; and finally, if Jupiter be not too low down, the egress of the shadow of satellite 1 may, perhaps, be caught at 11h. 44m. On the next night, that of the 18th, satellite 1 will reappear from eclipse at 8h. 54m. 41s. Satellite 4 will be occulted in bright twilight at 7h. 51m. on the evening of the 20th. Under similar unfavourable circumstances, the reappearance of satellite 3 from occultation at 7h. 57m.; the occultation of satellite 2 at 8h. 18m., and the disappearance of satellite 3 in eclipse at 8h. 37m. 44s. will occur during the evening of the 24th. Later, satellite 1 will begin its transit at 10h. 16m.; and its shadow at 11h. 18m. The observation of the latter phenomenon is problematical. The same may be said of the reappearance from eclipse of satellite 1 at 10h. 50m. 3s. on the night of the 25th; of the egress of its shadow at 8h. 7m. on the evening of the 26th, and lastly, of the occultations of satellites 3 and 2 on the 31st at 8h. 44m. in the evening, and at 11h. 2m. at night respectively.

Saturn is now coming into view again, but is only above the horizon for a short time and at very inconvenient hours. He rises on the 1st 49 minutes after midnight; souths at 4h. 54·1m. the next morning; and sets in bright sunlight at 8h. 59m. a.m. On the night of the 31st he rises at 10h. 43m., souths at 2h. 48m. 8s. the next morning, and sets at 6h. 53m. He remains in a very barren region in Sagittarius; and is still far too low down for effective telescopic scrutiny. He is, as mentioned previously, in conjunction with the Moon at 5h. 34m. a.m. on the 26th.

Uranus, very slightly to the east of the position which he occupied last month in Cancer, is so near to Jupiter that, for all practical purposes, the observations which we have made above with reference to the rising, southing, setting, and general visibility of the latter planet, will apply equally to him. He will be precisely south of μ^2 Cancri about the middle of May. His conjunction with the moon at 7h. 58m. a.m. on the 13th has been before referred to.

Neptune is much too close to the Sun to be visible.

It is exceedingly debateable whether anything like a well-determined shower of meteors occurs during this month. If such a one exists it should happen about the middle of May.

Peat Fuel in Canada.—Prepared peat has been used as a substitute for wood on the Grand Trunk Railway of Canada with a result that 100lb. of the peat lasted longer than half a cord of wood. It is reported that those concerned are satisfied of the superiority of the new fuel, the supply of which is practically inexhaustible.

METEORITES.

THE following is the substance of a lecture by David Forbes, F.R.S., delivered at St. George's Hall, London:—After giving a sketch of man's knowledge of the subject from prehistoric times, the lecturer referred to the superstitious ideas which commonly associate the appearance of these bodies with impending calamities, or even the destruction of our globe, and showed that in ancient times amongst the Greeks and Romans, as well as in later times amongst the Tartars and Negroes, meteoric stones were regarded with extreme veneration, and even worshipped as representatives of the gods themselves. The idea of their containing within them treasures, which often, even in this century, led to their being broken into fragments, might, he thought, have originated from the practice, common in still earlier periods, of concealing valuables within the statues of the gods to protect them from pillage. If this custom had prevailed in prehistoric times, it would have led to the discovery of a metal far more valuable to man than gold—viz., native iron, which composes the mass of many meteorites. He believed that iron had been known as a meteoric product ages before it had been extracted from its ores, and he regarded the fable that Vulcan forged the thunderbolts of Jupiter as evidence that the ancient Greeks knew fallen stars or meteorites to be composed of iron; and that the similarity of the Latin word "sideres," the stars, with the Greek "sideros," iron, was more than a mere accidental coincidence. Mention was made of several Asiatic and American nations who, without knowing the art of smelting iron ores, used meteoric iron for their weapons and tools, such as the Mexicans, Esquimaux, and Jakuts. Coming down to historical times, the Chinese were stated to have kept elaborate records of meteors from as early as the seventh century before Christ, which had now been translated and found to be of great value to European astronomers. Allusions were then made to those meteorites mentioned by the ancient Greek and Roman writers, and to the apathy with which this subject was regarded during the middle and last centuries. The modern study of meteorites was stated to date from the publication, in 1794, of Chladni's memoir on the great Siberian iron meteorite, which, although at first received with derision from his advocating the celestial origin of these bodies, directed the attention of the learned to their examination. A description of the phenomena attendant on meteoric falls was next given, with explanations of the causes of these appearances, and it was stated that, besides those which fall at sea or beyond the reach of observation, it had been estimated that 700 must fall per annum on our sphere, or about one each year on a tract of country as large as Great Britain and France. The mineralogy, chemistry, and physical structure of meteorites were next entered into by the lecturer, who remarked that in these respects meteorites are totally distinct from any known terrestrial products, natural or artificial. Of the sixty-four chemical elements which compose our globe, nineteen have been found in meteorites, and as no single element has been discovered in them which was not previously known on earth, it is supposed that the more distant parts of the universe are similar in composition to our sphere. The discovery that meteorites contain hydrogen occluded within them proves this gas to predominate in the space from whence they have descended, and consequently that the atmospheric conditions there must be totally different from those which obtain on the earth. The different theories which have, from the oldest time downwards, been propounded to account for these bodies were next inquired into, and shown to prove that the most probable, and now most generally received, explanation has its germ in a crude hypothesis of the ancient Greeks, and that the united labours of later scientific men, amongst whom Schiaparelli was the most prominent, lead to the conclusion that falling stars, meteors, meteorites, and comets are all similar bodies, differing only in size (probably composed of fragments of planetary bodies drawn within the influence of the sun's action), which from their extraordinary elongated orbits do not form part of our system as at first constituted, but are falling stars bearing the same relation to comets as asteroids bear to planets. In conclusion, the lecturer drew attention to the question of the utility of meteorites in the economy of nature—the two suppositions advanced being, first, that of Mayer, who maintained that by their falling into the surface of the sun they restored to it the heat which it loses by radiation to this earth and other parts of the universe; whilst the second is the startling hypothesis advanced last year by Sir William Thompson, that the origin of life on our globe, and introduction from time to time of new species, is due to the arrival of aërolites, which, being fragments of other worlds upon which life already existed, have carried with them the germs of seed, or even "living plants and animals." This later hypothesis the lecturer strongly protested against, both because the received theory of meteors teaches that they are bodies which have been revolving, probably for countless ages, in space devoid of atmospheric conditions; and because we find that meteorites have been so heated as actually to melt and vitrefy their external surface: so that no vegetable or animal seed or germ, could be expected, under such conditions, either to retain its vitality, or to reach the earth unconsumed.

THE NEW PHOTOGRAPHIC PROCESS.

THE new urano-bromide emulsion process, devised by Colonel Stuart Wortley, was made the subject of a paper recently read before the Dry-plate Club, from which we abstract the following details:—

It will not be necessary for me to occupy much of your time in giving you the formula, as simplicity is one of the most prominent features of the process; and you are all so well versed in the various technicalities of dry-plate photography, that the minor details need not have much time wasted over them. My search has been particularly directed to two points—one, the obtaining of a negative by a dry process which should have as much delicacy and quality as a wet negative, in opposition to the hardness usually associated with dry plates; and another, the preparation of an emulsion which will keep in a highly-sensitive condition, without change, for a month or six weeks. To do this I have availed myself of certain properties possessed by the nitrate of uranium.

A long series of experiments undertaken when I was working the Wothlytype process convinced me that a delicacy of image greater than could be obtained by other means was secured by the use of that salt; and as the collodion prepared and sensitised for Wothlytype remained in a sensitive state for years, I felt sure that I should obtain important results by using nitrate of uranium in combination with bromide and nitrate of silver. You will remember how strenuously I advocated last year the necessity of a very large excess of nitrate of silver if great sensitiveness were required in an emulsion, and I do not depart in any way from anything that I then said. In point of fact, every grain of nitrate of silver that is added to an emulsion up to saturation increases the sensitiveness of the resulting emulsion. Although nitrate of uranium is capable to a certain extent of replacing nitrate of silver, I do not prefer to use it in that way where great sensitiveness is required; on the contrary, I still use plenty of silver, and use the nitrate of uranium to give stability to the emulsion, extra sensitiveness, delicacy of image, and a power of restraining fog analogous to that possessed by free bromide, but without the loss of sensitiveness and other injurious tendencies which accompany the use of the latter.

Another remarkable point in connection with nitrate of uranium is the great advantage it has where redevelopment is required, as the uranium in the film is acted on by the silver in the developer, and great additional power is thereby obtained. I have made many experiments as to the use of the nitrate of silver and uranium separate, but have not succeeded so well as by combining them in an emulsion. I recommend you, if you wish to try the process, to commence with the following formula:—

Plain collodion	1	ounce.
Pure anhydrous bromide of cadmium..	7	grains.
Nitrate of uranium	30	„
Nitrate of silver	18	„

Samples of nitrate of uranium vary considerably, and I purify what I use in the following manner:—Dissolve one part of uranium in two parts of ether, and let stand for some hours; the water of crystallisation that is in the uranium will fall to the bottom of the bottle, leaving a top layer of ether containing pure uranium, and it is this top layer which is used for the preparation of the emulsion.

I think it is desirable that the nitrate of uranium should be acid; and should it not, after solution in ether, give an acid reaction to test paper, it will be advisable to add to it a minim or two per ounce of acid. Both nitric and acetic have answered in my hands, and, on the whole, I should be inclined to recommend the former. It must be remembered that great caution is to be exercised in the use of a mineral acid in collodion, as if too much be used the film becomes rotten and breaks up in washing.

This brings me to a point which I am anxious to impress strongly upon you—viz., that to succeed with an emulsion process the first and most essential requisite is to have a collodion suited to the work. Some kinds of cotton give a collodion from which a good result cannot be obtained, and I feel sure that many experimentalists fail in getting an emulsion to work satisfactorily from the use of a collodion unsuited to this peculiar work.

I hope this process may have a fair trial at your hands, and I must ask you not to forget that it is one of entire novelty, and that the conditions of its working are somewhat different to those of any process with which I am acquainted. I say this because there is an unfortunate tendency among photographers, when they try and do not succeed to their satisfaction with a new process, to throw the blame of their failure upon it; whereas, in truth, the blame should be laid upon their own imperfect acquaintance with the conditions of the process, or, what is still more likely, that they are using chemicals which are unsuited to the peculiarities of the process.

With regard to the development, I think I need not take up much time on that subject. I will say, however, that I prefer to use a strong alkaline developer. And here, again, nitrate of uranium has its use, as it certainly enables one to use (combined with its other good qualities) a developer sufficiently strong to render the development of a dry plate no longer a tedious operation. One point I must here ask leave to impress upon you strongly—namely, the great latitude allowable in the development of a plate with this emulsion, whether used wet or dry. In either of these cases the amount of bromide in the developer has a marked effect on the result. If, then, very sensitive negatives are required, or very rapid development, use bromide in the developer in minimum quantity. If, on the contrary, you like to be slow and sure, use plenty of bromide, and take your time about the development. Again: always intensify, if intensification be required, before fixing, so as to utilise the uranium in the film. One last point:—The light in your dark room must be as orange as possible, and a light which is quite sufficiently orange for the wet process will not be orange enough for working the emulsion process.

I may mention that, having been consulted by many friends as to the peculiarity of various dry plates that they were experimenting on, I found out in many cases that the failure was due to the weakness or badness of either the pyro. or the carbonate of ammonia. The pyro. that is used should certainly be of the best kind, and the carbonate of ammonia, as you are doubtless aware, varies much in its qualities, and in an old sample it frequently happens that but little ammonia is present.

I will not occupy your time with a discussion on preservatives, particularly as every one has, in all probability, a pet one of his own. I am somewhat pleased with my own latest one, however, as it possesses two peculiar advantages—one, in that it keeps any time after it is made; and another, that it obviates any tendency to blistering of the finished plate. I have brought down this negative to show you what, in my opinion, is the quality of negative we should seek for in a dry plate. It was taken with fifty seconds' exposure in my studio, with Dallmeyer's rapid rectilinear lens for 18 × 16 plates, of 28in. focus, and yet you will notice that under those adverse circumstances it has borne a somewhat pushing development without losing the delicacy of its lights, or bringing any fog into the shadows.

SOME RECENT IMPROVEMENTS IN ENGLISH AND AMERICAN BOILERS.*

By W. Forsyth Black.

ANOTHER most important enemy to combat is incrustation. In all cases it is a bad conductor of heat, and prevents the contact of the water with the plates of the boiler, so that they become overheated, and are, consequently, rapidly destroyed. Circulation of water in a boiler depends on the difference in weight of two columns, the lighter of which is displaced by the heavier. To produce this we must have one column or body of water exposed to the heat, by which means it becomes lighter, and the other protected from the heat, that its descent may not be prevented; as thus it remains heavier than the former by its lower temperature.

The following may be considered the essential principles to be observed in the construction of a good boiler, both for the economical raising of steam-power, and for the prevention of destructive explosions.

1. A steam-boiler should be constructed of the greatest practicable number of parts, or, as Mr. Miller calls them, "units," so that the giving way of one of these through excessive pressure will relieve the whole boiler.

2. Each part or unit should constitute, so to speak, a complete boiler, having its water space exposed to the fire, its steam space above the fire, and a receptacle for sediment below the influence of the fire.

3. All heating surfaces should be as nearly vertical as the principle on which the boiler is constructed will permit to the plane of the fire.

4. Free and perfect circulation of the water should be secured by exposing thin films of water to the heat, which water shall ascend, and large spaces for the water not exposed to the immediate action of the heat, which water from its lower temperature shall descend.

The most striking feature in the boiler I shall now proceed to describe is that cast iron is the material employed in its construction. This description of metal is an excellent conductor of heat, and when the material itself, or the form of the boiler, may be imperfect, a timely warning will be given by cracking, even under low pressure, when fire is applied, and when it breaks or gives way the fracture that ensues is sharp and square.

The strength of a boiler does not ultimately depend on the tensile strength of the material of which it is constructed, it depends primarily on the adaptation of its form to resist internal pressure, not on the strength of its weakest part to resist rupture. The extreme strength of Low Moor plates is 65,000lb. to each square inch of cross section, and that of cast iron of good quality is 40,000lb. Sir William Fairbairn has given it as the result of careful experiment that 25 per cent. must be deducted for even perfectly riveted joints, which approximates it more nearly to the cast iron strength. There is another element of weakness in wrought-iron boilers of the ordinary form which should not be lost sight of, and that is the great strain and even distortion to which several of the plates have to be subjected to bring them into the desired form. The plates so treated are stretched, pulled, and hammered sometimes more than the iron can bear, and their strength is, consequently, much diminished before they are fixed in the boiler.

There are few, if any, explosions which are not traceable to ignorance, carelessness, or cupidity on the part of somebody—the engineer, the manufacturer, or the purchaser of a boiler either known to be insufficiently and poorly constructed, or of which nothing whatever is known. It is impossible to guard against such things, but it is surely not impossible to construct a boiler of such form and material that its explosion shall occasion the least possible disaster to life or property, and that such explosion shall be localised, that this most essential end shall be obtained; and, in addition, that by such localisation, repairs shall be effected at the least outlay of labour and money.

The American cast-iron safety boiler, designed by Mr. J. A. Miller, of New York, has been proved successful from an experience of three years in this country, not to speak of what has been done in the United States, where it has been very largely employed. This boiler, as shown in the engraving (Fig. 2), is formed of cast-iron sections or units of two kinds. A series of one of said sections or units is employed over the firegrate, and a series of the other for the portion beyond the firegrate. Each section or unit is cast in one piece, and tested separately to 500lb. by hydrostatic pressure. The front units (Fig. 4) are arched, and are shaped like a U turned upside down, with a pipe at top for conveying the steam to the steam connecting pipe. The rear units (Fig. 5) consist of five vertical tubes cast in one piece, united by a transverse horizontal tube at top and bottom, and finished at top with a flange joint, to which is fixed a cover from which small pipes take the steam on to the steam connecting pipe. The several sections are bolted together at the bottom by flange joints, the front arched units at one leg, and the rear units a single connection in the centre; these connections form continuous longitudinal tubes at the bottom of the boiler, which are closed by flanged cap at each end, as shown in the drawing. The tubes of the front of fire-box units are 7in. diameter inside at bottom, and 6in. at top, and 2ft. 4in. wide in the arched opening; the vertical tubes of the rear units are taper in form, 4in. diameter inside at bottom and 6in. at top, and they are 2ft. 6in. long in the vertical portion, with an average of 2in. clear space between the tubes. The connecting flanges of the rear units are placed out of centre with regard to the tubes, so that simply reversing the units when fixing them together brings the space between the tubes of one unit opposite the tubes oi the next unit for the purpose of more effectually intercepting the flame and heated gases. The castings are ¾in. thick, the rear units weigh about 10cwt. each, and the front arched units about 5cwt. each. Special provision is made for maintaining the circulation in each part of the boiler. In the front arched units a feather is cast in each leg of each unit, and extends from nearly top to bottom, and by this means the ascending current of heated water on the inner or fire side is separated from the cooler water on the outer side of this diaphragm.

In the rear units an internal circulating tube is suspended in each of their component vertical tubes, causing the heated water to ascend through the outer annular space, and the cooler water to descend within the circulating tube, which is of cast iron, and is held in its central position by circular snugs cast on it.

The steam is carried from the top of each of the units by a 2in. wrought-iron pipe branch bent at right angles. These branch pipes are connected to a main horizontal steam pipe of cast iron ... diameter, which extends the whole length of the boiler, and is carried outside the brick setting.

The branch pipes are connected with thi...

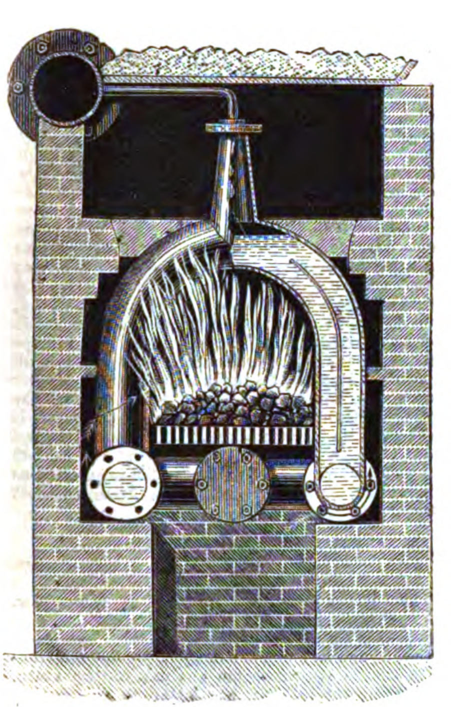

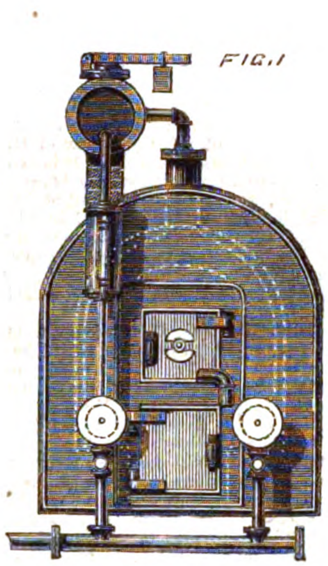

Fig. 5.

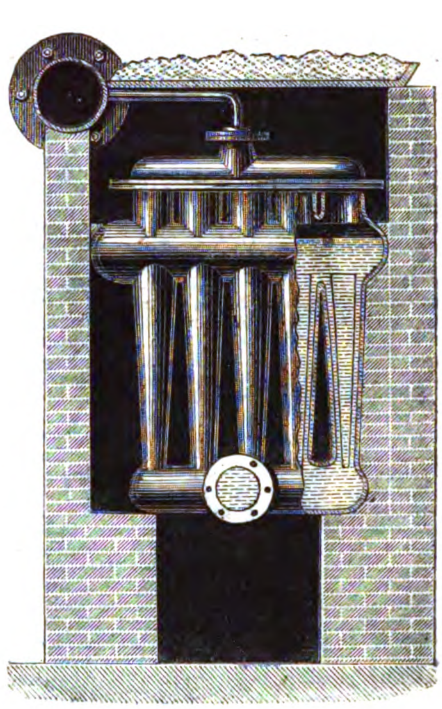

RECENT IMPROVEMENTS IN ENGLISH AND AMERICAN BOILERS.

connecting pipe and with the several units by flanges. The expansion of the cast-iron units when these are heated does not affect the joints, because in the case of the rear units the separate castings are connected together at the bottom only by a single joint, and are thus free to expand without any injury. In the front arched units the effect of expansion is to widen the arch to the extent of about three-eighths of an inch; the arched units are connected to the first of the rear sections for the purpose of affording a continuous water-way through the whole length of the boiler, but as this connection is at one end only they are left otherwise free to expand. The wrought-iron pipe branches connecting the units at top to the main horizontal steam pipe readily spring to a sufficient extent to allow for the excess of expansion of the units without throwing any objectionable strain on the joints.

The joints of the flanges are all carefully and truly faced, and put together with wire gauze and red lead; so that they can be readily separated and re-made if required; they are all finished to a standard template, so that any portion of the boiler can be readily removed and replaced, without disturbing the other units; for the front units are all duplicates, as are also the rear units. The front units are all to the same length of 11in. at the bottom joint, and the rear units to 12in. All joints are so placed that they are thoroughly protected from the fire, and are found to continue steam-tight. The bottom connecting joints are all below the level of the fire, those of front units being below the firegrate, and those of the rear units are covered by the deposit of dust in the bottom of the flue. The joints at the top are protected by a layer of brickwork which rests on the castings (Fig. 2), and the rear units are cast with a small projection which fills up the small spaces between the round parts at water-line, and thus a close top to the flue is formed. The whole boiler is inclosed by side walls of brickwork, which are carried up above, and the top is covered in with loose cast-iron plates that can be readily removed for inspection. A large sight hole with cast-iron cover plate is made in one side wall opposite every alternate unit, which allows of all the surfaces of the cast-iron tubes being cleaned from soot and dust by means of a jet of steam introduced by a flexible pipe through each of the holes in succession; this operation is repeated daily.

Blow-off cocks are fixed on the front ends of the two bottom side tubes, by which means all sediment forming in the boiler is regularly blown out at frequent intervals; the boiler is usually completely blown down once a week, and a small portion of the water is also blown off three times each week. Any deposit accumulating in the bottom portions of the boiler can be raked out when necessary by taking off the flanged bottom covers at the ends of the boiler. The feed water is introduced at the bottom of the boiler below the fire-level. The feed pipe is connected to one of the bottom main pipes of the first arched unit and to that of the first rear unit. The experience of three years' continuous working of this boiler has proved that when it is periodically blown out under pressure, sediment does not injuriously collect in any of the parts that are exposed to the heat of the fire or flue; and the crowns of the arched units which are directly acted on by the fire are found to be completely free from scale. In one instance one of these boilers had not been blown down for a period of seven months, and during that time had been kept at work almost constantly night and day; and the first of the rear units became entirely choked with scale in all the vertical tubes save one, and a crack took place in that tube at about the middle of its height. The fracture, being in cast iron, had a clean sharp edge. The water escaped through the crack, and the steam pressure was eased by this means without any other injury being inflicted, and without any of the brickwork being displaced.

The cast iron bears the heat without injury, because the steam is carried off as quickly as it is generated, and an efficient circulation is constantly maintained, so that the metal of the tubes is constantly protected by having solid water always in contact with it. This boiler has also been applied to balling and re-heating furnaces at iron works, and it appears to stand their great heat without injury.

(To be concluded next week.)

POSITIVE PHILOSOPHY AND MEDICINE.

M. LITTRE has lately published, under the title of "Médecine et Médecins," a series of fragments which had already appeared in various periodicals. He relates in his preface, says a writer in the *Pall Mall Gazette*, that, although he has no medical title and is not a doctor, he has none the less been half a physician all his life. He had completed his medical studies in 1827, and was about to go in for examinations, when the death of his father stopped his medical career by obliging him immediately to seek remunerative occupations. He soon devoted himself almost entirely to the dictionary of the French language undertaken by M. Hachette, but the curiosity of his philosophical mind, his early studies, the personal ties which bound him to famous physicians, always brought him willingly back to medical questions, especially to these in their relation to general science and Positive philosophy.

"Medicine," says M. Littré, "was at the time I began to study undergoing a considerable amendment in doctrine; until then pathology had been considered as a phenomenon which had its cause of being within itself; it was held that disease, fever, inflammation, cancer, was something possessed of independent existence, and having laws of its own. Thus, no connection was supposed to exist between the pathological condition and the physiological; the first was merely superinduced on the second, and the second did not lead to the first. This view was inevitable so long as physiology had not become positive; but it became so at the beginning of this century, and after the interval of time necessary for spreading the influence of the great methods it renewed the whole doctrine of medicine. It became established that no new and peculiar law is manifested in disease; that pathology is nothing but disordered physiology."

"This saying," observes a critic in the *Temps*, "is decidedly happy, and well describes the present state of science. It is certain that there is not, from a philosophical point of view, any sharply defined boundary between health and disease.

Nascentes morimer, finisque ab origine pendet.

The idea of development has not only been followed in the chain of organised beings, in the successive phases of the individual, it has been sought in the history of each anatomical element. Disease is but a disturbance in the development of certain anatomical elements determined by various causes. The experimental method has, of late years, been led into new ways unknown to Auguste Comte; the works of Claude Bernard and his school lead us much further into a knowledge of the organised being than the works of the medical men who have been M. Littré's contemporaries. And yet is not M. Littré surprised that M. Claude Bernard's conceptions have gradually assumed a character which differs more and more from those of the Positivist school. There are phenomena which seem withdrawn from any explanation derived from the purely descriptive and experimental method. Great surprise, for instance, was felt at first on seeing that if a fragment of periosteum be grafted on any fleshy part of the body, the fragment receives nourishment, assimilates the sanguineous elements it requires, develops itself, and becomes a rudiment of bone. Up to this point the phenomenon seems wholly favourable to the materialist school; anatomical elements appear to have a life of their own—a life independent of a more general existence, of a geometrical design, or of a functional arrangement. But what happens? Nature, deceived for an instant, so to speak, soon resumes her rights; that beginning of bone which has no part to play, which would be monstrous if it lasted, does not last; life undoes what it had itself begun; little by little the anatomical elements put out of place become atrophied, are reabsorbed, are drawn into the circulation, and rejected. How is such a phenomenon to be explained? May not the so-called spiritualist school find its account herein? Has it not a right to proclaim that life, that its forms, are subject to laws the expression of which cannot be found in simple contact and in the properties of anatomical elements alone? Is there not here an appearance of a design, of a pre-established anatomical harmony? I merely state the problem. I well know that the Positive philosophy disclaims being either spiritualist or materialist, it has given up searching into causes, and studies only phenomena. But the medical school which has sought its patronage is generally much more inclined to materialism than to spiritualism; and the most serious reproach one can make to it is a dogmatic tone and habits of assertion which seem to exclude all doubts, all hesitations. There is nothing, and perhaps there can be nothing, finished and perfect in the sciences which relate to life. In M. Littré's fine essay on Magendie will be found the most complete exposition of the principles of Positive philosophy in the matter of biology stripped of the exaggerations of some of its disciples. Magendie loudly confessed his ignorance when it came to explaining those vital phenomena which he observed with such rare penetration: 'If I know by what mechanism a membrane imbibes a liquid, I seek in vain that which makes the muscular fibre contract or renders the nerve sensitive.' M. Littré adds that Magendie was quite right to confess his ignorance of this, but this ignorance is neither accidental nor provisional. It is necessary and permanent. The physiologist is not, in regard to the property which renders the muscle contractile and the nerve sensitive, in any other position than the physicist in regard to the property which renders matter electrical, heavy, hot, or luminous. According to M. Littré, no more explanation can be given of physical or chemical qualities than of vital qualities. Science has completed its work when it reaches irreducible things—weight, electricity, life. Life is not in itself more capable of explanation than electricity or heat. One may also invert the proposition, and say that it is not in itself less explicable, and when one is imbued with this thought one is drawn into seeing nothing more complex and more marvellous in the phenomena of life and thought, than in the most ordinary phenomena of inorganic nature. A man who thinks, a stone which falls, are two irreducible phenomena; they exist, and that is all that can ever be known about them. Does not Positive philosophy, which has waged such a war against occult qualities, bring them to life again under another name, and without intending it?"

COAL-CUTTING MACHINERY.

THE importance of adapting machinery to the winning of coal, which, for the most part, has hitherto been accomplished by manual labour, has again, says the *Engineer*, been forced upon inventors and patentees by Mr. W. Firth, of Leeds, who has generously offered £500 to be given for the machine that will bore or hole in the most perfect manner, so as to reduce the quantity of manual pick labour to the minimum. This seems to be about the third attempt which has been made by prizes to induce patentees to develop and perfect this class of machinery. In 1864 the South Yorkshire Coalowners' Association announced their intention of subscribing £500 towards the cost of putting down three machines at as many district pits. The choice fell upon that of Mr. G. C. Jones, of the Elaina Ironworks, Monmouthshire, which consisted of a cylinder bedplate and bearing all in one casting supported on four wheels, the pick was so arranged that it could be fixed in any position, by which means vertical, horizontal, or angular grooves could be cut. After a time the machines were, however, withdrawn. From this time to 1867 no pecuniary inducements were held out, but patentees still contended against the innumerable difficulties which surrounded their track; some of them, as Mr. Firth, of Leeds, expending thousands of pounds in order to perfect as much as possible their own machines. Towards the close of 1867 the members of the South Lancashire and Cheshire Civil Association announced their intention of giving £800 divided in three prizes "for the best machine which, in the opinion of the committee appointed for that purpose, shall be most suitable to the requirements of the trade." To all appearance the progress and development which coal-getting machinery was likely to derive from this liberality promised to be great. This, however, was not the case, as when the conditions were announced it was found that patentees would not contend in consequence of the following clause:—"Inventors taking a prize must be bound by the following conditions, viz., that no annual payment or tonnage royalty as patent right shall be charged to any present or future member of the above association, but that such member shall pay a patent right on the purchase of each machine, to include the working thereof, which patent right shall in no case exceed 50 per cent. of the cost of the machine." This and other conditions caused only three competitors to send machines to be tested, and the committee withdrew the money prizes and substituted three medals. After a period of nearly five years another incentive is offered by Mr. W. Firth, who has deposited £500 in the names of three trustees with Messrs. William Williams, Brown, and Co., bankers, Leeds, pending a trial. That gentleman has expressly stated that the charge made by the owner for royalty or license shall not be a matter for the judges to consider, their decision being founded solely upon the relative merits of the machines produced for competition, so that the rock upon which the Lancashire and Cheshire competition foundered is clearly pointed out, or rather removed. Having pointed out the inducements, we might give a long list of machines which have from time to time been patented or otherwise produced. Many of the oldest pitmen in Northumberland are well acquainted with what was termed "Willie Brown's Iron Man," a machine now being used in the district collieries, as well as in the Scotch coal-field. In 1859 Messrs. Johnson and Dixon, of Newcastle-upon-Tyne, invented a machine which was successfully tested at the Broomhill Colliery, Northumberland, although the pit was worked on the pillar and stall system. In 1862 Messrs. Firths, Donisthorpe, and Ridley, took out a patent for a machine which was set to work in these pits, and, we believe, has remained in use, with the exception of short intervals, when repairs, &c., were necessary. The machine has from time to time been improved, and has stood the test remarkably well. Amongst the more recent inventors may be mentioned Messrs. Copley and Gillot, of South Yorkshire; Mr. Bartholomew, of Doncaster; Mr. Rothery, of the Waterloo Main Colliery, near Leeds; Mr. S. P. Bidder, of Harecastle Colliery, Stoke; Mr. Hurd, Wakefield, &c. Mr. Chubb's coal-breaking machine, which has recently been introduced into several of the Yorkshire collieries, is also working very successfully.

THE BISULPHIDE OF CARBON ENGINE.

THE following remarks on Ellis's bisulphide of carbon engine (illustrated on p. 526) were made by Dr. Vander Weyde at a meeting of the New York Polytechnic Club:—Mr. Ellis, of Boston, has lately constructed a bisulphide of carbon engine, using the waste steam from the engine to heat the bisulphide of carbon, and work another piston attached to the same engine. There have been two objections made to this, which I wish to answer. One objection is that we might just as well have two steam cylinders, making a compound engine, the steam from a high-pressure engine working a low-pressure engine. The other objection is, that if we are to use the bisulphide of carbon, we do not need the steam, and I will reply to this objection first. Volatile substances require very little heat to convert them into vapour. Water requires a temperature of 212 deg. to vaporise at atmospheric pressure, and 966 units of heat become latent. But ether will vaporise at 96 deg., and only 165 units of heat are required. That is an immense saving of fuel. On that idea, some 15 years ago, an ether engine was built at the Novelty Works, New York. But practical difficulties came up. First, it was difficult to get the joints tight; and when it leaked it took fire, and alarmed every one. Another difficulty was, that the latent heat was so much by weight, and the vapour of ether is nearly seven times as heavy as steam. It is a curious property of vapours, that whatever the temperature of vaporisation, and whatever amount of heat becomes latent, in units, the amount of latent heat in a cubic foot of vapour, is always the same; and as engines are driven, not by the weight of the vapour but by its volume, that takes away all the supposed advantage of volatile fluids with regard to their latent heat.

The first objection was, that we might as well use the steam from a high-pressure engine to drive a low-pressure engine. The simple answer to that is, that all the pressure you get from the waste steam becomes back pressure on the first engine, and you have all the machinery and friction for nothing. But if you pass your waste steam freely through tubes which heat bisulphide of carbon, there is no back pressure, and the pressure you obtain from the vaporisation of the bisulphide of carbon is a clear gain. Fairbank and Dunkin, in England, founded a method of judging of the performance of steam-engines, by measuring the water of condensation, as it was done in the recent trial at the American Institute Fair. In the best steam engine, the water of condensation is warmed somewhat, and that amount of heat is lost. Now let us see what is the pressure with different vapours:—

Ether.	Bisulphide of Carbon.	Water.	Pressure.
95 deg.	110 deg.	212 deg.	1 atmosphere.
115 „	130 „	250 „	2 „
125 „	119 „	276 „	3 „
133 „	148 „	291 „	4 „

Now, if we take the steam at 212 deg., you see that it will produce a pressure of much more than 4 atmospheres in the bisulphide of carbon. It is asserted that, by this engine, a nearer approach has been made to theoretic perfection, in the power produced, than ever before.

Another point. In heating water from 212 deg. to about 218 deg., you double the pressure; so that at least 2 deg. are necessary for every pound of additional pressure. But if you heat it to 500 deg., where the pressure is 50 atmospheres, then 15 deg. will produce 15 atmospheres more pressure, or a whole atmosphere for every degree. Here we have to keep the water at 500 deg. and upwards: but there are other liquids that do not require that temperature. Take the liquefied carbonic acid gas, which boils at 148 below zero. Heat it to 100 deg. below zero, and you have 2 atmospheres pressure; an additional atmosphere for about 48 deg. But heat it to 32 deg. and you have 32 atmospheres; and at 50 deg. you have 50 atmospheres, making a whole atmosphere for every degree. It is only necessary, then, to maintain the ordinary atmospheric temperatures, and in the summer all you have to do is to heat with the atmospheric temperature, and to cool with ice. Your engine will require no coal. But you will have this drawback, that melting ice only consumes 140 units of heat, whereas the combustion of coal gives out 14 000 units of heat. For every pound of coal, therefore, you will want 100lb. of ice; and ice is not so easy to keep, especially in the summer, as coal. Another difficulty is that the boiler must be strong enough to stand 50 to 65 atmospheres of pressure. Of course, this whole plan is intensely absurd; but as Cicero said that no theory was so absurd that no man would adopt it, so in mechanics, no plan is so absurd that no one will try to carry it out; and there is a young gentleman now endeavouring to carry out this plan. He will have a back pressure of 50 atmospheres on his piston—a very respectable back pressure.

SILICIAN STEEL.

A SERIES of very interesting steel-making experiments have lately been made in Cleveland, Ohio, which are said to have been completely successful. The materials used were "Silician" ore, mined in York County, Pa., and common Lake Superior pig, puddled together and making steel. Some time since, to solve its doubts, the Cleveland Iron Company ordered several tons of this ore for an experiment. The shippers gave directions as to how it should be used, and 12 per cent. of the pulverised ore was added to a furnace of common pig iron. The mass was worked in the same manner as if bar iron was to be produced, and in one hour after passing through the same operation as the bar does the company had several tons of very fair steel. Tools were made from it. A bar was sent to a manufacturer of springs, and he pronounced it the most tenacious and malleable he had ever tried, and the company immediately secured a contract with an Ohio railroad company for five hundred tons of steel rails. Last week, having procured a quantity of the ore, the Otis Works, of Cleveland, also made an experiment. The per cent. of the "Silician" ore was increased to twenty, the mass was put through the same process as common bar iron, and the result was steel, which has been pronounced equal to any which the cutlers of England can produce. A manufacturer of cutlery in that city gave some of the steel a thorough trial, and he says of it: "Although drawn from ingot to the small sizes we use for blades under very unfavourable circumstances, it comes out, when worked down and hardened, as fine almost as silver—finer even than the best English steel we ever used. It seems to work well all the way through; it works kindly under the hammer, scales well when hardened, polishes black when finished, edges right on the oil-stone, and cuts well and holds an edge. Could I get this steel in the right shape and size, I should like to use it for pocket-knives all the while." Desiring to make a further and severer test, a specimen of the steel was sent to the Remington Manufacturing Company, to see how it would work up in a gun-barrel. The barrel passed through the tests, and was only burst when filled with powder and discharged. It has been tried as springs for watches and clocks, and found to meet every demand required.

THE STAR DEPTHS.

MR. RICHARD A. PROCTOR, Hon. Sec. R.A.S., gave his second lecture on this subject last Saturday at three o'clock. The first portion of the lecture was devoted to the consideration of the spectroscopic analysis of the stars, and its interpretation; the latter to the double stars, and star systems generally. About twenty illustrations were exhibited by means of the electric lamp (worked admirably by Mr. Ladd). Some of the coloured illustrations were of great beauty. Five photographs of the eclipse of December 12 last, taken by Mr. Davis at Baicull, were exhibited, as illustrations of the appendages which we must conceive to surround all the stars regarded as so many suns.

THE DOMESTIC USES OF AMMONIA.

THE utility of ammonia in various domestic transactions is not unknown to many of our readers, nevertheless, it is not so widely recognised as it might be, save when presented under some fancy name at an exorbitant price. We extract the following remarks upon the subject from the *Country Gentleman* (U.S.), with the qualification, however, that the ammonia used for horticultural purposes is invariably the sulphate, which should be dissolved in the proportion of ½oz. to 2 gallons of water:—Ammonia is nearly as useful in housekeeping as soap, and its cheapness brings it within the reach of all. For many household purposes it is invaluable; yet its manifold uses are not so generally known as they should be. It is a most refreshing agent at the toilet table; a few drops in a basin of water will make a better bath than pure water, and if the skin is oily, it will remove all glossiness and disagreeable odours. Added to a foot-bath, it entirely absorbs all noxious smell so often arising from the feet in warm weather, and nothing is better for cleansing the hair from dandruff and dust. For the headache it is also a desirable stimulant, and frequent inhaling of its pungent odours will often entirely remove catarrhal cold. For cleansing paint, it is very useful

[Doubtful. Will it not gradually remove the paint?] Put a teaspoonful of ammonia to a quart of warm soap-suds, dip in a flannel cloth, and wipe off the dust and fly specks, grime and smoke, and see for yourselves how much labour it will save you. No scrubbing will be needful. It will cleanse and brighten wonderfully; to a pint of hot suds mix a teaspoonful of the spirits, dip in your silver spoons, forks, &c., rub with a brush, and then polish on chamois skin. For washing mirrors and windows, it is also very desirable; put a few drops of ammonia upon a piece of newspaper, and you will readily take off every spot or finger-mark on the glass. It will take out grease spots from any fabric; put on the ammonia nearly clear, lay blotting paper over the place, and press a hot flat iron on it for a few moments. A few drops in water will clean laces and whiten them finely; also muslins.

For cleaning hair and nail brushes it is equally good. Put a teaspoonful of ammonia into one pint of warm or cold water and shake the brushes through the water; when the bristles look white, rinse them in cold water, and put into the sunshine or in a warm place to dry. The dirtiest brushes will come out from this bath white and clean. There is no better remedy for heartburn and dyspepsia, and the aromatic spirit of ammonia is especially prepared for these troubles. Ten drops of it in a wineglass of water are often a great relief. The spirits of ammonia can be taken in the same way; but it is not as palatable a dose. Farmers and chemists are well aware of the beneficial effects of ammonia on all kinds of vegetation; and if you desire your roses, geraniums, fuchsias, &c., to become more flourishing, you can try it upon them, by adding five or six drops of it to every pint of warm water that you give them; but don't repeat the dose oftener than once in every five or six days, lest you stimulate them too highly. Rain-water is impregnated with ammonia, and thus it refreshes and vivifies vegetable life. So be sure and keep a large bottle of ammonia in the house, and have a glass stopper for it, as it is very evanescent and also injurious to corks, eating them away.

THE PROGRESS OF GEOLOGY.—CONTAMINATION OF WATER SUPPLY.*

(Continued from p. 116.)

IT has been already mentioned that below a certain level permeable strata are necessarily always saturated and water logged, and that any additional quantity added to this constant quantity cannot be held permanently. It follows that wherever, in all water bearing strata, after allowing for any abstraction, usually but comparatively small, by wells, the surplus rainfall must, when the stratum is full, find its escape by natural means, *i.e.*, by means of springs. The power and size of these are necessarily dependent upon the dimensions of the strata by which they are supplied. In the gravel they are small, in the Lower Tertiary sands moderate; while in the Chalk they are very large. The permanence of the spring depends on the lithological character, as well as on the dimensions of the strata. Thus, in sands, where the water can permeate the mass, the stores are large, and the delivery moderately quick; in Limestones, where the water is confined to cracks and fissures, the delivery is quick and not lasting, though often large; in rubbly Oolites, which are also practically porous, the springs are well maintained; while in Chalk, owing to the characters before named, the water delivery is slow, and the springs are large and very permanent.

At the same time the storage capacity increases with the resistance. Taking the extreme case of the Chalk, the transmission of the rain water is so slow, that, on the chalk hills, it takes four or six months to pass from the surface to the line of water level at the depth of 200ft. to 300ft., so that the heavy rainfall of winter is not felt in the deep springs until the summer, and Mr. Beardmore estimates that the minimum effect of a hot dry summer and autumn is not reached until at the end of about sixteen months, or that the storing power of the chalk is of sixteen months' duration. To estimate this power we have to take the height and extent of the hills, and to note the lithological characters of the permeable strata. If these latter are underlaid by impermeable strata at above the level of the rivers in two adjacent valleys, then the base of the underground water store will be coincident with the level of the impermeable strata, and its surface line will rise, as it recedes within the hill, in proportion to the resistance offered to the water's escape by the character of the permeable strata, and it will thus form a curve between those two points, the height of which will vary in proportion to the rainfall. When, on the other hand, the permeable strata continue down to a greater or less depth beneath the surface of the adjacent rivers, then, as there is no underground escape for the stored water, the line of water-level on these permeable strata will rise to, and be always maintained by, the level of the rivers, and therefore all the additional supplies furnished by the rain must, after traversing the interior of the hills, find an escape along the bottom of the valleys, and by the side or in the bed of those rivers.

The same general rules govern the springs of all the more varied strata of the upper part of the Thames basin, where, in place of the Cretaceous and Tertiary series, we have a series of Jurassic and Liassic strata. Omitting the drift or gravel beds, the following are the average dimensions, character, and superficial areas of each of these formations in that area:—

STRATA OF THE THAMES BASIN ABOVE WALLINGFORD.

	Area.	Average Thickness.	
	Square miles.	Permeable strata.	Impermeable strata.
Chalk (above Kingston 1047)	60	1000	—
Upper Greensands	62	100	—
Gault	129	—	130
Lower Greensands	23	200	—
Purbeck and Portland beds	46	60	—
Kimmeridge clay	132	—	300
Coral Rag and grit	103	40	—
Oxford Clay	307	—	400
Great and Inferior Oolites	327	450	—
Fuller's Earth	16	—	40
Lias	170	—	500

But although many of these water bearing strata are of large dimensions and well stored in the upper part of the Thames basin, none of those below the Gault, except the Lower Greensand, are available for a well supply at London. The Upper Greensand, so important in Wiltshire, is reduced to a few feet of comparatively impermeable argillaceous sands under London. The Oolitic series, so rich in springs in the district of the Cotswold Hills, have been ascertained to thin off as they range eastward; and Mr. Hull has shown that the inferior Oolite and underlying sands in particular die out, in all probability, under the Oxford clay about the centre of Oxfordshire. Even apart, therefore, from the discovery made at Kentish Town, we should now have excluded the Oolitic series as a possible source of supply to deep wells in the London district; although, as sources of springs' supplies, they contribute so important a share to the maintenance of the Thames. Few of those strata are, however, so homogeneous as the Chalk and the London Clay. The permeable formations often contain subordinate impermeable clays—seams which form water levels of more or less importance, whilst the impermeable clays sometimes contain subordinate beds of sand or of rock which constitute small local water bearing beds. It is for the geologist to assign its relative value to each of these subordinate features, and to distinguish the minor from the major sources.

Taking the Thames basin above Kingston, there is, according to Mr. J. D. Harrison, an area of 1,233 square miles of impermeable strata, and of 2,412 miles of permeable strata, and the mean annual rainfall in that district amounts to about 27in. From the impermeable strata the rain flows off immediately as it falls, and is carried at once to sea; whereas a large portion of that which falls on the permeable strata is, as we have shown, stored for a greater or lesser time, and discharged in perennial springs. It is these which give permanence to our rivers. The evidence taken before the commission showed that the daily discharge of the Thames at Kingston, even in the driest season after weeks without rain, never falls below 350,000,000 gallons, while the average for the year gives, according to Mr. Simpson and Mr. Harrison, 1,353,000,000 gallons, or, according to Mr. Beardmore's longer observations, 1,115,000,000 gallons daily, the mean of 1,250,000,000 gallons being equal to a fall of about 8in., or rather less than one-third of the annual quantity, the other two-thirds being lost by evaporation and absorbed by the vegetation. This seems the proportion usual under the like general conditions in these latitudes.

In districts where impermeable strata predominate, the total water delivery, therefore, will be greater; but it follows close upon the rainfall; whereas, where the permeable strata predominate, a large portion of the rainfall is stored in the hills, and its delivery is thereby spread over a greater or lesser period of time, according to the dimensions of those hills. This is well exemplified in the case of the basins of the Thames and the Severn, which latter is formed in large part by the slate rocks of Wales. The former has an area above Kingston of 3,670 square miles, with an annual rainfall of 27in.; whereas that of the latter above Gloucester has an area of 3,890 miles, with an average rainfall of probably not less than 40in., and the mean daily discharge for the year is for the Thames 1,250,000,000 gallons, and for the Severn about 1,600,000,000 gallons. Yet the summer discharge of the Thames averages 688,700,000 gallons daily, against 297,599,040 gallons of the Severn; and while the minimum discharge of the Thames in the driest seasons never falls below 350,000,000 gallons, that of the Severn falls below 100,000,000 gallons. Again, in the case of the Lea, where there is a still larger proportion of permeable strata, the daily discharge at Broxbourne for the year is, according to Mr. Beardmore, 108,000,000 gallons, while for the summer months it remains as high as 71,000,000, and in the driest seasons does not fall below 42,000,000 gallons.

Let us now look at one of the geological questions dependent upon the solvent action of the water on the strata it traverses. The analyses, made for the commission by Drs. Frankland and Odling, of the waters of the Thames and its tributaries in the Oolitic and Chalk area, show that every 100,000 parts or grains of rainwater has taken up a quantity varying from 25·58 to 32·95 grains of solid residue, or an average of 29·26, which is equal to 20·48 parts or grains per gallon; another analysis of the Thames water at Ditton gives 20·78 grains per gallon of solid residue. It was also shown by Drs. Letheby and Odling and Professor Abel that the unfiltered waters of the Thames Companies, which take their supplies above Kingston, contained 20·82 of solid residue. If from the average of 20·68 we deduct 1·68 grain for organic and suspended matter, we have 19 grains of inorganic residue for every gallon of water flowing past Kingston. This is, of course, apart from the sediment carried down in floods.

Taking the mean daily discharge of the Thames at Kingston at 1,250 million gallons, and the salts in solution at 19 grains per gallon, the mean quantity of dissolved mineral matter carried down by the Thames every twenty-four hours is equal to 3,364,286lb. or 1502 tons, or 548,230 tons annually. Of this daily quantity about two-thirds, or, 1,000 tons, consist of carbonate of lime, and 238 tons of sulphate of lime, while limited proportions of carbonate of magnesia, chlorides of sodium and potassium, sulphates of soda and potash, silica and traces of iron, alumina, and phosphates, constitute the rest. If we refer a small portion of the carbonates, and the sulphates and chlorides chiefly, to the impermeable argillaceous formations washed by the rain water, we shall still have at least 10 grains per gallon of carbonate of lime, due to the Cretaceous and Oolitic strata and Marlstone, the superficial area of which, in the Thames basin above Kingston, is estimated by Mr. Harrison at 2,072 square miles. Therefore the annual quantity of carbonate of lime carried away from this area by the Thames is 290,905 tons, or 797 tons daily, which gives 140 tons removed yearly from each square mile; or, extending the calculation to a century, we have 14,000 tons removed from each mile of surface. Taking a ton of chalk as equal to 15 cubic feet, this is equal to a removal of the 900th part of an inch from the surface in the course of a century, so that in the course of 13,200 years a quantity equal to a thickness of about one foot would be removed from our Chalk and Oolitic districts.

I had some faint hope that this wear might furnish us with a rough approximate measure of time in reference to some of the phenomena connected with the Quaternary period; but we are not in a position to apply it. Those curious funnel shaped cavities, called sand and gravel pipes, so common in many chalk districts, are the result of slow solution of the chalk by water at particular spots, whereby the superincumbent sand and gravel have been let down into the cavity so produced. Some of them are but a few feet deep, while others attain dimensions of 80ft. in depth by 15ft. to 20ft, in diameter at top, tapering irregularly to a point at bottom. It is, however, evident from the variation in size that the wear has been unequal; and it is also clear that the surface waters have been conducted through these particular channels, where they existed, to the underground water level, in preference to passing through the body of the chalk, so that the ratio of wear at these points is in excess. Nor can I see at present how otherwise to apply this measure. If it were possible to find a spot where the exposed surface of the chalk has been worn uniformly, and, from the quantity of flints left after the removal of the chalk and the known distance apart there of the seams of flint, to determine the number of feet or inches removed, we might have a base to proceed upon, provided all the quantities remained constant. But such is not the case. Also, although the annual rainfall in the Thames now averages 27in., and has probably not varied much from this amount during the present period, it was evidently much greater during the Quaternary period; for I have elsewhere shown that, in the South of England and North of France the rivers of those areas with the same catchment-basins were of much greater size than at present; and Mr. W. Cunnington had before pointed out the same fact in the upper part of the basin with respect to some of the rivers of Wiltshire. M. Belgrand has made an attempt to estimate this quantity with reference to the Seine and its tributaries, and he arrives at the conclusion that, during the Quaternary (or, as he considers it, the Glacial) period, the rainfall was so heavy that the discharge of the river was from 20 to 25 times greater than at present. I do not altogether concur in this view, but I can conceive that our rivers formerly were of five or six times the size they now are. This is an important element to be considered in all questions bearing on the denudation of land surfaces.

* An abstract of the annual address of the President of the Geological Society.

vital phenomena which he observed with such rare penetration: 'If I know by what mechanism a membrane imbibes a liquid, I seek in vain that which makes the muscular fibre contract or renders the nerve sensitive.' M. Littré adds that Magendie was quite right to confess his ignorance of this, but this ignorance is neither accidental nor provisional. It is necessary and permanent. The physiologist is not, in regard to the property which renders the muscle contractile and the nerve sensitive, in any other position than the physicist in regard to the property which renders matter electrical, heavy, hot, or luminous. According to M. Littré, no more explanation can be given of physical or chemical qualities than of vital qualities. Science has completed its work when it reaches irreducible things —weight, electricity, life. Life is not in itself more capable of explanation than electricity or heat. One may also invert the proposition, and say that it is not in itself less explicable, and when one is imbued with this thought one is drawn into seeing nothing more complex and more marvellous in the phenomena of life and thought, than in the most ordinary phenomena of inorganic nature. A man who thinks, a stone which falls, are two irreducible phenomena; they exist, and that is all that can ever be known about them. Does not Positive philosophy, which has waged such a war against occult qualities, bring them to life again under another name, and without intending it?"

COAL-CUTTING MACHINERY.

THE importance of adapting machinery to the winning of coal, which, for the most part, has hitherto been accomplished by manual labour, has again, says the *Engineer*, been forced upon inventors and patentees by Mr. W. Firth, of Leeds, who has generously offered £500 to be given for the machine that will bore or hole in the most perfect manner, so as to reduce the quantity of manual pick labour to the minimum. This seems to be about the third attempt which has been made by prizes to induce patentees to develop and perfect this class of machinery. In 1864 the South Yorkshire Coalowners' Association announced their intention of subscribing £500 towards the cost of putting down three machines at as many district pits. The choice fell upon that of Mr. G. C. Jones, of the Blaina Ironworks, Monmouthshire, which consisted of a cylinder bedplate and bearing all in one casting supported on four wheels, the pick was so arranged that it could be fixed in any position, by which means vertical, horizontal, or angular grooves could be cut. After a time the machines were, however, withdrawn. From this time to 1867 no pecuniary inducements were held out, but patentees still contended against the innumerable difficulties which surrounded their track; some of them, as Mr. Firth, of Leeds, expending thousands of pounds in order to perfect as much as possible their own machines. Towards the close of 1867 the members of the South Lancashire and Cheshire Civil Association announced their intention of giving £800 divided in three prizes "for the b machine which, in the opinion of the commit appointed for that purpose, shall be most suit to the requirements of the trade." To all pearance the progress and development which getting machinery was likely to derive from liberality promised to be great. This, ho was not the case, as when the conditions w nounced it was found that patentees wo contend in consequence of the following c "Inventors taking a prize must be bound following conditions, viz., that no annual or tonnage royalty as patent right shall b to any present or future member of the sociation, but that such member shall p right on the purchase of each machine, the working thereof, which patent rig case exceed 50 per cent. of the cost of t This and other conditions caused on petitors to send machines to be te committee withdrew the money priz tuted three medals. After a period years another incentive is offered b who has deposited £500 in the nam tees with Messrs. William Willia Co., bankers, Leeds, pending a tri man has expressly stated that th the owner for royalty or licer matter for the judges to consi being founded solely upon the r machines produced for competi upon which the Lancashire a tion foundered is clearly poin moved. SCIENTIFIC SOCIETIES.

ROYAL ASTRONOMICAL SOCIETY.

THE ordinary monthly meeting of this Society was held on Friday, April 12, 1872; Professor Cayley, President, in the chair.

Insufficiency of National Observatories.

Colonel Strange read an important paper entitled as above, and in introducing it he remarked that it might be considered as aggressive, when we had so efficient an observatory at the head of astronomical science in England, presided over so ably by the Astronomer Royal, but he hoped to show that the paper was by no means aggressive. Of late years astronomy had made great advances, especially as regards the physics of the bodies composing the universe. The Royal Observatory was founded in the interest of navigation, and well and nobly had it done its work. The unbroken series of meridional observations, made under the direction of the distinguished astronomers who had from time to time presided over its operations, had conferred an incalculable benefit on astronomy; but the branch which might be appropriately styled "the physics of astronomy" was beyond its present range of observation. He (Colonel Strange) had only to refer to the paper read at a late meeting of the society on devoting an observatory to the especial work of observing the eclipses and transits of Jupiter's satellites (see ENGLISH MECHANIC, No. 357, Jan. 26, 1872, p. 479), to bear him out in advocating the importance of the establishment of observatories for investigating "the physics of astronomy." During a comparatively recent period much had been effected in extending our knowledge of the physics of the sun. In addition to the earnest seizing and utilising of the few precious moments of the intervals of totality on the occasions of total eclipses of the sun, a large amount of time and money had been expended in obtaining a valuable series of photographic pictures of the sun which, he learned with regret, had been brought to a close. He need not mention the men who stood foremost in the ranks of earnest inquirers into solar physics; they were known to us all, but such was the nature of private effort, especially requiring pecuniary outlay, that at any moment a series of observations might suddenly be brought to a close, and to remedy this defect he urged upon the society the importance of placing such inquiries as he had alluded to on a stable footing. There were also men who had taught us how to map the moon, but such was the extent of work required that private resources were quite inadequate to complete it in any reasonable period. Colonel Strange in his further remarks adverted to the connection of meteorology with astronomy. All the variations of climate, alternations of temperature, &c., could, he said, be traced to the dominant influence of the sun, and he, therefore, deemed it expedient that an exhaustive systematic study of the sun should be set on foot, and that a national establishment should be founded for the daily registration of solar phenomena.

The Astronomer Royal, in commenting on Col. Strange's paper, remarked that he had had great experience in the history of observatories, and the general impression on his mind was that no observatory will stand unless it be connected with some secular object—an object of worldly importance. The Greenwich Observatory, he said, was founded for the benefit of navigation and the determination of the longitude, and for these objects steady observations of the moon were necessary, and it should be borne in mind that these observations were not undertaken and continued to the present time for elucidating the lunar theory, but primarily and essentially for the determination of the longitude, and collaterally for this object a branch of the observatory work, to which he had personally given great care, was the rating of chronometers, and no less important was the dissemination of time signals, which were transmitted daily from the Observatory. The Astronomer Royal further remarked that when the Royal Observatory was founded, the theory of gravitation was established, and to employ this theory in the vital question of the longitude needed an extensive series of observations of the moon. To show the importance of the connection of a subject of worldly interest with an observatory, the Astronomer Royal said that, speaking to a friend of the assistance rendered by the Government to the Harton Colliery experiment, the greater portion of the expense of which he had personally borne, his friend replied that as a taxpayer he should protest against the employment of public money for such purposes.

Dr. De La Rue, in connection with the paper read by Colonel Strange, called the attention of the meeting to the importance of establishing a daily record of solar phenomena. He said that the Government have gone to a great expense, no less than £10,000 annually, in obtaining meteorological data, with a view to prognosticating the weather, and issuing weather signals. Seven observatories have been established, at which self-recording instruments are continually at work, and in addition numerous other stations furnish information which is received in London at 8 a.m. daily. This information is published and distributed by 2 p.m. of the day of its reception. The observations thus accumulated are arranged and discussed in various ways with a view of ascertaining the laws of weather changes. This method Dr. De La Rue considered as very cumbrous; centuries, perhaps, might elapse before the laws were discovered, and he pointed out that a secular change of a quarter of a degree in solar radiation would materially affect all our climatic relations. It was his impression that a series of solar pictures during a period of thirty or forty years, at an annual expense of from £300 to £400, would be very important for the Government to take up at this juncture. A picture of the sun obtained every day, furnishing data for the study of sun spots, faculæ, and solar prominences, during cycles of ten or eleven years, would throw much light on meteorological phenomena, for while local influences had great effect on the weather, solar influence was by far the most efficient agent in determining its character.

In referring to the work of an observatory established by the Government, the Astronomer Royal said that it was not that of groping, as it were, in the dark after the causes of phenomena, but the making and collecting of observations for a definite object, immediately connected with some secular advantage to the State.

The Rev. Professor Selwyn announced that the series of sun pictures which had been taken under his superintendence during the last nine years, would be continued until February, 1874, completing the eleven years' cycle.

Discovery of Minor Planets.

M. Borelli communicated a paper containing observations of the newly-discovered minor planet Peitho (118), and of Ægina (91); also of six new nebulæ, and a new variable star. Telegrams had been received at the Royal Observatory from M. Delaunay within the last few days, announcing that two minor planets had been discovered at Paris (119) and (120). Referring to Peitho, discovered by Dr. Luther, Mr. Dunkin stated that this was the nineteenth minor planet which the doctor had discovered, being the greatest number yet discovered by one astronomer.

Binary Stars.

Papers were read from Mr. Hind on the orbits of ξ Boötis, and Σ 1938 (μ^2 Boötis). Observations of ξ Boötis during the next few years will possess great value, and also those of Σ 1938 during the next four years.

The Recent Solar Eclipse.

A paper was read from Mr. Tebbut, of Paramatta, containing observations of the partial phase of the eclipse of December 12, 1871, in which the times of bisection of spots on the sun's disc are enumerated, and on which the Astronomer Royal remarked that such observations were of no use whatever. As regarded the eclipse itself the Astronomer Royal took this opportunity of stating that he had received telegrams from India in the morning of the day of the eclipse, and had forwarded them to the London newspapers in time for publication in the afternoon of the same day.

Mathematical Papers.

The following were read or announced:—

On Proposition 38 of the Third Book of Newton's "Principia," by Todhunter.

The second part of a memoir "On the Development of the Disturbing Function in the Lunar and Planetary Theories," by Professor Cayley.

"On the Method of Least Squares," by J. Lee Glaisher.

At the close of the meeting Mr. Browning exhibited Lord Lindsay's photographs of the late solar eclipse, combined stereoscopically, and Mr. Brothers exhibited a negative of the eclipse of 1870.

Amongst the presents we noticed a fine portrait of the late Charles Babbage, one of the founders of the society.

Removing a Furnace-Shaft Bodily.—The great chimney of the Cabot mill, at Brunswick, Maine, ha been moved 20ft., to allow of the enlargement of the mill. The work was done by a process similar to that by which ships are launched, the chimney being slid along on greased planks. The chimney is 70ft. high and nearly 8ft. square at the base, and it was moved, the flues connected, and the fires started, in eight hours and a half.

Burnt-in Photographs.—The burnt-in photographs in enamel are well known to many of our readers, but it may not be generally known that the process is applicable to the ornamentation of glass. The pattern is drawn by hand on thin transfer paper, and the glass being prepared with a mixture of gum arabic and bichromate of potash, the transfer paper is placed over it and exposed to light. The colouring material is dusted on. This adheres to all parts not affected by the light, and a pattern is obtained which can be burnt in. Prints and woodcuts are by this method easily transferred to glass, but for portraits this process does not work fine enough.

There is yet another point which, although not in our direct field of research, yet depends so essentially upon the geological conditions we have discussed, and is one, in a public point of view, of such paramount importance, that I will say a few words on the subject. In an uninhabited country, the rain passes through the soil and issues as springs, bearing with it a certain proportion of mineral matter, and only traces of such organic matter as existed on the surface. This would be solely of vegetable origin, and the proportion would be in most cases very small. As man appeared, those conditions would be at first but little altered, for animal matters exposed on the surface rapidly decay and pass away in a gaseous form; but with increasing civilisation and fixed residences the necessity of otherwise getting rid of all refuse would soon be felt. I have shown how population followed the range of shallow permeable strata and the course of valleys, so as to obtain readily that indispensable necessity of life, a sufficient water supply. But with the art of well digging it soon became apparent that, let the well be carried down but half-way to the level of ground springs, it would remain dry, and that then, so far from holding water, any water poured into it would pass through the porous strata down to the water-level beneath, keeping the shallower well or pit constantly drained. So convenient and ready a means of getting rid of all refuse liquids was not neglected. Whilst on one side of the house a well was sunk to the ground springs, at a depth, say, of twenty feet, on the other side a dry well was sunk to a depth of ten feet, and this was made the receptacle of house refuse and sewage. The sand or gravel acting as a filter, the minor solid matter remained in the dry well, while the major liquid portion passed through the permeable stratum and went to feed the underlying springs. What was done in one house was done in the many; and what was done by our rude ancestors centuries back has continued to be the practice of their more cultivated descendants to the present day, with a persistency in the method only to be attributed to the ignorance of the existence of such a state of things among the masses, and to the ignorance of the real conditions and actual results of perpetuating such an evil—an evil common alike to the cottages of the poor and, with few exceptions, to the mansions of the rich.

Not a county, not a district, not a valley, not the smallest tract of permeable strata, is free from this plague spot. It haunts the land, and is the more dangerous from its unseen, hidden, and too often unsuspected existence. Bright as the water often is, without objectionable taste or smell, it passes without suspicion until corrupted beyond the possibility of concealment by its evil companionship. Go where we may, we never know when the poisoned chalice may be presented to our lips. The evil is self-generating; for the geological conditions supplying our necessities lend themselves to its maintenance and extension. The knowledge necessary to remedy it is of very slow growth, and the too frequent want of that knowledge, or disregard of the subject, even amongst able architects and builders, is such that, without legislative enactment, I do not see how the evil is to be eradicated for many a long term of years.

But even our deeper and apparently inaccessible springs have not escaped contamination. As before mentioned, the underground water will, when tapped by artesian wells, rise to or above the surface, according to the relative height of the surface of the ground at the well, and of the outcrop of the water-bearing bed or beds, so that if the former is higher than the latter, or if by artificial means the line of water level in a given area becomes lowered, then the surface of the water belonging to those great underground natural reservoirs will be established accordingly at a certain fixed depth beneath the surface. As each well deriving its supply in a stratum of this description represents a column of water communicating with one common reservoir, it follows that any cause permanently lowering the level of one well will tend to lower the level in the other wells in proportion to their number and distance. Further, it has been discovered that a well of this class can absorb a quantity of water equal to that which it can furnish; and as these wells give greater supplies than shallow wells, the absorbing wells of the same class are alike powerful in proportion to the others. The perverse ingenuity of man has here, again, taken advantage of these conditions to get rid of offensive waste waters by diverting them into such deep wells, whence they pass away in hidden underground channels, unseen and unsuspected, and mingle with those deep seated water sources feeding the artesian wells dependent upon them for their supply.

In Paris, where there are several alternating beds of permeable and impermeable strata, and the depth to reach them is not very great, this system of absorbing wells connected with factories became, until regulated by the municipality, very common, to the great injury of many of the underground springs. From this and the other causes before alluded to, a great number of shallow wells have there become so contaminated as to necessitate their abandonment. Our own system of surface drainage is generally too good, and the depth to the lower water-bearing strata too great, to have rendered the use of such wells here equally advantageous; nevertheless, I have reason to believe that they do exist, and that the sources even of our deep well water supply in the Lower Tertiary Sands and in the Chalk are thus to some extent polluted and injured.

Nor do the great and perennial springs supplying our rivers altogether escape the evils arising from these obnoxious practices. On the high Oolitic ranges and amongst the undulating Chalk hills, the line of water-level is often so deep below the surface, that only in few cases are wells made—the population being generally dependent on rain-water for their water supply. But this does not prevent the construction of dry wells for the disposal of sewage and refuse. It is true that the population in these hills is sparse—here and there a farm, a few cottages, and scarcely a village. Still, as the ground is everywhere absorbent, and there are no streams even in the valleys (I am now speaking of the higher districts), every dwelling contributes its quota; for the rain and all liquid matter absorbed in these strata necessarily pass down to the great underground reservoirs of water feeding the springs thrown out in the deeper river valleys. In these cases, however, the thickness of strata through which any liquid has to pass before reaching the line of water-level is such as to produce a more or less efficient filtration and complete decomposition; and as the injury caused is in proportion to the relative volumes of the water-sources and to the artificial additions, the great extent and dimensions of these water-bearing strata and the scanty population of such districts reduce it to a minimum.

Owing to these conditions, great as the evil is, experience teaches that it has, in some cases, its vanishing-point. It may be considered at its maximum in some of the wells of Paris; our own London shallow-well pumps follow next in order; in our river waters away from towns it is but slight; in some of the springs of the Chalk and Lower Greensands it is hardly appreciable, while in the deep well-waters, especially those of Caterham and Grenelle, it sinks to the minimum attained by any potable waters, with the exception of rain-water. It is also a fortunate circumstance that the wonderful powers of oxidation possessed by air and water, and the powers of absorption and decomposition by soils and earths, are such as, even in the surcharged gravel-bed of London, to remove all the more offensive characters, and leave its spring-waters at all events limpid and bright; whilst the quick eddy, the moving ripple, the bright sunshine, the brisk breeze, the living organisms, are ever at work in our rivers, destroying the almost inevitable accompaniments of the presence of man, and restoring the waters to that original state of purity so essential to his health and welfare.

With regard to the character of waters as dependent on the geological nature of the strata, while the evidence showed that the waters flowing off hard and insoluble rocks were, from their much greater freedom from mineral matter, more economical for many domestic and manufacturing purposes, yet that for drinking purposes waters such as those derived from our Chalk and Oolitic districts were, on the whole, as good and wholesome as those from any other sources; while as regards quantity and permanence, the conditions presented by a large catchment-basin of a varied geological structure presented the most favourable conditions for the large and maintained supply so essential for a great city. And if, from any cause, it should at some future time be thought desirable to have a supply of a yet more assured and undoubted quality than a river supply, the large springs of the Chalk and the Lower Greensand, or the great underground reservoirs of the most efficiently filtered water stored in those formations in Surrey and Hertfordshire, might, I believe, be resorted to with advantage, by means of ordinary and artesian wells, as auxiliary sources of supply for domestic and drinking purposes, supposing the engineering difficulties connected with a double water supply could be overcome—a difficulty which it, however, seems to me would possibly be less one of construction to our engineers than of cost to the public. But in a great health question there are other considerations than these which are of more primary importance.

(*To be continued.*)

GEOLOGY IN RELATION TO PLANT LIFE.

WHILE many branches of science—notably chemistry and vegetable physiology—have done much to further a better knowledge of plant life, and, in consequence, of plant culture, geology, from which we might have expected so much, has up to this time done comparatively little. The fact is, the majority of geologists, says the *Gardeners' Chronicle*, have occupied themselves with the study of the order and mode of deposition of the older strata, and have done comparatively little to unravel the mysteries of the superficial deposits, which are of the most importance to cultivators. From a geological point of view the London Clay and the Lias Clays are totally distinct formations, so are the enormous Limestone beds of the Oolitic and of the Cretaceous periods respectively. Yet for cultural purposes there is not that great difference between them.

We know that certain fields invariably grow, under proper culture, good wheat crops, while from the adjacent fields a good crop cannot be looked for. In the case of fruit trees, the difference between neighbouring gardens is often still more marked. A pear which in one garden produces fruit of first-rate quality, yields fruit of indifferent quality in the next, and this often without any obvious difference in management, or even exposure. The experience of every fruit grower and market gardener could furnish numerous examples of the differences we allude to, but the causes producing these differences are often not obvious. Botanists turning their attention to limited areas are often enabled to draw up lists of clay plants, limestone plants, sand plants, seaside plants, plants of boggy ground, and the like, and to a certain extent these differences hold good. But when the observations are made over a wider area, the distinctions are apt to break down. Many of our wild plants, which are confined to clay and limestone, or even to boggy wet places in this country, are found elsewhere growing in equal profusion and luxuriance in soil of a totally different character. The beautiful Chlora perfoliata is a characteristic limestone plant, yet we have seen it on gault clay, and abroad it is by no means limited to a limestone soil. Orchis latifolia, a bog or marsh plant with us, grows equally well on dry soils in Switzerland. It follows, then, that the rules laid down for one country will not always apply to other lands. Some years since we carefully compared the wild plants of Oxfordshire with those of East Kent, with special reference to the nature of the soil on which they grew, and we came to the conclusion that the large majority of the plants were ubiquitous or indifferent, so far as the chemical nature of the soil was concerned. Limestone soils, whether of oolite or chalk, produced much the same vegetation in the two districts; and, to a less extent, this was the case with clay plants or sand plants. The number of plants, however, that could be enumerated as peculiar to one or the other description of soil was extremely limited; and when a comparison was made with the observations of Continental authorities, these few dwindled down to insignificant proportions. Under cultivation, too, we see plants from all parts of the world, inhabiting various regions, and naturally growing in very different soils, all thriving in soil of much the same character. The first greenhouse one enters will afford abundant illustration of this fact. The common purple Loosestrife (Lythrum Salicaria) was long since noted by Mr. Darwin as a marked illustration of this indifference to the nature of the soil. Naturally growing by the banks of rivers, with its roots submerged, at least in very damp soil, it does just as well in any ordinary garden soil. The Osmunda is another instance: it does best in a bog, but it will grow almost anywhere. Rhododendrons, so commonly thought to require peat soil as a *sine quâ non*, will do equally well in a stiff loam, and, indeed, anywhere where there is not too much lime.

It seems obvious, then, that, setting apart extreme cases, the chemical nature of the soil has less to do with the quality of the vegetation it produces than the physical characteristics. The difference in the vegetation of drained and undrained land respectively supports this view of the case. It is even a question whether the mechanical changes produced by certain manures on the soil are not to the full as important, as a general rule, as the chemical ingredients supplied. See, for instance, the great changes produced in the texture of the soil in the case of such experiments as have been carried on so long and on so extensive a scale at Rothamsted. See how some manures applied as a top-dressing, or, at least, superficially, affect the subjacent soil to a much greater depth than the others; how certain manures get washed down, or by some means penetrate to a much greater depth than others, altering the character of the soil as they go to a corresponding extent. Note, too, the varying quantities of water that issue from the drains in adjacent plots drained to the same depth and to the same extent, but treated with different manures. In some cases a large proportion of the surface-water runs through, while in other instances, as where farmyard manure has been applied, the outflow is comparatively small. All these facts, and many others that might be cited, show how desirable it is for us to gain a greater insight than we have at present into the nature and diversities of the soil in which we grow our plants, and into the mode of growth or general habit of the plant itself, as modified by the soil on which it grows. To this end we seem to require, to a much larger extent than we have yet had, the co-operation of geologists with vegetable physiologists and chemists. The problem is a very complex one, and it is only by investigating it from different stand-points, and then comparing notes, that we can hope to solve it or draw useful practical inferences from it.

PROFESSOR MORSE.

SAMUEL FINLEY BRESSE MORSE has passed away from among us; he died on Tuesday evening, the 2nd of April, at the ripe age of 81. Professor Morse's name will be for ever so closely associated with the development of the electric telegraph that we feel it our duty to give some notice, though it be a brief one, of his life. He was the son of the Rev. Jedediah Morse, well known as a geographer, and was born in Charlestown, Massachusetts, on the 27th of April, 1791. Samuel Morse was educated at Yale College, but, having determined to become a painter, he came to England in 1811, formed a friendship with Leslie, whose portrait he painted, and in 1813 he exhibited at the Royal Academy a colossal picture of "The Dying Hercules." He returned to America and endeavoured to establish himself as a portrait painter, but without much success, until in 1822 he settled in New York, and painted for the corporation a full-length portrait of Lafayette, who was then on a visit to the United States. We find Mr. Morse again in England in 1829, remaining here until 1832, when he returned to his own country. His companion on this voyage was Professor Jackson, the eminent American chemist and geologist, who was then returning from Paris, where the question of the time occupied in the passage of the electric current through a good conducting wire was occupying the attention of scientific men. From Dr. Jackson Mr. Morse appears to have first learnt that the passage of the electric fluid was absolutely instantaneous, and it occurred to him that it might be used for conveying intelligence from one place to another. The friends of Professor Morse claim for him that during the voyage he had written out the general plan of his telegraphic arrangement. In 1835 he certainly placed in the New York University a model of his "Recording Electric Telegraph," and in 1837 he filed his *caveat* at the Patent Office in Washington. It was not, however, until 1840 that the patent was perfected, and then Professor Morse set about getting his telegraph used. Four years, however, passed away before he succeeded, the first electric telegraph completed in the United States being the line between Washington and Baltimore, which began to work in 1844. Since that time the recording electric telegraph of Morse has been adopted over the whole country, and at the time of his death there were not less than 20,000 miles of electric wires stretching over the States between the Atlantic and the Pacific Oceans. Mr. Morse's first telegraph was a chemical one, the electric current being used to decompose the acetate or carbonate of lead, or turmeric paper moistened with a solution of sulphate of soda. He, however, gave up this arrangement, and adopted the electro-magnetic system instead. This was, however, in his hands, a rather ponderous affair, his electro-magnet weighing 158lb., and the instrument was not sufficiently delicate for long distances. Experience enabled Mr. Morse to simplify his arrangements, and his "Simple Morse Circuit" was thought to be so complete that in 1857 the French Administration of Telegraphs adopted the Morse instrument before all others. The "Morse Code," the "Morse's Transmitting Plate," his "Embosser," and Morse's telegraph worked by induction currents are sufficient to show how completely the American artist has connected his name with the system of employing electricity to pass as the messenger from man to man, over earth and under the sea.—*Athenæum*.

Practice Makes Perfect.—Mr. Bessemer, giving evidence before a committee of the Society of Arts, the other day, said:—"I have observed the sleight of hand that men acquire in various mechanical arts where they have a certain thing to do, and that only; and it is really marvellous how, in three or four weeks, a man will do with ease what would have been pronounced an utter impossibility. Take, for example, the forging of steel. A man will take a bar of steel, which has to be forged into an octagon shape, and he will pass it under a heavy hammer, striking about 300 blows a minute, and will turn it exactly one-eighth of a revolution at each stroke, and the whole of the bar is forged with the greatest exactitude, though he has to alter the angle every 300th part of a minute."

New Mode of Washing.—The ill effects of soda on linen has given rise to a new method of washing, which has been extensively adopted in Germany, and introduced into Belgium. The operation consists in dissolving two pounds of soap in about three gallons of water as hot as the hand can bear, and adding to this one tablespoonful of turpentine and three of liquid ammonia; the mixture must then be well stirred, and the linen steeped in it for two or three hours, taking care to cover up the vessel which contains them as nearly hermetically as possible. The clothes are afterwards washed out and rinsed in the usual way. The soap and water may be re-heated, and used a second time, but in that case half a tablespoonful of turpentine and a tablespoonful of ammonia must be added. The process is said to cause a great economy of time, labour, and fuel. The linen scarcely suffers at all, as there is little necessity for rubbing, and its cleanliness and colour are perfect. The ammonia and turpentine, although their detersive action is great, have no injurious effect upon the linen; and while the former evaporates immediately, the smell of the latter is said to disappear entirely during the drying of the clothes.

SCIENTIFIC SOCIETIES.

ROYAL ASTRONOMICAL SOCIETY.

THE ordinary monthly meeting of this Society was held on Friday, April 12, 1872; Professor Cayley, President, in the chair.

Insufficiency of National Observatories.

Colonel Strange read an important paper entitled as above, and in introducing it he remarked that it might be considered as aggressive, when we had so efficient an observatory at the head of astronomical science in England, presided over so ably by the Astronomer Royal, but he hoped to show that the paper was by no means aggressive. Of late years astronomy had made great advances, especially as regards the physics of the bodies composing the universe. The Royal Observatory was founded in the interest of navigation, and well and nobly had it done its work. The unbroken series of meridional observations, made under the direction of the distinguished astronomers who had from time to time presided over its operations, had conferred an incalculable benefit on astronomy; but the branch which might be appropriately styled "the physics of astronomy" was beyond its present range of observation. He (Colonel Strange) had only to refer to the paper read at a late meeting of the society on devoting an observatory to the especial work of observing the eclipses and transits of Jupiter's satellites (see ENGLISH MECHANIC, No. 357, Jan. 26, 1872, p. 479), to bear him out in advocating the importance of the establishment of observatories for investigating "the physics of astronomy." During a comparatively recent period much had been effected in extending our knowledge of the physics of the sun. In addition to the earnest seizing and utilising of the few precious moments of the intervals of totality on the occasions of total eclipses of the sun, a large amount of time and money had been expended in obtaining a valuable series of photographic pictures of the sun which, he learned with regret, had been brought to a close. He need not mention the men who stood foremost in the ranks of earnest inquirers into solar physics; they were known to us all, but such was the nature of private effort, especially requiring pecuniary outlay, that at any moment a series of observations might suddenly be brought to a close, and to remedy this defect he urged upon the society the importance of placing such inquiries as he had alluded to on a stable footing. There were also men who had taught us how to map the moon, but such was the extent of work required that private resources were quite inadequate to complete it in any reasonable period. Colonel Strange in his further remarks adverted to the connection of meteorology with astronomy. All the variations of climate, alternations of temperature, &c., could, he said, be traced to the dominant influence of the sun, and he, therefore, deemed it expedient that an exhaustive systematic study of the sun should be set on foot, and that a national establishment should be founded for the daily registration of solar phenomena.

The Astronomer Royal, in commenting on Col. Strange's paper, remarked that he had had great experience in the history of observatories, and the general impression on his mind was that no observatory will stand unless it be connected with some secular object—an object of worldly importance. The Greenwich Observatory, he said, was founded for the benefit of navigation and the determination of the longitude, and for these objects steady observations of the moon were necessary, and it should be borne in mind that these observations were not undertaken and continued to the present time for elucidating the lunar theory, but primarily and essentially for the determination of the longitude, and collaterally for this object a branch of the observatory work, to which he had personally given great care, was the rating of chronometers, and no less important was the dissemination of time signals, which were transmitted daily from the Observatory. The Astronomer Royal further remarked that when the Royal Observatory was founded, the theory of gravitation was established, and to employ this theory in the vital question of the longitude needed an extensive series of observations of the moon. To show the importance of the connection of a subject of worldly interest with an observatory, the Astronomer Royal said that, speaking to a friend of the assistance rendered by the Government to the Harton Colliery experiment, the greater portion of the expense of which he had personally borne, his friend replied that as a taxpayer he should protest against the employment of public money for such purposes.

Dr. De La Rue, in connection with the paper read by Colonel Strange, called the attention of the meeting to the importance of establishing a daily record of solar phenomena. He said that the Government have gone to a great expense, no less than £10,000 annually, in obtaining meteorological data, with a view to prognosticating the weather, and issuing weather signals. Seven observatories have been established, at which self-recording instruments are continually at work, and in addition numerous other stations furnish information which is received in London at 8 a.m. daily. This information is published and distributed by 2 p.m. of the day of its reception. The observations thus accumulated are arranged and discussed in various ways with a view of ascertaining the laws of weather changes. This method Dr. De La Rue considered as very cumbrous; centuries, perhaps, might elapse before the laws were discovered, and he pointed out that a secular change of a quarter of a degree in solar radiation would materially affect all our climatic relations. It was his impression that a series of solar pictures during a period of thirty or forty years, at an annual expense of from £300 to £400, would be very important for the Government to take up at this juncture. A picture of the sun obtained every day, furnishing data for the study of sun spots, faculæ, and solar prominences, during cycles of ten or eleven years, would throw much light on meteorological phenomena, for while local influences had great effect on the weather, solar influence was by far the most efficient agent in determining its character.

In referring to the work of an observatory established by the Government, the Astronomer Royal said that it was not that of groping, as it were, in the dark after the causes of phenomena, but the making and collecting of observations for a definite object, immediately connected with some secular advantage to the State.

The Rev. Professor Selwyn announced that the series of sun pictures which had been taken under his superintendence during the last nine years, would be continued until February, 1874, completing the eleven years' cycle.

Discovery of Minor Planets.

M. Borelli communicated a paper containing observations of the newly-discovered minor planet Peitho (118), and of Ægina (91); also of six new nebulæ, and a new variable star. Telegrams had been received at the Royal Observatory from M. Delaunay within the last few days, announcing that two minor planets had been discovered at Paris (119) and (120). Referring to Peitho, discovered by Dr. Luther, Mr. Dunkin stated that this was the nineteenth minor planet which the doctor had discovered, being the greatest number yet discovered by one astronomer.

Binary Stars.

Papers were read from Mr. Hind on the orbits of ξ, Boötis, and Σ 1938 (μ^2 Boötis). Observations of ξ Boötis during the next few years will possess great value, and also those of Σ 1938 during the next four years.

The Recent Solar Eclipse.

A paper was read from Mr. Tebbut, of Paramatta, containing observations of the partial phase of the eclipse of December 12, 1871, in which the times of bisection of spots on the sun's disc are enumerated, and on which the Astronomer Royal remarked that such observations were of no use whatever. As regarded the eclipse itself the Astronomer Royal took this opportunity of stating that he had received telegrams from India in the morning of the day of the eclipse, and had forwarded them to the London newspapers in time for publication in the afternoon of the same day.

Mathematical Papers.

The following were read or announced:—

On Proposition 38 of the Third Book of Newton's "Principia," by Todhunter.

The second part of a memoir "On the Development of the Disturbing Function in the Lunar and Planetary Theories," by Professor Cayley.

"On the Method of Least Squares," by J. Lee Glaisher.

At the close of the meeting Mr. Browning exhibited Lord Lindsay's photographs of the late solar eclipse, combined stereoscopically, and Mr. Brothers exhibited a negative of the eclipse of 1870.

Amongst the presents we noticed a fine portrait of the late Charles Babbage, one of the founders of the society.

Removing a Furnace-Shaft Bodily. — The great chimney of the Cabot mill, at Brunswick, Maine, ha been moved 20ft., to allow of the enlargement of the mill. The work was done by a process similar to that by which ships are launched, the chimney being slid along on greased planks. The chimney is 70ft. high and nearly 8ft. square at the base, and it was moved, the flues connected, and the fires started, in eight hours and a half.

Burnt-in Photographs.—The burnt-in photographs in enamel are well known to many of our readers, but it may not be generally known that the process is applicable to the ornamentation of glass. The pattern is drawn by hand on thin transfer paper, and the glass being prepared with a mixture of gum arabic and bichromate of potash, the transfer paper is placed over it and exposed to light. The colouring material is dusted on. This adheres to all parts not affected by the light, and a pattern is obtained which can be burnt in. Prints and woodcuts are by this method easily transferred to glass, but for portraits this process does not work fine enough.

PHOTOGRAPHIC NOTES.

To Prevent Albumen Paper from Blistering.—Some brands of albumen paper are subject to blisters when taken from the hypo. solution. To prevent this remove the prints, when fixed, from the hypo. into a dish of salt water (a handful of salt to a gallon of water) before the regular washing; let them remain several minutes in the salt water.

Removing Organic Matter from a Bath.—A correspondent of *Anthony's Bulletin* says:—"A friend informed me that he had treated stubborn baths successfully in the following manner:—After filtering out the free iodide, and evaporating in the usual manner, add, while the solution is warm, from five to ten drops of ammonia. I did so, and in five minutes my sick bath turned black as ink. I then boiled it about half down, and set it aside to cool. The next morning I filtered out about a teaspoonful of black organic matter, and then added to the bath enough acid (chemically pure nitric) to turn litmus. It requires considerable to do this, and care should be taken not to get an overdose of acid. If you do, a small quantity of ammonia will remove it. After this treatment my bath worked splendidly, and was as good as new. I do not think this has ever appeared in print."

The Adulteration of Wax.—A method of detecting the adulteration of wax with tallow by means of alcohol is described by Dr. Hardy, in the *Journal de Pharmacie et Chemie*. He first prepared pure beef suet, and carefully determined the specific gravity of this substance, which he found to be 0·8863; next he prepared an alcoholic fluid of such a degree of concentration that a piece of the suet alluded to remained suspended (that is to say, sunk therein to a certain depth, and then remained at rest) in it. This alcohol was found to have a specific gravity of from 0·8882 to 0·8857 (between 71° and 72°); the specific gravity of wax is between 0·962 and 0·963; hence it follows that alcohol at 29° will keep wax suspended. Starting from these data, Dr. Hardy constructed a tabulated form, by the aid of which it becomes possible to detect adulterations of wax with suet (tallow).

Photographing Children.—A photographer of San Francisco has adapted to his camera an adjunct which he finds of use in taking children's portraits. Instead of the cloth or brass cap which covers the tube of the camera, he employs a disc of brass or other metal, consisting of two semilunar portions, which open and close like the blades of a pair of scissors. They are worked noiselessly and instantaneously by the slight pressure of a little knob on the top of the instrument, and the plate is exposed and closed again without any manipulations that can be seen by the sitter. The operator waits until the child assumes a favourable expression, when he presses the spring, exposes the plate, and takes the picture without making any motion that attracts the attention or causes a motion of his sitter. Like all useful inventions, this is exceedingly simple, and may be attached to any photographic camera.

Maynard's Collodion Filter.—This consists of a pear-shaped vessel with a stoppered mouth, the narrow end holding the filtering paper or wool fitting firmly into the neck of a cylindrical graduated pint measure. As our readers know, volatile liquids must be filtered under cover to check evaporation, and various plans have been contrived for effecting this. The especial claim of the filter under notice is the elegance and convenience with which the operation is effected. An indiarubber tube connects the two vessels, and when the filtered liquid passes from the upper vessel to the lower one, the air displaced must pass through the tube into the upper vessel to take the place of the liquid which has passed through the filter, the proper pressure being thus steadily maintained without any communication with the air outside the vessels. Collodion, varnish, and all volatile substances, are thus filtered with ease, and without loss or change. A pint of collodion or varnish, it is stated, may be thus filtered in ten minutes.—*Photographic News.*

The Chemical Influence of Solar Light.—It has been observed that the intensity of the diffused light of the sky (not of that reflected by the clouds) is proportional, within certain limits, to that of the sun. When the altitude of the latter above the horizon does not reach 10°, the intensity of the chemical action of its light is practically nothing, while the action of that which is reflected from the sky is quite appreciable. Now, we know that the chemical intensity of the solar light increases constantly and regularly according as its altitude increases, and that it reaches its maximum when it has passed the meridian. These phenomena are easily explained if we recollect that the higher the sun mounts in its apparent course, the less distance do its rays have to traverse in the absorbing atmosphere of our planet. As the sun sinks in the afternoon, we remark a corresponding decrease in the active power of its light, and the relation pointed out exists without reference to variations in the state of the atmosphere.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the English Mechanic, *31, Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. Passmore Edwards.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

*** *In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

ON AN ARTICLE IN "NATURE."

[4006.]—There was an excellent article in *Nature* lately about newspaper science. With nearly all contained in it I cordially concur, and especially with the denunciation of the advertising style of science-writing; an attack obviously suggested by the reports of a late scientific expedition in a daily journal of high standing, in which one name was repeated in a manner intended to be friendly, but most mortifying, doubtless, to the person thus obtruded *ad nauseam* on public notice. But I cannot agree with the writer of this capital article in commending the style of a paper entitled "A Voyage to the Sun," which appeared in the *Cornhill Magazine* for March last, as worthy of general adoption. Surely science should not be taught as in that fanciful narrative, in which inferences were presented as facts, and all the reasoning omitted on which those inferences have been based. The very nature of such a narrative rendered this absolutely necessary; but it is unsafe to recommend that style of writing for imitation.

I say this in no spirit of hostility towards the writer of the "Voyage to the Sun." Indeed, I write as I do with his full knowledge and with the sanction of his opinion. After carefully reconsidering the subject he takes quite my view of it; and, unless I mistake, he is unlikely to write again in the same style.

Richard A. Proctor.

TERRESTRIAL GRAVITATION.

[4007.]—I do not possess Thomson's and Tait's "Natural Philosophy," nor have I ready access to the volume. Would "F. N.," who refers to it (letter 3969, page 119), oblige by quoting the reasoning of the eminent Scotch mathematicians, or describing its general character? It is always possible, in trying to solve such problems by geometrical considerations, that a simple mode of proof may escape one's notice; but I certainly have long believed that there is no simple proof of the law of attraction for spheres on particles outside of them. That the relation may be established without using the symbols of integration I can readily believe—in fact, I am convinced that *so much* can be done in half a dozen different ways. But I should not consider that the integral calculus had been dispensed with *if* there occurred anywhere in the proof the device of dividing the sphere, or any portion of it, into n equal parts, obtaining an expression for the attraction in terms of n, and then evaluating this expression on the assumption that n is made indefinitely great. This is only the integral calculus disguised. Nor again should I consider that the integral calculus had been dispensed with if the elementary attractions were represented by ordinate elements of a plane space having curvilinear boundary, and so summed by a reference to the known area of such space. It was a fashion of mine when at Cambridge (most unfortunately, so far as examination successes were concerned) so to treat problems really involving the integral calculus; and I have in my desk at this moment a fruit of such labours in a geometrical (?) solution of the following problem, the last example in Todhunter's "Integral Calculus":—

A messenger M starts from A towards B (distance a) at a rate of v miles per hour; but before he arrives at B a shower of rain commences at A and at all places occupying a certain distance z towards but not reaching beyond B, and moves at the rate of v miles an hour towards A; if M is caught in this shower he will be obliged to stop until it is over; he is also to receive for his errand a number of shillings inversely proportional to the time occupied in it, at the rate of n shillings for one hour. Supposing the distance z to be unknown, as also the time at which the shower commenced, but all events to be equally probable, show that the value of M's expectation is, in shillings:—

$$\frac{nv}{a}\left\{\frac{1}{2}-\frac{u}{v}+\frac{u(u+v)}{v^2}\log.\frac{u+v}{u}\right\}$$

But I know *now* perfectly well that this laboured proof (which is very much at your readers' service if they would care for it) is based merely on a disguised integration; and that by a direct use of the integral calculus the above problem can be solved in half a dozen lines.

What I should consider a simple proof of the problem "T. A." is troubled about is such a proof as is given of the corresponding problem for the attraction exerted by a spherical shell on a particle within it. Here it is shown that if the particle be the vertex of a double cone of minute vertical angle, the parts of the shell included within the conical surface on opposite sides of the particle exert equal, opposite, and therefore counterbalancing attractions on the particle. Thence the counterbalancing of all the attractions exerted by the shell is inferred, for what is true for a conical surface is true for a pyramidical surface of small angle, and pyramidical surfaces may be made to include the whole substance of the shell. It is a direct and obvious proof such as this that I have again and again tried to find, and I shall be somewhat surprised, and a little disappointed with myself, if any such proof be shown to exist.

Of course "T. A." may rest quite satisfied that no *plus* sign has been changed by inadvertence into a *minus* sign in the solution. The problem, regarded as one of integration, is of extreme simplicity, and has been independently solved many thousands of times, always with one result.

His inference from the behaviour of drops is of a very unsafe character to begin with, for in drops cohesion is able to overcome gravity. But assuming that an oblate spheroid of water (say) as large as our earth and at rest in space, would take the globular form, then (though the polar parts of the oblate spheroid would retire from the centre, and the equatorial parts approach the centre) it by no means follows that the attraction on the polar parts is less than the attraction on the equatorial parts. "T. A." confounds the attraction at a point or on a particle with the resultant of the forces exerted on the particle. If a fluid in a U-shaped tube stands higher in one leg than in the other, the fluid in the former leg will descend, and that in the latter will rise, but the attraction to which the particles are exposed in the two legs are not therefore unequal.

Richard A. Proctor.

[4008.]—When writing letter 3304, p. 406, I fancied the statement there condemned as a glaring error would be so readily recognised as such by any one at all conversant with the subject, that the remark of so able a mathematician as Mr. Proctor, in letter 3386, p. 454, completely surprised me. To ascertain the nature of the reasoning upon which it was founded, I put query 10702, which elicited the opinion that, before we could attack the problem of the difference in weight of an attracted particle, at the equator and poles of a non-rotating oblate spheroid of equal density, it was necessary to calculate the exact amount of attracting force the spheroid exerted; which, being the special work of the integral calculus, could be undertaken by no one but an accomplished mathematician. The decided character of the answers of course precluded all discussion, but I fail to perceive the force of this objection.

If the difference in attractive power between two globes of unequal densities and volumes was the problem to be solved, then indeed it would be requisite to employ the integral calculus for their summation. But in the case of a particle upon the surface of a spheroid, the same amount of power is exerted at any point. This, however, is not the question, which is, whether a particle is drawn to the surface with greater force at the poles than at the equator. Here, I apprehend, the application of the integral calculus is useless, because a particle may be so situated upon the surface of a mass as to have the attraction of its molecules nearly neutralised—for instance, the centre of a flat disc; while if the same disc is rolled into a cylinder, the attractive force of all its molecules can be exerted upon the particle in one direction, for instance, at either end. The subject is, however, ably reasoned out in the last edition of Ganot's "Physics," section 127, p. 93, article "Capillarity." Those who are desirous of discovering the truth concerning this question are recommended to study chapter 2 of this excellent work.

T. A.

SUNDRIES.

[4009.]—There are so many subjects referred to in No. 369, in which some reference is made or question put to me, that I am compelled to write for once a sort of gossiping letter, just touching here and there upon a variety of matters as they turn up while running over the columns.

(3965.)—Concrete Multiplication.—"No. 170" has made a most extraordinary oversight when he states that the arithmetics give rules for multiplying concrete numbers by themselves. Now, this is one of those extraordinary absurdities which clever people commit. On the very face of the matter, multiplying pounds by pounds, or by pints, or by yards, is a proposition worthy only of a lunatic; it is a downright absurdity. But multiplying feet by feet is an entirely different matter, because there is such a thing as a square foot or a cubic yard, while even an idiot would scarcely imagine to himself a pound square or a gallon cube. It is difficult to speak with common patience of such absurdities as the multiplication by concrete quantities.

The Pound and the Metric System.—There would be advantages in the use of the dollar as suggested by "No. 170" (especially as our thin-skinned Yankee cousins might be so delighted as to set it off against the Alabama claims altogether), but the sovereign is an English institution known and highly respected all the world over; and while thinking, as a matter of personal opinion, that it would be well if the nations would agree upon some equal and exchangeable money system, I still think that the inconveniences of a money change would so overbalance the advantages that the sovereign would be best retained as the money unit, issuing decimal divisions of it to be used along with existing coins till the latter were gradually withdrawn; in fact, the florin was coined for this very purpose. The coin question is quite distinct from that of weights and measures, because it is mainly an internal one. Our money only requires a decimal division to make it suit with the metric system in accounts, and a very simple percentage correction would convert it into foreign decimal moneys. No such reasons apply to adoption of the metric measure system, which is complete in and by itself, and would equally adapt itself to any decimalised monetary system, while the dismay produced by the loss of the familiar sovereign, and the alteration of the values of vast money concerns, stocks, companies, &c., would prove a great obstacle to the adoption of the metric system if the public were once persuaded there was a necessary connection between the two.

"J. K. P." (let. 3977, p. 120) is in error in supposing his remarks were at all misunderstood. I quite read his letters as meaning what he now says in all respects; but why should he regret that we should think he asked "questions with a view to obtaining knowledge instead of taking the trouble of reading for it?" He gives a good deal of information, and has good title to ask for any he requires. I do not often ask questions myself, because in the various subjects in which I am interested I have the means of at once obtaining the knowledge I want; but if I desired some information out of my ready reach, I should surely ask for it in these pages, and feel that it was the right thing to do to avail myself of the more ready facilities or special information of others, whom in return I might instruct in my own special subjects. For instance, I have often thought of treating myself to a lathe, and when I do I shall very likely ask "J. K. P." some very simple questions, to save myself the trouble of finding out the answers.

ARE ANTS PIRATES?—W. Gaucho suggests a doubt whether this can possibly mean "do ants rob at sea?" I can very distinctly say that they do. I remember with a shipload of sugar being so swarmed with small red ants that they almost rendered the ship uninhabitable. I have left a basin of water containing sugar as a trap, and caught a pint of them in a night.

"Saul Rymea" (let. 4005, p. 126) doubts the utility of some experiments lately recorded as to the influence of cold upon vegetation, but if he considers for a moment he will surely see the utility of any experiments which seek to discover the processes by which Nature conducts her operations. Any given experiments may be erroneous or badly conducted, but even then they give some lessons, if only as to errors to be avoided.

In reference to the process for destroying aphides (given on p. 133), readers should be cautioned as to the very poisonous character of the smoke produced, and the necessity of care in avoiding the breathing of it.

SIGMA.

A BATCH FROM MR. BOTTONE.

[4010.]—FEW things have given me so much pleasure lately as the perusal of Mr. Geo. E. Davis's sensible, kind, and instructive letter. That gentleman has, in a most masterly manner, shown forth the absurdity of binding oneself to any one set form of belief with regard to theories or hypotheses. His remarks on Dr. Frankland in particular, and other examiners in general, are perfectly in accordance with my own experience; and I did my best to point out the same in my letter (No. 3426). With regard to the convenience of typic and graphic formulæ his ideas coincide with mine. Two or three slight misconceptions appear to have arisen (probably from some carelessness of expression on my part) as to my ideas of the valency of nitrogen, phosphorus, &c. I would wish it to be distinctly understood that I do not for a moment deny that these bodies *sometimes* act as if *pentavalent*. I have only sought to show that there is no *necessity* for considering them such, and that they cannot be considered as otherwise than *trivalent* when we measure their valency by direct reference to their compounds with that body (see letter 3470 *et seq.*). As I do not look upon hydroxyl as the replaceable part of acids, I feel that I should be placing myself in a false position were I to attempt to prove what I do not believe. I may be wrong, but I must plead guilty to a partiality towards considering *all* acids as being referable to the hydrochloric type, single, doubled, or trebled (see table).

—	Graphic Formulæ.	Salts with Monads.	Salts with Diads.	Salts with Triads.
MONOBASIC ACIDS:—				
Hydrochloric acid, 1 molecule (type)	(H }′ ′{ Cl)	(M }′ ′{ Cl)	(M }″ ″{ Cl, Cl }	(M }‴ ‴{ Cl, Cl, Cl }
Derivatives:—				
Nitric acid …………	(H }′ ′{ ON^O_O }	(M }′ ′{ ON^O_O }	(M }″ ″{ ON^O_O — ON^O_O }	(M }‴ ‴{ ON^O_O — ON^O_O — ON^O_O }
Iodic Acid …………	(H }′ ′{ OOOI)	(M }′ ′{ OOOI)	(M }″ ″{ OOOI, OOOI }	(M }‴ ‴{ OOOI, OOOI, OOOI }
DIBASIC ACIDS:—				
Hydrochloric Acid, 2 molecules (type)	{ H, H }″ ″{ Cl, Cl }	{ M, M }″ ″{ Cl, Cl }	(M }″ ″{ Cl, Cl }	{ M‴, M‴ }vi vi{ Cl′, Cl′, Cl′, Cl′, Cl′, Cl′ }
Derivatives:—				
Phosphorous Acid …	{ H, H }″ ″{ POOOH)	{ M, M }″ ″{ POOOH)	(M }″ ″{ POOOH)	{ M‴, M‴ }vi vi{ POOOH, POOOH, POOOH }
Sulphuric Acid ……	{ H, H }″ ″{ OO, S, OO }	{ M, M }″ ″{ OO, S, OO }	(M }″ ″{ OO, S, OO }	{ M, M }vi vi{ OO, S, OO — OO, S, OO — OO, S, OO }
TRIBASIC ACIDS:—				
Hydrochloric acid, 3 molecules (type)	{ H, H, H }‴ ‴{ Cl, Cl, Cl }	{ M, M, M }‴ ‴{ Cl, Cl, Cl }	{ M″, M″, M″ }vi vi{ Cl, Cl, Cl, Cl, Cl, Cl }	(M }‴ ‴{ Cl, Cl, Cl }
Derivatives:—				
Phosphoric acid ……	{ H, H, H }‴ ‴{ –O–O, –O–P, –O ⁄ }	{ M, M, M }‴ ‴{ –O–O, –O, –O >P }	{ M, M, M }vi vi{ OO, O^P, O — OO, O^P, O }	(M }‴ ‴{ OO, OP, O }
&c.	&c.			&c.

Far be it from me, however, to give these ideas, or the formulæ connected with them, as being absolute; I am so convinced that nothing in this world is capable of *absolute* proof, that when I find an individual make an absolute statement, I begin from that very moment to doubt his veracity. All our knowledge is essentially relative: hence if I and Mr. Davis agree to consider hydrogen as a monad, we are perfectly justified in saying that chlorine is a monad, oxygen a diad, nitrogen a triad, and silicon a tetrad; *relatively*. But were we to take iron (for example) as our monad, these relations would probably no longer hold good.

With regard to the valency of hydrogen, it is worthy of remark that a compound has been described (see Gmelin's "Dictionary") in which two atoms of iodine are supposed to be united with one of hydrogen. The name of this anomaly is hydriodous acid; its formula is given as I_2H. Now, until the existence of this body be disproved, we cannot look upon hydrogen as invariably monovalent; hence we are once more brought face to face with a grave objection to the valency theory as it at present stands.

Mr. Davis will, I am sure, pardon me if I venture to point out that I did not attempt "to make chlorine appear to be first a monad and then a dyad." I simply showed that, with hydrogen, chlorine forms only one compound—viz., HCl, and that with iodine, &c., it formed compounds, of which our usual idea of its valency gave no satisfactory explanation.

On the grounds of the varying valency of iodine, chlorine, bromine (I care not whether they be artiads or perissads), I must object to such compounds as triethylsulphurous iodide being brought forward as proofs of the quadrivalence of sulphur.

It would appear that *ammonium* has been isolated, for Professor Roscoe describes it as being a blue metallic-looking fluid, existing only at low temperatures. (See Roscoe's "Elementary Chemistry," p. 213, last edition.)

With regard to the metric system, I agree perfectly with Mr. Davis in every particular. Were we to attempt to introduce another decimal system, we should segregate ourselves from nearly all our Continental neighbours.

"The Harmonious Blacksmith" has mistaken my meaning in reply 11393. I stated that the *ordinary* metal harmonicon was a toy: I certainly did not allude to the *adaptations*, which both he and I have concurred to praise.

Spontaneous combustion of oily waste, rags, &c., is no myth. Many well authenticated cases have occurred, especially in Russia. (See "Natural Magic," by David Brewster.)

For Mr. Tonkes's edification, I may state that I bought, some time ago, from Fries and Bianco, of Turin, a small pocket medical coil and battery, each of which packed into a little cylindrical ebonite case, 1¼in. long by ½in. in diameter. Amused by the minuteness and efficiency of the thing, I made one on the same model, which worked equally well.

S. Bottone.

"F. R. A. S." AND GEO-MYTHOLOGY.

[4011.]—I can assure "A Fellow of the Royal Astronomical Society" that if he could not see anything has yet been *shown* him about contacts of comets with the earth (let. 3960, p. 117) there are other eyes as worth showing and that partly have been, and still more will be shown a little, before we have done. Also to Mr. Scrope I shall return, and we shall have some Scropiana and Lyelliana rather amusing when there is time. But, meanwhile, our "Fellow of the Astronomical Society" quite leaves his science and all comets (which are not mentioned in his letter, but only in its title) to thrust upon the thousands of your readers a bit of neither astronomy, geology, nor even Lyell or Scrope, but simply the most sensational line or two from the first "preface" of poor honest ignorant little Bishop Colenso, exactly copied with every blunder, as the Chinese copy a worn picture! Certain cones in Auvergne—there are something between 100 and 150, observe, in that province—certain of these are of Pliocene or Eocene antiquity as volcanoes. Granted. "And upon the steep sides of these cones lie, absolutely undisturbed, scoriæ, lapillæ, and pumice-stone, which anything in the nature of a flood, sixty thousand—to say nothing of *six* thousand—years ago—[my theory, and that of all the chief geologists of Europe puts it at *five*, observe, not six]—must inevitably have swept away"!! Admirable! But how long have the scoriæ been there to be swept away? What has the "Eocene" age of the cone they "cover" to do with it? Is not Primrose Hill, London, an Eocene clay hill and covered with grass? Are we to conclude the grass is Eocene, and prove some Lyellian wonder thereby? Or is not Stromboli a volcano of, at least, Pliocene origin, and is it not covered with loose matter that any flood would have swept away? Yes, but part thereof was only thrown out last week, and there has been no deluge since last week! The conclusion that "hence, wherever the Noachian deluge went it did *not* penetrate to the Valley of the Auvergne" (which, by the way, is the exact reverse of a valley; it is what Dartmoor is to Devonshire, or as the French say, the chief *massif* of their country) is amusingly unlike the conclusion I believe, the three first geologists living, De Beaumont, D'Archiac, and De Villeneuve-Flayox have now come to—namely, that if there should even have been *no* general cataract or skyfall of scouring deluge elsewhere, since Quarternary times, there certainly *has* been on that very province, Auvergne!

The parallel of me to "a certain man called Hampden" goes equally by contraries. Mr. Hampden, as "F. R. A. S." says, was to set *all the world* right, not a little English coterie and mutual admiration society, amusing themselves with the lightest of light science, and too careless even to note that their Sir Oracle keeps them as hopelessly behind and counter to *the world*, the real advancers of knowledge out in the civilised *orbis terrarum*, as Voltaire complained that Cartesianism had kept his countrymen when he began teaching them Newton. I am only siding with the majority, with continental men of science. What other country's cosmology and geography is it that Mr. Hampden seeks to introduce to us?

Now, as "A Fellow of the Royal Astronomical Society" has chosen to thrust again upon us this Auvergne myth (or whatever it be—myth, as far as yet appears) this famous cone and pumice-stone, which made some noise ten years back, may I venture to hope he will proceed to favour his numerous readers with what I have vainly sought from either Lyell or the whole Geological Society for at least eight years past, the situation of this famous cone, and the evidence as to how long its last ejectments have lain upon it? A cone in Auvergne is no more information than "a hill in Yorkshire." It must be in some parish, of some commune, of some canton. Even if it were in central Australia, instead of France, it must have ascertainable latitude and longitude. Am I to take it and believe in it, as the mediæval Jews did in the "sabbatical river," that every one knew was "in Tartary," that flows only six days of seven, and (as every Israelite knows) triumphantly refutes the Nazarenes by keeping its Sabbath not on Sunday but on Saturday? As our ex-astronomical correspondent puts it to us, and as Lyell and the geologers have left it all these years, their pumice-stone and this "sabbatical river" are exactly of the same value to science. One proves precisely as much as the other.

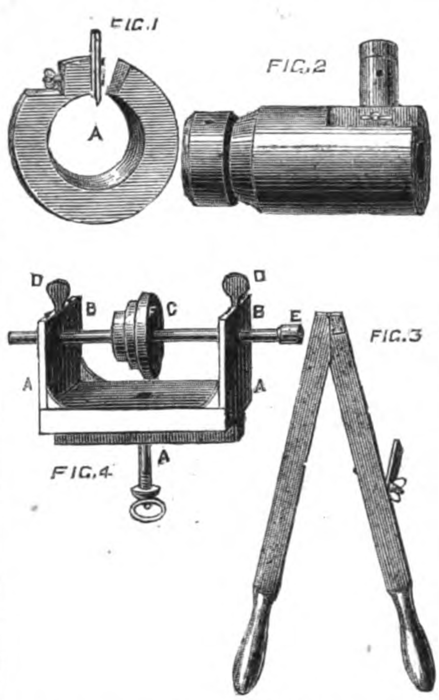
I may add that, about eight years ago, in a widely circulated paper, still well known, I so far adopted Mr. Hampden's method as to offer £10 towards the expenses of whoever would produce the evidences I now ask our "F.R.A.S." for—the situation, namely, of this pumice-stone, and the tangible facts that may indicate it to have lain *in situ* (say) fifty centuries. I could not afford to offer more personally, the intention being that others interested might add similar offers, and make up a sufficient bribe. To my great surprise (especially as the paper chiefly circulates among the clergy) no one has followed, or offered a single shilling! However, as I have not changed either my name or residence, here I am, to be sued for the £10 by "F.R.A.S.," or whoever may answer this request for him, and think it worth claiming. Of course, I must in any case be sued for performance of the contract, the whole object being to bring the evidence, or whatever and whoever is essential to it, before a jury of Englishmen, the only test of the power of evidence that I acknowledge, or the law acknowledges.

Our correspondent has chosen to make statements. I must press him to give the particulars and proof of them precedence before any other work. Even the planetary positions for next month, I would suggest, can wait if necessary.

E. L. G.

ORNAMENTAL TURNING.—X.

[4012.]—According to promise, and in answer to a correspondent ("Joiner," qy. 11168), I send sketch of a chuck by means of which a rod, the size of a penholder, or less, up to a cornice pole, could be turned. The chuck can be used on the ordinary mandril, but only for short lengths; if long lengths are required, then a hollow mandril must be used. I may here state that a hollow mandril is constructed from a piece of tube steel, and running in two bearings, it has no back centre. In some respects same as ordinary mandril, but being hollow, allows the work to pass through after being converted from square wood into circular. 1. Front view of chuck. The hole of the chuck, A, must be but little larger than the rod required when finished, but must taper inwardly for 1in. past the mouth; the cutter is an ordinary jack plane, iron; set fine it for hard wood; not so fine for deal or other soft woods. Fig. 2. Side view of the chuck, and ordinary wood chuck fastened into the ordinary iron chuck described in No. 368, p. 98. Rods 1ft. long can be made in this chuck, but if required longer I advise a hollow mandril. I have made taper articles in a chuck



similar to the one described. I had a quantity of spiles or vent pegs to make—the pegs are sold to the warehouses at 2s. 6d. to 8s. per 1,000, wood included, and made by hand in a kind of lever machine. The work being too tedious for me, I made a chuck as described; the only alteration was that the iron cutter, instead of being fixed square with the chuck, was fixed taper to the angle required. The wood was split up into nearly the size, and held with a pair of pincers. In making rods I advise the same, but as the rods may require to be longer, I send sketch of a tool called a trap, and also sketch of a temporary hollow mandril I constructed for my own use. The sketch of the trap will partly explain its use. The wood to be converted into a rod is fixed between centres, the corners previously being taken off with a plane; the trap placed over the wood and worked gently, end for end. Do not use much speed at first, and do not close the trap all at once, but gradually. It is a very quick way of making small rods. If very long, 3ft. or more, use a back steady, and only work one part at the time. Fig. 4. Sketch of temporary hollow mandril. A, frame made of dry beech; at B B cut and bored for bearings to allow the mandril C to revolve; the bearings are cut after boring and fastened with coach screws, so that as the wood bearings wear they can be screwed tighter or renewed. To make the mandril, proceed as follows: Obtain a straight piece of steam tube, about 1ft. in length, fix it in the lathe, and having previously marked where the bearings will run, turn a groove in the tube the width of the bearings, and three-sixteenths deep. The groove should be slightly bigger in the centre to allow more freedom in working. D D, lubricators when at work. I find nothing to beat the needle lubricator. E, a socket to fit the tube; it will be given with the tube on purchasing the same. To fasten the chuck, turn a hole the reverse side of the chuck, and drive in the socket, having previously judged the same, not forgetting to put an iron ring round the end of the chuck to prevent splitting. F, the pulley. The quicker the speed the cleaner the work, if by steam power or fly-wheel. A vast quantity of rods can be turned, and one great advantage is that it matters not the wood being warped, as the distance in the chuck is so little that it will turn to the shape of the wood. For light work a 1¼in. iron will answer, but for heavy work a 2¼in. iron will be required.

A mandril of this description can be made by an amateur, and need not cost more than a few shillings. If for small articles, and to be worked by the foot, I should advise the steam tube to be what is called ¾in. steam tube. If steam tube cannot be procured, gas tube will answer. Dry oak or mahogany is best for the frame, or, better still, teak wood, not being so liable to warp out of shape. In cutting rods, it is advisable for two to work at the mandril, as when it passes through the mandril a boy can hold and steady the remaining cut after leaving the hand of the operator, and also allow the rods to be entered quicker.

Samuel Smither.

ANNEALING STEEL, LINT, AND GILDING STRIPS OF WOOD.

[4013.]—(11650.)—Annealing Steel.—Heat to a dull red in the forge, and bury in the ashes, so as to allow it to cool very gradually. When cold it will be sufficiently soft for all practical purposes.

(11599.)—Lint.—Old linen sheets, &c., are preferred to new cloth on account of the softness of the fibre. It is generally cut in pieces 10in. or 12in. broad, washed and dried, then taken to the lint machine. This machine consists of a steel knife-blade, with parallel sides, the edge of which is blunt, but perfectly straight; this knife is fixed in a horizontal position in a frame, which is made to reciprocate by means of a pedal. When this pedal is pressed by the workman's foot it causes the blade to descend vertically with its edge across a board, covered with leather, upon which the linen is placed; on taking the pressure off a pedal the knife is lifted from the work by the agency of springs. The linen is rolled very evenly upon a cylindrical stick, with the weft in the direction of the stick; a few inches of the cloth being uncoiled, and a few threads of the weft pulled off at the end, leaving a fringe of the warp projecting; the roller is held steadily with both hands by the operator, who begins by placing the end of the cloth in such a position upon the workboard, that when the knife descends by the pressure on the pedal its edge shall pass between the first and second thread of the weft and press across all the warp threads; whilst the latter is thus held down to the table, the operator pulls back the stick through a space of from a quarter to half an inch; the weft thread is thereby pushed further along the warp threads, and from them is scraped the lint by their being drawn under the edge of the knife. The foot being lifted from the pedal the knife ascends, and the operator pushes the cloth forward again to take the next thread, which, by the pressure of the knife and the pulling back the cloth at the same instant, is moved along the threads of the warp after the first, and thus raising more lint. In this manner the operation is conducted thread after thread, until all the cloth on the stick is worked off, and thus is produced, when the work is dexterously performed, a sheet of thick downy lint. The difficulty of the operation consists in making accurate movements by the hands with great quickness; for if a weft thread is crossed by the knife, the work is checked or spoiled instead of forwarded.

(11627.)—Gilding Strips of Wood.—First prime your wood with two or three coatings of boiled linseed oil and white lead to fill up the pores of the wood, and to render the surface smooth and even. When the priming is dry, lay on a coat of gold size. When the gold size is sufficiently dry cut leaf-gold into strips, take up on the point of a brush, and apply to the parts already sized; press gently all over with a ball of cotton wool; the gold adheres to the sticky surface, and after a few minutes the superfluous gold can be wiped off with a camel's-hair brush. For burnished gilding proceed to cover the surface to be gilded with parchment size; after the first coat drying seven or eight more must be applied, consisting of the same size mixed with fine plaster of Paris or washed chalk; and when the whole is perfectly dry a moderately thick layer of size mixed with bole or yellow ochre must be applied. Before this last coat drys the gold-leaf is applied as before, and while the size remains the parts intended to be bright must be burnished with a dog's tooth or agate burnisher. Wm. Hamilton Hey.

THE HOLLIS OBSERVING SEAT.

[4014.]—I write to thank the inventor of this very excellent seat, which is advertised in your columns. It is of very simple construction, but very neat and effective; it affords support for the head, as well as the rest of the body, keeping it perfectly steady in any position, and is therefore a great assistance in making observations. Its price is so very low that I should imagine it would be well within reach of any who possess even a £5 telescope, and I can say from experience that it would be a most valuable addition to such an instrument. As I happen (unfortunately for myself) to live in a smoky atmosphere, my observations are necessarily confined to short distances from the zenith, and I greatly appreciate anything that enables me to examine a vertical object, not only without dislocating my neck, but as comfortably as if lying on a sofa.

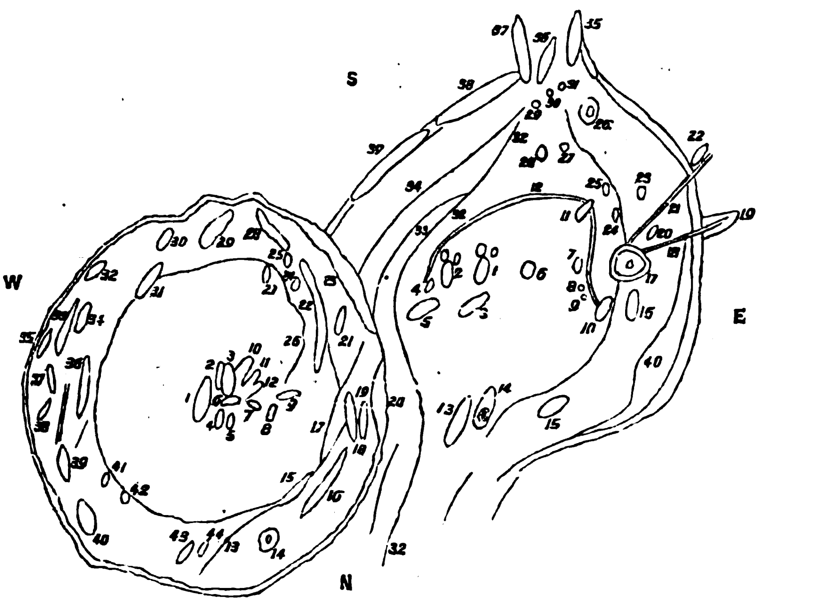
Sirius.

THEOPHILUS AND CYRILLUS.

[4015.]—I SEND you a sketch and description of the two craters, Theophilus and Cyrillus, in the hope they will be of some use to a few of your readers. I observed these objects on April 14, 1872.

THEOPHILUS.—THE FLOOR.—1 is the principal central mountain; 2 and 3 are also two mountains, but 2 is partly hid by, and lower than, 3; 4 and 5, on the N. are two hills, and 6 is another hill lying in direction at right angle with 3; 7, 8, 9, are also hills. The object E. of 3 and 6 seems to me very suggestive. Suppose a mountain, uplifted by an interior force, and its materials rushing down in a S.E. direction, the result would be very much like this object. It terminates by the three digits 10, 11, and 12, but the two last are not so easily seen as the first. On this object, between the digits 10 and 11, is a small lacuna or a marking of that kind, I think, and shown in the sketch by two short parallel lines. The line 26, S.E. of the central hills, shows the boundary of a depression W. of it.

THE INTERIOR SLOPE, N.—The line 13 shows the boundary of a large mound occupying all this portion of the slope, and upon which is the crater 14; 15 and 16 are mounds with a longitudinal form. The portion of the slope between 17, 18, and 20 stands in contrast with 23, where the border is well defined. At first sight it looks like a roundish form, with no particular marking on it; but, on closer examination, three mounds, 18, 19, and 20, with corresponding valleys, reveal themselves and give a sort of satisfaction for the steady gaze they require (would "L. C. E.," let. 3884, believe it?). 21 a mound; 22 a ridge; 23 is the well-defined border of the crater; 24, 25, 27, mounds; 28 to 44, mounds of various sizes. Between 36 and 38 a short valley or cleft runs in a somewhat N. and S. direction. Also E. of this valley there is another, but not so well seen, and shown in the sketch by a single line.



CYRILLUS.—THE FLOOR.—1 and 2 central mountains, having each two small hills at their S. end; 3 and 4, mountains belonging to the same group; 5, large low mound; 6 and 7, two mountains; 8 and 9, two very minute hills with power 227; 10, a mountain, on the S.W. of which emerges a cleft which runs in a southward direction with a gentle curve, until it reaches the mountain 11, behind which it disappears. It emerges again on the W. foot of mountain 11, takes a western direction, and, with another gentle curve, turns towards the N., and ends near mountain 4. This cleft, which I have seen before, is marked 12 on the sketch.

THE INTERIOR SLOPE, N.—13, low mountain or mound; 14, a mound on which is a crater on the N.; 15 and 16, mounds; 17, the largest crater in Cyrillus, with a peak in its interior; 18, a cleft cutting across the slope and ending in a depression; 19, E. of Cyrillus; 20, a mound; 21, another cleft running from crater 17 across the slope, and ending N. of a mound 22, E. of Cyrillus. This is the first time I have seen these two clefts; they seem formed by confluent craterlets, as their borders are very rugged. As the silver of my mirror is now much worn out, I had some difficulty in seeing these two clefts satisfactorily. 23, 24, and 25, mounds; 26, a crater; 27 and 28, mounds; 29, 30, and 31, small hillocks. The lines 32, 33, and 34, show the places of three large terraces; 35 on the S., to 37, are mountains; 38 and 39, higher portions of S.W. border of Cyrillus. The line 40 on the E. is intended to show the place of a long sinuous valley between two terraces.

I am glad Mr. J. Birmingham (let. 3917, p. 91, Vol. XV.) has seen the valley shown in my sketch of Tycho, and thank him for what he says on this occasion with regard to myself. I the more fully agree with him in his remarks about that valley, that a perusal of my letters 3485, p. 508, and 3698, p. 616, show that I would myself rather call this object a valley than a cleft. And here allow me to correct a mistake contained in my letter 3698 towards the end, where it is stated that the end of this valley reaches the east of Street. It must be "the east of crater *a* of Beer and Mädler, west of Street."

Jumet-Hainaut, Belgium. G. GAUDIBERT.

ATMOSPHERIC DUST.

[4016.]—MY reasons for thinking that comparatively recent sewage is more dangerous than sewage which has undergone putrefaction or is actively decomposing (let. 3918, p. 92) are the following:—

The substances excreted by an animal, although worn out by the wear and tear of its machinery, do not die immediately; they possess a sort of vitality, and in that state are active poisons to the animal, if retained, or again taken into the system. An instance of this may be found in the danger of dissecting wounds when the subject is not perceptibly tainted, the danger passing away when putrefaction has taken place. We are not only constantly generating poisons and throwing them out by natural processes, but are most probably taking such animal poisons in, and are for the most part saved from the consequences by the power which indubitably the organism possesses of ridding itself of injurious substances, and doubtless we are indebted more frequently than we are aware to a smart attack of dysentery or diarrhœa for deliverance from the consequences of such poisoning. There is not a shadow of evidence to show that zymotic or infectious diseases are in any way caused by vibrios, bacteria, or the other small deer that disinfectant-mongers alarm us with; but there is a mass of evidence to favour the theory that these diseases are produced by what may be called the degraded constituents of our bodies. I especially dislike the word "germ," and with the permission of "L. C. E." would propose instead the term "Nosogen," which is elastic enough to suit any of the theories put forth to explain the origin of zymotic diseases. Now, if we take the case of small-pox, we find the matter produced by the disease is an active nosogen not only during the life of the patient, but long after death. For it has frequently occurred that medical students have caught the disease by merely standing about a subject whose death had been the result of this malady. And here let me remark that Dr. R. D. Thomson does not appear to think that any gases or vapours, the composition of which is known to the chemist, cause zymotic diseases, although he considers it certain that the nosogens possess a condition resembling the vaporous, for how otherwise can he account for catching these diseases when no contact takes place? I believe that these nosogens are allied in nature to cadaveric poison, to depraved secretions, like that of rabies—perhaps of syphilis; and that the maladies caused by mere putrefaction are totally different, taking the form generally of boils, more or less malignant, having no regular symptoms nor well-observed course. Considering the horrible stenches from privies and cesspools in which the greater part of the population lives, I think it is evident that these odours, however disagreeable, are not dangerous like the emanations and excreta thrown off from the bodies of even healthy persons, which, when concentrated by want of ventilation, act with deadly effect. It is not at all necessary for persons to be sick to produce such poisons. They are constantly being generated and being thrown out by natural excretion, and give rise to what are called sporadic cases, on any other theory perfectly unaccountable. Infusoria are no more poisonous than oysters, and moreover, do not exist in the virus of small or cow pox—*par example*—except when decomposing, when, observe this, "Saul Rymea," it ceases to inoculate, but in the latter case gives rise to symptoms which produce the feeling in some quarters so hostile to the Vaccination Act. M. PARIS.

ARE ANTS PIRATES?

[4017.]—IN the article on ant piracy (let. 3778, p. 667), signed "Saul Rymea," is a warning given to show no mercy to ants in our gardens. But a plea for the insect may be put in: ants prey upon all kinds of larvæ, &c., and in woods the large ant attacks the blossoms of shrubs and trees only when extreme dryness cuts off all other supplies of food. I have never seen a blossom touched when sufficient moisture kept animal and vegetable life going on the soil.

GERARD SMITH.

LIGHTNING.

[4018.]—MR. TONKES does not explain (letter 3922, p. 93) the *modus operandi* of lightning. If we call to mind the extraordinary pranks played by flashes, it appears to me we must grant that if steam plays no part, at least the sudden expansion of air, and, perhaps, volatilisation of the substances disrupted, may produce the effects. Some time ago I saw a tree that had been struck: a great part of the trunk had been converted into small strips like lucifer matches. When we bore a hole through a sheet of glass by means of a spark I think there is no thickening of the edges of the hole. If so is not the glass vaporised? The lightning must use some tool to bore with, and I believe this instrument to be, generally, enormously heated air. In the majority of the cases I have noted there does not appear to have been steam at work. M. PARIS.

AURORA.

[4019.]—ON the evening of the 10th April there was a rather fine display of aurora. As the twilight faded the northern and north-western horizon was occupied by a pale blue homogeneous light extending to a height of about 15° above some remarkable branching dark cirrus clouds, which appeared to radiate from the magnetic north. These clouds were almost stationary, and the same form of clouds had been persistent all day, especially at about 3h., when some streamers of thin light haze radiated in a remarkable manner from a point above the WNW. horizon, and were so sharply cut off on their south sides as to appear almost solid matter. (The same remarkable branching cloud polarised in the magnetic meridian was visible in front of the fine aurora of April 9th, 1871.)

At 9h. 30m. numerous fine streamers shot up, all perpendicular to the horizon, and in a few minutes merged into one another, and assumed a pale rosy glow. The light in the north brightened, and at 11h. 30m. became very intense in the magnetic north, where some superb blue and carmine streamers shot up to within 15° of the zenith. The aurora was still in the north at midnight.

On the 11th extraordinary bands of haze radiated from points in the NE. and SW. (in which places the sky was exceedingly luminous), and stretched across the sky in gigantic arches.

Champion Hill, April 12. HERBERT INGALL.

INFLUENCE OF COLD ON VEGETABLE GRAINS.

[4020.]—I OBSERVE "Saul Rymea's" criticism (p. 126) of M. Duclaux's experiments, and my account of them, and would make a remark or two in explanation.

The conclusion drawn by M. Duclaux was, that cold had some influence on the germination of those grains of Belle-de-Nuit and Volubilis. Some of the grains that had been exposed to cold had germinated; none of those not exposed had germinated; and, although in one of the Volubilis pots none of the grains had germinated (though previously exposed to cold), yet this did not destroy the preponderance of evidence on the other side. Well, then he adds that some grains that have not been exposed to cold—that have been kept all winter in a heated chamber—germinate, nevertheless, at a certain time (and, perhaps, if I had said nevertheless, for none the less, it would have been more accurate). Germination takes place spite of non-exposure to cold, so that the cold is not indispensable to the germination. Nevertheless (and there is nothing now stated which conflicts with this inference), the fact that those grains experimented upon have their germination affected (in some way) by exposure to cold is a presumption that other grains do not escape the influence in some way or other of cold, when they are exposed to it. The fact of germination in some cases, where there has been no exposure to cold, does not preclude the possibility of some influence of cold on the mode of germination where exposure has taken place.

A. B. M.

GLAZING CONSERVATORIES.

[4021.]—THE plan recommended by our friend "Saul Rymea," at page 38, under the heading of "Improved Method of Glazing," is an old, tried, and costly one. I am of opinion that the old putty system equals it. Knowing a glass-house constructed on the iron system, it has not answered well or anything like one efficiently glazed with putty. The chief objection is the expansion, I know, but there are other ones besides this. In fact the owner told me he would not have another roof glazed on the principle on any account. It is well enough for "Rat-Tat" to raise a pane for ventilation; let him try it. I am afraid he will break some in the experiment. I maintain a conservatory glazed well on the putty system, well sprigged, &c., drives all iron and glass slate roofs into the shade. I should like to hear "Jack of All Trades'," and a few able correspondents' opinions. H. B. E.

BOILERS—CASTINGS—ROTATING SHOT.

[4022.]—There have lately been several designs of engines for amateurs in our Mechanic, but hardly anything has been said about boilers, a part of the subject which seems to me to require quite as much attention, and afford almost as much scope for design, as the engine itself. Indeed, I suspect it often happens that the amateur, having completed a highly-finished engine, finds himself "stumped" by the want of a boiler which he does not feel sure he can make safely himself, and of which he does not quite know the most suitable kind to order. I should think that a vertical boiler would be the best, and, if possible, fired with gas, burnt through wire gauze, as recommended by "Houblon" some time ago. Some small field-tubes might be added, or a few tubes bent to the shape of a U, with one leg longer than the other. The shorter leg being fixed in the crown of fire-box, the bend would hang down in the fire, and the longer leg would reach nearly to lowest water-level. I should think there would be a rapid circulation set up. Would this be so? Would it also be practicable to make the steam-pipe go down inside the boiler, and, if possible, through furnace? This would superheat the steam, and very little pipe would be exposed to the air. Have any of "ours" tried a boiler, illustrated in one of the first volumes, formed of a sheaf of tubes connected top and bottom to two tubes encircling the whole? A few particulars as to cost (if admissible here) would be acceptable.

I hope "Proven" (let. 3996) will favour us with some more particulars about casting with cera perduta. I have often thought it would be just the thing for an amateur with the aid of a Griffin's gas furnace. Is common beeswax used, and how are the moulds made and baked?

I believe that the plan suggested by "Philanthropist" (letter 3992) is employed to rotate stickless military rockets, which have in the rear end a central hole for the propelling jet, and a circle of oblique ones for rotating. Faber.

HOUSEHOLD ELECTRICITY.

[4023.]—Under this head one of your Transatlantic contemporaries makes the following statements, which bear upon a discussion recently carried on in the English Mechanic. The moralising which follows them is not of a character to interest your readers, so I merely send this portion of the article, and can only express the personal opinion that Boston must be a favoured city indeed. No need of Pulvermacher's chains there—or even lamplighters:—

"During the extraordinary clear cold weather which prevailed in February and March the electrical phenomena observed in some houses excited much interest. In our own dwelling, for many days, no member of the family could walk across a room and come in contact with a metallic substance without receiving an electrical shock, accompanied with a spark and report. The door knobs, stop-cocks connected with steam radiators, gas-cocks, registers, &c., were so electrically spiteful that they were handled with caution. Our children amused themselves in the evening by lighting the gas with their fingers, and altogether the electrical condition of the atmosphere was quite unusual. In order that this exhibition of household electricity may be witnessed in perfection, it is necessary that the weather be clear and cold, and that the rooms be carpeted with heavy carpets, and these should be insulated by paper mattings beneath. Under these favourable conditions, a person scuffing or even walking across a room becomes so charged with electricity that he can ignite a gas-jet readily by applying to it the tip of his finger."

G. J. H.

NEW DOUBLE STARS.

[4024.]—I have not been able to do much recently in the way of finding new double stars, and have only the following to report:—

Geminorum.—Weisse VII., 689, 7h. 24m. 51s., N. 33° 7′ : 8, 11½ : 155° : 7″. About one degree *s* of Castor, and 1m. 25s. *p*.

Aurigal.—L 10696, 5h. 34m. 10s., N. 29° 47′ : 8, 11½ : 200° : 6″. This is 3m. 52s. *f* 26 Aurigal, and about 37′ further *s*. It is nearer Σ764, which is about half a degree *sp*. This pair is similar to the one in Gemini, neither of which are difficult or very interesting. I notice a second companion to 26 Aurigal not mentioned by Struve or Webb, but it is too easy an object to have escaped observation entirely. It is about 12m., the position angle being 115°, and the distance a little more than double that of Struve's companion, or in the neighbourhood of 30″.

Crateris.—L 21697, 11h. 17m. 11s., S 9° 42′ : 7½, 10½ : 80° : 2″. A very pretty double star about 30′ from *ι* Crateris *np*; seen but once; but, probably, only moderately difficult.

Hydræ.—L 19393, 9h. 47m. 26s., S. 18° 52′ : 7½, 9½ : 90° : 5″. A fine, but very easy pair; about 35′ *sp*, a 5m. star. The bright star is omitted on Proctor's maps, but given on Argelander's. Having loaned the catalogue accompanying the "Uranometria Nova," I am unable to give its designation there, but it is No. 19433 of Lalande.

Canis Minoris.—7h. 55m. 44s., N. 3° 26′ : 8, 12 : 180° : 2·5″. The only difficult pair for a 6in. aperture in this list; found on the same evening with *γ* Canis Minoris, and probably more difficult than that pair. It is about 1° *s* of P VII., 289, a star visible to the naked eye a short distance following 14 Canis Minoris; both shown on Proctor's maps, the first without designation. The double is *nf* a 7m. star, both being in a low power field. There is an exceedingly minute pair about 100″ *np* this pair, similar to that near *γ* Canis Minoris, but much fainter and closer.

Sextantis.—10h. 15m., S. 9° 7′ : 8, 10½ : 190° : 1·75″. I open my letter to add this fine pair, found last evening. I have not ascertained its place exactly, but give the nearest minute in R.A. It is some distance *f* 17 and 18 Sextantis, but 1° 20′ *s*. It is also *sf* a 6m. star the designation of which I am not certain.

I am obliged to Mr. Knott for his measures of some of the double stars. I have recently obtained a micrometer, but for want of suitable clockwork can do nothing in the way of measuring double stars. I have been agreeably disappointed, however, in finding that minute points of light near brighter stars are rather better seen with the instrument illuminated than otherwise. I have never before seen a micrometer attached to a telescope, but had the impression that the light from the lamp tended to extinguish faint stars. Possibly the fact that I have been obliged to illuminate in a way never intended by the maker may have something to do with it.

Chicago, April 9. S. W. Burnham.

ALLINGHAM'S PROPELLER.

[4025.]—I would be extremely obliged to Amos Appleyard (letter 3919), if he would inform me where there is any published account of a method of propulsion similar to mine, as I have never met with anything similar, although well read up on such subjects, and used all precaution before commencing to patent same. Would also suggest to him that it is, to say the least, foolish to pass a sweeping assertion relative to any apparatus which he has never witnessed in operation. I have exhibited a model, 7ft. long, propelling quickly against the ebb tide of the river Mersey, running out at, perhaps, five miles per hour, as well as the united force of the wind and waves, all three forces against her, and am ready to show it to any one interested in such matters. There were scores of people saw it do so, and engineers declared that no steam-engine fitted to a boat same size could accomplish it. Size of boat, 7ft. × 8in. beam, and draught, 2in.; depth of blades from surface, 20in. This apparatus would be invaluable for lifeboats, as the time they are most needed is that in which the singular advantages of my invention are brought into play—viz., against a head wind.

John James Allingham.

HORTICULTURAL JOTTINGS.

[4026.]—I send a few clippings which may be of interest to many of your readers. Some time back I spoke of the advantages which accrue to the persevering horticulturist in a commercial sense, as well as the pleasure afforded in watching the growth and development of new varieties of plants. This was, I think, in connection with a discussion on the possibility of obtaining a change in the colour of primroses by means of chemicals, or of raising plants of certain kinds with flowers of a colour at present missing—*e.g.*, blue roses or dahlias. In reply to this it was asserted that there is no genus of plants which yields blooms on its different species of the so-called three primary colours, blue, yellow, red. One of your correspondents immediately pointed out the incorrectness of this statement, but as Mr. Sowerby has recently published a list of the genera having species of these three colours I copy it for the benefit of those interested in the question. He says:—An assertion is often made respecting the colours of flowers of plants which is scarcely verified by facts. It has been said that plants with flowers of the three primitive colours, red, yellow, blue, are not found belonging to the same genus; the following, however, contain species with the three colours more or less distinctly defined, and if pink be included as a red colour, the list might be much extended. The list is copied from a catalogue of plants, but many of the genera are familiar to all growers of plants:—

Ajuga	Hibiscus	Phaca
Allium	Hyacinthus	Polygala
Aloe	Ipomœa	Pourretia
Amaryllis	Iris	Rondeletia
Auchusa	Ixia	Salvia
Anemone	Justicia	Scutellaria
Aquilegia	Lachenalia	Sedum
Asterocephalus	Lælia	Senecio
Astragalus	Lathyrus	Solanum
Babiana	Lavatera	Stachys
Billbergia	Linum	Statice
Bromelia	Lobelia	Symphytum
Centaurea	Lupinus	Tephrosia
Cereus	Martynia	Teucrium
Chorozema	Meconopsis	Thunbergia
Cineraria	Miltonia	Tillandsia
Clitoria	Mimulus	Trichonema
Convolvulus	Monarda	Trifolium
Curcuma	Ononis	Trigonella
Eranthemum	Orobanche	Tropæolum
Erinus	Orobus	Vanda
Eupatorium	Oxytropis	Verbena
Goodenia	Pelargonium	Vicia
Heliophila	Pentstemon	Viola, &c.

The Magnolia conspicua deserves to be grown much more extensively than it is. A magnificent specimen is to be seen at Hatfield House (Lord Salisbury's). The girth of its stem close to the ground is nearly 4ft.; it covers a space about 35ft. in height and over 20ft. wide, and is covered with blossoms from bottom to top, so thickly placed that 50 flowers may be counted in a square yard. Considering their size and colour, this plant must be a picture of beauty while in bloom. This Magnolia, where it has attained anything like the size to which it is capable of growing, is certainly one of the most attractive plants that it is possible to behold, and Mr. Record, the gardener at Hatfield, says truly:—"I am much afraid that in these sensational times, gardeners—many of them, at any rate—are committing an error when planting, by not assigning a place to some of our old servants, and especially to this beautiful and noble-looking Magnolia."

Blood manures, phosphated ditto, and sundry others which, in the "unhappy" position of their elements are exceedingly offensive, become serviceable friends when their powers are exercised in helping the rose to manufacture its perfume. After pruning the heads of rose trees, dress with a mixture of soft soap and black sulphur. This is said to make the buds less inviting to those caterpillars which bore into and eat out the hearts of the buds just when they should be bursting into leaf. Light-coloured roses are especially appetising to these little posts. Saul Rymea.

COMMUNICATING ROTARY MOTION TO BALL FIRED FROM SMOOTH-BORED GUN.

[4027.]—"Philanthropist's" idea would be of no practical use. Even supposing that the projectile could be rotated in a satisfactory way, the line of trajectory would be too high, and the shot would travel too slowly. In "Philanthropist's" plan the interior of the shot is shown as being filled with a slow-burning composition—how would he contrive a shell? It is a *sine quâ non* that a gun must fire a shell; in fact, in our light guns we seldom use anything else. The idea is, in reality, the same as what we see in Boxer's rockets, in which the rocket is rotated during its flight by the escaping fire acting on a metal fan in rear; in fact, it is the principle of "Barker's Mill."

The second query might certainly do. The Germans have floating corn-mills on the Rhine, which, being moored fast, have their paddle-wheels turned by the force of the stream, and so work the machinery inside. Artillery Captain.

THE DECIMAL SYSTEM.

[4028.]—"An ounce of practice is worth a pound of theory." I fairly confess I do not understand a good deal of the talk your learned correspondents indulge in about the decimal system; but then I do understand the system itself, ay, and use it and have it here in mine own house. Some years ago I went to the United States (I am sure if I had read anything like the learned disputations the opponents of the decimal system indulge in, I should not have ventured); I fell in with the mode of notation there easily enough, and worked with it without giving it much thought or theorising about it. When I came home I had, of course, to adopt our barbarous style. But I soon found I was using a mass of figures much greater than I had found necessary in the States, and that in many cases I could not get the nice accuracy I required. I returned to decimals, and now never use anything else, except where compelled by the usage of those around me. As a manufacturer, in estimating cost of production I find it exceeding useful—in fact, I do not see how I could get along without it. Having this experience I marvel at the stupidity of the people who oppose the introduction of the system here. To speak after the manner of women, "it's awful!" About as bad, in fact, as our railway carriages. C. J. H.

CO-OPERATIVE SOCIETIES.

[4029.]—Having propounded a definite and practical problem of vital importance to co-operators, I am not going under this head to fill your columns with diffuse generalities, nor be led away from my subject into the untried paths of social science with "E. L. G." Let me, therefore, make this, my last letter, as concise as possible.

"Philo's" "check system" is the commonest, simplest, and best that has come under my notice; but there is a flaw in it, as in every system yet tried. It is that many purchasers do not take their vouchers, especially if they are non-members, or the amount of their purchase is insignificant. In these cases, if the shopman be dishonest, he has merely to pocket the money, and omit to make the entry.

"Philo's" system is chiefly useful as furnishing the data for a proportionate re-partition of profits (so called), but, as a "check system," it may be easily evaded, except the delivery of a voucher (of which copy is kept) can be insured in every case. In practice, I believe this to be impossible, unless a clerk is kept to take the money.

The metallic check system is open to the same objection. I would refer "Philo" and any other reader interested in this subject to the *Co-operative News*, special edition, April 4, wherein a full account of the various systems in operation is given, as discussed at the Co-operative Congress. I still fail to comprehend "E. L. G.'s" "check system," if his letter be supposed to give any. Is he not aware that if a shopman were to be responsible for the invoiced weight of goods, he would have to bear the loss in retailing (which is an unknown quantity)? It is not merely the profit (so called) which has to be checked (that is not an easy matter), but also the loss from retailing, technically termed leakage. If you make the shopman's allowance sufficient to cover this loss, you offer him a premium to give the purchasers short weight and measure. On the other hand, if you let this leakage loss fall on the society, it is a very difficult thing to determine what amount of cash profit the shopman ought to hand over I am not discussing "E. L. G.'s" definition of co-operation. In another place I should try to show that his definition is false, his elaborate schemes chimerical, and his social theories both immature and pernicious; but, as far as concerns this discussion, "Philo" has sufficiently vindicated the commonplace Co-operative Society from the attacks of the "roaring lion" in his admirable letter, No. 3166, Vol. XIV. F. C. S.

[4030.]—I AM afraid "F. C. S." will not derive much advantage from the replies to his appeal for a description of an effective check system; whether he pays "E. L. G.'s" secretary, or pays the stationer for "Philo's" rather expensive cash-book, the result will, from a pecuniary point of view, be, I fear, equally unsatisfactory. But the difficulty may be got over (not by a check system), and has been got over by more than one large firm I could name, who have to employ managers of branch retail businesses where constant personal supervision is impracticable. Let "F. C. S." take a ledger—enter on the debit side the stock on hand (taken for the purpose) at selling prices, adding afterwards from time to time the amount of invoices for goods received at selling prices. Enter on the credit side the amounts of cash handed over by the manager. After a convenient interval take stock again, enter the amount on the credit side, the balance will show the amount of loss by—well, we will call it waste—during the interval between the two stock-takings. Now, the manager must be made responsible for this waste, that is, he must be engaged subject to the liability of making good all loss which may arise, which cannot be accounted for—*i.e.*, not arising from bad debts, legitimate deterioration in stock, &c. Of course, this liability would have to be considered in the salary offered, but I venture to say that if "F. C. S.'s" present loss is 5s. per week, and he offers an increase of salary to the manager of 2s. 6d. per week on the above conditions, the manager will make 1s. 6d. per week out of the transaction. LOACH.

PIANOFORTE ACTIONS.

[4031.]—PROBABLY the subjoined observations on the actions engraved in No. 368 of the ENGLISH MECHANIC may tend yet further to elucidate this subject, which is of great importance to both musicians and pianoforte-makers.

I did not think it worth the space it would occupy to send a diagram of the continuation of the sticker O, Fig. 1, downward, showing its connection with the lever and the hopper, by which the latter is lifted. These parts of the common cottage action—of which Fig. 1 is but a modification—are so familiar that it seems needless to illustrate them; but I may remark that I much prefer to connect the sticker O with the lever on which it rests by a bird's mouth, because of the facility it affords for removing it. I know no better method of checking the hammer in a sticker action than that patented by Stewart, 1843, which is, however, only a method of applying Stumpff's modification of Erard's inside check—*i.e.*, placing it on the hopper. Some better way of setting off the hopper than the usual clumsy one of employing the motion of the key to "drag" it off would seem very desirable. Probably cranking the hopper and causing the cranked portion to impinge against an adjustable stop, *à la* Erard, is the very best method now in use, nor do I think it can be improved on.

The butt in this action has its lower part forked to receive projections from the hammer-rail and sticker in which the centre wires are supported. That projection P which connects the sticker O with the butt E may, if preferred, be made in two parts, embracing the centre wire of the sticker joint. This method, which is a very good one, is often employed by French makers, because it enables the parts to be disconnected. I have, for cheapness, represented the projecting piece P a cylinder five-sixteenths of an inch diameter (glued into an oblique hole bored in the sticker O), flattened at its sides where it enters between the fork of the butt E. If made in two parts, that portion which projects must be made of rectangular section, and deep enough to afford sufficient hold for the clamping-screw. The top piece, which clamps the centre wire, may either be of metal—as the French makers prefer—or of hard wood, say beech or hornbeam.

Should it be preferred to attach the damper to the hammer, the butt must be extended ⅜in. below its centre—*i.e.*, sufficiently to receive the damper wire, and the projecting piece P made long enough to bring the sticker O sufficiently forward to allow room for the damper behind it when the hammer strikes the strings.

Fig. 2. This diagram shows that besides the advantage of enormously increasing the force of the blow without adding to the weight of the hammer—a very important consideration in the treble—another great advantage results from the hammer being propelled through rather more than half its path by the last third of the key's descent, because it necessarily follows from this that when the key is allowed to rise the same quantity—viz., one-third of its path—there is nothing to prevent the hammer from falling back from the strings as far as the last third part of the key's path propelled it towards them—to wit, rather more than half its path. Now, just mark the practical consequence of this fact. Under these circumstances there can be no necessity in this action to check the hammer very near to the strings, although this is a necessity in ordinary actions for obtaining the power of repetition without much rise of the key. If—as is the case in this action—a rise of the key equal to one-sixteenth of an inch allows the hammer to recede from the strings about one inch, and the hammer be checked at (say) 1¼in. from the strings, it follows that but a comparatively small portion of its weight can remain supported on its centre. Practically, the hammer's centre of gravity recedes so far from the vertical plane of its centre that its own weight causes it to fall so rapidly that it requires but little assistance from the counterweight D to compel it to "follow the finger," as a pianist would express it. I need hardly add that this is very important indeed when the treble hammers are returned by counterweights, because the lighter the latter can be made for them to act effectually the less "thuddy" the blow, and consequently the less "blocky" the tone will become.

While writing on the subject of these actions, I may as well add that I found it possible to make a yet cheaper satisfactory action than either by making the sticker O rest in a socket formed in the key, as shown by L, Fig. 4. When the regulating screw was adjusted so that the key raised the hammer to within ⅜in. of the strings, I found the momentum of the hammer quite sufficient to carry it through the remainder of its path, and to cause it to strike the strings with sufficient force even when playing pianissimo. No doubt the hammer could not have reached the strings unless some separation between the clothing of the bottom end of the sticker and the head of the adjusting screw had occurred, but that separation was of so small amount as to be quite imperceptible, at which we need not be very much surprised, when, by the study of Fig. 2, we have learned that the vertical rise of the sticker during the last ⅜in. of the hammer's path is almost inappreciable. For forming an elastic connection between the key and the sticker I made a saw cut in the side of the latter, inclining downward at about 30°, on the bottom of which a very weak wire spring rested, similar to that of an old grand jack, but not so stiff, the other end of which spring was inserted in the key. The sticker and the hammer to which it was hung were thus compelled to descend with the hinder end of the key whose rate of descent could be determined by loading it sufficiently.

I think it would be difficult to make any upright action which can surpass this as a repeater or excel it in cheapness. How it will work with very heavy hammers I cannot say, not having tried, but if the strength of the tie spring and the loading of the key be proportionally increased I see no reason why it should not act at least as well in the bass as the common action does. With the very light-headed treble hammer (the sticker also being made as light as it can be with the needful rigidity) in the model it answers admirably, the hammer exhibiting no tendency to return to the string and again strike it—in fact, it is almost as steady as it would be if held by a check.

In this model the confining rail M M, Fig. 4, does not exist, it not being required. Only about ⅜in. of the lower end of the sticker is rounded to enter the socket in the key. By lifting the tie-spring out of the saw cut in which it normally rests, the key may be taken out, as also may any one sticker if made so that it can be disconnected from the hammer butt. When needful to take this action out of the instrument leaving its keys, all the tie-springs must be disconnected from the stickers by pushing them aside, which may be a slight disadvantage, but after all the doing of this, and their after replacement when the action is reinstated, is but the work of a few minutes. So this "mechanick" is not very bad; indeed, the greatest defect I discovered in it is the difficulty of silently stopping the key's motion in time to prevent the hammer blocking against the strings. However, not liking to be beaten, I succeeded in overcoming this difficulty by employing a back touch, about 2in. wide on its lower surface, which was inclined at about 10°. On the top of the key an inclined plane at the same angle was fixed, and by sliding this plane to or from the key balance the key was silently stopped "dead" in the required position. Of course the cloth washer under the front of the key was packed up by paper discs until the descending key came in contact with it a trifle earlier than its hinder part impinged against the back touch, because the clothing of the latter was considerably thinner than the cloth washers beneath the fronts of the keys.

In Fig. 2 the proportions are about those which I think would be generally preferred, but it must be obvious to any mechanic that those proportions may vary, so that the force of the blow may be increased in the treble if thought desirable, or diminished in the bass. The first may be effected by allowing the notch or shoulder in the hammer butt to travel further back towards the plane of the hammer centre, so that the leverage may be yet more diminished, and thereby the hammer's velocity yet further increased. It is obvious that, if at the instant it strikes, the leverage be diminished to one-half that represented—*i.e.*, from one-eighth to one-sixteenth of an inch, the hammer's velocity must be doubled, and the force of its blow increased in proportion. Under these circumstances the rise of the hopper would not be sensibly increased, but it would impel the hammer through more degrees of the circle—in other words, the length of its path would be increased.

There is no reason why the radius of the hammer should not exceed 4in.; hammers 5in. and even 6in. long, have been employed. Now, *cæteris paribus* it is obvious if the hammer's length be increased from 4in. to 5in., its head must travel ⅝in., and if increased to 6in. 1¼in. further, thus increasing the hammer's velocity 25 and 50 per cent., without causing its centre wire to rotate through a larger number of degrees.

As the centre of gravity in such long hammers must be further from the vertical plane of the hammer centre, the finger will necessarily be more resisted at the commencement of the key's motion than it is by the preponderance of a 4in. hammer, but if the same additional velocity be imparted to the 4in. hammer — to effect which its total path must also be increased—the additional resistance to the finger, caused by the greater distance which the 4in. hammer's centre of gravity is in front of the vertical plane of its centre, will not be nearly so much felt, because it then becomes needful to commence the hammer's motion with the notch or shoulder in the butt considerably lower. Now, the lower that shoulder descends—until it descends to the level of the hammer centre—the further in front of the hammer centre it must be, which is only saying, in other words, the greater the leverage becomes at which it acts on the hammer. This lowering of the notch is a necessity if the distance the hopper rises be not diminished—a thing which can only be done without altering the relative velocities of the key and hammer by reducing the depth of the touch, doing which might be unpleasant to a performer accustomed to touches from five-sixteenths to three-eighths of an inch deep; but after all, this is merely a matter of what you are used to, and, for anything to the contrary with which I am acquainted, old Bach, Mozart, Clementi, and others of the old school of pianists (who are commonly supposed to have been tolerable executants) may have played none the worse in consequence of the fact that the keys of their ancient pianos only descended about ¼in. On the contrary, I find a rather shallow touch is much easier for the performance of rapid runs, shakes, trills, &c.

The hopper in Fig. 3 is sufficiently cranked to allow the path of the hammer to be increased to 2½in., quite as long, I think, as it is desirable to make the path of a heavy middle C hammer. Of course, as we ascend towards the treble the dampers may be made shorter. The more this is done the further the hammer can descend without being stopped by the damper block touching the back of the hopper before the hammer arrives at the string, until we arrive at C above the lines, 7½in. long in my scale, above which note it is not customary to employ dampers. There will then be nothing to prevent the hammer being allowed to descend until it recedes to 3¼in. from the string. This will require the hopper to be lifted three-tenths of an inch, exactly 50 per cent. more than it rises when the path of the hammer is only 2¼in., as represented in Fig. 3, the hammer in which is impelled about eighteen times faster than the key descends under the finger. By increasing the path of the hammer to 3¼in., and diminishing the leverage, at which the hopper acts on the butt shoulder or notch, to one-tenth of an inch, the velocity of the hammer (in consequence of that diminished leverage combined with the increase of 50 per cent. in the total rise of the hopper) becomes rather more than doubled. It is, in fact, driven about forty times faster than the descent of the front end of the key. Of course the head of a hammer driven at this velocity must be comparatively light, or the touch must become heavy.

THE HARMONIOUS BLACKSMITH.

COLOUR.

[4032.]—I DENY Mr. Benson's right to assume certain "doctrines" as "accepted," as he does at p. 97. There cannot, as yet, be said to be any "accepted" doctrine regarding colour sensations. To my mind his experiment with red spots on black and white surfaces is quite inconclusive as regards the point in question, for he may make the spots gray instead of red with similar results; gray being, according to my view, not a colour, but merely complete light of a certain intensity.

Mr. Benson speaks of my mentioning only one thing in support of my views. I, however, indicated that other facts might be brought forward, and of one of these, which is well-known, Mr. Benson has in his books attempted an explanation, but not, to my mind, a satisfactory one. When the eye is for a considerable time subjected to light of one colour—for example, in a room lighted only by windows of some one colour—a gradual change seems to take place, which is commonly described by saying that the eye becomes less sensitive to that colour. This, however, is accompanied by the remarkable circumstance to which I would draw particular attention, that the strength or quantity of the light does not seem to diminish. The light becomes apparently whiter; but how can this be if white is a compound colour? The window is supposed to exclude those very rays which the entering rays require to combine with, on the composition theory, to make white. Then, in all attempts to measure the relative intensities of the different coloured rays composing daylight a very considerable preponderance is assigned to the yellow rays, and we have every reason to believe that daylight is really very yellow, but yet we regard it as pure white.

What Mr. Benson refers to in his third paragraph presents no difficulty in connection with the non-compound views as to white. I have not suggested that the rays combined in white light are not heterogeneous, and it is easy to understand that if the sensitiveness to certain of those rays has from any cause been diminished, other rays tending to produce an opposite disturbance will produce a colour sensation. In my former letter I suggested that any ray giving rise to the simplest colour sensation also always produced accompanying whiteness.

The first sentence in Mr. Benson's last paragraph is peculiar; he describes a certain fact in two different ways, and apparently imagines he has stated the effect in one description and the cause in the other! The remainder of the paragraph calls for no particular remark, as it is not "difficult to imagine" a great many things.

Since I last wrote on this subject in January certain facts have come to my knowledge which, I think, favour the theory of five simple colour sensations—red, yellow, green, blue, and violet. Formerly green was held to be compound, because it was supposed to be producible by mixing blue and yellow; but is now held to be simple. We should, therefore, be warned against hastily assuming that yellow or blue are compound, because they can apparently be produced, one by mixing green and violet light, and the other by mixing green and red light. When one looks through a prism at a strip of white on black, which is wide enough to show some white, the white is seen in the middle, dividing the colours into two different sets, one set having red shading rather suddenly into yellow and finishing with a slightly greenish yellow, and the other set having violet shading into blue and finishing with a slightly greenish pale blue.

A person of my acquaintance, with a good eye for colour, and who normally sees the colours under the stated circumstances as just described, has recently had his eyes peculiarly affected after taking a strychnine tonic. Without noticing any particular difference in the colours of objects generally, excepting that he seemed to miss seeing some of the finer and richer shades of blue, this person had his attention (one day recently) drawn to a broken cut-glass gaselier pendant, and accidentally looking through a prismatic part of it towards a window was at once struck by a remarkable difference he observed in the colours exhibited as compared with what he was accustomed to. He, of course, at once got a proper colour prism, but still found the same difference. The series of colours beginning with red did not appear altered, excepting that the red seemed, if anything, a little more than usually inclined to crimson; but in the other set of colours the violet seemed richer and more like purple, the blue almost absent, and the light blue inclining to green, changed to the ordinary rich green seen in the spectrum of a narrow slit. On looking through the prism at a shaded lamp, in which was burnt an oil believed to be photogene or petroleum spirit, blue was entirely absent, although seen ordinarily, and a rich violet was seen graduating quite suddenly into a rich green. These peculiarities seem difficult to explain on any assumption, excepting that the sensitiveness to simple blue was much reduced, and that, therefore, the normal eye must be capable of transmitting separate simple sensations for green, blue, and violet, at any rate, and in that case it is obviously most probable that it can also transmit separate simple sensations for both yellow and red.

Why should we (mentally) recognise these five distinct colours and no others? It is useless for the "three-primary" theorists to say this or that colour can be made by mixing two of the three primaries, for the "three-primary" theory requires six distinct colours, and six distinct colours do not exist. There is no distinct colour between pure blue (untinged with violet) and pure green, between green and yellow, or between yellow and red; and although violets, purples, pinks, and crimsons are spoken of as between blue and red, blue and red are suggested by every one, and the only colour that can be called distinct between blue and red is one, whatever be its name, in which neither blue nor red preponderates.

Glasgow. E. H.

DOOR HANDLES OF RAILWAY CARRIAGES.

[4033.]—Permit me through your columns to throw out a small hint relative to railway carriage doors generally. It is simply this: That a handle (similar to those now in common use in most private carriages) be fixed inside the doors of all the three classes—viz., first, second, and third; in connection with the one outside; so as to obviate the necessity, when opening the doors, of putting the windows down when up, as well as being obliged to put the hand and arm outside; thus avoiding at the same time a certain amount of risk. It is an easy matter, and might be done by all railway companies at a very little extra cost when constructing their carriages; and would also be conferring a great convenience to the vast multitudes who travel upon our iron roads. I hope that you will insert my letter, and that the idea may meet with approval.

Nathaniel Waterall.

AMATEUR TURNERS' SOCIETY.

[4034.]—What is now wanted is mechanical instruction to amateurs by competent workmen, so that they may acquire an amount of skill and practice not to be attained in private. Many of our readers (this I can answer for from my own personal knowledge) are employed by firms or in offices year by year, and naturally enough take to mechanics as a pastime and recreation. If a society is started in London, as nearly central as possible, open to any respectable man on payment of the usual fees (as moderate as possible, and payable at the option of the member—monthly, quarterly, or yearly), I have no doubt it would succeed. I would propose something like the following: That a suitable place be hired annually, and, as before stated, tools, &c., fixed; that honorary members be admitted at a lower premium; that two or more meetings take place in the year, on which all business should be brought forward; and further, that the committee should place themselves in communication with private firms (for premiums) to allow a few members at a certain time to visit the manufactories, and by that means gain practical knowledge. The advantages to the members would be numerous. They would gain real knowledge and practice in the handling and working of the lathe and its accessories, also an insight into the art of cabinet-making, polishing, &c. Should any member require advice—such as recommending or purchasing any article for the use of himself relating to turning, cabinet-making, &c.—it should be given gratis. Any articles that should be turned out in a finished state by the members should be sold, and the profits arising be carried to the society, unless the same has been finished throughout by one member only. In a few weeks I will advertise an address, whereby I can be communicated with by post only.

Samuel Smither.

A TRAVERSING SCREW CHUCK.

[4035.]—A traversing mandril for cutting short screws with accuracy and certainty would be coveted by many amateur turners were it not that its cost and, still more, its injurious action upon the lathe for general purposes more than counterbalance its admitted advantages for that one purpose.

I have lately designed and made a tool which seems to possess all the advantages of a traversing mandril, without its defects; and as it can be adapted to any lathe, I hope it may be generally useful. I propose to call it "the traversing screw chuck." The following is a description of the apparatus, with reference to the accompanying drawing:—

A. A steel cylindrical holder, which screws upon the nose of the lathe mandril, having a longitudinal key-groove *a a* (or it may have a left-handed spiral key-groove of one turn per inch, which would probably work even better than the parallel key-groove; but the latter, as I have made mine, is sufficient).

B. A gun-metal cylinder fitting nicely, and without shake, upon A, having a key (*b*) which enters the groove *a a* and prevents it from turning upon A, though it is free to traverse longitudinally. The cylinder B ends in a boss, having at its extremity a screw exactly like the screw upon the nose of the lathe mandril, and upon this screw any of the ordinary chucks for holding the work to be operated upon can be screwed so as to run true in the lathe.

C. A steel guide-screw (of which there may be several of various pitches) fitting tightly and keyed upon B.

FIG. 1

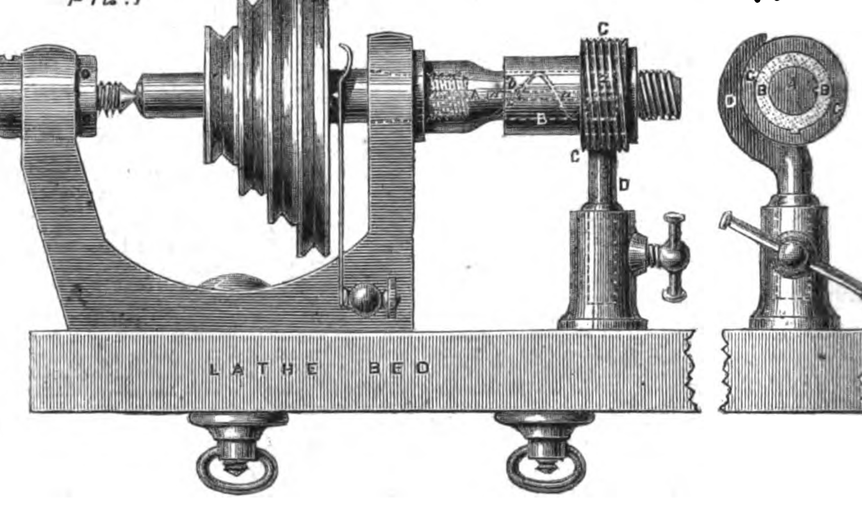


FIG. 2

D. A fixed screw-guide (of brass or gun metal) fitting the thread of the steel guide-screw C, and partly embracing its periphery, as shown in the cross section Fig. 2.

The screw-guide is here shown (as I have made mine) held fast in the socket of the T hand-rest, but a better plan would be to have the several screw-guides formed on portions of the circumference of a brass or gun-metal disc, about ⅜in. thick, centred upon an eccentric or cam, on which it could be turned and made to gear with the corresponding screw-guide C, just like the brass screw-guide fixed at the back of the head-stock of Messrs. Holtzappfel's best ornamental lathes, having traversing mandrils.

Note.—When this apparatus is used the proper screw-guide D is put into gear with the steel screw-guide C, and compels the latter, with the chuck and work which it holds, to advance at the rate required for cutting a screw upon the work by means of a single point tool or chaser, held in the slide-rest or by hand. The resulting screw will be an exact copy (as to pitch) of the steel guide-screw C (except that if a spiral key-groove is adopted in A it will have one turn per inch less than the guide-screw). John F. Stanistreet.

Abercromby-square, Liverpool, April 16.

THE "TURRET" TRICYCLE.

[4036.]—As I know several of your readers are interested in the bicycle and tricycle movement, I forward you a sketch of a tricycle I have designed and constructed. I drive direct off the crank without the intervention of connecting rods. I form a slot in the lever which pivots on an arm bolted to the frame. The lever is bent at right angles so that the feet may assist in working; cords lead from the handles to pulleys attached to the angle of lever, up to the frame, and thence to guiding axle. By employing rollers on the crank pin the friction may be much reduced, travelling in the slot. I mark the various dimensions on the sketch. The arms on which the levers pivot, as well as the stay, should be strong as well as the levers themselves. I have thought of replacing the pair of guiding wheels by a single wheel in a fork under the seat, steering it with the cords, but fear it might be difficult to preserve a balance. I believe you could spin along at a great speed with a single guider.

The handles are attached to a disc of hard wood in which the cord runs in a groove. The length of crank arm is 4in. The end of arm on which the lever pivots must be directly under the axis of the wheel, so that the levers may travel to and fro equally.

C. Townley.

A NEW AND EXCELLENT SUN-SCREEN FOR ALL TELESCOPES.—CENTREING THE FLAT OR PRISM OF NEWTONIAN REFLECTORS.

[4037.]—The following mode of defending the eye in viewing the sun is the most perfect that can be conceived. A film of silver is deposited either on the field lens of the eyepiece itself or upon a concave lens inserted where the Barlow is usually placed: in either case the silvered side should be turned away from the eye. The interposition of this partly transparent film of pure silver, as brilliant as any mirror, has the effect of turning back all the rays of heat, while it allows light enough to pass to produce the sharpest definition. The film may be made so thick that the eye can bear the whole aperture of any telescope, but it is better to have it only of such a density as to require a rather pale glass screen to be used with it. The action of this simple contrivance is so perfect that the eye-lens is not heated in the slightest degree, nor is there any heat upon the eye.

The process of silvering is extremely easy, and may be done by any one in a few minutes. I find the cost of chemicals for three lenses is one farthing. A still better place to insert the silvered concave is between the flat and the big speculum, close to the former.

The following will be interesting to all who use Newtonian reflectors. The want of perfect adjustment in the secondary mirror, whether a flat or a prism, is one of the chief causes of their frequent imperfect performance. I have never till now been satisfied with my centreing, nor have any of the published methods been absolutely perfect. The following mode leaves nothing to desire.

Together with my dynamometer is sold a very simple and inexpensive microscope which clips on to any eyepiece for reading this power-gauge, which it does to the one-thousandth of an inch; around the little bright image of the aperture seen thus in front of the eye-lens are certain darker circles which are the images of the inside of the tube, the rim of the flat-holder and the eye tube. If these are not all exactly concentric the fault is in the flat (or prism), which must be re-adjusted till they are so.

Though not so important this little contrivance detects the slightest want of coincidence between the axis of the great tube of a refractor and that of its eye-tube.

If any of the readers of the English Mechanic desire any further information upon either of the above hints I shall be glad to give it.

Vicarage, Romsey. E. L. Berthon.

P. S.—Since writing the above I have received a letter from Mr. Browning, to the effect that five years ago he tried silvering the second lens of an eyepiece, and a Barlow lens for viewing the sun. I am surprised that so admirable a plan has remained so long unused. Mr. Browning says that he found it better to insert a plane of glass silvered on both sides, and placed at an angle of 45°; but it must be very difcult to obtain such a piece of glass with *perfectly* flat and parallel surfaces, and it was this difficulty which led me to prefer a concave lens. I do not find the heat reflected back into the tube productive of any of the supposed disturbances, or that it impairs definition. Mr. Browning's method requires a hole in the side of the tube for the escape of the heat, and this is not always convenient. Let any amateur observer silver a concave spectacle-glass, and after fixing it in a paper tube, insert it inside his adapter, and he will see sun-spots, &c., as he never did before.—E. L. B.

SOLAR PHENOMENA.

[4038.]—As it is my custom to make a daily sketch of the solar surface, when clouds do not hide the sun from view, I have been able to trace the progress of several phenomena of great interest. Not the least remarkable among them were the shifting movements of a small spot, which I perceived for the first time on April 12th. It lay to the south of a tolerably large opening, situated upon the west limb, in the northern hemisphere. On the days mentioned below, the position angles (the intersection of the wires being at the centre of the larger spot) were as follows:—

April 12th	5h....................................	242°
,, 13th	,, ...	233°
,, 14th	,, ...	152°
,, 15th	,, ...	158°

On the 16th the pair were so advanced towards the extreme edge of the disc that I was unable to find any trace of them, with a power of 140.

It will be noticed that, with the exception of the slight retrogradation on the 15th inst., the motion was from west to east, by the south. This direction was also observed by Mr. T. W. Backhouse, of Sunderland, to be taken by a spot in its revolution round another, which was visible on the northern zone on May 9th, 1870. The line joining them rotated through an angle of 80° or 90° in 5½ days. "It is interesting to observe," says a writer in *Nature*, "that the direction of this rotation (from south to east) is the same as that in which cyclones rotate in the earth's northern hemisphere; in the southern hemisphere they rotate in the opposite direction. This coincidence gives some support to the theory of solar spots being produced by cyclones." (September 1, 1870.)

But the retrograde movement of the spot on the 15th inst. (from east to south) has its counterpart in a large opening which I observed in July, 1870. The small companion to it moved from south-east to south-west, through an angle of 35°, in 23h. This also occurred in the sun's northern hemisphere.

The solar surface, especially in the equatorial regions, has of late been diversified by vast groups of spots, which, from day to day, have presented a most interesting and astonishing series of changes. Had it struck me earlier, I might have delineated some of the principal groups in detail, to exhibit, in a succession of drawings, their daily alterations in appearance as they passed across the disc. Yet, on several occasions, the complexity of many of these spot-aggregates was extraordinary, and might have severely taxed my artistic skill—whatever that may be!

I do not think that "P. S. T." (qy. 11548) would find a revision of double stars, and of other oft-inspected heavenly objects, an occupation of such transient interest as he seems to apprehend; on the contrary, if he once got over a few preliminary difficulties, I feel sure the pleasure of the labour would excite him to continue it. Guided at first by a work such as Darby's "Astronomical Observer," or Smyth's "Celestial Cycle," a telescope would soon cease to be a mere toy in his hands, and would afford him many a pleasant hour of unfailing and instructive employment in one of the most soul-stirring of the natural sciences. But, supposing for a moment that "P. S. T." found his interest in such studies to be on the decrease, he might endeavour, with a good 9¼in. or 10¼in. reflector, such as Mr. Browning supplies, to aid the Moon Committee in their Selenographical labours. Our little satellite, though so much examined, is still a wide field for research, and can never fail to yield a store of detail to a careful observer, provided with the requisite means. Reflecting telescopes (equatorially mounted) of the sizes mentioned would cost "P. S. T." from £100 to £150, a price about one-fourth of the value of an equatorially-mounted 6in. refractor. As such reflectors perform best in an observatory, constructed on the plan of that described by the Rev. E. L. Berthon in No. 342, Vol. XIV., of the ENGLISH MECHANIC, "P. S. T." would have at his disposal great power and efficiency, combined with small expense, by purchasing one of them. But I have no doubt Mr. Proctor will give a fitting reply to his inquiries, and he could not have applied for an answer to a more competent guide.

April 18. W. BROWN.

REVOLVING FURNACES—DRILLING MACHINE.

[4039.]—SEVERAL years ago I read in a newspaper a report that the Manager of the Dowlais Iron Works had constructed a revolving furnace, which was giving great satisfaction, and specimens of the puddled iron had been exhibited at a meeting of the trade in the Midland Counties. It was likewise stated to be the intention of the Company to erect more furnaces on the same plan. I hope it is not asking too much, if those capable of doing so would let us humble readers know, if such had been the case; or, if not, what was the reason? As it is reported here, Danke's patent has been declared invalid, and the agreement with the English iron masters broken through. A full statement of this, if true, might be a very proper subject for the pages of "ours." A universal angular drilling machine is figured on p. 57 of this volume. How is the ratchet motion used on such machine, as it is not shown in the engraving? A tool for the same purposes was figured in the *Penny Mechanic*, August 17, 1868, as invented by Messrs. Westroy and Forster, Barrow-in-Furness, Lancashire, which seems to me to have a stouter and better sliding bracket. Those who may have seen both tools would oblige by giving their opinion of both machines for actual hard service.

LINUM.

COMPRESSIBILITY OF THE ATMOSPHERE.

[4040.]—OWING to this property, it follows that at lower elevations, two or more, or many given volumes must be compacted together in a space, which at higher elevations one such volume suffices to occupy. Hence, as the density of air is to that of water, so, though in a far less degree, is the density of the air at any level to that of the air immediately beneath it.

It follows, therefore, that the bullet fired horizontally from a gun must be deflected upwards, though in a far less degree in its course through the air, even as it is by striking the surface of the denser fluid, water.

I wish to ask your learned correspondents whether they have ever considered that the well-known phenomenon—viz., the rise of the bullet from a gun above the line of aim, is thus accounted for. I beg also to express my conviction that the spinning top is supported, placed or even replaced, in its vertical position from the same cause. If I am right, a top should not be able to spin in a vacuum. I have no means of trying this experiment, but feel convinced that it will not.

Seer Green Vicarage. J. M. TAYLOR.

THE FAIRLIE LOCOMOTIVE.

[4041.]—THE letter Mr. Fairlie has sent (page 41), signed by G. Allan, though giving many particulars, is very far from complete.

1st. It makes no mention of the diameters of the cylinders of the three engines: and, unless I am mistaken, the Fairlie had slightly the largest.

2nd. No mention is made of the stroke of either the "Wonder," "Pony," or "Giant."

3rd. The pressure on the driving wheels is not mentioned, and though the total weight of the Fairlie is half a ton less, yet if in the "Pony" or "Giant" there was less pressure on the driving wheels than in the Fairlie, the tractive power would, of course, be less.

4th. It does not state whether sand was used by any of the engines after they first started.

5th. It is stated that the Fairlie engine is economical in fuel, but no mention is made of what average amount per mile, and as engines made from the same design and exactly alike, as far as can be ascertained in every respect, are some more economical than others, one cannot be surprised at some difference existing in this case.

6th. As regards steam pressure, if we compare it at the different points given on the journey, we shall find it as follows:—

	Giant.		Welsh Pony.		Little Wonder.
At starting ...	150	...	150	...	160
At far end of embankment	160	...	142	...	165
At Weigh-house	Not stated	...	140	...	167

Thus, in every instance given, the pressure in the Fairlie was in excess of the others. Here again is another omission—viz., the pressure in the Fairlie at the point where the other engines were pulled up.

7th. The diameter of the driving wheels is not mentioned, either of the Fairlie or the other engines.

8th. A point is made of the diminution of oscillation, consequent on the use of bogies; but were not these used on the ordinary engines some years before the first Fairlie was built? and as it is not a thing belonging exclusively to this particular class of double engine, we are not, therefore, obliged to adopt the Fairlie system because we want to diminish oscillation.

I must say I agree with what our correspondent "Osa" (let. 3864, p. 41) says in his last paragraph. Now, I suppose, Mr. Fairlie would say he intends his engines for drawing extra heavy loads on the ordinary gradients as well as on very steep banks. Now, as there are engines on one of our main lines, whose load is 40 full or 60 empty trucks, surely Mr. Fairlie would not advocate trains of 80 loaded or 120 empty trucks, making a train of about 650 yards long, causing a fearful strain on the couplings, and rather unmanageable if it was necessary to pull up quickly. But if the Fairlie is designed for overcoming steep gradients, why run so much unnecessary power when not required? If it was any advantage to have so much extra power, what is to hinder two ordinary locomotives being coupled to one train?

Our correspondent "G. R." (let. 3987, p. 96), though perhaps right as respects the 50 Fairlie, with 5 laid up being about the same as 100 ordinary engines with 10 laid up, yet seems to forget that engine boilers, &c., are not so easily interchangeable as the parts of a military rifle, and that an engine must needs be "laid up" in order to have its boiler or whatever is necessary changed. Then he says that another advantage is the regularity of water-level on inclines; but he forgets that the Fairlie has not an upright boiler, but a horizontal one.

Again he says "the contingency of one of the motions breaking down when three cylinders will remain effective," is an advantage overlooked. But, if this is so very desirable, why not do as I said before—viz., couple two engines to one train? This would have one decided advantage over the Fairlie, inasmuch as if an axle or tire of one of the two engines broke, or any part which totally disables an engine, you could at least use the other engine, but with the Fairlie if one end was thus disabled the whole would be useless.

Whilst writing on the subject of the Fairlie system, might I refer to a statement I saw in print a few months ago, with what truth I cannot say, to the effect that Mr. Fairlie had invented a new kind of buffer to facilitate the passage of trains round sharp curves? It consisted of a single central buffer instead of the ordinary double one. Now, in the "Engineers' and Mechanics' Encyclopedia," published in 1836, at page 571 (Vol. II), is an engraving of an apparently similar construction that was used on the Dublin and Kingstown Railways.

I am sorry I was unable to answer Mr. Fairlie's letter sooner, but was unavoidably prevented.

A. G. BOYD.

Cheshunt, Herts, April 17.

[4042.]—GRANT space but for a few words more, because, as I take it, the object of the Fairlie locomotive, or, rather, that which should lead the public to have an interest in it, is similar to that of the ENGLISH MECHANIC—namely, the opening up of new fields of operation and research. And the latter brings the same principles to bear—to wit, flexibility of (wheel) base, easily adapting itself to the various curves and inclines, often very great, of the different branches (of knowledge); steadiness; smallness of gauge (of type); and length (26 pages solid). Amos Appleyard says (page 96), that the companies could easily build far heavier engines than they at present use. He does not say how this is to be done, seeing that the limit of adhesion is already quite reached, and every inch of width is taken up. So much so, that in some recent goods engines on the Brighton line, the slide valves are put underneath the cylinders to gain room, also to admit of longer bearings on the crank axle. Moreover, it is not found advantageous to couple more than six wheels together.

However, our present trains are quite heavy enough, and it is not likely that Fairlie engines would be generally required for the 4ft. 8in. or wide gauge, the Mexican railway being an extreme case, as abounding with steep inclines and sharp curves. But the Fairlie principle supplies the possibility of building an engine for the 3ft. gauge of the same power as our present heaviest goods engines; and it is possible to make a line on the smaller gauge which will pay where the expense of the wider would be simply ruinous. So that whole districts in this and other countries hitherto debarred from the advantages of railway communication may be opened up and become valuable feeders to the existing trunks. Indeed, so satisfactory has been the working of the little Festiniog line, on which 35 miles per hour have been run, although its gauge, only 1ft. 11in., is admittedly less than it would have been had it been originally intended for steam, that the Indian and Russian Commissions both reported in favour of a narrower gauge with Fairlie engines. And a bill of the London and North-Western is now before Parliament to extend the Welsh line on the same gauge to Bettws-y-Coed. The difficulty with regard to the flexibility of the steam and exhaust pipes has been also so completely overcome that they are now said to give very little trouble. G. R.

WARMING AND VENTILATING.

[4043.]—WILL "E. L. G."—who considers that any one who proposes to ventilate a room in any other way than by withdrawing, or allowing the escape of, its air from its very top, supports a "misleading and mischievous fallacy," and that any plan which permits any of the air which has once been breathed to mingle with that which will be breathed, "a murderous arrangement"—kindly explain to us how it is that though all warm-blooded animals do, whenever they breathe, draw back into their lungs a large proportion of the air which has just left their lungs, they are not injured, but benefited thereby? Such being the universal arrangement for respiration, it is, of course, the right arrangement, even though it be in direct opposition to "E. L. G.'s" dictum, and that it is the universal arrangement cannot be disputed by any one who remembers that a large proportion of the air expelled from the lungs on expiration necessarily remains in the windpipe and other air channels, to mingle with and help to warm the air drawn into the lungs at the next inspiration. I do not know the proportion of the air inspired which does not enter the lungs; but it is, probably, not much less than half, and this accounts for the proportion of carbonic acid in expired air being much greater in that forced from the lungs by a very deep expiration than that of ordinary breathing, the air so forced being less mixed with air which never entered the lungs at all.

It is clear, therefore, that "E. L. G." is quite mistaken in attributing dire effects to the mere mixing with air of a small part which has been once breathed, for that we are doing constantly, yet it is quite essential to health and comfort that air that has been breathed should be quickly removed, and I allow also that it is desirable to let it escape from the top of the room; but deny that it is essential to [illegible] is very frequently not done in rooms wh[illegible] ventilated, as any one may prove b[illegible] a fire is burning air enters the ro[illegible] however high, unless, indeed, it [illegible] chimney. To make openings t[illegible] for every cubic yard of inclosed space to let in and out just as much air as is breathed, neither more or less, or anything like it, I will believe to be possible when I see it done.

Has "E. L. G." any evidence to prove that the air at the very top of a room is materially different except in temperature from that which has just descended from the top from being cooled by contact with the cold glass of the window, when it is not cold enough to condense the moisture by the removal of which the air would be somewhat purified? If not, how will be prove that it is essential to remove the air from the very top of the room? M. R. C. S.

DR. CARPENTER AND PERSPECTIVE.

[4044.]—How many more times will M. Paris need to be told that perspective is totally unconcerned with what the eye may notice or not notice (p. 119); being matter of pure mathematics, and dependent on *the plane of projection* chosen? On a vertical plane, all really vertical lines must be projected vertical, and no tower not tapering can have its picture tapering *at all*. Whether its height be 100ft or 100 miles, a hair's-breadth of convergency is wrong, nor will any *levelled* camera make its photograph converge one hairs'-breadth. Tilt the camera upward, and, of course, the lines will converge—"painfully" if viewed as a vertical picture, but be equally right, rightly viewed. M. Paris shows that he has the very first notions of perspective yet to begin. E. L. G.

DUODECIMAL SYSTEM.

[4045.]—Though the last paradox of the author of letter 3965 (p. 118) would be far better answered by the "F.R.A.S." than *I* can pretend to do; yet, as our learned and indefatigable astronomical instructor has, by going out of his way and rôle (let. 3960) incurred, as I contend, the paramount duty of going to the bottom of his geological statements, it becomes mine, however imperfectly, to help in the defence against "the multipliers of £19, &c., by £19."

Feet can no more be multiplied by feet or inches, than pounds can be multiplied by pounds or shillings. In finding an area of a rectangle you are told to multiply the units in length by the units in breadth, merely because we have chosen as the unit of area the square whose side is a unit of length (and this not always, for an acre and a rood are only units of area, not related to any particular linear unit). That an oblong of 3 inches by 5 contains 15 square inches is only a short way of saying its area is to that of one an inch long and an inch broad as 15 to 1. There is no natural reason for fixing on the *square* of a linear unit as the superficial unit, rather than the equilateral triangle on the same base, or the circle (which is, perhaps, the most natural). If we used *circular* inches, the length and breadth of an oblong multiplied would *not* give the units in its area. But the inches in the length and breadth of an ellipse would give its area exactly, by mere multiplication. So, if we used *trigonal* inches, a trigon whose base was 4 would have its area 16 exactly; but a square or oblong would *not* have their areas expressed by the product of length and breadth. Thus lineal and areal measures are as distinct in kind as shillings and degrees of heat, and the connection between the units we choose of each is purely conventional.

Feet, therefore, multiplied by feet, do *not* make square feet. Not at all. No more than feet multiplied by lb. make the mechanician's foot-pounds. To say that they "make square feet" is merely a compendious way of expressing the use of an arithmetical dodge; a way of saying shortly that the number of feet in one line multiplied by the number in another line will give a product equal to the ratio between certain areas. But regard it how you will, let feet × feet make square feet, then, as one has told you, £ × £ can only make square £. Till you show us a "square pound," or its worth, or explain to us what it is, and what it will buy, your computation has no meaning.

Hind's figures have plain meanings as units of area. The first denomination are square feet; the next, twelfths of square feet; the third, square inches. But the working by multiplication is never used but by schoolboys. The rule of "Practice" is the only rational and practical treatment of such "squaring and cubing." E. L. G.

TO "THE HARMONIOUS BLACKSMITH."

[4046.]—If our obliging friend "The Harmonious" visits the Exhibition early in the season, perhaps he will say which of the pianofortes are most worthy of attention, and thus oblige many who, like myself musically inclined, will only be able to spend one day in the building, and, consequently, will want to economise time as much as possible. A. B. L.

Fastening Loose Window Sashes.—The most convenient way to prevent loose window sashes from rattling unpleasantly when the wind blows is to make four one-sided buttons of wood, and screw them to the stops which are nailed to the face casings of the window, making each button of proper length to press the side of the sash outwards when the end of the button is turned down horizontally. The buttons operate like a cam. By having them of the correct length to crowd the stiles of the sash outwards against the outer stop of the window frame, the sash will not only be held so firmly that it cannot rattle, but the crack which admitted dust and a current of cold air will be closed so tightly that no window strips will be required.—*Industrial Monthly.*

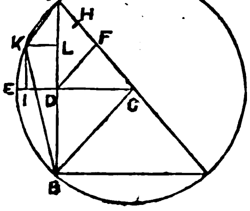
REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[9440.]—**Mathematical Question** (U.Q.).—The diameter of a circle being one, to inscribe in it a triangle, the rectangle of whose two sides shall be equal to the square of half the base of the triangle. Also to show what are the values of the three angles of the triangle, and of the sector in which the said triangle is found. Let angle of sector $= 2\,m$; and A C Q be the diameter. Let A C Q = unity; C, the centre; A B, the base, bisected in D by radius E C, equal to ½; then



A D into D B = ½ × ½ × sin.$^2\,m$ = altitude of triangle × diameter of circle (Euclid VI., C.). Draw D F perpendicular to A C in the point F; then A F = A D × sin. m; but A D = A C × sin. m = ½ × sin. m, ∴ A F = ½ × sin.^{2} m, therefore, if we bisect A F in H, we shall have A H = ½ × ½ × sin.^{2} m, as in the first deduction. Make D I = A H; draw K I parallel to A D, cutting the circle in K, and draw K L parallel to I D, and therefore equal to it or to A H; join K A and K B and (Euclid VI., C.) we have K A into K B = K L into A Q = A D into D B = square of half the base of the triangle, which was demanded. Also, let the arc K E be equal to (n), then the side K A will be equal in value to sin. $\left(\frac{m-n}{2}\right).1$; and K B = sin. $\left(\frac{m+n}{2}\right).1$; and A B will be equal to sin. $m.1$; or sine of half the number of degrees in the sector; and, lastly, the angle A K B = 180° − m, of which the last named is also the sine.—*Q. E. D.*—Thetamu, Horsham.

[10640.]—**A Reason Wanted.**—I am, and have been for many years, accustomed to use a means of lifting heavy weights, such as cabinets of minerals, chests of drawers, &c., with ease, namely by laying hold of the cabinet, &c., breathing out steadily, and lifting simultaneously with the breathing; and I learned the method at college, where we placed a man on the ground, and took hold, each of us, four in number, of an arm or a leg. He came up easily while we breathed out, and fell as easily when we ceased to do so! The breathing out brings all the bones of the chest into a compact form, and draws upwards the arms.—Gerard Smith.

[10664.]—**Angle of Reflection and Incidence.**—Dufton, in his work on "Practical Billiards" says the angle of incidence is the acute angle made by the incident line with a perpendicular line touching the cushion. "Billiardist" and "F. N." take opposite views of the difference between the forces of compression and restitution. I always understood that the momentum destroyed in restitution bears to that destroyed in compression a constant ratio; that is, a ratio independent of the intensity of the impact; but if this were the case it would follow that in a case of oblique impact, as when one ball is played at another, a half ball division, the balls should take the same directions whatever be the magnitude of the momentum, but it is well known to all billiard players that the harder you strike the wider the balls fly apart.—A. P. S.

[10664.]—**Angle of Reflection and Incidence.**—"Billiardist, on p. 100, thinks I am in error in stating that the co-efficient of elasticity is the force of restitution divided by the force of compression, and that the co-efficient of elasticity diminishes with increase of momentum. If I err it is in good company, as I made the statements, not on my own authority, or from my own observations, but on what, I think, will be admitted to be the very highest authority, although in strictness I ought to have employed the word velocity instead of force. But, in the first place, allow me to state that "Billiardist" is quite correct as to the generally accepted meaning of the words angle of incidence and reflection. Sometimes, however, the angles made with the plane struck are employed instead of those made with the perpendicular, and in my reply to the query I unfortunately did so by mistake. Now, as to the meaning of the phrase co-efficient of elasticity, most writers on Mechanics use it in the sense in which I employed it—viz., the ratio of velocity of recoil to velocity of approach. I thought of using the phrase co-efficient of restitution as being more correct, but did not like introducing any new term. I have since observed, however, that Sir Wm. Thomson has proposed that very expression as being more in accordance with facts. Again, as to the statement that this co-efficient diminishes with the momentum, I have several authorities; my chief, however, is M. Athanase Dupré, who, two years ago, published the results of his experiments, being the most elaborate and carefully executed series ever undertaken with the view of determining the laws of collision of elastic bodies; he experimented with ivory balls of seven different sizes, from 1¼in. to 2½in. diameter; falling on a marble slab from all intermediate heights, from eight-tenths of an inch to 8in.; also, with these same balls, suspended by threads over 10ft. long, and allowed to strike the same marble slab, and each other, horizontally in every possible way, from distances varying from 1in. to 40in., and, of course, velocities in the same ratios. The number of carefully recorded experiments is over 200, and in every instance was the co-efficient of restitution less with increased momentum. That this should be the case, I think it would not be difficult to give a good and sufficient reason, if my remarks had not already extended too long; but, nevertheless, I should be most happy to have "Billiardist's" proof to the contrary. I stated in my first communication that there was a very great variety of matters to be considered in calculating the angle of reflection of a billiard ball, most of which tend to make the angle of reflection greater than that of incidence; but there is one cause of a contrary effect—viz., the soft nature of the cushions, which by yielding cause the ball to rebound more towards the perpendicular, and, no doubt, is quite sufficient to produce the results which "Billiardist" describes. My remarks and all the experiments with which I am acquainted, have been with hard elastic bodies, such as glass, steel, ivory, marble, &c. I should like much to have "Billiardist's" proof that the harder the blow with which one billiard ball strikes another, the greater is the ratio of recoil to approach, as it is contrary to all experiments with which I am acquainted.—F. N.

[10731.]—**Fastening Escape Wheel in Lever Watch.**—I am surprised to find "West Cornwall" finding fault with my reply on page 100. If the job had been sent to me I should have done it without soft solder. I was influenced by two considerations in my reply—(1) the wording of "S. H. L.'s" query led me to believe that he had little practical knowledge, and not the skill to make the nicety of fit to get the wheel right height for the pallet stones, therefore I gave him a simple method by which he could make a tolerably good job of it; (2) I sent the information in the belief that it would suit his particular case. I spoke of the soldering iron because I had in my mind some men who when they have had a verge contrate wheel or lever escape come loose on the staff, have used the blow-pipe and softened both staff and pinion. Not a particle of soft solder in the original composition of the watch. "W. C." surely knows that the fusee and stop are soldered on to the arbor; that all verge colets (both English and French manufacture) are soft soldered on, and I have often met with balance staff colets done the same. For twenty years I have been seeking the best methods of doing all kinds of jobbing work, and I am a learner yet. If soft solder forms the great mainstay of all my operations, I can yet give watch querists a few practical wrinkles.—A Yorkshire Pivot.

[11024.]—**Stuffing Birds.**—"Frank M.," or any other of our readers, would, indeed, want to use their judgment if they depended on A. J. Shaw's information. I will try and help "Frank M." from my practical experience. Let the bird cool so that the blood will coagulate, then stuff a piece of cotton in the mouth to soak up any moisture; dislocate the wings by turning them over the back towards the head; by doing so the bird will be easier to skin. Make an incision from the centre of breastbone to vent, just large enough for the body to pass through; having come to one of the legs, cut the second joint across with a pair of scissors, skin to the bend of the knee, and strip the flesh off the bone; then take hold of the foot, and draw the bone back in its place, treat the other leg the same; next cut the tail within a quarter of an inch of the stumps of the feathers, and cut off all flesh and fat; then stick a hook in the rump-bone, and suspend the bird; turn down the skin carefully and skin to the wing-joints, disjoint, and serve same as legs. When you come to the head skin a little below the eyes, but be very careful not to cut the eyelids; then cut off the neck at the poll; keep the body as a guide, lay the skin on a table, and cut as small an aperture as possible at the base of the skull, and take out the brains. Remove the eyes and roots of tongue, cut off any fat that may be on the skin, and apply any preservative you wish. I use ground alum four parts, saltpetre and pepper one part, and find it a first-class preservative. Previous to skinning take a piece of wire of suitable thickness and measure from the centre of bill to tip of toes, have the wire twice that length and double it in two, and point the double end with a hammer; do not separate them; point the other ends with a file. Having put in the eyes and twisted some cotton on leg bones, and filled up the aperture in skull with a piece of cork, thrust the double end of the wire through the cork, and let it enter the base of the beak; then twist some cotton or tow round the wire same thickness and length as neck; then separate and form a shoulder on each wire, roll up some tow same size and shape as the bird's body, and twist some thread round it; then thrust the wires through it, one at each side; then carefully turn the skin over your artificial body, in doing so place the wing bones in their right place; then pass the wires through the back of the legs inside the skin, add a little tow if required, sew up the aperture, and fix on stand by the wires; then form a piece of wire same shape as a hair-pin, and pass under and through tail into the body to keep tail up; tie the bill with a piece of thread till it sets; then give the bird the natural set, fix the wings in the right position, and pass a thread with a long needle through the body and last joints of wings and tie, not too tight, and tie tips of same at tail. Pay particular attention to the eyes, replace stray feathers with a needle, and brush down with a camel's-hair brush.—FREDERICK R. ROHN.

[11045.]—**The Bug Bible** (U.Q.) was printed by John Day, 1551, with a prologue by Tindall. It derives its name from its rendering of Psalm xci., 5, which reads, "So that thou shalt not need be afraid of the bug by night." This edition is very scarce, and rarely finds its way into the book-market.—JOURNEYMAN PAINTER.

[11054.]—**Calculating Contents of Cylindrical Vessels.**—"Excelsior" will see that his formula is incorrect. I gave the more usual and simple one. Had he said, multiply half the circumference by half the diameter to give the area, he would have been right, and that sum multiplied by the height (if vertical) will give the cubical contents.—TUBAL-KAIN.

[11083.]—**Treacle Beer** (U.Q.).—I see this in the list of unanswered queries, and as it is a refreshing, harmless drink, it should not remain unanswered. It was, and I suppose still is, a popular drink in Forfarshire, and was made in perfection somewhat as follows:—Heat four gallons of water to the boiling point, and dissolve in it four pounds of treacle. Let it cool to 170° Fahr., and then add a quarter of a pint of fresh yeast, or two pints of new ale taken from the fermenting tun, and stir briskly till thoroughly mixed. Bottle, but don't cork, for from twelve to twenty-four hours, during which time the bottles should stand in a warmish, or rather, not in a cold place. The time to cork is when the yeast rises fungus-like half a finger's length from the mouths of the bottles, and the beer will be in excellent condition in two days thereafter. The bottles should be pretty strong, as the quantity of carbonic acid formed is considerable. I am not sure that the proportions here given are the best: I write from memory of thirty years ago. They will, however, make a good beer, but any one who will take the trouble to experiment a little with varying proportions may make it better. One thing, however, must be kept in mind, the yeast or new ale must on no account be added to the solution of treacle till the temperature has fallen to the 170°, or at the highest 175°.—AULD REEKIE.

[11120.]—**A Question of Sight.**—J. Barwick must surely have taught our lively satirist "A. J. V. G." by this time the inutility of anything "wrote sarcastic" with the querists wherewith "ours" has to do. It is useless to be "agape with speculative wonder," and expect the virtue of an "if," even in italics (as our satirist says he meant to "speak in italics," p. 674) to prevent J. Barwick regarding the sun "as a point," if it happened to land them in novelties they have the distinction of not finding "noticed by any one but myself." By the way, it was not I who asked "A. J. V. G." seriously "why he should regard the sun as a point." He will see (p. 20) I merely questioned his luminous point "illuminating half" his globe, which seems not to have been "wrote sarcastic." Being thus on the subject of Mr. Barwick's last questions, first, I may as well proceed to remind him he is making no distinction between the space whence all rays or the space whence part of the rays of a luminary are intercepted. In other words, he is regarding the sun "as a point"—something whereof you cannot hide any without hiding all. Shadow is not, as he tells us, "the absence of intercepted rays." It is the absence of all rays (or all direct rays) of the luminary that casts the shadow. The spaces whence a part of its rays, but not all, are intercepted, are not called shadow by any one, scientific or not. There is no call, in common matters, to mention such space; and, therefore, the unscientific have no name for it; but astronomers and opticians call it "penumbra." The peculiar distinctness of shadows cast by an electric or lime light arises from their smallness, and the consequent small amount of penumbra round the shadow. These lights may show J. Barwick the shadows of his single hairs, even at some feet distant from him; which the sun never can at one foot, or even 3in., because his diameter causes all shadows he casts to be bordered by penumbra, the darker portion of which, next the shadow, seems a shading off, destroying its sharpness; but really the edge of shadow is a distinct line that may always be traced with care (at least when received on a white surface), while the limit of penumbra cannot, and the outer portions of penumbra are quite invisible to any eye, even on snow. Hence the moon is not eclipsed by merely touching our penumbra, nor is anything reckoned as a lunar eclipse but her touching the earth's shadow, the only shade whose limit we can see as a distinct line. On the other hand, we reckon as a solar eclipse every time the moon's penumbra touches our globe, for every point in her penumbra has part of the sun hidden. Her shadow need not touch the earth at all, and does not in eclipses that are nowhere total—and a majority of solar ones are of this kind—and in the minority, where the shadow does reach the earth, it can never exceed two or 300 miles wide; so that very few places, in a given century, have been in the moon's shadow, those only that have seen a total solar eclipse, while every place has, more than once, even in a child's life, been in her penumbra. Now Mr. Barwick has only (as I suggested to "A. J. V. G.," p. 20) to hang up a globe or bead in the sunshine, and measure how far its shadow (as distinct from penumbra) extends, which he will find between 108 and 112 times its diameter, and about three diameters farther in July than in January, to have the proof he asks, that the earth's shadow does the same (and also the moon's). The shadow ends at the point where an eye will have the sun exactly hidden by his globe, but by nothing a hair's-breadth narrower than his globe. Now as he knows that the moon sometimes makes annular eclipses of the sun, and yet sometimes total ones, he knows that her shadow may or may not be long enough to reach the earth, according to its variation of length with time of year, but more according to her own monthly variation of distance from us, which is greater than ours or hers from the sun. If he admits then that the earth is less than 4 times the moon's diameter, he must admit that "our" shadow, though always extending to the moon's orbit and even much farther, can never extend above 4 times as far. The penumbra of even the smallest thing (which is what he falsely calls "shadow") extends, if he will, to infinity. We are in Mercury's penumbra whenever we see him transit the sun, which, in fact, is a small annular eclipse of the sun. Now, returning to his first subject, what can he mean by 1130 *feet* per second being the "one hundred and seventieth part" the velocity of light; namely, some 180,000 *miles* per second? It is the 170th of the 5280th part! But if air and ether are each composed of atoms (and one or other is, but we have no sure grounds for saying both are) we have nothing here to inform us which atoms are nearest. If, however, you take a 6in. cube of air, and let it expand into 8 such cubes, or a foot cube, Mr. Barwick will grant, probably, that we may be quite sure the atoms (if any) are now just twice as as far apart. Well, this can obviously be done in gas-pipes or sewers long enough to try experimentally at what rates sound may reach their end. This has been done under Paris by M. Regnault, with air varying in density as 5 to 1, the distance of atoms, therefore, as $\sqrt[3]{5}$: 1, or about 19 : 11, and the velocity of sound was just the same at a given temperature. At different degrees of heat, though with the very same number of atoms in the same pipe, the speed differs, as was well known. Long before this experiment (which was repeated in various pipes, Mem. de l'Acad: tom. 37, pp. 113, 171, 551), climbers on the Alps, as Stampfer and Myrbach, 1823, Bravais and Martens, 1844, had measured the speed of gun reports where the air is only about half as dense as at sea level, and the same equality had been found. Heat or cold alters the rate, though the atoms be at one unaltered distance; but distance of atoms alters it not at all, at a given temperature. Lastly, let Mr. Barwick observe that long before any of this had been tested by experiment, Sir Isaac Newton had predicted it all mathematically, from the mere mechanical properties of air, as settled in the well-known "Law of Mariotte." Therefore, what J. Barwick has succeeded in "impressing on" me (whether "anxious to impress on 'E. L. G.'" or not) is that however little any of us know of what air and other matter *is*, we may know it is *not* a number of things kicking one another, like J. Barwick's bits of needle; and that Newton knew rather more of it, even two centuries ago, than Mr. Barwick in 1872.—E. L. G.

[11120.]—**A Question of Sight.**—Tyndall says that, according to Wertheim, sound travels through iron at the rate of 16,822 feet a second, at a temperature of 20° C., quickening to 17,386 feet at 100° C. Mr. Barwick, p. 128, gives only 11,090 feet per second. I have very little doubt which is right, but Mr. B. will probably state his authority.—SAUL RYMEA.

[11120.]—**A Question of Sight.**—Mr. J. Barwick states that sound travels through air at a velocity of 1,130 feet per second, and as many readers of "ours" may not have seen the account of some late experiments on that subject made at the Cape of Good Hope, I subjoin the result. Further particulars, and the details of the experiment, will be found in the *Philosophical Magazine*, Vol. 43, No. 284, pp. 153-154, for February, 1872, on "An Experimental Determination of the Velocity of Sound," by J. E. Stone, F.R.S., Astronomer Royal at the Cape, on February 27, 1871. "There were 38 observations, and in the reduction of the equations, the co-efficient of elasticity of the air under a constant volume (that is to say, the ratio of the increment of pressure for an increment 1° F. of temperature to the pressure at 32°F.), was regarded as an unknown quantity, as well as V, the velocity of sound at 32° F. The reduction of the equations furnished by the observations gave—

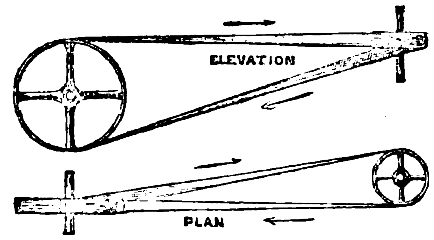
$$V = 1090{\cdot}6 \text{ feet per second.}$$
$$a = 0{\cdot}0019 \quad " \quad "$$

Regnault's value of a being 0·0020. There appeared to be but little difference between the residual errors as dependent on the motion of the air. The author grouped the residuals into two classes, according to the dampness of the air, but there appeared to be no appreciable difference in the velocity as dependent upon dampness."—LINEA.

[11129.]—**Greek "Upsilon."**—Nobody pretends that our transliteration is meant to convey the true sounds of either Greek or Latin. It is purely historical and matter of grammar, and after 2000 years, admits, I must again insist, of no innovation whatever, as long as Roman letters are used at all.—E. L. G.

[11166.]—**Area of Segment of Circular Ring.**—"J. K. P." has correctly but very needlessly figured, on p. 128, the most curved of the forms I remarked that "Thankful's" segment might have had. I should call it as much a "segment" as his own figure, p. 650. In the broadest sense, anything is a segment that is cut off, whether by one straight cut or two. It is not a sector unless the two cuts are directed to the centre, and there being no hint, either in the query or drawing, that this was intended, I could not see my way to any such conclusion. I therefore gave "Thankful" a rule equally applicable whether he meant "sector" or not.—E. L. G.

[11196.]—**Turning Perpendicular Shaft.**—Samuel Smither's sketches A and B would possibly mislead an unpractised hand. The wheels shown in sketch A are bevel and not spur-wheels, and in sketch B the positions of the pulleys will not carry the belt. I inclose sketch, plan, and elevation: were they put as he has shown them, they would not drive, unless they were a



very great distance apart in comparison with their diameters. My sketch shows the relative positions of the pulleys to lead the belt right. If the shafts are required to move in the opposite direction, they would have to be reversed in positions to lead the belt right.—TUBAL-KAIN.

[11208.]—**Incubators.**—My only wish was, if possible, to find an incubator that would hatch to a certainty, and I thought "Shylock's" plan would not, as there is no heat over the eggs. I have got several expensive patented ones, and none of them will do it to a certainty. Brindly's, of Derby, does it the nearest, and the heat there is conveyed in copper pipes over the top of the eggs. I have this night put eggs in an incubator of my own make, and if I succeed I will give you a drawing of it. I have eggs above and below the heat, and a very fine jet of steam conveyed across the top of the eggs, but not touching them. I have from 1,500 to 1,600 eggs per year, many of which I try in my incubators, and I must say spoil. I should be glad to hear if "Hatcher" got any chickens out of the one he made (Cantelo's).—M. O.

[11223.]—**Stereotyping.**—I am under the impression that the mode of stereotyping with the plaster process has been given in back volumes. "H. W. R." must oil his type well, and remove the superfluity with a brush, then put an edging round it, and having the plaster mixed rather thinly pour it on. When dry remove and bake in an oven, standing the cast on edge. He will now want a casting-box, which consists of a tray with a lid capable of being screwed down, and what is known as the floating-plate—a plate of cast-iron with notched edges fitting the bottom of the tray. The plaster-cast having been oiled or plumbagoed is placed face downwards on the floating-plate at the bottom of casting-box; the lid, which has pieces cut off two corners to allow the molten metal to flow in, is then put in position and secured by the screw so as to give the requisite thickness of metal for the plate. The whole is then plunged into a bath of the molten metal, which flows in through the holes at the corners, lifting the floating-plate slightly as well as the cast, but by means of the notches in the edge of the floating-plate the fluid metal gradually spreads over and into the crevices and lines in the plaster cast, and owing to the pressure of the metal in the bath a solid cast is obtained. The process is not an easy one for an amateur; the plaster casts require a high temperature to bake them, and need careful handling afterwards. But such is an outline; if "H. W. R." wishes for details I will help him, or possibly some of "our" friends, who may have succeeded in getting good casts with more simple apparatus, will come to the rescue.—SAUL RYMEA.

[11226.]—**Concertinas.**—I do not know what is the peculiarity of a "trio" concertina, but a "bass" is merely an instrument supplied with reeds yielding bass tones instead of the usual treble ones; a "piano" is one with soft-speaking notes, and a "chromatic" is one with semitones. They are, of course, similar in construction to the German concertina and are as easy to play. The only thoroughly chromatic concertina is the English.—E. M.

[11233.]—**Marine Engineer.**—Presuming that "E. W. B." wishes to determine the proper velocity of the piston I copy the rule given by Templeton: Multiply the log. of the *n*th part of the stroke at which the steam is cut off by 2·3, and to the product add ·7. Multiply the sum by the distance in feet the piston has travelled when steam is cut off, and 120 times the square root of product will equal the proper velocity of piston in feet per minute. In condensing engines the approximate velocity of piston with stroke of 22in. would be about 150ft. per minute.—E. M.

[11237.]—**Four-Wheeled Vehicle.**—Your carriage would be drawn easier up hill with large wheels than with small ones. The reasons for which you will see fully gone into in the number of the ENGLISH MECHANIC for January 12, 1872 (reply 10054).—101, PARK-STREET.

[11255.]—**Farm Estate Agent's Duties.**—The duties of an estate agent (read the "General Text-Book for Architects, Engineers, Surveyors, Land Agents, Solicitors, and Others," by E. Ryde; and "For Landowners," by J. Donaldson; also the "Book of the Landed Estate," by Robert E. Brown) being thus so multitudinous, it is evident that the person undertaking them must be a man of high and general qualifications, such, indeed, as the most liberal, practical, and scientific education can alone confer. In the first place, it must be his business to make himself thoroughly acquainted with the property, and with a things and persons connected with it. He must superintend and conduct the whole of the work that is done on the estate, give all orders himself to the subordinate officers (each foreman in every department), and see that each performs his duties. He ought to have a thorough knowledge of the principles and the best practice of good farming, to enable him to encourage the system of culture best calculated for the soil, the climate, and the peculiar circumstances of the estate. The best practical book on farming I have met with is "The Book of the Farm," by Henry Stephens. Also read Morton's "Cyclopædia of Agriculture," and "The Journal of the Royal Agricultural Society of England." For a general knowledge of agricultural chemistry and geology, read the books written by James F. W. Johnston. Of arboriculture, or the raising of forest trees, planting and forming new plantations, the general management of old woods and plantations, and of different descriptions of fences, read the book written by John Grigor, The Nurseries, Forres, N.B.; "The Forrester," by James Brown; "The Transactions of the Highland and Agricultural Society of Scotland;" and "Transactions of the Scottish Arboricultural Society of Scotland." Of surveying for making plans of roads, new plantations, drainage, and computing the contents of pieces of land in exchange between estates, farms, &c., for general improvements; on architecture, for the making of plans for farm buildings, cottages, &c., making specifications and estimates of all buildings and all other works on the estate, see the "Book of Farm Buildings: their Arrangement and Construction," by Henry Stephens and Robert Scott Burns. Also, in the above-named books will be found a lot of useful information on this matter, and the valuation of landed property, of the soil, houses, woods, minerals, manorial rights, royalties, fee farm rents, tenant-rights, &c. He has, moreover, to let the farms, cottages, &c., to the tenants under such conditions as shall induce them to cultivate the land to increase its productiveness—this should be his constant aim. Collecting rents: This is a very simple matter to do when the money is forthcoming—see the above-named books. A little knowledge of law between landlord and tenant is quite necessary. Read "Every Man His Own Lawyer," Dixon's "Law of the Farm," Rouse's "Practical Man," and Archbold's "Landlord and Tenant."—Thirteen Years' Agent.

[11294.]—**Dividing Metal Disc.**—So simple a problem does not require an elaborate answer. Take D = the exterior diameter of disc in inches, and n = the number of equal area smaller discs to be cut out of the same. It would be, $a = \frac{D^2}{n}$ = area of the several discs in circular inches; then for the smallest disc $\sqrt{a} = d$, the diameter in inches, the next size $\sqrt{2 \times a} = d$, then $\sqrt{3 \times a} = d$ and so on.—Tubal-Kain.

[11299.]—**Tarpaulings for Railway Carriages in the Tropics.**—I have seen a material invented by Spill and Co., Bow Common, which is as pliable as a glove, and always remains so, not being affected by either extreme of temperature. It is the result of twenty years' experiments, and the amicable co-operation of two substances hitherto as opposed as fire and water. It is in use on several English, American, and Indian railways.—Amateur.

[11318.]—**Setting Lathe.**—To F. Hume (additional).—I don't think the screws between the beds are intended to be moved; but if they are, could you not make a mark to indicate exactly how far you have to set them back after altering? My contrivance for tapering is merely a hardened cone-point screwed into a hole in the collar-plate, or into a separate plate of the same description, if there is not a convenient place in the collar-plate itself, of course taking care to keep the centre at the right height, and set the head up with a hammer. Screws cut taper with this plan would not be drunk if, as well as pulling the back centre over towards you, you also alter the mandril-head so as to be truly in line with the back centre itself. But taper screws (true ones) are rarely, if ever, wanted. I think if I had to use your lathe I should take out one set-screw or both and fit in a parallel piece of iron (or brass) on each side to regulate the position of the mandril-head, and the said pieces of metal need only be (say) 1in. square or less, and if they had a rivet or stud sticking out ¼in. on one side, which you could insert into the old screw-hole just when you are putting the head-stock back in its place, they would not drop out. Don't pinch your fingers in doing it. My mandril-head is held by a thin wedge on one side.—J. K. P.

[11339.]—**Astronomical.**—It is asked "why does the polar star always occupy the same place when the earth's axis, by reason of its orbit, changes position?" The polar star may occupy the same place as compared with other stars, but it does not occupy the same place as compared with the Pole, or rather the Pole does not occupy the same place as compared with the star. In the year 1790 the Pole and the star were about 1° 49′ apart; in 1839 the distance between them was about 1° 33′, and now it has decreased to about 1° 22′ only. Mr. Porter may consult with advantage upon this subject Sir J. Herschel's "Outlines of Astronomy" (a new edition of which, I see by the English Mechanic, has just been brought out), and the astronomical vol. of Orr's "Circle of the Sciences," and, doubtless, other works on astronomy, but I mention these because I happen to know of them. The star does now appear to describe a small circle in the heavens once in twenty-four hours, but this arises from the rotation of the earth on her axis, not on account of her revolution in her orbit.—C. W. M.

[11354.]—**Fire Balloons.**—If your correspondent, William McDonald, refers in his question to fire balloons, the proper material for a fire balloon of 20ft. in circumference will be 12lb. double crown paper, that is paper of double crown size, each sheet measuring 30in. by 20in., and weighing 12lb. per ream. To inflate it, a cotton pad soaked in spirits of wine is fastened to the junction of two cross wires arched upwards in the mouth of the balloon, and the balloon itself must be supported by a loop at the top fastened to a head line, so as to hang 5ft. clear of the ground, and fastened so that by pulling a string the attachment can be cast loose. The balloon should be held out above the mouth by two persons, the spirits of wine lighted, and when the balloon is thoroughly inflated the string is pulled and the balloon let go. It is generally the fault that they are let go much too soon, and before they have power to rise rapidly. A balloon of the size mentioned will require some small weight as a car to be attached to it to keep it steady, and the mouth should be about 12in. or 14 in. in diameter.—J. F. E.

[11387.]—**Sundials.**—"Philanthropist" must excuse my mentioning it, but it appears to me that his reply to this query may mislead some persons. That edge of the gnomon which casts the shadow which indicates the time on a sundial must be parallel to the earth's axis, and therefore, although in an erect south dial it should form an angle with the plane or face of the dial, equal to the co-latitude of the place, yet in a horizontal dial it should form an angle with the plane of the dial equal to the latitude of the place. For a place having 45° of latitude, the angle would be the same for either of the above-named dials. A dial may be drawn upon a plane in any position, but the above rule for fixing the gnomon must be adhered to.—C. W. M.

[11393.]—**Metallic Harmonicon.**—What does "Zoo Andra" mean (in his reply to query 11393, p. 108) by "similar to an inverted aquarium," and then further on, saying that this "inverted aquarium is to be partly filled with a solution of alum"? Does he mean an "inverted fern case," or what?—Tuba.

[11398.]—**Stinging of Bees, Hornets, and Wasps.**—Take a pinch of tobacco, damp the palm of your hand, work and rub the tobacco until you get the juice well out, then rub the spot where stung well with it for five or ten minutes. I have found this a perfect cure for bee stings, and used it with success only last Sunday. Let the sting be withdrawn as soon as possible.—S. W.

[11409.]—**Canine.**—The dosing with Dr. Rooke's Oriental Pills, recommended on p. 103, should be "for about three weeks," not "eight weeks" as printed.—Amateur.

[11415.]—**Scarlet Runners** are scarlet runners!—*i.e.*, there is only one *scarlet runner*, a variety of tall-growing or running bean. There are white runners, Painted Lady, and black-podded or Negro runners; there is also a so-called giant variety of the scarlet—not a bit better than the common scarlet as grown by hundreds of cottagers, but more than double the price. Sow as soon as you like, now; dig deep, at least 2ft.; put in rotten dung if you have it; make a tolerably firm trench or drill, lay the seeds 6in. apart at the bottom, and cover them about 2in. When up about 3in. draw the earth round them up to the seed leaves. If the soil is well dug, they will not require water in ordinary weather—*i.e.*, watering at the root—but they do require almost daily syringing. You may, however, give them all the soap-suds you can get—either overhead or at the root. Stop them at 5ft. high, or some little distance before they reach the top of your supports. Try a row as dwarfs by stopping them at a foot, and pinching the growing shoots afterwards. If you have no manure ready give liberally of guano or artificial, and they will pay you handsomely. Your blooms fell off through weakness or sourness of soil, shallow digging (or rather scratching), or want of the syringe.—Saul Rymea.

[11423.]—**Surgery.**—Having suffered from a thing very similar—viz., a curled shaving passed with the graver, when engraving a steel plate, into the fore part of the middle joint of the forefinger; and in cutting some German steel plate up that was hard, a piece either from the chisel or plate struck into the middle joint of the little finger, and in carelessly using a pump drill it slipped and entered the ball of my thumb and broke about three-sixteenths of an inch off and left in behind, all of which were sore troubles for four or five years. The former was the cause of the other mischief. The severe pain in handling things made me clumsy. It is only dangerous in boring it about trying to get it out. The two former do not trouble me, and although entering on the inside have worked along to the outside just under the first joint. They never festered or gathered, but a hard core, like a wart, kept growing out of the place where they entered for a long time, which, when touched, was exceedingly painful, which led me to cut and bore it about to no purpose. You might as well look for the article in a load of hay. If it appears inclined to gather, take a strip of lint or a small portion of cotton wool, and place upon it wet, and keep it constantly moist. Place over that a piece of oiled silk and a finger stall. This is the best form of poultice, and will greatly assist the opening and the ejection of the enemy. Do not apply every nostrum, drawing salve, or plaster in succession that is recommended, for thereby many lose their limbs and frequently their lives.—Jack of All Trades.

[11436.]—**Harmonium.**—I am "musician and mechanic enough to know" that the channels of a harmonium pan (there are no channels in the reservoir) should be graduated the whole way through; but "Practical Horologist" will excuse me if I tell him he is evidently not a practical harmonium maker. What I wish to know is whether in practice an inequality of (say) 1-64th of an inch in cutting the channel frame for divisions makes any material difference in the tone of the note the unequal-sized channel is intended to give?—K. T. L.

[11442.]—**Old Wives' Science.**—If "A., Liverpool," just glances at Dr. Brewer's "Guide to Science," he will at once perceive the following answer to the question, why does the sun shining on a fire make it dull and often put it out, is, because the air (being rarefied by the sunshine) flows more slowly to the fire, and secondly, the chemical action of the sun's rays is detrimental to combustion. The sun's rays are composed of three parts, lighting, heating, and actinic or chemical rays. These latter interfere with the process of combustion.—Wee Pet.

[11442.]—**Old Wives' Science.**—With respect to reply on page 105, I beg to say, not only for "A.'s" information, but also for that of S. Bottone's, that there is very good foundation for the statement that the sun shining on a fire puts it out, and the following are the only true and proper reasons:—1. Because the air (being rarefied by the sunshine) flows more slowly to the fire. 2. The chemical action of the sun's rays is detrimental to combustion. The sun's rays are composed of three parts: lighting, heating, and actinic or chemical rays. The two latter interfere with the process of combustion. 3. The air flows more slowly to the fire for being rarefied, because the greater the contrast between the air in the room and that which has been heated by the fire, the more rapid will be the current of air towards the fire. 4. Because rarefied air contains less oxygen than the same bulk of condensed air (or air that has not been rarefied by the heating influence of the sun's rays, in other words shaded, and therefore condensed). 5. In frosty weather the air being more condensed by the cold than at other times, as indicated by the high readings of the barometer during a frost, supplies more oxygen than a similar volume of warmer air, and consequently falls more rapidly into the place of the hot ascending air, and as we all know, makes a fire burn very brightly.—Science.

[11444.]—**Bursting of Compressed Air Receivers.**—The effects would be the same as those of steam, except the scaldings. Too large for any purpose. A series of egg-ended receivers, 2ft. diameter, 10ft. long, would be far better.—Jack of All Trades.

[11450.]—**Adjusting Equatorial.**—"Inquirer's" latitude is 53° 50′, and as ι Ursæ Minoris is 7° 45′ 42·4″ from the Pole, it is plain that his circle should read:—

$$\begin{array}{lr} & 61° 35' 43'' \\ + \text{ ref.} & 32'' \\ \hline & 61° 36' 15'' \end{array}$$

north declination at the instant of transit, or

$$\begin{array}{lr} & 90° \\ & -\ 61° 36' 15'' \\ \hline \text{N. P. D.} = & 28° 23' 45'' \\ \text{S. P. D.} = & 151° 36' 15'' \end{array}$$

—Thomas Buchanan.

[11451.]—**Weight for Safety Valves.**—If E. Naylor had the time and means to look up past vols., he would find sufficient information on the above. The following is an answer to his specific question:—Obtain a weight 9½lb., which at 16in. from fulcrum will give 39·96lb.; at 14in. from fulcrum, will give 34·66lb.; at 12½in. from fulcrum, will give 30·08lb.; at 10¼in. from fulcrum, will give 24·84lb. This is worked out according to Templeton. The effective weight of lever is correctly obtained by multiplying its length in inches by its weight in pounds, then dividing by twice the distance in inches from fulcrum to point of resistance. Thus a 60in. lever, 15½lb. weight, at 10in. from fulcrum, pulls 46½lb.; and at 20in. from fulcrum, pulls 23¼lb.—Mutual Improvement.

[11457.]—**Motive Power for Amateurs.**—The sketch shown is of no practical use, except to waste power by friction, and possibly to render the motion regular. Whatever the length of the pendulum (which is the way this would act) from the point of suspension to the centre of gravity of the suspended weight, so would be, in all ordinary cases, the number of vibrations per minute. Better apply your power, whatever it may be, in the simplest and most direct way.—Tubal-Kain.

[11459.]—**Printers' Ink.**—The recipe given by "H. B. E." (p. 130) is for common red ink, not printers' red ink.—A Barrister.

[11460.]—**The Beehive.**—In my reply to Mr. Godden I said that glass hives were dangerous things in a house, but I did not mean that they were likely to go raving mad and bite any one. The particular danger to be guarded against is the breaking of them, by which the bees might be let into the room, perhaps among nervous ladies or children. On that ground only I consider them dangerous, and recommend that they be always kept under cover, for accidents will happen. "Philo's" hive in the conservatory is a different affair certainly; but if his bees ever get loose he will find some difficulty in getting them back to the hive unless he be an expert. The reason the bees go into the conservatory is not because they see the hive there or their fellows, but because there is some attractive aroma, probably from the hive itself, which pervathe closed conservatory, and becomes palpable to the bees immediately on its being opened. Bees are "led by the nose" into all sorts of places, but glass houses bother them amazingly, as they do not perceive the difference between an open window and a closed one, and so they beat themselves against the glass until they exhaust themselves, or accidentally obtain egress. Many stocks are much injured through being in proximity to greenhouses from this cause, as they are induced to enter them by the aroma from blossoms therein, and perish there, and this in early spring causes great loss.—C. N. Abbott.

[11460.]—**The Beehive.**—I think no further proof is needed to show where the honey comes from than the diversity of its flavour, that from wild thyme, heather, and Narcissus being very strongly marked.—Inquiring Mind.

[11461.]—**Reviving Black Cloth Coats, &c.**—Black galls, bruised logwood, copperas, sumach, ½oz. of each, vinegar, 1 pint; macerate in a close vessel with heat for twenty-four hours; strain off the clear liquid and the copperas, and shake twice a week. Keep in a corked bottle, apply with a brush or sponge; this is improved with a little sugar or gum.—Inquisitive.

[11461.]—**Reviving Black Cloth Coats, &c.**—Those that look white I should think are cloth-dyed and mixtures; if you see Indices you will find revivers; if it is nap you require to use urine and ox gall, and a hard brush, a teasel brush, or a brush made of a piece of worn cotton cord. It strikes me that they have had too much brush, and nothing but turning will make them presentable.—Jack of All Trades.

[11465.]—**Problem.**—Mr. Tonkes appears to have misapprehended this query in his letter (4004, p. 126). "Puzzled" does not say that the trains move with equal but with uniform velocities. There is very little difficulty about the question. I see no answer to it, however, except Mr. Tonkes's rather weak criticism. The united velocity of the two trains is (92 × 84=) 176ft. in a second and a half, or 117⅓ft. per second. Now, the trains move with velocities such that one runs over 176ft. in six seconds of time less than the other, or, in other words, moves with a velocity $\left(\frac{176}{6}=\right)$ 29⅓ft., a second greater than the other. The united velocity of 117⅓ft. per second must, therefore, be divided into two parts, of which one must exceed the other by 29⅓. By a simple equation it is found that these parts are 73⅓ and 44, whence the velocities of the trains are 73⅓ft. and 44ft. per second, or 50 and 30 miles an hour.—V. B.

[11465.]—**Problem.**—The trains move at the rate of 30 and 50 miles respectively. Their united length is 176ft., which is passed in 1½ sec., = rate of 117·3ft. per second, and 29·3ft. per second = $\frac{176}{6}$.

$a + b$ = 117·3ft. per second.
$a - b$ = 29·3ft. „ „
b = 44ft. per sec. = 30 miles per hour.
a = 73·3ft. = 50 „ „ „

—Thomas Buchanan.

[11465.]—**Problem.**—Mr. Tonkes says (p. 126) that this problem (p. 80) is badly propounded. I consider it correctly worded and easy. First, take what is given last—viz., that the fast train passes the other 92 + 84 feet in six seconds, which gives us 29⅓ft. per second as the difference of their speeds. Next, when they meet, as in the beginning of the question, they will pass each other in the same time, as if one stood still and the other ran by with the joint velocities of both. Let the velocity of the slow one be v feet per second, then that of the fast one is v + 29⅓, and their joint velocity $2v$ + 29⅓, and at that speed 176ft. are by the question covered in 1½sec., or $\frac{176}{2v + 29\frac{1}{3}}$ = 1½sec., and v = 44, which is the velocity of the slow train, and 44 + 29⅓ = 73⅓ that of the fast train, or 30 and 50 miles an hour respectively. Mr. Tonkes has missed the signification of the word "uniform," which is that the velocities of the trains, though different, remain unaltered, while the "same" means that in the second half of the problem each train has the same velocity as in the first half.—J. K. P.

[11471.]—**Bows.**—Nothing can equal Spanish yew. Its return when loosed has that excessive velocity which gives the greatest vigour to the arrow's flight. Hickory, ash, and American elm are very tough, but very sluggish. They are excellent, therefore, for the backs, but useless otherwise in bow-making. Lancewood is very good when backed with any of the tough woods. I made some twenty years ago, and when shooting with them for Cheshire against Warwickshire, could have sold them for high prices. They were made of bright coloured lancewood, backed with hickory. After being shot with a day or two till they remained a little bent when unstrung, I cut out a piece of the lancewood from the centre of each bow, about 4in. long, right through. In place of these two rather longer pieces were glued in, throwing back the horns of the bow. They proved in this state excellent target bows, and very durable as well as handsome.—J. M. Taylor.

[11473.]—**Weak Voice.**—Practise singing daily, standing and leaning back. "Os homini sublime." The gamut in long sustained notes sung *crescendo* and *diminuendo* will be found useful. Over-exercise of the vocal organs is injurious. The rule "Ne quid nimis" is always good as a check to enthusiasm.——I thank Mr. Birt for pointing out my neglect of parallax. What I wrote of refraction causing the lunar orb to appear quite above the horizon when really below it, is true of the sun, the parallax of which is 8½ seconds. The parallax of the moon is a quantity far exceeding refraction, except at the horizon, when the two effects (parallax pushing down and refraction raising up—the bulls and bears of the superterrestrial exchange)—will nearly counterbalance each other. I have seen a case of unusual refraction at the horizon, when an invisible rifle butt was raised so as to look like the tower of a church, equal by estimation to four degrees.—Thomas Buchanan.

[11476.]—**Pattern Making.**—I know of no work on pattern making. To become a pattern maker you must have some idea of moulding, and it is only to be learned by practice. If there is any special patterns you require instructions to get out, there is not the least doubt but what you will find assistance in "our" columns.—Jack of All Trades.

[11479.]—**Tempering Cutting Tools.**—To prevent a lead bath from becoming oxidised when heated for such purposes is out of the question. Colza or Gallipoli oils and Ginseng oil are the best both for hardening and tempering. The raw oils are best for hardening, but they must be well boiled for tempering. Have a wrought-iron cistern set upon some bricks the size you require for your job, and a cover to fit, in case it should fire, which it will very readily at that heat, and your cistern not more than two-thirds full.—Jack of All Trades.

[11481.]—**Organ Building.**—It does not matter if the pipes touch at the back and sides, but they must be so firmly fixed that they will not rattle against each other. If "Aleph" is in any difficulty about what I have already written upon, I will be glad to answer any question, but if prospective difficulties, I must say "wait." I am sorry I shall not be able to continue my letters for a few weeks, being confined to bed with a broken leg, and 100 miles from home.—J. D.

[11483.]—**Dyeing Parchment.**—Have you tried Judson's dyes? To prevent them being affected with water or grease, use a weak varnish of shellac; one ounce of shellac put into a pint of spirit, and shaken up for a minute or two and poured off answers well for such purposes.—Jack of All Trades.

[11484.]—**Manures and their Values.**—Johnston's "Manual of Agricultural Chemistry," or Sibson's "Agricultural Chemistry" (published by Routledge), preferably the former, will afford the information Mr. Richardson requires. Johnston's lectures, particularly the appendix, would be useful, also the articles on "Agriculture and Manures" in the *Encyclopædia Britannica*, if these are available. As regards information to a beginner on the cultivation of a few acres of land this could not readily be given without some knowledge of the nature of the soil. Cannot the querist scrape acquaintance with some bucolic neighbour and obtain a wrinkle from him?—William Glazier.

[11485.]—**Florentine or Brown Bronze.**—No. These bronzes will not do for tinwork, but a red bronze can be given to tinwork with a very small portion of sulphate of copper dissolved in water and applied. It can be done over after with blacklead and polished with a soft brush, and lacquered with dark or light lacquer, as the case may be, and if the tin ware is wet all over with diluted muriatic acid before it will give it a frosted appearance, and it may be varied according to strength of solutions.—Jack of All Trades.

[11487.]—**Preventing Rust.**—Take an old stocking foot and daub it over with a mixture of four parts beeswax to one of olive oil, and one of turps, melted, and keep in a pot for use. When the above is well daubed over with it your wiper will last some time without a renewal of compost. After well polishing your work, well rub with the above rubber.—Jack of All Trades.

[11488.]—**Coating Wooden Concrete Moulds.**—Use a wash at first of alum water. When dry coat it with a strong solution of soap.—Jack of All Trades.

[11491.]—**Kid Dressing.**—If black, dress the face with a strong decoction of elder bark, afterwards with a decoction of nut gall and acetate of iron, finish with a coat of glair and rub down with a piece of old cloth with a few drops of olive oil upon it.—Jack of All Trades.

[11493.]—**Indiarubber Overcoat.**—Get some pure rubber and dissolve it in ether to a thick paste, and apply. The ether will soon evaporate and leave the seams sound.—Jack of All Trades.

[11497.]—**Removing Oil Stains from Billiard Cloth.**—Use finely-powdered Bath brick and a warm iron. Afterwards well brush.—Jack of All Trades.

[11500.]—**Welding Cast Iron.**—Should be welding cast steel. Two parts silver sand and one of sulphate of lime, or plaster of Paris, which is the same, will do for the job. Heat your article and dust it with the above, place in the fire again until you get a good heat, and it will weld.—Jack of All Trades.

[11505.]—**A Wooden Pump.**—Put in a metal working chamber or barrel in which the bucket shall work, it may be either of copper, brass, or cast iron.—Tubal-Kain.

[11510.]—**Defective Sewing Machine.**—The brush is there for retaining the loop until the point of hook has entered the next descending loop from the needle, and should then become free. I expect the edge of the recess in the hook is worn away, and the spool not having anything to support it, drops down between the hook and shield and jams the thread; if so, it can be made deeper in its place by taking a tennon saw file, and grinding the shape and using a block of wood for a rest, turn it out in its place. I have cured several by these means.—Jack of All Trades.

[11511.]—**Rubber Tires.**—I can assure "Constant Reader" that rubber tires do not "draw" harder than iron ones, but easier over rough roads. On smooth roads there would be no advantage. There is no suction between the tire and the road, which querist will find if he attempts to lift the wheel from the road. If there was, I do not think it would be an obstacle to a rolling motion. An indiarubber tire eases the draught by lessening the vertical motion. Whatever force goes in lifting the machine and rider over obstacles—that is, in vertical motion—is a dead loss to the desired horizontal motion. The analogy between indiarubber and soft roads does not hold good. The perfect elasticity of the rubber alters the case altogether. Force is consumed in compressing the rubber; but it is again given out to the wheel when it is restored to its original state; and it then urges the wheel forward as much as it offered an obstacle to the forward motion at first. Mud remains in a compressed state, consequently there is work done, and force consumed.—101, Park-street.

[11513.]—**Refining Animal Oil for Sewing Machines.**—This can be done with a weak mixture of sulphuric acid and water, after with potash or soda, and finally with lead shavings or zinc chips.—Jack of All Trades.

[11513.]—**Refining Animal Oil for Sewing Machines.**—The two chief impurities in oil for delicate machinery are margaric and stearic acid. For gun locks and, I believe, for watchmaking also, where the principal object is to prevent clogging, take, of course, to begin with, the purest neat's-foot or trotter oil, put any quantity in a wide-mouthed bottle, well corked, and scrape into it a quantity of bright, soft lead shavings, nearly half fill the bottle with the lead, which must be bright. Cork and expose to bright sunshine for a fortnight, shaking the bottle every time you go near it. If not perfectly clear and limpid at the end of that time, pour off oil, scrape in a fresh quantity of lead, and repeat process. Margarate and stearate of lead are formed, and the acids removed from the oil.—M. A. B.

[11514.]—**Brunswick Black.**—Boiled oil and asphalte, thinned down with turps.—Jack of All Trades.

[11514.]—**Brunswick Black.**—Fuse 2lb. of asphaltum in an iron pot, add of hot boiled linseed oil one pint; mix well, remove the pot from the fire, and when cooled a little add of oil of turpentine two quarts. Some makers add driers.—A Barrister.

[11516.]—**Veneering.**—Level the ground work, tooth, and size it, wet the veneer on the top side, glue the other side evenly (which is the great secret in veneering clean), work the glue out with a veneering hammer. If very large wet the veneer again and rub on a hot flat to melt the glue and work the hammer again, in this way you may lay a veneer any size. I have laid one 15ft. long without assistance. For French polishing see back numbers.—M. O.

[11516.]—**Veneering.**—Veneers are laid on by the trade by means of a veneering hammer or caul, but for an amateur a common light-headed hammer will do as well, if not better, as the use of the caul with advantage requires a certain amount of practice. In veneering by the hammer the ground should be warmed by the fire, and the outside of the veneer wetted with warm water or glue made very thin, applied by means of a sponge, and the side to be laid covered with a coating of thin glue, and warmed at the fire. The veneer should next be laid on the ground or on a table, and worked with the hammer backwards and forwards till neither air nor glue will come out. Even for experienced workmen veneering with the hammer is best when the veneers are straight and even, but as that is seldom the case, work is generally done with the caul. There are some favoured individuals who take to the caul as naturally as a duck to the water, but I have found the hammer to serve all requirements; but, of course, every one has his prejudices. A caul is an instrument made of solid wood shaped to the surface to be veneered, consequently the making of cauls will be rather expensive, especially for amateurs who have only one or two things of each kind to veneer. The caul should be well heated, then oiled and greased; it is screwed down upon the veneers, and the heat and pressure sends out the glue, causing the veneer to bed close to the ground. The veneers should be of an even thickness when worked by a caul, otherwise the glue will collect and the work is liable to blister; it should not dry too quickly. The great fault with amateur veneering is blistering, and the workman's skill is exercised in no small degree in getting rid of these unsightly blemishes. The way this is generally done is as follows:—First, wash the exterior of the blister with boiling water, and with a coarse cloth remove dirt and grease; then place it before the fire, or heat it with a caul; oil its surface with common linseed oil; place it again to the fire, and the heat will make the oil penetrate quite through the veneer and soften the glue underneath, then while hot raise the edge gently with a chisel, and it will separate completely from the ground; be careful not to use too great force or you will spoil your work again. If it should get cold during the operation, apply more oil and heat it again; repeat this process till you have entirely separated the veneer; then wash off the old glue, and proceed to lay it again as a new veneer.—P. W. H. J.

[11518.]—**Respirator.**—"Jersey Crapaud" will find a piece of ordinary calico, unglazed, with a string sewn on both ends answer his purpose; if one thickness is not close enough, use two.—Elektro.

[11518.]—**Respirator.** — An excellent respirator may be made of a thick sheet of carded cotton wool placed between two pieces of muslin. Professor Tyndall's experiments show that nothing stops dust more effectually.—A BARRISTER.

[11518.]—**Respirator.**—Take some cotton wool and place between two pieces of horsehair cloth. Makes a very good one for grinding, millstone dressing, or saw sharpening, bind it round the edge with kid leather.—JACK OF ALL TRADES.

[11522.]—**Goldfish.**—See that the fins and tail are unbroken, that no scales are rubbed off, and that there is no appearance of what I may call (for want of a better name) mouldiness about the fish. This latter indicates a disease very common and almost always fatal to fresh-water fish when kept in confinement, and strongly resembles the white mould which appears on stale bread, fruit, &c. It is very contagious; therefore, if apparent on one or more fish in an aquarium, all the others should be considered doubtful.—LOACH.

[11522.]—**Goldfish.**—These fish should be bright and lively, with perfect scales and fins. If any of the former are rubbed off, or the latter split, they never do well, and generally die soon. Goldfish require frequent feeding. The best food is vermicelli, or dried beef, powdered, given in small quantities. — A BARRISTER.

[11522.]—**Goldfish.**—When in good health the tails of these fish are perfectly flat. The opening and shutting of their gills occurs at regular intervals of about one second, and the eyes have a blue tint. If the tails are crumpled at all, or the eyes are at all red, the fish are not good, and I should advise "S. K." not to buy them.—ANON.

[11524.]—**Pitch of Roof.**—The proportion of the height of the roof above the eaves to half its breadth is the pitch. What is called the true pitch is 1 : 1, or 45°. Houses are seldom built now with roof so steep. See Bennycastle's "Practical Geometry."—PHILANTHROPIST.

[11525.]—**Fresh Water Aquarium.**—I have an aquarium 3ft. 6in. × 1ft. 8in. × 2ft., which contains altogether the following fishes and animals, which live in harmony together. I think "S. K." will find it a good example: 2 goldfishes, 1 silver carp, 1 small torpedo eel, 12 minnows, 2 efts, 2 tritons, 6 water beetles, 1 pollock, 2 long-noses, 8 fresh-water whelks, and 1 small cassavery. I feed them on watercresses and lob-worms; bread crumbs I put in for the silver carp and toast for the copper ditto.—ANON.

[11525.]—**Fresh Water Aquarium.**—Any kind of fish, but keep them as much as possible of the same size. Small fish, as a rule, will damage any larger ones in the same collection, unless the aquarium be very large. Plants: Fontanalis antipyrectica (if procurable): Anacharis alsinastrum (procurable everywhere). The former is best, as carp and other coarse fish will eat Anacharis but I never knew of any fish eating Fontanalis.—LOACH.

[11525.]—**Fresh Water Aquarium.**—Almost any fish may be kept, except sticklebacks. These little wretches, although very interesting when kept by themselves, destroy all other fish, large or small, by splitting their fins and tails, which soon brings them into a state of disease. I have kept gold fish, carp, tench, gudgeon, minnows—these will do well for years. Roach, dace, perch, bream, and mullets will live for a time, but are much more delicate. The best plants for an aquarium are Valisneria and Anacharis. — A BARRISTER.

[11527.]—**Barrister.**—A person wishing to become a barrister must enter at one of the Inns of Court, pay about £30 for fees, deposit £100, and find two sureties who undertake that he shall conform to the rules of the society, &c. The £100 is appropriated for the fees when he is called to the bar, or is returned should the student take his name off the books. The actual qualification consists in appearing in Hall a certain number of times, in each of twelve terms, at the dinner hour (commonly called eating terms), and the student must have been a member of the Inn at least three years. There is no doubt that very shortly a strict legal education will be required as a qualification; at present I believe the only examination is a voluntary one upon the subjects of the lectures lately instituted by the different societies.—A BARRISTER.

[11527.]—**Barrister.**—Qualifications required are too numerous almost to mention, but these are some of them.—A good classical, and yet more, a good mathematical education, a knowledge of the statute and common law, the power of speaking, confidence in one's own powers, and a good constitution.—JANNIFRED.

[11531.]—**Water Wheel.**—V = velocity of stream of water in feet per second; then, quantity = $2{\cdot}0 \times {\cdot}25 \times V = Qv$ (1). The power = $\cdot075 \times Qv \times 80$ = H.P. (2), allowing 65 per cent. of the effective power of the water available for useful purposes.—TUBAL-KAIN.

[11531.]—**Water Wheel.**—Before I can answer the first part of this query I must know with what velocity the stream of water runs, and the angle at which it strikes the buckets; also, I might as well ask whether, by centrifugal engine, "Columbo" means a rotary engine, because, if so, I would say don't. A rotary engine is the rock upon which the inexperienced split. No really practical man will now advocate a rotary engine. In spite of all inventors may say to the contrary, the rotary engine has not been made that will beat the reciprocating engine. One may be invented some time, but it seems far distant. If "Colombo" will answer the above questions, I will see whether I can satisfy his requirements.—P. W. H. J.

[11532.] — **Steam Fire-Engine.** — Shand and Mason's engines are very powerful for their weight. I extract the following from "Recent Improvements on the Steam Engine," by Bourne, 1869, p. 304:—"In an experiment made with one of these engines at Messrs. Pennison's factory in 1864, with an engine having two cylinders of $6\frac{9}{32}$ in. diameter, and 7in. stroke, the power generated with steam of 120lb. pressure in the boiler, and with 152 revolutions per minute, was about 15 horse-power." Another case is stated on page 306:—"The engine exerted 32½ actual horse-power, and as the total weight of the engine was only 32 cwt., the weight was about 1 cwt. per actual horse-power, a very remarkable result." Further information if desired.—PHILANTHROPIST.

[11533.]—**Area of Boat.**—A cubic foot of water weighs 62½lb., so the tonnage can be readily calculated from the solid content of the immersed portion, the area varies according to the model, being greater for a given tonnage in a long, narrow, or sharply built boat.—PHILANTHROPIST.

[11534.]—**Cleaning Metal Buttons, Jackets, &c.**—Cut out of a clean piece of thin deal, a protector like sketch, put the button through the large hole and run the slit up on shank. This is to protect the cloth. Clean

with very fine (not gritty) whiting and water, with soft nail brush and elbow grease. Rub white cloth with pipe-clay, and brush off well, repeat if necessary; this will not remove grease. Clean German silver with rotten stone and oil.—M. A. B.

[11534.]—**Cleaning Metal Buttons, Jackets, &c.**—Use finely washed whiting for jacket, take pollard or middlings and a fresh baked loaf, the above will do for keys for flute. Preparation of whiting:—Take a ball of whiting and pour boiling water upon it, and make it of the consistence of new milk, let stand for two or three minutes, pour the liquor quietly off into another vessel to settle for use.—JACK OF ALL TRADES.

[11535.]—**Small Wheel-Cutting Machine.**—See indices. There was one given to be fixed upon lathe bed.—JACK OF ALL TRADES.

[11536].—**Character of Curve.**—This curve will naturally vary according to the place where the water is poured upon it, and it would, I should think, assume the character of the different conic sections, but it is worth experiment.—P. W. H. J.

[11537.]—**Scott's Patent Moulding Machine** is nothing more nor less than a worm wheel dividing plate revolving round upon a pedestal, and furnished with a horizontal slide or radiating arm. It has a vertical slide, which is furnished with jaws for the insertion of the templates, which are made by the pattern maker of wood for the pitch. It is generally made with two or three teeth. There is a train of wheels, the same as an ordinary wheel-cutting machine.—JACK OF ALL TRADES.

[11537.]—**Scott's Patent Moulding Machine.**—Better write to the patentee and maker in Manchester. He, no doubt, will be glad to supply information. There is an older patent, by P. R. Jackson, which does not appear to be so generally used. Nevertheless, it is possible to make good wheels without either of them.—TUBAL-KAIN.

[11539.]—**Wooden Beehive.**—Many thanks to "H. A. D." for his good opinion of my suggestions for improvement in hives, but with all respect, and in perfectly good temper, I beg to refer him to Mr. Woodbury's own description of his improvements in hives for apiculture, and the bar frame in particular. Mr. Woodbury was the first adapter and promulgator of bar frames and bar frame hives in England; hence the hive bears his name. I am glad to give information at any time, but think it unfair to other inquirers and subscribers to occupy space on a subject which may be found so well treated of elsewhere at so trifling a cost. If "H. A. D." will advertise his address, I will send him a bar frame as a pattern if he will pay the postage.—C. N. ABBOTT.

[11543.]—**Amateur Observatories.**—See Wm. Brown's letter on "Solar Phenomena."

[11545.]—**Sulphur.**—This has been answered several times. Take a pitch kettle and fill it about one-third full of oil, and place upon a fire to boil. At first it will seethe and spit, afterwards becoming calm and the surface beginning to smoke. The temperature will be then between 500° and 600°. Then put sulphur in in proportion of 1oz. to every lb. of oil, and stir. It will become mixed, and when cold have the appearance and consistency of Stockholm tar.—JACK OF ALL TRADES.

[11548.]—**Bending Amber.**—Drop it into some hot beeswax; after it has remained there a few minutes take it out and before the fire bend it to any shape.—JACK OF ALL TRADES.

[11549.]—**Water Floats.**—Floats are scarcely ever used now for boilers using so high a pressure as "Young Fireman" mentions, because the stuffing-box is a fruitful cause of mischief, from corrosion. Wherever floats are used it will be necessary to raise the float up and let it fall at least twice a day to prevent corrosion. The water-gauge (glass) is so immensely superior that few modern boiler makers, having the interest of the buyer at heart, would supply a float, if offered his choice which he should supply. There is no doubt but that floats could be, and are, made to act perfectly, but at the cost of an immense amount of trouble. I would advise "Young Fireman" to get or ask his employers to get a glass water-gauge.—P. W. H. J.

[11549.]—**Water Floats.**—Don't use them, they are worthless and unreliable, give endless trouble, and never to be depended on. It is so difficult to get the packing around the wire the exact tightness —too loose, it "leaks;" and too tight, it "jams." Many a boiler has gone up like a balloon that was set with such a defective fitting, and the poor unlucky "stoker" has, in many cases, had all the blame cast on his head when he little deserved it.—TUBAL-KAIN.

[11549.]—**Water Floats.**—Yes, they are of use if made to act upon a valve in feed pipe, but are a nuisance through the boiler, by reason of the wire and gland.—JACK OF ALL TRADES.

[11550.] — **Preserving Eggs.** — "Young Nest Hunter" had better leave the poor birds alone, unless he has the definite object in view of benefiting some public museum or assisting the cause of natural history. Being "wishful to form a collection" seems to point too sadly to decreasing the number of specimens in this country of the more rare birds—such as kingfishers, green woodpeckers, &c.—as one can scarcely fancy even a youth collecting linnets' eggs. Pierce and blow the eggs; the "white skin" cannot and need not be removed. White hard spirit varnish, where there is reason to believe colours will fade, will have a retarding effect.—JANNIFRED.

[11551.]—**Cement.**—After the meerschaum is manufactured there is nothing will cement it to make a job of it.—JACK OF ALL TRADES.

[11551.]—**Cement.**—I have heard that a cement for meerschaum pipes can be made with quicklime and white of egg, but I think if it had proved satisfactory it would be more frequently used.—SAUL RYMEA.

[11552.]—**Meerschaum.**—The safest way to test a pipe is to try if it will float lightly in water, as I have never seen any composition which could be mistaken for meerschaum which would do so.—A., Liverpool.

[11553.]—**Agriculture.**—The best book for "Agricola" is undoubtedly "Evans on the Chemistry and Machinery of the Agriculture of the Present Day." In attending to its simple rules I have been very successful in hops, oats, &c.—CINCINNATUS.

[11557.] — **Treasury of Botany.** — The latest edition of this book was published in 1865. Cloth, 8vo. Its price is 7s. 6d.—ANON.

[11558.]—**Refuse Paint.**—Make it hot with a small portion of linseed oil, and rub through some gauze wire with turps. It is coarse, but good for outdoor work.—JACK OF ALL TRADES.

[11558.]—**Refuse Paint.**—See reply, p. 623, Vol. XIII., Sept. 8th, 1871, by "Os." If correspondents would search back vols. before sending queries, it would save much time and trouble. By-the-bye, what has become of "Os" and "Eos." I hope they will soon re-appear after this protracted silence.—H. B. E.

[11558.] — **Refuse Paint.** — Dissolve sal. soda, ½lb. in rain water, 1 gallon; cover the refuse paint with sal. soda water for two days, then heat it, adding oil to reduce it to a proper consistence for painting and straining.—INQUISITIVE.

[11560.]—**Gold Polishing on Stone, &c.**—This requires putting on in a peculiar manner, and I believe the ground is laid in with Armenian bole; it can then be polished with an agate burnisher.—JACK OF ALL TRADES.

[11563.]—**Moon.**—The moon influences our distance from the sun in two ways. 1. It causes us to be nearer to the sun at the time of full moon than at new moon, and *vice versâ*. This is because the common centre of gravity of the earth and moon describes an exact ellipse round the sun; if we leave out the small difference made by the perturbation caused by the other members of the solar system. This being the case, and the earth revolving round this common centre of gravity, M. Paris will see that the earth is alternately within and without the said orbit, being without it at time of new moon, and within at the full moon. 2. The presence of the moon causes our mean distance from the sun to be greater than it otherwise would be, for the distance is altered in inverse proportion to the joint square root of the mass of the sun and earth and moon; the moon being left out the joint mass would be diminished by the twenty-five millionth part, and we should revolve in an orbit further from the sun by nearly two miles, a difference which, of course, would be wholly imperceptible; the distances of the other planets too would be influenced in a like proportion.—G. F. H.

[11566.]—**Equisetum.**—I have seen the movement of the pollen myself, and would send M. Paris a specimen if I knew his address.—M. D.

[11567.]—**Rigging Model Yacht.**—Fasten mainsail to mast with fifteen brass rings, and foresail to mast with thirteen ditto; these should not be too large for the respective masts, but just large enough to travel easily at the mast near deck, they will then be quite slack at top, or bounds of masts, when sail is set up to place. The neatest and best way to secure shrouds to the hull of model is, use the brass screw eyes, small size, used or sold to hang up small pictures, these have a very good screw cut on them, and if screwed to margin of deck as proposed in my article on "Model

Yacht Rigging" in a former volume, will be out of harms way, then pass end of shroud through the eye and draw tight, and take two half hitches and cut off ends, allowing a little surplus end for convenience. A good way to prevent ends of shrouds fraying out, is to tip each end with a little hot pitch or sealing-wax.—W. F. W.

[11568.]—**Turbine.**—Better go to a maker and give him the fall you can obtain for your water, and the quantity in a given time.—TUBAL-KAIN.

[11570.]—**Furniture Polish.**—My answer to qy. 10585 was not a furniture polish, but a French polish reviver. The French polish sweats and the surface becomes rough, and the sharpness of the acid is to take it off, and if it will not remove it take some very fine brickdust on your cloth and rub well without scratching. The quantity of oil is about one tablespoonful to a pint, well shaken, which gives it a creamy appearance. Finish off with a clean cloth, and see that you leave no oil on the face.—M. O.

[11572.]—**Compressing Water.**—I consider this question to be one of great importance. Water has always, in my experience at least, been considered to be practically incompressible. Unless further particulars are given of this case, I should say that the extra gallon or so pumped in goes to waste by leakage.—C. S.

[11572.]—**Compressing Water.**—Water is certainly compressible. There is an instrument called the piezometer for measuring the compressibility of water, and by its use it has been found that at a pressure equal to that of the atmosphere water is compressed ·00005 of its original bulk. This, it will be observed, is a very small amount; but it shows an appreciable degree of compression, and probably the enormous pressure in an hydraulic press would compress water to the extent indicated by the gallon pumped in after the press is up.—SAUL RYMEA.

[11572.]—**Compressing Water.**—No doubt but that the water with the pressure exerted was slightly compressed. The remainder was that of the elasticity of the cylinder, the four side bars and nuts, and the two large blocks spoken of. Always remember "Smeaton's" rule; Nothing is elastic, and (so to say) nothing is non-elastic, but every substance has more or less of elasticity.—TUBAL-KAIN.

[11572.]—**Compressing Water.**—Water is incompressible in itself, but consisting of an infinite number of globules, the spaces between these are occupied by air, and it is this air which is compressed, and allows of some more water being forced in after the cylinder is apparently full. Is J. Westwood aware that if a ball of gold be made with a small hole in the centre, fill the ball with water, screw a plug and hard solder it, then place under a hydraulic press, that the water will be forced out like high pressure steam through the pores of the gold ?—A., Liverpool.

[11574.]—**Gas.**—Try one of Carnaby's patent regulators.—H. B. E.

[11574.]—**Gas.**—Let "H. J. W." turn down his main cock a little more, and use Bray's patent burners, and turn off the gas from the servants' rooms himself every night, and then report progress.—L.

[11575.]—**Well Sinking.**—You had better have the well sunk of the usual diameter about 4ft., and brick it up to any diameter, and fill in round it. It would be difficult to bore larger than about 4in., and even then you must go down to the rock, as it is called, by well borers. Water will not always rise to the top of the earth; it depends upon where it is supplied from.—M. O.

[11582.]—**Spiral Turning.**—See p. 557, Vol. XIV., February 16, 1872, with drawing.—M. O.

[11583.]—**Vacuum in Barometer Tube.**—"Never Rust" had better take the tube out of his barometer, then empty the quicksilver of the bottom short tube; place thumb of right hand over the open end tightly, and turn the tube bottom upwards; now lay baize or cloth doubled several times upon counter or table, and keeping end covered, commence jarring the tube upon this pad till he sees the air bubbles have all risen to the surface of quicksilver. Let the jarring be performed in quick succession. All that is required is a quick light hand; well warming the whole tube (especially the bulb) before a good fire facilitates the operation; patience and the above must succeed. Having got out all bubbles, refill as before by pouring silver in tube, and repeat the inverting and jarring process; or if he thinks the quicksilver is dirty, see Vol. VIII., p. 566, for recipe to clean quicksilver. Having cleaned it, refill tube in usual way. To adjust weights, let the one which rest upon silver be heaviest, the whole five in frame.—A HOROLOGICAL MECHANIC.

[11584.]—**Cleaning Cornopean.**—Mix a little vitriol with warm water, and run through the instrument; it will clear all dirt out.—J. P.

[11584.]—**Cleaning Cornopean.** — Let "Wee Pet" fill his slides with water and clean by means of a small bottle-brush. Then put in the slides and pour warm water into the bell, and gradually turn the instrument, so that the water may run through the tubes and out at the mouthpiece. The little water remaining may be blown out at the valves and water-key.—C. T. B.

[11584.]—**Cleaning Cornopean.**—I don't think it requires if the inside of the tubing of a cornopean is furred or dirty. I keep mine in a very good state by running through it every month a mixture of half vinegar, half water, working the valves well at the same time. You may put it by for months after this, and the valves will not stick.—J. G. S.

[11589.]—**Dry Steam.**—The higher the pressure of steam the less the quantity of water contained in any given quantity of it. Steam from a tea kettle, evaporating at 212°, will burn you severely, while you may place your hand in high pressure steam with impunity. You cannot see steam until it condenses on exposure to the cold air, consequently when at high pressure there is very little water to be condensed, although there may be great heat to fly away.—A., Liverpool.

[11592.]—**Medical.** — The ammonia citrate, or potassic tartrate of iron.—M. D.

[11593.]—**Lime Juice and Glycerine.**—The article sold under this title is simply a calcareous soap, which "Duffer" may imitate thus :—Take an ordinary wine bottle and fill it to the depth of three inches with good olive oil, or olive and castor oils mixed, add 2in. in depth of fresh lime water, half an inch of glycerine, and ten drops each of essence of bergamot and essence of lemon, or any other scent which he may prefer. Shake it well and keep it in a moderately warm place, or the ingredients will soon separate. This preparation was originally introduced from America under the name of "Lime Julep," which is what it really is. The ingeniously misleading name of "Lime Juice and Glycerine" was a happy thought of some sharp perfumer. It is very palatable (without the castor oil), and with the addition of one-fourth part of vinegar makes a capital salad dressing.—J. L.

[11593.]—**Lime Juice and Glycerine** (so called).—Take of almond oil 4lb., lime water 4½lb., oil of lemon 1oz. Weigh the almond oil into a dry bottle, add the lime water in quantities of about 5oz. or 6oz. at a time, with agitation, lastly, add the oil of lemons.—A. P. S.

[11598.]—**Long and Short Rifles.**—The data given are not sufficient, the bore of rifle, weight of powder and bullet, also the initial velocity must all be taken into account.—A BARRISTER.

[11598.]—**Long and Short Rifles.**—What reason has A. G. Miller for wishing to reduce the length of the barrel of his rifle? It would not shoot so well if cut down to 26in. As a rule, the shorter the barrel, the quicker should be the twist of the rifling, for example, the long Snider has one turn in 6ft. 6in., whereas the artillery carbine, carrying the same ammunition, has one turn in 4ft. If A. G. Miller will say what description of rifle he has, and the distance between the fore and hind sights, I will try to assist him with respect to the sighting.—ARTILLERY CAPTAIN.

[11604.]—**A Task for Chemists.**—EXTRACTING RESINOUS AND SILICIOUS MATTER FROM WOOD.—If Geo. E. Davis will cut his wood into chips about 1½in. or 2in. long, ¼in. thick, put them into a solution of caustic soda and water—about 1lb. soda to 25lb. water. A heat to indicate 380° Fahr. must be given and maintained for an hour and a half or more; then he will find his wood as soft almost as wool, with all the resinous and silicious matter quite dissolved out. 380° heat means about 181lb. pressure per square inch, which is the great objection to the present system of boiling wood for the purposes of paper making, and so far as I know there is no other system that answers. I have seen wood shavings boiled for 86 hours under a pressure of 50lb. per inch with the caustic liquor at 16° Tw.: the only change visible when taken out was their colour being redder, otherwise they were as tough as ever. A certain amount of heat is wanted to dissolve the resinous substances, and with the chemicals at present in use the requisite amount of heat can't be got without pressure of from 180° to 200° per inch.—DEVONSHIRE.

[11607.]—**Ebonising Wood.**—The wrinkle in this case is to use blue polish. Stain work as before, adding powdered nut gall to the logwood and copperas solution, dry, rub down well, oil, then use French polish made tolerably dark with indigo or finely powdered stone blue. N. B.—This is a trade secret worth a little fortune to the querist. As some acknowledgment, I would respectfully suggest that "W. C. W." forthwith obtains at least one dozen new subscribers to "ours."—WILLIAM GLAZIER.

[11608.]—**Boiling by Steam.** — In reply to "A. W. B.," have an outside casing on your boiler or vessel, with inlet and blow-off cock, this latter cock to be regulated to take away condensed water only. The steam will surround the vessel, and is used instead of a coiled pipe inside.—DEVONSHIRE.

[11610.]—**Defective Coil.**—The fault is in the coil, not the battery. In all probability the secondary wire is broken, and the two ends only slightly touch; it is also most likely that this occurs at one of the points of attachment to binding screws or connections, and that the vibration of the contact breaker jars the wire away. This is assuming that I understand "G. F. L." correctly, and that the contact breaker works properly, but the shock is unreliable and unsteady. The truth would easily be discovered by using a galvanometer in the circuit.—SIGMA.

[11612.]—**Injury to Vacuum Tubes.**—Paste a minute circle of tinfoil over the broken end of platinum, pressing well down to insure contact; place over this any small bell of metal that has a loop attached, a brass button with the top cut out, and the lips neatly turned back, for instance; fill the top of the bell with tinfoil, and fasten it to the glass tube with coaguline—viz., isinglass dissolved in acetic acid. At many of the opticians you may buy little bells, made on purpose, price 2d. each, but the toy bells children hang round a kitten's neck, or a good brass button, answer every purpose. I find it a good plan to put them on my tubes directly I get them, and before the platinum loop is broken.—PRIAM.

[11617.]—**Numismatical.**—1. Obverse, arms of Coventry,"Coventry Halfpenny." Reverse, Lady Godiva on horseback, "Pro Bono Publico, 1792." Edge, "Payable at the Warehouse of Robert Reynolds & Co." Some of this date are "Payable at Nuneaton, Bedworth, and Hinkley," towns in the locality. It is an ordinary halfpenny token issued by the above-named at the time (1792), and is one of the commonest of the immense issue of tokens at that period; of no value except it is a fine cabinet specimen. 2. Is a copper penny token issued by the Cornish Mines Company, and is described in my work on the British and Colonial copper currency; it is very common. The first is between blocks of lead and tin. 3. Is a weight for a gold coin value 10s. of the reign of Charles I., and is worth about 6d.—D. T. BATTY.

[11618.]—**Deadening Sound.**—If the partition is but a single board, the best way will be to make it double by affixing studs upon one side—*i. e.*, pieces of deal about 2in. × 3in. as long as from ceiling to floor, 15in. or 18in. apart, and board it upon the studs, have the boards tongued, and fill up all the spaces solid with sawdust.—HELPMATE.

[11619.]—**Electrical.**—I have no doubt the Leyden jar alluded to by "F. T. Z." is made of glass containing lead. The thin German phials make the best Leyden jars, and the whiter and clearer the glass, the better the insulation usually.—PRIAM.

[11621.]—**Killing Roots of Trees.**—I think if "A Gardener" bores a large hole and fills it with sulphate of iron (common green vitriol), he will soon kill the root, and at the same time stain the wood of a very nice gray colour.—A BARRISTER.

[11622.]—**Colouring Walls.**—The best liquid to be used with distemper colours is skim milk; this will give a surface almost equal to paint.—A BARRISTER.

[11624.]—**Photography.**—Rain-water will answer all photographic purposes if prepared thus: Collect in a clean tin vessel, and boil and filter it; if for a nitrate bath put a crystal of nitrate of silver in it, and expose to the sun for a day; shake it then and filter any chloride of silver which may have formed. What is sold as pure distilled water often spoils solutions; if your nitrate bath does not act well with this add excess of washed black oxide of silver and sun it, then filter and add dilute nitric acid till there is the faintest reaction to litmus.—M. A. B.

[11631.]—**Income Tax.**—A "Maiden Lady" should apply to the assessor of her parish, or the surveyor of takes for the district in which she resides, and obtain some claims of exemption (No. 40) and fill them up according to the printed directions contained in them and then send them to the tax surveyor, and in due course she will receive a letter from the Special Commissioners of Income Tax, authorising repayment of the tax deducted from her dividends, either at Somerset House, if in London, or at the nearest stamp office if in the country. "Helpless" can fill up the forms for her, but they must be signed by the claimant herself. Should it be inconvenient for her to make a personal application for the money she can authorise any one to receive it for her, by filling up and signing a form on the back of the repayment letter. Repayment is limited to three years preceding the 5th April in the year in which the claims are made. A separate form, No. 40, must be made for each year claimed for.—TAX SURVEYOR.

[11633.]—**Fever Tree.**—The scientific name of this tree is Eucalyptus Globulus, or blue gum tree, a native of Australia, but cultivated in Corsica and South Europe. A tincture of the leaf, in two drachm doses, is used in intermittent fever; it has also stimulant, tonic, expectorant, and antiseptic properties. I will refer "Quinquina" to Savory and Moore for all the preparations of the drug. Not adopted in the Pharmacopœa.—OPALINE.

[11638.]—**Silkworm Disease.**—The "credible cause" of the silkworm disease will be found on p. 9, Vol. XII. ENGLISH MECHANIC, forming a portion of Professor Huxley's address to the B. A.; see also a paper by Dr. Bastian in a recent number of the *British Medical Journal*.—SAUL RYMEA.

[11639.]—**The Rock Inscriptions.**—The neglect of which "H. E. H." speaks, is quite as great a mystery to me as to him. Ever since hearing of them, at the time of Forster's book and the Crimean war, I have thought them obviously the most important antiquities to be examined or preserved on earth. As far as I can make out, the sudden collapse of all interest in them ensued on Dean Stanley's very singular remarks in the volume I referred to. He had galloped through the country in a few days, happened to pass very few of the inscriptions (which are scattered over a country as large as Yorkshire), and set down that their number and importance "had been greatly exaggerated," and so the whole matter seems, for this age, to have ended, perhaps luckily or providentially; for after the miserable "Moabite stone" and similar catastrophes, we may well pray Heaven to keep any such things from nineteenth century discovery.—E. L. G.

[11646.]—**Electric Spark.**—The simplest way to get a spark would be to have a small induction coil giving such a spark as desired, and to use a bichromate cell with it, mounting the zinc on a spring, to be depressed, as required, by a revolving cam mounted on the shaft at disposal, the ordinary break of the being screwed down, as the depression of the zinc into the liquid would produce one spark. Another plan, not so reliable, would be to rig a glass plate with rubbers, &c., on the shaft, in fact, to make it work an ordinary electric machine, and connect to a small Leyden jar, arranged to discharge at ½in., the first would be the simplest plan, and a coil and cell for the purpose could be had for £3. Cost of working would be trifling, and it would be in order for years if taken care of.—SIGMA.

[11647.]—**Cabbage Plants.** — "Anon." cannot prevent cabbage plants from running to seed, when once started, save by "heroic" measures—viz., cutting off the tops and leaving the stumps to sprout, or pulling them up altogether. His soil is too poor; but if all the plants have not started for seed he might find a dusting of bone-dust and superphosphate assist in saving some of them. Cabbages require manure—mineral manure in "Anon's." case very likely.—SAUL RYMEA.

[11648.]—**Bee Management.**—If "Apis" will carry out the following directions, driving bees will give him no trouble, and one trial will suffice to show him this. Blow two or three puffs of smoke into the hive to be driven to send the bees up into the combs. Invert the hive on a bucket and place an empty hive (of the same size) on it, making the junction secure by winding some calico round it and fastening this cloth with string. Then drum the sides of the lower hive with the hands or two sticks. The bees will soon run up, and in five to ten minutes he will have a good swarm taken off, but he must be careful to leave enough bees to cover the combs. The hives must be separated and put in their places at once, or the bees would soon descend to their old home. Wearing a veil is quite optional, and stupefying material worse than useless. Large hives do not show signs of swarming so much as small ones.—E. D.

[11655.]—**Making Gold and Silver Leaf Adhere to Fabric.**—I was told by a manufacturer that glaire of egg is used with gold or silver leaf on smooth silk or satin fabrics, but that a mixture of powdered resin and dextrine is employed for velvets or any rough surface.—A BARRISTER.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "Thetamn" has answered 9440; "Journeyman Painter," 11045; "Auld Reekie," 11083.

QUERIES.

[11663.]—**Steam Power.**—Will some correspondent kindly inform me if I shall obtain enough steam to drive two 1in. bore and 2in. stroke cylinders, from a vertical boiler 13in. high, 6in. in diameter with inclosed firebox, 4in. in diameter at top, and 5in. at bottom? Also what weight must the fly-wheel be, so as to make 200 revolutions per minute? The exhaust is conducted to the chimney, which is 1in. in diameter, and the fuel burnt is charcoal.—T. W. J. M.

[11664.]—**Polishing Bullock's Horns.**—How can I polish a pair of bullock's horns?—W. POWER.

[11665.]—**Ink.**—Will any of your numerous readers be so kind as to give me the recipe for making brown ink, used in perspective drawings?—R. F.

[11666.] — **Qualitative Analysis.** — Would Mr. Davis or any of our chemical friends kindly inform me of a simple method for detecting the impurities in water?—GRATUS.

[11667.]—**Carbon Points.**—I am desirous to know what these are. How are they produced, and where, and are they expensive? Will "Jack of All Trades," "Tubal-Kain," or any other kind correspondent give me this information?—H. S. C.

[11668.] — **Astronomical.** — The appendix to White's "Ephemeris," for 1835, contains a valuable table to abridge the computation of the longitude and latitude, the right ascension and declination being given, or the contrary. This table has been computed by J. C. Buckhardt to the obliquity 23° 27′ 50″. Will some one of our able astronomical correspondents, who may possess a copy, kindly show how to make the necessary correction for the present obliquity, so that in practice this table may continue to be used without sensible error? Also, I should be glad to know how to find the latitude when the "diff." is nil; *i.e.*, between Arg. + 0·30 and 0·51, or between + 2·00 and 10·00.—ASTRÆA.

[11669.]—**Trunk Engine.**—Will any of our readers kindly inform me if a trunk engine with 2 cylinders, 1½in. bore and 1in. stroke, would drive a 8ft. boat, with 6in. paddles? Also, would they give a drawing of a cheap pump for the same?—A. PEDD.

[11670.]—**Electrical.**—1. W. H. Coffin, in answer 10447, gives, on Mr. Highton's authority, the details of a battery. Can any reader speak from experience as to the merits of the arrangement? And particularly I wish to know the proportions of nitre and mercury used to amalgamate fused zinc. 2. Can any reader give me an opinion about M. Bouman's Leclanché, mentioned in No. 357, p. 479? Will Mr. Tonkes say whether felt can take the place of a porous pot? 3. What is the best work on electro-metallurgy, at a reasonable price? 4. Where can I get the "needled manganese" used by Leclanché?—M. D.

[11671.]—**Spectrum Analysis.**—Will some one kindly tell me whether it is possible to conduct any sort of spectrum analysis with a very small pocket spectroscope? And also what is the best work on the subject?—R. M. F.

[11672.]—**Birth and Death Rates.**—Might I ask some of "our" mathematical readers to help me to solve the following problem? Given the following:—What will be the yearly death rates per 1,000 living in A and B each year for 20 years? Also what will be the population of A, and what that of B at the end of 20 years? A is a town of 100,000 inhabitants; B is a town of 100,000 inhabitants. The numbers in each town of the same age are the same. The birth rate in A is 40 per 1,000 per annum; in B it is 30 per 1,000 per annum. The death rate to be taken is 183 in 1,000 in the first year of life; 18 in the fifth; 6 in the tenth; 5 in the sixteenth; 8 in the twenty-first; 13 in the forty-first; 33 in the sixty-first; 70 in the seventy-first; 153 in the eighty-first; and 307 in the ninety-first year of life.—P. Q. P. V.

[11673.]—**Hydraulic Rams.**—What modifications are made in the ram when intended to lift water to a great height? What is the practical limit to the height to which the water can be raised by a ram with a given fall? What is the modulus of the ram or the proportion of the power utilised by it?—PHILANTHROPIST.

[11674.] — **Stretched Indiarubber.** — How much power in units of work may be accumulated by stretching an indiarubber band or rope round a drum? And would this be any use as a motive power for amateurs, or for propelling ferry boats?—PHILANTHROPIST.

[11675.]—**Solder for Britannia Metal.**—Will any of "our" kind readers tell me what kind of solder is used for Britannia metal, and how to use it, and the proper flux to use in soft soldering copper?—LEARNER.

[11676.]—**Lemonade Syrup.**—Can any reader tell me how to make lemonade syrup for aërated drinks?—LEMONADE.

[11677.]—**Rendering Wood Incombustible.**—Is there any easy and cheap way of making deal boards wholly or partially incombustible? Is there any cheap material for roofing, incombustible? I wish to erect a summerhouse, or small cottage of two rooms, in a garden that I rent. Boards would be the most convenient material for my use, because they could be easily removed at the expiration of my tenancy. I am told that, if I paint all the boards that I use for walls, &c., with white lead, or some similar paint, on both sides, and use some sort (query, what sort) of felt for the roof, then my building would be as safe from fire as most houses are. Is the advice given me correct, or can I adopt any better plan?—CLERK.

[11678.]—**Photographic.** — As the photographic season for amateurs is coming on, it will be a great boon if you can give some more useful hints, more particularly about the new dry plan of coating the plate with a collodion prepared with silver. If any of your numerous scientific correspondents have tried the process, and been successful, a hint from such would be gladly received by a gormandiser of the ENGLISH MECHANIC.—A. CHALMERS.

[11679.]—**Fork and Wedge Valve Motion.**—Having just noticed in your last issue a reply (10883, p. 100) from one of your correspondents referring your readers to the fork and wedge valve motion fitted to one of Stephenson and Co.'s engines in 1844, I wish to ask your correspondent or any of your numerous readers if they could tell me to whom the honour of that invention is due. One would naturally suppose from reading "C. E. S.'s" letter that the invention is due to Stephenson, which, Mr. Editor, I very much doubt; in fact, I believe that Stephenson in this manner gets praise for a good many inventions that he is not at all entitled to.—ONE IN SEARCH OF THE TRUTH.

[11680.]—**Mildew in Boat Sails.**—Will any one give a recipe for curing the above? What do they use in bleaching factories for the purpose? Would carbolic acid have effect?—KIRKWAY.

[11681.]—**Water Glass.**—How would this do for the purpose of painting the bottoms of boots used in salt water?—KIRKWAY.

[11682.]—**Wheatstone's Bridge.**—I have a small Wheatstone's bridge for ascertaining the resistance in wire. The screw for tightening the gland on the main spindle is made of copper. Now, I am of opinion that this tends to lower the resisting medium below what it ought to be, and below what it would be if the screw were made of some neutral metal, such as iron or nickel, so I cannot depend on my results. I should like Mr. Tonkes to inform me whether I am right; and if so, what metal I had better use for the screw.—ANON.

[11683.] — **Height of Sea Waves.** — Would "F.R.A.S." or Mr. Proctor kindly solve, if possible, the following? Is there any recognised method of telling, in the case of sea waves, suppose a wave be 20ft. from trough to summit, how much of that height is above the level of the ocean when perfectly quiescent? and if there is no fixed rule bearing upon the subject, would they kindly offer their opinions?—A., Liverpool.

[11684.]—**Pressure on Cork of Bottle.**—Given, an ordinary bottle of soda-water, which is filled to within 2½in. of the cork: Is there more pressure on the cork when the bottle is standing cork downwards or upside down and the air space right above the liquor than when it is lying on its side?—SODA-WATER.

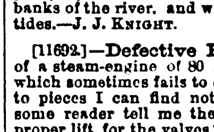
[11685.]—**Canary's Song.**—I have a mottled canary, which commenced its second moulting last August, which was over apparently about Christmas, but up to the present time it has not sung at all. It is very lively, and apparently in good health. I have repeatedly changed its food, and occasionally hung it out in the open air within hearing of another bird, a good songster, but it only chirrups a few times. It has not, to my knowledge, received any fright or injury. Can any fellow reader inform me of any means of getting it to sing again, as last year it sung very well?—EXON.

[11686.]—**Cement for Fixing Glass Letters.**—Does any reader know of any recipe for fixing glass letters on glass? Colour of the cement no object, only it must resist wet.—HOWE.

[11687.]—**Speeding Machinery.**—Will any of our numerous readers kindly inform me what is the most simple and certain mode of obtaining the correct diameters of pulleys, or wheels to increase or diminish the speed of a machine? I find the rules laid down in most scientific works are so complicated that I cannot use them. I will give a case in point. Suppose my driving shaft runs 60 revolutions per minute, and I want to drive a machine (say) 135 revolutions per minute, what size wheels and the number of teeth in ditto, or pulleys, would be required to obtain that speed?—A READER.

[11688.] — **Cleaning White Sheepskins.** — Can any of your subscribers inform me of the best way of cleaning a white sheepskin hearth-rug at home? Professional cleaners charge very high, about half as much as the rug cost at first.—A HOUSEKEEPER.

[11689.]—**Reel for Rotary Sewing Machine.**—Allow me to ask for instructions how to make a reel for a rotary shuttle sewing-machine (the shuttle of which I send you a sketch), also a winder for the same? I have a machine of this class, minus shuttle reels and winder. I can make them if I see a sketch, however rough. The machine is made by Drake, of Huddersfield.—Z. A.



[11690.] — **Anchovy and Bloater Paste.**—Will some kind subscriber inform me the way that those are made, not in very large quantities?—HENRY FRANKLIN.

[11691.]—**Tidal Mill.**—Would any reader oblige me by giving a description of the best form of tidal mill, for pumping water or driving machinery? I am on the banks of the river, and want to utilise the force of the tides.—J. J. KNIGHT.

[11692.]—**Defective Feed Pump.**—I have charge of a steam-engine of 80 horse-power, the feed pump of which sometimes fails to do its work, and when I take it to pieces I can find nothing under the valves. Will some reader tell me the cause of its failing, and the proper lift for the valves? The plunger of the pump is 5in. diameter, and the stroke 16in.—AN ENGINE DRIVER.

[11693.]—**Ice Chest and Refrigerator.**—Will any one who has constructed or purchased a good ice chest, to economise from 5lb. to 10lb. of ice per day, give a description of it? I want it to cool (say) 3 or 4 sodas, 1 or 2 quart bottles, and a plate of butter at the same time. Also that I may be able to chip off a lump of ice if required, and that the ice as it melts may trickle into a cistern, from which I can draw off a tumbler of cold water. And all this with as little loss as possible. I hate those which require the ice to be wrapped up in rotten blankets. Kindly state expense.—M. A. B.

[11694.] — **Green Fly.** — Can any of "our" correspondents inform me of the most effective way of killing the green fly which is beginning to cause great damage amongst my plants. My conservatory is too large and lofty to admit of their destruction by burning tobacco. I have tried syringing with soapsuds but without any effect. An army of spiders, large and small, of every shape and description, has made its appearance within the last few days. How can I destroy them? Any information will oblige.—H. T. C.

[11695.]—**Succession Duty.** — Would any correspondent favour me with information on the following, or refer me to a work on the subject? I have succeeded to some property left by will from my father. It consists of two leasehold houses, worth £1,100, producing £90 per annum. What I wish to know is how the duty is calculated, whether charged on the £1,100 or as an annuity, and how much it would come to. I am told I have to pay 1 per cent., but on what?—C. P.

[11696.]—**Decaying Ivory Carving.**—Some time ago I brought some ivory carving home from China. It is now turning black, and seems to be rotting away. Will some brother reader tell me if I can bleach it or stop the decay?—JOURNEYMAN PAINTER.

[11697.]—**American Lathe Chucks.**—I have seen a chuck to take in drills up to ⅜in. It has got three grabs, which close equally to the centre by turning a collar. The drills for it are from ⅜in. downwards, with a groove straight along each side of the drills. The heads of them are flat, like a tap, for screwing. There is also screw drills for chucks. All above are American inventions, I believe. Can any reader say if these are to well, and are durable? also, if either of the above-shaped drills is adapted to bore into solid metal?—JOE.

[11698.]—**Improving Memory.**—Would one of your correspondents kindly state if there is any means of improving a rather dull memory?—GEORGE J. B. HAYTER.

[11699.]—**Organ Cleaning.**—Will any of our practical organ builders kindly say how much an organ of about 24 stops would cost for thoroughly cleaning, tuning, and re-wiring? Also, the extra charge for tuning from unequal to equal temperament?—A. B. L.

[11700.]—**Ginger-Beer Making.**—Will any reader give me a good recipe for the syrup used in ginger-beer making—that put in the bottles before pumping the gas and water into them?—HYDRAULICAN.

[11701.]—**To Mr. Knott.**—Has Mr. Knott obtained any measurement of the close companion of ζ Cancri during this season? and if so, would he kindly give it? I have seen it two or three times lately, and it seems very close. By estimation, its position angle is between 200 and 180.—C. GAUDIBERT.

[11702.]—**Curry and Rice.**—Will any old Indian of "ours" give, in detail, the process of how rice is boiled so as to fall into grains, not into a pasty mass? I have tried several times the recipe quoted at p. 107, No. 368, from the *Food Journal*, unsuccessfully. Would he also give the ingredients, specifying quantities (procurable here), to make a really good curry powder?—M. A. B.

[11703.]—**Ink.**—Will any of "ours" who has the recipe for a reliable ink powder, which he has proved, kindly give it? I have used many ink powders, but most are bad, and, as sold, of course, about 300 per cent. above actual cost. I want a powder mixed which will not decompose abroad, and which, by the addition of water, will make a good black ink. What quantity of sugar candy or lump sugar added to the pint will make it good for copying?—M. A. B.

[11704.]—**Rats.**—Can any of "ours" tell me what essential oil ratcatchers use to entice these vermin? They shun my trap, but I have heard oil of rhodium sprinkled on the floor is attractive. It is, however, very expensive—my druggist asks 8s. per fluid ounce. Is there any other, and is rhodium good?—M. A. B.

[11705.]—**Small Yachts.**—Can any one give me information regarding the construction of small yachts (about five tons), especially of iron? How are the ribs held in position during construction, and how counterstern stiffened? what distance apart are ribs, and thickness of iron?—L.

[11706.]—**Optician's Lacquer.**—Will any of "our" readers inform me of a good lacquer (one similar to that used by opticians), and how to use it?—J. W. CARD.

[11707.]—**Para.**—Would any subscribers having any practical experience of Para give some information about it? 1. What would be the cost of passage out? 2. The port to start from. 3. What to take in way of outfit. 4. The possibility of obtaining shelter and food, while looking round to see what one could do. 5. The smallest sum in way of an annuity on which one could rub along. 6. And would it not be possible to form a co-operative society, to colonise some portion of the banks of the Amazon, where land is a drug and very little labour required to make it very productive? I believe many industrious men would be happy to join in such a movement, if it could be started under safe principles.—A DRONE AGAINST MY WILL.

[11708.]—**Gas Burners.**—Will any subscriber inform me what amount of gas different sizes of ordinary burners will burn per hour?—LOACH.

[11709.]—**Smoking Cap.**—I have a smoking cap made of blue velvet, and braided with amber. By the action of perspiration, the blue and yellow have become changed into a shade of green. The braid has suffered the dyeing most. Can any reader of "our" MECHANIC advise me of the means of taking out the dye, and regaining the proper colours?—HECTOR.

[11710.]—**Cleaning Oil Painting.**—I have an old oil painting. Will some one instruct me how to clean it, so as to bring out the colours without injuring them?—E. PARKER.

[11711.]—**Time at Our Antipodes.**—Will any reader kindly explain to me whether the time at our antipodes is 12 hours earlier or 12 hours later than our own? because, although we well know there is a difference of 12 hours, it appears to me that it can be demonstrated with equal plausibility to be both. For example, supposing it to be Tuesday, 12 o'clock (noon), in London, it will be 6 o'clock Tuesday evening at Calcutta, 90° east, and, therefore, 12 o'clock Tuesday night, at a point close off New Zealand, 180° east—our antipodes. But, also on the other hand, if it be Tuesday midday here, it must be Tuesday, 6 o'clock a.m., at New Orleans, 90° west, and, therefore, just commencing Tuesday morning at the aforesaid point off New Zealand, 180° west—our antipodes. The argument appears equally conclusive either way, but the result somewhat perplexing, because at the same point, at the same moment, it can be proved to be both the close of Tuesday night and the commencement of Tuesday morning.—T. S.

[11712.]—**Barlow Lens.**—Will "F. R. A. S." oblige by giving the focal length of a double concave lens, which will about double the power of the eyepieces of a 6in. object glass (focal length, say, 15 diameters), and its proper distance from the eyepieces, which are of the positive form?—S. W. BURNHAM.

[11713.]—**Composition for Moulding.**—Will any brother reader help me out of a difficulty? I am in want of a composition similar to that used by gilders, colour no object, to be used by pressure of fingers only. It is required to dry hard but must be pliable, to mould before drying, and not to make moulds dirty used for moulding, as they are used for another purpose. An early reply will greatly oblige.—J. S.

[11714.]—**Test for Sugar.**—Will any of our esteemed chemical correspondents be kind enough to give me a reliable test for adulteration of sugar, whiteness being the object? The sugar we use is the best that can be procured, and sent to the drug grinders to be ground, and, when returned, is sometimes very good, and at others not so. When mixed with water (not dissolved) it has the appearance of being mixed with starch, and when dissolved in the mouth has a pasty feel, instead of dissolving quickly, and sometimes has a chalky appearance.—J. S.

[11715.]—**Testing Acetic Acid.**—Would Geo. Davis, S. Bottone, or some other talented chemical correspondent, kindly describe a simple and easy method of testing common commercial acetic acid for the presence of mineral acids and other impurities likely to occur? A simple test might be of great use to many persons for testing vinegar, as it is often mixed with sulphuric acid.—ACETICUM.

[11716.]—**α Draconis.**—Will "F. R. A. S.," or any astronomical subscriber, inform me if I am right in supposing that the once pole star, now known as the star "α Draconis," takes 600 years in performing its cycle or revolution?—J. X. T.

[11717.]—**Removing Gold from Plated Articles.**—Will some practical subscriber inform me of a simple way to remove gold from old work thickly plated? I have tried nitric acid and salt, but it destroys the brass plates before the gold is half removed, with an ebullition and dreadful fumes; also the battery process, but have failed. Can "Jack of All Trades" assist me, as I have a quantity to strip, and want to use the gold again?—ELECTRO.

[11718.]—**Cheap Water Filter.**—In yours of April 12, p. 87, you describe this as being made of galvanised iron, with zinc and lead trays, &c. Will not the zinc and lead render the water dangerous for drinking purposes?—A SUBSCRIBER.

[11719.]—**Gut Lines.**—Can any one inform me how to make transparent gut out of sheep's guts?—EDWARD JACKSON.

[11720.]—**Extracting Zinc from Plumber's Solder.**—What is the best way of extracting zinc from plumber's solder? and the best way of bending brass pipe, from ½in. to 1in., without bulging?—INQUISITIVE.

[11721.]—**Assayers' Duties.**—Will "Un Irlandais" kindly give me the information that he promised to do in No. 351, p. 335 on this subject, particularly that relating to copper, as I am in immediate want of the knowledge, which, would no doubt, be valuable to many others?—G. T. H.

[11722.]—**Eyebrows Falling Off.**—I should be grateful if any kind reader could inform me of something that would prevent my eyebrows and eyelashes rapidly falling off.—A SUB. FROM THE FIRST.

[11723.]—**Contact Breaker.**—I have recently made an electric bell, but am puzzled about the contact breaker. 1. A weak spring with a flat head acted on the hammer, which was placed about half way thereon, the head of the spring being brass and acting on flat brass. Result: The strokes were very slow but continuous. 2. The spring head was placed quarter distance on hammer and flat tables as before. Result: Quick loud strokes, but the action would stop itself and require an alteration in the pressure of the spring (which was adjusted by a screw); then commence and stop again. I now bent the spring head and found the result the same. Will electrical readers inform me what form is best for break of contact, whether a point, curved wire on flat surface, or two flat tables? I may remark that the tables were perfectly clean, and a strong battery was used; the magnets also were strong.—T. H. SOMERVILLE.

[11724.]—**Discharge of Water Over Weirs.**—May I beg some readers to inform me what book or table is the best to use for ascertaining the discharge of water over weirs? An answer to the following question, with a formula for producing the same, would also greatly oblige. The water from a reservoir is conveyed by a valve into a large stone basin. In the middle of one side of this basin there is placed a gauge or weir (being a strong iron plate), 4ft. in length. What quantity of water will discharge itself over this fall in twenty-four hours, supposing the depth of water flowing over the gauge to be 2¼in.?—B.

[11725.]—**Reversing Gear for Double-Action Oscillation Cylinders.**—I will be much obliged to any brother reader who will explain the reversing gear for two double-action cylinders for a model screw steamer. A drawing would oblige.—ERIN.

[11726.]—**Toughening Cast Metal.**—Can any of your numerous obliging readers say whether it is possible to toughen cast metal? and if so, how it is done?—W. G. L.

[11727.]—**Cork-Cutting Machine.**—A subscriber would feel obliged if any of your readers would have the goodness to give some information regarding the best cork-cutting machine, and price of same.—BALMARINO.

[11728.]—**Adjusting Balances and Mainsprings.**—Will "West Cornwall," or any other horological subscriber, kindly inform me how to adjust compensation balances, and also ordinary balances? also, are the bobs of an adjusting rod to be placed on a certain part of rod when adjusting a mainspring?—APPRENTICE.

[11729.]—**Teeth of Spur Wheels.**—Will some reader inform me the correct method of setting out the teeth of spur wheels with the true epicycloid curves? What I wish to know is how to get the proper curves and shape of teeth of wheels and pinions for any number of teeth and any pitch. Wheels of equal number of teeth, of course, would be alike in shape; and as the shape of the teeth of a wheel and pinion to work together would be different in shape, I should like to know the correct form of both of them (say, a spur wheel, 150 teeth, 1½in. pitch, and a pinion to work into the above with 12 teeth). Any information respecting the correct method of setting out the teeth of wheels would oblige.—A PATTERN MAKER.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, April 23, and unacknowledged elsewhere:—

Miller.—Brightonian.—Horos.—J. D. H.—Musa.—W. Nicholson.—Comet.—Ignoramus.—G. Marshall.—James Rogers.—H. and Sons.—The Ross Union.—J. O. Frazer.—Wm. Brown.—E. Pigott.—G. R. Hallam.—Wm. Waghorn.—J. B. Winspear.—F. G.—H. Hicks.—G. P. Compton.—W. Hunton and Co.—Jos. Washurst.—Hy. Mercier.—Gay and Co.—Robert A. Whitelocke.—F. F. D.—C. Colman.—G. J. B. Hayter.—R. L. G.—A New Subscriber.—R. A. Proctor.—Bobo.—J. Round.—F. C. C.—The Harmonious Blacksmith.—M. A. B.—Dentiste.—One in a Fix.—Apprentice.—W. L.—W.—Camera.—H. G. Nash.—A Subscriber.—Touchweight.—Fred. Gibson.—Ralph Lowdon.—A Subscriber.—Thetamu.—Hedera.—W. N. Oswad.—A. Brothers.—Starley and Company.—E. G. Capon.—Webb and Son.—J. W. Matteson.—A. M. Festing.—W. H. Coffin.—J. H. Brabazon.—Rev. E. L. Berthon.—Philanthropist.—Sigma.—G. and Co.—W. H. M.—Archer.—Zeta.—Amateur.—J. J. Allingham.—Undergraduate.—John Negus.—Edward Sutton.—Elizabeth Davis.—Robert Campbell.—A. Monckton.—F. J. Gedden.—W. M.—E. F. C.—J. F. Stanistreet.—Disc.—H. P. H.—J. H.—Professional Adviser.—Guano.—Wood Sawyer.—G. H. Howell.—H. G. W.—W. Fox.—H. D. W.—Senicio.—Afloat.—H. O'B.—Goux.—J. Guthrie.—A. C. and D.—J. T. E.—P. H.—W. H.—Edgar Davis.—W. D.—Bed of Stone.—Champagne Charlie.—W. C. B.—Dane.—Harmonic Chord.—John Rae.—Rat-Tat.—Der-Sunthal.—J. B. P.—J. Barwick.—C. A. S.—J. L.—W. H. Cash.—W. H. Hughes.—Apiarian.—H. R.—Joe.—Mountaineer.—Ethyl.—A Subscriber.—A Mechanic's Wife.—H. B. J.—E. L. C.—A. P. Bower.—M. Paris.—P. H. Holland.—E. Sutten.—Grapeshot.—Philo.—Duet.—Digby.—A Young Beginner.—James Wilson.—F. R. S. A.—W. R. Birt.—J. B. Youngman.—No. 10.—Carboy.—Humphrey Clinker.—Paul Gregor.—Alpha.—J. Bolton.—Saul Rymea.—W. Tonkes.—Mineralogist.—A Three Years' Subscriber.—J. L. Foster.—Bookworm.—A Sufferer.—W. French.—F. B. A.—An English Engineer.—B. A.—An Emigrant.—Carambolo.—F. A. Edwards.—Excelsior.—Capt. Maxse, R. N.—G. S.—Civil Engineer.—W. A. N.—B. R. Mills.—Howard.—Smith, Starley and Co.—Sundial.

THE DECIMAL SYSTEM.—We must bring this discussion to a close, not because it is uninteresting or unimportant, or because the subject has been exhausted, but because "E. L. G." has imported an unusual and an unnecessary amount of personal feeling into it. "No 10," in a letter full of eloquence and sarcasm, has answered "E. L. G.'s" letters on the subject at great length, but he adds no new argument to the discussion, and his letter, if inserted, would in all probability provoke a similar rejoinder from "E. L. G." Mr. Bottone has also answered "E. L. G.," in an unusually long and unusually able letter, which we cannot insert for pretty much the same reason as that given for not inserting "No. 10's" letter. We have also a letter from "E. L. G" in answer to "Sigma's" last letter. "E. L. G.," as usual, is courageous and provocative. As "Sigma" is not one who will quietly take a blow without returning it, and as we have no room for highly-spiced controversies, however eloquent, we must serve "E. L. G.'s" letter in the same way as we have those from "No. 10," and Mr. Bottone.

H. O'BRIEN sends us her "personal thanks" for our article on the alcohol question, and asks whether "a kindred subject—that of women's suffrage—would find admittance in our pages, as it is fairly a public question." With every desire to gratify correspondents, and fair ones in particular, we cannot well open our pages to the discussion of women's rights, as it is, to all intents and purposes, a *political* question. If she will refer to our article on alcohol, she will see that we treated the question on its scientific side, and if our correspondent or any one else can show us that the "women's suffrage question" has also essentially a scientific side, we will let them discuss it. The editor, however, believes with Mrs. O'Brien, that now we have a rating suffrage, if a woman occupies a house and pays her rates and taxes, she ought to be entitled to vote for parliamentary as well as for parochial representation.

HENRY NEWMAN.—Space will be given you.

CHARLES FRANK.—We cannot report on the merits of the lamp. As you want it, you had better get it and try it, and then give us your experience of it.

"42 INCHES."—In asking such a question, the least you could do was to put your own name to it, so that the correspondents referred to might know with whom they had to do.

W. B. E., writing from Burslem, asks what has become of the scheme for founding an English mechanic colony. We cannot say, and the scheme is not sufficiently interesting to a vast majority of our readers, to be rediscussed in our columns.

AUTODIDACT.—Pray read the motto under "Letters to the Editor," and try and know something about the subject on which you write.

J. T. SPRAGUE says: "I am preparing papers on electro-metallurgy, but pressing business matters on hand take up most of my time and attention."

P. T. D.—Mr. Denning has not sent any chess problem yet.

Communications which can only appear as advertisements to hand from Gymnast, A Novice, J. S. (first query), F. A. R. (second query), Morning, A Young Henkeeper.

Exon.—Yes; 2½d.

C. J. K.—We could not promise till we saw it.

Linea.—Please send. The advertiser you mention is to be depended upon.

Neville.—The first question is one you should put to a patent agent, and *pay him* to make a search at the Patent Office in order to answer it. Your second appears to answer itself. The use of the instrument is indicated by its name.

Fantail.—For hints on the extermination of mischievous stray cats, see pp. 166, 191, 215, 266, 415, and 287, Vol. XIII.

R. T.—The discussion on the subject is now closed. If you wish to communicate privately with "Jack of All Trades" on the subject, you had better advertise your address.

Musa.—For information on whitening ivory, see p. 241, Vol. XIII., and previous vols.

R. J. H.—Advertise it; but if you wish to sell it do not ask a guinea an ounce for it.

Sulphur.—The writer who gave the information has been appealed to by other correspondents to explain the process. He has not done so, however, and we believe he was misinformed.

An Old Subscriber.—For recipe for making ice cream, see p. 98, No. 316, Vol. XIII.

Manchester.—For information on means of cure of squinting, see replies 11334, p. 49, No. 366.

G. F. Glasgow.—So many directions appear in back vols. for making chain belts, that we think we can hardly be expected to engrave a new form which you have devised—and find will not act.

S. M.—Sketching in oils appeared in Nos. 822, 322, 324, 325, 326, 327.

A Would-be Tinker.—We should think you might acquire a knowledge of the art of soldering by carefully perusing our back volumes, each of which contains a number of practical directions on the subject. At all events we know of no book that contains plainer or more trustworthy directions. Read up the information in our back volumes, and if you meet with any difficulty, send a query. You will get an answer.

X. N.—A similar query to yours forms the subject of a discussion in recent numbers. See pp. 596, 621, 644, Vol. XIV., and pp. 18, 74, 127, present volume.

W. H. Neal and W. G.—Many thanks. What can we do when dishonest advertisers adopt such tactics.

F. W. Robinson.—See pp. 461, 296, and 99, of Vol. XII., for information on diamonds, and their discovery in South Africa.

Proven.—Your letter on personalities would only add fuel to the fire.

J. Barwick.—Please not seal your communications on which halfpenny stamps are affixed.

E. F. Mitchell.—Consult back numbers for information on bicycle construction.

W. Quy.—Your answer to 11188 was not inserted, because it was wrong.

"A Thinker on Aeronauts."—Fantastical and foolish.

Beacon Lough.—Your long letter was prepared for the printer, and like several others of a similar length that week was pressed out. The controversy may now be considered at an end.

H. Wilson, Scraper, Hy. Axon, B. M., W. J. W., see "Hints to Correspondents," No. 4.

A Subscriber.—Your pet question about the revolution of the earth being caused by a gas exuding from it was discussed almost *ad nauseam* some months ago. It has cropped up in various forms, and always, we think, directly or indirectly from the same hand. There was never a particle of proof adduced to prove your theory.

Philo sends an answer to the charge of "Khoda Bux." He says: "If 'Khoda Bux' will refer back to my letters he will find that I have been the attacked and not the attacking party. I never, as some of your correspondents do, call those from whom I differ ignorant, or accuse them of misrepresenting, and do not like to be classed with those who are foolish enough to do so."

A. M. Festino.—See our note on the Decimal System. The discussion for the present, at all events, must be closed. We should, however, be glad to hear from you on other matters.

Ralph Lowdon.—If commenced at all, the discussion would assuredly take a theological turn, which we must try to avoid.

John Jones.—A respectable firm, we believe. Your query was an advertisement.

C. S.—We never heard of a barber's hair *cutting* machine, and if we did your query could not have been inserted, as it was to know the seller of such machine and the price.

Stopping Pinholes in Lead Pipe.—A correspondent in an American journal writes:—"The supply water-pipe which extends from the street, along the top of our cellar to the sink in the kitchen, had a very small hole in one side, so that a stream of water spun out, not so large as a cambric needle. If I had known that the difficulty could have been remedied by placing the square end of a tenpenny nail on the hole and hitting it two or three light blows with a hammer, the knowledge would have saved me much trouble and expense. But I did not know that a small hole in a lead pipe can be stopped by battering the metal just enough to close the orifice, therefore I went and called a plumber. Of course he was employed by the day, and cost me a dollar and a half, when any one who can handle a hammer could have closed the issue in half a minute if he had thought of how to do it."

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING APRIL 16, 1872.

1045 W. Williamson, High Holborn, for improvements in washing and wringing machines.

1046 H. A. Bonneville, Piccadilly, for a new and improved process for treating metals or metallic ores. A communication.

1047 W. E. Gedge, Wellington-street, Strand, for improvements in feeding bottles. A communication.

1048 T. S. Derham, Leeds, for improvements in machinery for manufacturing bricks.

1049 W. R. Lake, Southampton-buildings, for improvements in ditching or trenching machines. A communication.

1050 S. Bennett, Manchester, for improvements in construction and fixing cocks or valves for high or low pressure.

1051 J. H. Johnson, Lincoln's Inn-fields, for improvements in the treatment of animal and vegetable substances. A communication.

1052 A. Browne, Gracechurch street, City, for an improved glove-sewing machine. A communication.

1053 S. Danks, Southampton-buildings, for an improved method of lining rotary puddling furnaces.

1054 E. Sonstadt, Ramsey, Isle of Man, for improvements in the manufacture of iodide of potassium and of bromide of potassium.

1055 E. G. Brewer, Chancery-lane, for improvements in tuyeres or tuyere pipes. A communication.

1056 J. Greene, Pall Mall, for improvements in the manufacture of types, logotypes, and phrasotypes.

1057 A. S. Guttman, Park-road, Holloway, for a shade or covering for the protection of outside passengers of omnibuses, tramway cars, and such like public vehicles.

1058 A. V. Newton, Chancery-lane, for an improved spring motive power. A communication.

1059 W. Thornton, Nottingham, for improvements in machinery for the manufacture of looped or knitted fabrics.

1060 A. Fraser, Edinburgh, for improvements in apparatus for distributing types.

1061 A. M. Clark, Chancery-lane, for an improved postal or correspondence card. A communication.

1062 H. Larkin, Theydon Gernon, Essex, A. Leighton, Liverpool, and W. White, Hampstead, for improvements in the production of iron and steel.

1063 K. W. Zenger, Charing-cross, for improvements in the purification of iron, copper, and zinc.

1064 W. R. Lake, Southampton-buildings, for improvements in the manufacture of sieves. A communication.

1065 L. A. Badin, New Ormond-street, Middlesex, for a new or improved method of deodorising human excrementitious matters, and of its manufacture into farm manure suitable for all descriptions of agricultural purposes and to all localities.

1066 S. C. Reed, Fulham, for improvements in the construction of portable stretchers and bedsteads for military and other purposes.

1067 F. Render, Manchester, for improvements in reins for driving and riding.

1068 G. Winram, Manchester, for improvements in spring mattresses and seatings.

1069 J. Worrall, Manchester, and J. Kershaw, Wadsworth, Yorkshire, for an improved apparatus for scouring pile fabrics.

1070 J. Worrall, Manchester, and J. Kershaw, Wadsworth, Yorkshire, for an improved mode of and apparatus for finishing cotton cords.

1071 J. Heberlein, Southampton-buildings, for improvements in apparatus for working brakes in railway trains.

1072 W. Cullen, Belfast, Ireland, for improvements in apparatus for grinding grain.

1073 J. Bell, jun., and T. Bell, Wishaw, N.B., for improvements in apparatus for discharging horizontal retorts.

1074 H. Ashworth, Walsden, Lancashire, for improvements in apparatus for spinning and doubling cotton and other fibrous substances.

1075 G. Luttringhaus, Prussia, for an improvement in machinery or apparatus for cutting out metal plates to pattern.

1076 J. H. Johnson, Lincoln's Inn-fields, for improvements in preparing linen thread for dyeing. A communication.

1077 J. H. Johnson, Lincoln's Inn-fields, for improvements in rotatory steam engines. A communication.

1078 H. A. Bonneville, Piccadilly, for improvements in machines for spinning wool, cotton, silk, and other fibrous materials. A communication.

1079 H. A. Bonneville, Piccadilly, for painting the surfaces of woven jute, alone or combined with flax, hemp, and cotton, in imitation of paintings well known as tapestry of the Gobelins or of Beauvais. A communication.

1080 J. J. Bodmer, Hammersmith, for improvements in the manufacture of iron and steel.

1081 J. R. Croskey, Portsdown-road, Maida-hill, and G. Remington, Mansfield-road, Haverstock-hill, for improvements in rails for railways.

1082 H. Jones, Birkenhead, and W. Green, Tranmere, Cheshire, for improvements in apparatus for putting out, lowering, and detaching ships, life, and other boats.

1083 D. Foxwell, Manchester, for improvements in cards used in carding engines and other similar machinery.

1084 N. Lloyd and R. E. Green, Manchester, for improvements in preparing cloth or yarn for dyeing or printing.

1085 T. Hicken, Bedford, for an improved corn sheafing and binding machine.

1086 W. H. Maw, Bedford-street, Strand, for the construction of floating stations or docks for floating fire engines.

1087 R. F. Fairlie, Westminster, for an improved means of increasing the adhesion of railway trains on steep gradients.

1088 W. R. Lake, for an improved process of converting cast iron and articles made thereof into steel.

1089 J. Anderson, Newbuildings, Ireland, for improvements in refining iron, in obtaining malleable iron and steel, and in apparatus therefor.

1090 E. Manico, Bedford-street, Strand, for an improved means of raising sand or shingle covered by the tide to the level of high water, and therewith forming embankments for the construction of sea works.

1091 F. Lamy, France, for improvements in the production of a puce garnet colour of colours from naphtylamine and its derivatives.

1092 E. W. Pugin, Victoria-street, Westminster, for improvements in printing, which said improvements are chiefly applicable to the printing and publishing of advertisements.

1093 W. Wilson, jun., Manchester, for improvements in kitchen boilers for more effectually heating water for domestic purposes and preventing choking of the flues by cinders.

1094 J. Liddington, Liverpool, for improvements applicable to tramway cars, omnibuses, and other passenger carriages, parts of which may be used to record the number of persons entering or leaving public buildings and other places.

1095 D. D. Kyle, Victoria-street, Westminster, for improvements in traps for preventing the escape of foul air and gases.

1096 J. Betteley, Liverpool, for improvements in the construction of ships or vessels, and in appliances connected therewith.

1097 H. G. Keyworth, Cirencester, Gloucestershire, for improvements in cases or receptacles for receiving and retaining letters, papers, or documents in alphabetical or other order.

1098 A. M. Clark, Chancery-lane, for improvements in machinery for blocking or pressing hats, part of said improvement being applicable for regulating the pressure of fluids and liquids generally. A communication.

1099 E. R. C. Morgan, Swansea, for an improved means or apparatus for instantaneously communicating between the passengers and guard or engine-driver of a railway train.

1100 R. Clarke, Lincolnshire, for improvements in the manufacture of cranked shafts or axles, and machinery for the same.

1101 A. Lilly, Stockton-on-Tees, for improvements in lubricators or steam greasers.

1102 G. Luttringhaus, Prussia, for an improved lock for travelling bags, applicable also to other purposes.

1103 R. Tiernan, Liverpool, for an improved manner of treating tobacco.

1104 T. White, Birmingham, for improvements in nutcrackers and lobster crackers.

1105 W. Walton, Denton, Manchester, for improvements in the manufacture of wire cards.

1106 M. F. Jenkins, Exeter, for a new sheath or protector for crochet-needles.

1107 W. J. Porritt, Lancashire, for the manufacturing of woollen cloth applied to the spindle rails of throstles, upon which cloth the ends of the bobbins rest, whereby sufficient drag is applied to them, and also lubrication of the spindles is secured in a superior manner.

1108 W. Spence, Quality-court, Chancery-lane, for improvements in metallic coverings for roofs and walls of buildings. A communication.

1109 W. E. Newton, Chancery-lane, for improvements in compositors' type cases. A communication.

1110 A. Browne, Gracechurch-street, City, for improvements in lamps. A communication.

1111 S. Danks, Southampton-buildings, for improvements in rotary puddling and heating furnaces employed in the manufacture of iron and steel, and in apparatus to be used in connection therewith.

1112 W. R. Lake, Southampton-buildings, for improvements in the feed mechanism of sewing machines. A communication.

1113 R. McKenzie, Achnasheen, N.B., for improvements in railway, steamboat, and other similar tickets, and in the means employed for producing the same.

1114 W. Tongue, Kennington, for improvements in machinery for combing fibrous materials.

1115 R. Stone, Liverpool, for an improved system of casting or moulding, applicable to ceilings, internal and external walls, roads, navigable vessels, and other large surface structures.

1116 J. Ingham, Blackburn, Lancashire, for improvements in looms for plain weaving.

1117 G. Stavers, Morpeth, Northumberland, for improvements in apparatus for steering and manœuvring vessels.

1118 J. Long, Little Tower-street, City, for improvements in apparatus for bottling wines and other liquids, and in the means for facilitating the removal and cleansing of the parts thereof.

1119 W. E. Gedge, Wellington-street, Strand, for improvements applied to boots and shoes. A communication.

1120 W. E. Gedge, Wellington-street, Strand, for an improved method of raising and floating sunken or stranded vessels. A communication.

1121 J. H. Johnson, Lincoln's Inn-fields, for improvements in the manufacture of files, rasps, rubbers, taps for screwing, and other tools requiring hardness and durability. A communication.

1122 P. Jensen, Chancery-lane, for improvements in the construction of coke ovens, in the utilisation of the waste heat therefrom for the manufacture of refined salt, and in the apparatus therefor. A communication.

PATENTS SEALED.

2719 E. Butterworth and J. Heap, for improvements in boilers and furnaces.

2720 S. L. Redpath, for improvements in knitting socks, stockings, and other similar articles, and in the machinery or apparatus employed therefor.

2735 A. C. Duncan and A. Duncan, for improvements in madder dyeing.

2744 J. MacLaren, for an improvement in the manufacture of boots and shoes.

2760 J. B. Pow, for improved arrangements for filtering and purifying, also for collecting for utilisation, the solid matter in suspension in sewage, especially applicable for obtaining pure potable waters.

2763 W. Crookes, for an improved disinfectant and deodoriser.

2788 Sir A. Brady, H. E. Dresser, and M. M. Harris, for improvements in couplings.

2855 W. J. Hay, for improvements in preparing cork for use as a protecting medium, and for filling in spaces in ships, vessels, rafts, pontoons, and other structures.

2902 J. Shand, for improvements in fire-escapes.

2937 C. Moseley, for improvements in the manufacture of bowls for calenders and other purposes.

2961 T. B. Gibson, for improvements in the manufacture of certain figured fabrics, and in the modes and means employed therefor.

3106 C. Burrell and G. J. Fowell, for improvements in elastic wheel tyres.

3480 W. R. Lake, for improvements in apparatus for supporting and adjusting the seats, and parts connected therewith, in sulkies and other vehicles.

3590 C. Binks, for improvements in treating a certain residual matter left in manufacturing aniline dye, for the manufacture therefrom of valuable products.

445 H. Walker, for improvements in breech-loading small arms

2752 G. Rydill, for improvements in the process for extracting, dyeing, or staining and changing the colour of woollen piece goods, woollen rags, and animal substances.

2753 G. Rydill, for improvements in apparatus and machinery and method or methods for extracting vegetable substances from and preserving the colour and staple of wool, woollen rags, and animal substances, and re-using certain agents employed in the process, also removing dark shade.

2754 G. Rydill, for improvements in the means of and apparatus and machinery for extracting vegetable substances, and preserving the colour and staple of wool, woollen and silk rags, and animal substances, and removing dyed colours.

2765 E. Davis, for improvements in the construction of axle-boxes.

2766 J. Gurrin, for an improved apparatus for fastening immediately and securely any broken bar, carriage pole, shaft, oar, scull, mast, or scaffolding.

2767 J. Holdsworth, for an improved feed or supply pipe for supplying illuminating gas to gas burners.

2769 C. A. McCalla, for a new metallic clip or fastening for securing the strings of ladies' hats or bonnets and other articles of dress.

2782 J. J. Cousins, for an improved apparatus for raising and lowering window sashes.

2785 J. Swan, for an improvement in augers and bits.

2790 F. A. Marshall, for improvements in the manufacture of metal.

2799 E. Edwards, for improvements in photo-mechanical printing and in apparatus to be used in such printing, parts of which apparatus are also applicable to other purposes.

2800 W. T. Henley and H. Horstman, for a new or improved self-acting method of signalling by magneto-electric apparatus.

2807 G. Rydill, for improvements in machinery for drying and cleaning animal and vegetable substances, known as the shaking willies.

The English Mechanic
AND
WORLD OF SCIENCE AND ART.

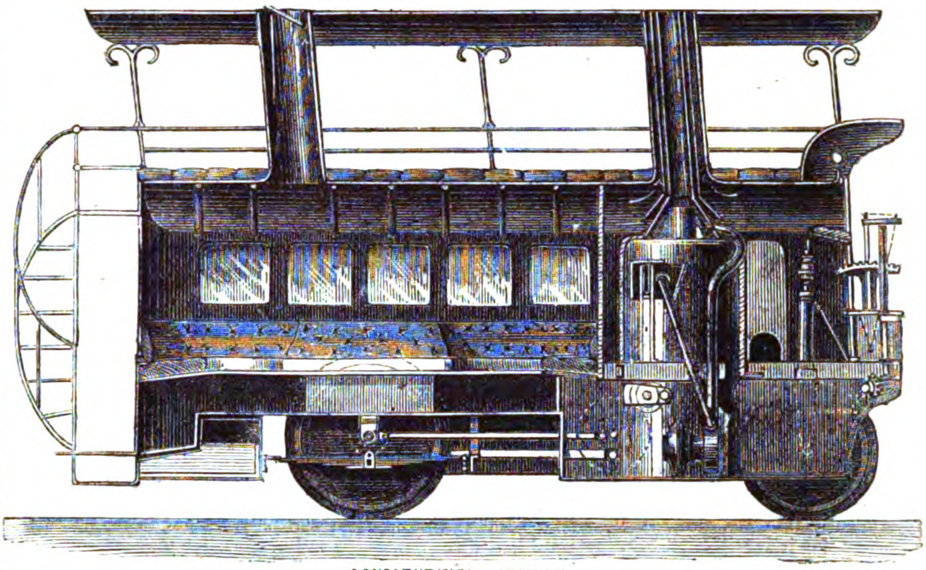
FRIDAY, MAY 3, 1872.

ARTICLES.

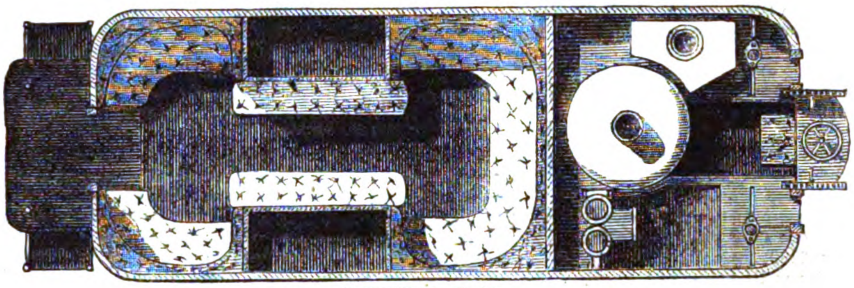
A NEW STEAM 'BUS.

AN idea of the general arrangement and principal features of the design of the steam 'bus patented by Mr. Leonard J. Todd, engineer, Leith, will be easily gathered from the accompanying engravings. It will be seen that it is not unlike an ordinary horse 'bus of rather large dimensions, being painted and finished outside so as closely to resemble one, for it has been found that by doing this the horses think it a familiar object, and provided that it can be made to run in perfect silence they in a very great measure cease to be afraid of it. This desirable end is also promoted by the apparent absence of any machinery or working parts—as boiler, engines, funnel, &c., and also by the fact that there never is the slightest appearance of either smoke or steam; in fact, the more ignorant among the general public fail to comprehend how or by what means the machine is propelled. It will, however, at once be remarked that it is a very simple matter to make such statements on paper as that the 'bus will be silent, smokeless, &c., but that it will not prove so easy or feasible to carry all this, not only into practice, but into a really successful and durable practice. This remark is no doubt fully justified by the many crude schemes for different mechanical arrangements which are continually brought forward by enthusiastic individuals who have little acquaintance with actual practice, and but the slightest knowledge of what is wanted to attain a desired end. It may be as well, therefore, in the first place to consider what is wanted in a self-contained steam 'bus, and then refer to the means employed to attain the desired results, taking note at the same time of what has actually been done in this line and of what is new. We shall also slightly examine into the commercial part of the matter, as to fares, working expenses, profits, &c., so that the entire scheme in all its bearings may be clear to our readers. We need not add that the subject is one of much interest to many classes of society. In the first place we may state that the only self-contained steam 'bus which has yet been made is the "Pioneer," proposed and designed by Mr. Todd, which ran between Edinburgh and Portobello last summer. Of course, many attempts were made in this direction some twenty or thirty years ago by Scott Russell, Hancock, and others, but there is no necessity here to do more than mention the fact. The term "self-contained," as applied to a steam 'bus, refers to the plan of combining the boiler, engines, and carriage in one machine, as opposed to that of drawing a 'bus by means of a separate engine. The "Pioneer" was made as closely to resemble an ordinary horse 'bus as possible—indeed, on several occasions, persons got into it and rode to the end of their journey without knowing that they were in a steam 'bus. It was 22ft. 6in. long over all, by 6ft. 6in. wide, and the same height as an ordinary bus; the boiler was in front, with a horizontal funnel under the seats of the outside passengers. It ran on only three wheels, one leading and two drivers 40in. diameter, to which were coupled direct three cylinders $7\frac{1}{2}$in. diameter by $10\frac{1}{2}$in. stroke. The working pressure was 180lb. The total weight with fifty passengers on board was eleven tons. A great many defects in this arrangement speedily developed themselves in practice: with the horizontal funnel above, and the cylinders below, the floor, it was most uncomfortably warm inside; while the three wheels rendered it liable to upset, especially when turning. The horizontal funnel to enable the boiler to keep steam required a much heavier blast than is usual in any kind of locomotive, the three cylinders exhausted through a hole $\frac{15}{16}$in. diameter, and we are afraid to tell our readers how much the back pressure was greater than 30lb. per square inch, in case they should not take it seriously. Enlarging the nozzle was found to be worse than useless, for the boiler then simply would not keep steam, unless the 'bus ran at a rate of about sixteen miles an hour. It also proved an exceedingly dangerous arrangement to throw the greater part of the weight on to a cranked driving axle. In a six-wheeled rail locomotive, if the inside cranks should break, the engine cannot come down; while as it runs on a perfectly smooth road the crank axle will last a number of years; whereas, when running on a rough road — perhaps over new-laid metal—its duration can only be reckoned at a very few months, especially if rigid wheel-tires are used. There were also many other minor objections to the "Pioneer," which need not be further specified, such as the noise of the blast, &c.

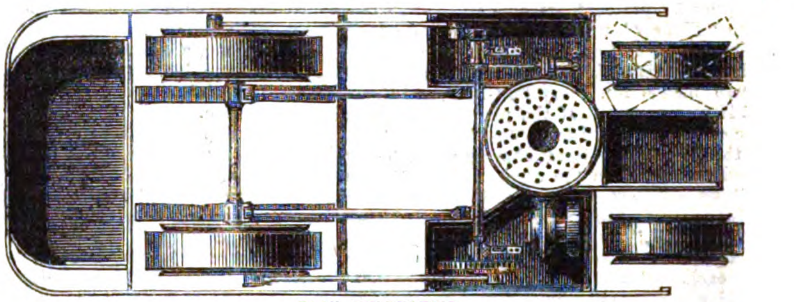
As far as can be discerned at present, it would seem that the best method of applying steam motive power to omnibuses for traffic in streets,



LONGITUDINAL SECTION



SECTIONAL PLAN



PLAN OF GEARING

or in the neighbourhood of towns, is some form of self-contained 'bus in preference to separate engines drawing 'busses. They occupy much less space, and cause less alarm to horses than the use of separate engines; at least, as at present made. These remarks, it must be observed, are not intended to apply to the use of steam on tramway lines, a branch of the subject requiring separate consideration.

We may now more particularly refer to our engravings of the steam 'bus "Edinburgh." A space at the fore end is partitioned off, in which the boiler and engines are placed, the funnel going straight up and emerging at the top of the awning, so that it has thus a good natural draught. The cylinders, 7in. by 10in. stroke, drive a counter shaft by a gear of 4 to 1, and side coupling-rods transmit the power to the driving wheels. By this arrangement the much sought after, but hitherto unattained, desideratum is found—viz., that the main axle can be hung on very sensitive bearing springs, yet gearing can be used, and the whole combined arrangement will work smoothly and silently even at the very highest speeds. The main axle also is straight, and so will not be so liable to break. The next principal feature is the "blast suppressor," by means of which the 'bus can at all times, even on the steepest hills, run in perfect silence, and yet keep abundance of steam. There have been only two plans hitherto proposed to avoid the puffing noise from the exhaust steam in road locomotives: one is the use of an ordinary blowing fan, and the other is to fit the engine with a condenser into which the exhaust can be turned when passing horses. The ordinary blowing fan has practically proved a failure, not only because the noise by it cannot be avoided, but because by its use the steam cannot be kept up at a regular pressure. If the engine is going slowly up hill and steam is wanted, the fan also goes slowly, and the pressure falls. On the contrary, if running fast down hill, requiring little steam, the fan then runs at a great speed and raises far too much steam, which must be blown off at the safety-valve. The condenser, again, is a more inferior contrivance than the common fan, and a great want of judgment is shown in employing it. An engine fitted with it has entirely to rely upon the usual blast-pipe for its power of making steam, and the condenser only furnishes the means of doing away with the noise of the exhaust for a very short time together—say, a si[illegible] minute on a hill. A moment's reflection however, show that precisely the same object can be much better attained by using an adjustable nozzle fitted with a hand lever, so that it can be quickly opened and shut. But all these contrivances are not what is wanted, as is shown by the fact, that although they have all been before the public for many years, yet there is no sign of them coming into general use; indeed, they have only been fitted to a very few engines.

What, however, is wanted, and what any engine intended to work regular passenger traffic in crowded streets *must* have, is some contrivance by means of which it shall at all times run in perfect silence, and yet always keep a uniform steam pressure, as is the case with the common blast-pipe, so that it may go quietly up hill and yet have plenty of steam, or again go down hill without making too much steam to blow off at the safety-valve and startle all horses within hearing.

This second great desideratum is obtained in the "Edinburgh;" by placing a jet turbine-wheel fan in communication with a close ash-pan the ordinary adjustable blast-nozzle is caused to discharge the exhaust steam against the turbine wheel so as to rotate the fan. From this arrangement it will be seen that the speed of the fan, and consequently the draught, will be as perfectly regulated as if the blast were in the funnel in the usual manner, for a moment's reflection will show that the two actions depend for their success on precisely the same principle—viz., that in any steam-engine the back pressure of the exhaust varies directly according to the power that the cylinder is giving out. With the fan, whenever the engine starts the fan starts; if it stops the fan stops; when going up hill the back pressure increases and the fan runs fast, when going down hill it falls away, and the speed of the fan becomes in the most perfect measure reduced. It will thus be seen that so far as relates to their capabilities of regulating the intensity of the fire, the blast-pipe and the steam-fan stand just on the same footing; with the blast-pipe, however, the exhaust is projected violently into the atmosphere, while with the steam-fan it is still kept, being retained in a pipe, and may be condensed or otherwise disposed of, the best plan being to superheat it and then allow it to escape into the funnel through an opening so large that not the slightest noise will be heard. The superheating, of course, makes it invisible. The absence of all smoke is avoided by the use of nothing but Brancepeth coke. It may finally be added that the four road wheels are each fitted with patent rubber tires.

Having thus described the leading features of this steam 'bus, we may shortly refer to the financial part of the scheme. In the first place the "Pioneer" ran fourteen consecutive weeks last summer between Edinburgh and Portobello, a distance of three miles. The total sum earned was £280, thus giving £20 a week, or 5s. 10d. for each run that the 'bus made. The working expenses were £12 a week, thus leaving £8 a week clear profit, which is at the rate of £400 a year, thus paying 50 per cent. on an outlay of £800. But the "Pioneer" was not run to nearly the greatest advantage; it only made one run each way every hour, or sixty-eight runs a week, whereas the horse 'busses ran every half-hour, and thus made 144 runs a week. If the pioneer had done this the earnings would have been about doubled, while the wages and interest charges would have remained constant. In the case of the "Edinburgh," by allowing it to make 144 runs a week and only to draw 5s. each run, instead of 5s. 10d., as did the "Pioneer," which it should easily do on a good route, as its carrying capacity is greater, the receipts each week will then be £36. From this take £14 for working expenses and interest charges, and the clear profit remaining is £22 a week, or £1,100 a year, thus paying 110 per cent. on an outlay of £1,000. These figures are founded on actual fact, for as far as the "Pioneer" is concerned they are simply what has actually been done, and can no doubt be repeated to as great advantage as has been stated.

The advantages to the general public by the use of this patent steam 'bus may be summed up as follows:—

1. It will be much softer to ride in than even tramway cars.
2. The fares will only be one half of what is usual.
3. The outside seats are covered from the weather.
4. The inside can be warmed in winter.
5. It will run much faster than tramway cars.
6. It will set down passengers near the footpath, and not in the middle of the street, as do tramways.
7. No kind of weather or state of roads can interfere with its running.
8. It will at all times run in silence as regards noise from steam, &c.
9. The public cannot see any boiler, machinery, or means of propelling it.

MICROSCOPICAL NOTES.

CERTAIN readers of the ENGLISH MECHANIC have frequently complained of the uncertain results they obtain from the use of semi-fluid media in mounting microscopic objects, and it occurs to me that a few stray hints may be of general service to them and others beyond the circle of my own immediate acquaintance. I therefore take this opportunity of replying to the several queries on the matter that have been addressed to me privately through the post.

GLYCERINE JELLY.—This is a cause of constant vexation to some of my friends, especially to those who use it for mounting fish-scales. The complaint is that although the object may be perfectly clear and transparent when mounted, yet sooner or later "air-bubbles appear all over the slide, and completely spoil the object." It so happens that these are not air-bubbles (usually, at all events), but vacuoles, and are caused by one of two things. The object perhaps is very elastic, or has too much "spring" in it, and hence gradually raises the cover away from the object, straining the medium, and producing vacuoles, which have to the inexperienced observer all the appearance of air-bubbles. In one slide which has been sent me this is evidently the case, for a beam of plane polarised light at once shows lines of unequal tension lying most heterogeneously throughout the thin film of jelly. Or the object may not have been sufficiently soaked before being mounted (if soaked in too fluid a medium, as water or spirits, the same effect will be produced), the object, consequently, absorbs fluid from the jelly, leading to the production of spaces. Lastly, the slide may be covered with paper without the precaution of securely luting in the jelly with varnish having been taken. In this case, the paper absorbs moisture from the jelly, and either air spaces or vacuoles at once appear. Slides should never be papered if any of these fluid or semi-fluid media be made use of. Having thus pointed out the causes which lead to our friends' disappointment, it is easy to point them to the means of prevention, which they will, I think, admit is better than cure.

First. Objects to be mounted in glycerine jelly should be carefully prepared by prolonged soaking in glycerine. Very delicate objects may be brought (and should be) to this stage gradually by adding at intervals a few drops of glycerine to the water in which they are first immersed. When removed to the slide all surplus glycerine should be absorbed by blotting-paper, and the slide gently heated to the melting point of the medium, which should then be placed upon or near the object, and all air-bubbles removed with needles. The thin cover, slightly warmed by being held in the steam from boiling water, may now be carefully placed on the object and secured by a very little pressure. Only just sufficient pressure should be applied to secure the flatness of the object, and prevent the cover from slipping. The whole should be set aside to cool, the jelly cleaned off from the edges, and a neat luting of dammar in benzole applied to make all safe. When fish-scales are mounted in this medium it is always safest to use a thin cell, unless a very tough and secure cement be applied immediately the jelly is set. It is hardly necessary to add that care must be taken not to overheat the jelly in rendering it fluid. A hot-water bath should always be used, and it is advisable to warm only a small quantity more than is actually required, keeping the stock bottle cool and dry.

The great value of Mr. Rimmington's jelly in preparing vegetable structures has caused me to have a tolerably extensive acquaintance with both its good and bad qualities, and I can unhesitatingly say that if proper care be used in the preliminary soaking of the object and subsequent luting, that few, if any, disappointments will arise, and that the objects will for all practical purposes be perfectly preserved.

There are some few substances, however, that require a somewhat less dense medium than jelly prepared according to Mr. Rimmington's plan. One of these is starch. After prolonged trials of every likely medium in which to put up specimens of starch for purposes of measurement and comparison, I have hit upon the following:—Two parts of Rimmington's jelly to one part of glycerine, in which a piece of camphor has been immersed for some days. This medium *must* be luted down, but sets sufficiently to enable the luting to be done easily. To mount starches without the inclusion of air-bubbles is a matter of difficulty, as heat must only be applied in bare sufficiency to melt the medium, and the objects cannot be put through the course of preliminary soaking. Those who *will* not have bubbles, from a constitutional abhorrence of them, had better lay in a Baker's microscopical air-pump, and try their luck with it. *Pour moi*, the bubbles rest in peace.

GLYCERINE AND GUM WATER.—For delicate sections of young tissues, sexual organs of flowers, and some starches for exact observation, I prefer a medium prepared as follows:—Take of picked gum arabic 1oz., and having washed it in cold water to remove dust, add as much cold water as is just sufficient to dissolve it to a very viscid fluid; add an equal quantity of strong glycerine, and mix. Place a small lump of camphor in the bottle, or add two grains of arsenious acid (white arsenic), and allow the whole to stand a few days; after which, if clear, it will be ready for use. If not clear, it must be filtered. For excessively delicate tissues, where it is desired to retain the form and position of the protoplasmic masses as much as possible, the above medium, plus one part of camphor water, is well adapted. The above medium is always fluid and must be treated accordingly. Dammar in benzole is the best cement for it.

A medium that I have lately used in the examination of pollen, and also in the study of materia medica "vegetables" with good results, is one I should be thankful to learn how to "keep in." I allude to an essential oil, such as thyme, anise, cassia, bergamot, &c. Dammar answers pretty well for a few weeks, but, of course, a gradual escape goes on, and sooner or later the slide becomes nearly dry. If any microscopist, given to experimenting, will light upon a cement which will resist these oils and yet be usable cold, let him publish its formula and earn my hearty thanks.

H. P. H.

EFFECTS OF FAULTS IN VISION ON PAINTING.

ON Thursday evening last week Dr. R. Liebreich delivered a lecture on this subject at the London Institution. The following is an outline of it:—

On one occasion, when visiting the National Gallery, Dr. Liebreich was struck with the difference between Turner's earlier and later paintings. The cause of this did not clearly appear from Turner's life, though during the last five years of it the painter's vision and intellect were known to have suffered, for the changes had first appeared 15 years before that, Dr. Liebreich was therefore led to seek for the cause in a scientific study of his paintings. The prominent feature in this change consists of a vertical *streakiness*; each luminous point is changed into a vertical line. In his earlier works the sun, *e.g.*, has a clearly defined disc, the light radiating equally to all parts; in his later, a vertical yellow streak divides it into two distinct halves. So with less luminous objects—houses standing near water, or figures in a boat, are made to blend with their reflection, and all becomes a conglomeration of vertical lines, while all tracing of detail vanishes under such lines.

The first appearance of change is in 1831, consisting of an increased intensity of diffused light from illuminated parts. From 1833 this diffusion begins to get vertical, and the tendency increases in the following years.

Now, it is commonly supposed that Turner adopted a peculiar manner, and exaggerated it more and more. The fact appears to be that his change of manner arose from a change in his eyes, and that he reproduced scenes as he saw them.

As age advances, the crystalline lens of the eye (at no time perfectly transparent) gets dimmer, and disperses the light more strongly, throwing a haze over illuminated objects. In Turner's case, a clearly-defined opacity was formed in the dimness of the lens, and had the effect of dispersing the light vertically. This increased till not only the aspect of Nature was altered, but he could not see his own pictures correctly.

While these later paintings have many merits, it is yet a mistaken notion which leads people to admire the defects referred to, and call them Turner's style, from which they would form a new school.

Dr. Liebreich illustrated some of the above effects by experiment. Projecting a picture of Venice, distinct in its outlines, on a screen, he then interposed a lens, which gave the picture the streaked appearance of Turner's later paintings. A picture of a tree was also thus altered into one of "Turner's trees," which, the lecturer said, were entirely unlike anything in Nature, and unknown to botanists.

Turning to another class of cases, we find irregularities of refraction in the eye affect an artist's work. To see an object distinctly, its image must fall on the retina. But to effect this, the eye must accommodate itself to the different distances of the objects seen. It does so by changing the form of the crystalline lens. For the nearest point, the lens is at its greatest tension; for the farthest, in complete repose. This latter state of the eye constitutes its refraction. There are three different kinds of refraction. 1. That of the normal eye, in which rays parallel, or from an infinite distance, unite on the retina. 2. That of the short-sighted eye, in which they unite in front of the retina. 3. That of the oversighted eye, in which they unite behind the retina. In the second case, when looking at distant objects, concave glasses are used to make the rays *diverge* on approaching the eye; in the third case, convex glasses are used to make the rays *converge*.

Now, it may occur that an eye is normal in one direction and short-sighted in another. Conceive the eye as a globe with one pole in front, and two meridians on the surface at right angles to each other. If these meridians have different curvatures, we have a difference of refractive power in the two directions. This constitutes astigmatism. The effects of this, in artists, vary with the particular kind of it, and with the subject painted. Thus Dr. Liebreich knew a landscape painter and a portrait painter who had the same kind of astigmatism, their sight being normal for vertical lines while they were slightly short-sighted for horizontal lines. In the landscapes there was no disturbing influence in the distant parts, where sharp outlines were not requisite, but rather undefined and blending tones of colour. The foreground represented water with gently moving waves, and Dr. Liebreich noticed some short horizontal strokes of different colours that did not seem to belong to the water. Using a glass which gave him the same kind of astigmatic vision as the painter's, he saw the strokes indistinctly and mixed together, and the effect became quite natural and good.

The portrait painter had at one time a high reputation, though some thought his portraits showed too great indistinctness in details. This was due really to astigmatism. Latterly, his portraits had become very much worse, the neck and oval of the face being elongated out of all proportion, and all the details distorted. The effects of astigmatism were doubled in this way: the painter having become far-sighted for vertical lines (for which he had normal vision before), sees a distant person at whom he looks elongated vertically. The picture being near, is seen enlarged horizontally, and thus he paints the person even more elongated than as the latter is seen. Some illustrations of these results were given. Square figures were projected on the screen, and a cylindrical lens being interposed, these were elongated vertically or horizontally, according to the position of the lens. This effect was also shown on a portrait.

We come next to colour-blindness and its effects. The primary sensations of colour are red, green, and violet. What we call colour-blindness occurs when one of these is absent, and an artist who has this defect should confine himself to drawing otherwise his work will be marred. There are, however, slighter degrees of colour-blindness, thus the perception of red may not be quite wanting—only diminished. To a person thus affected, strong bright red will appear red, while less intense red will look green. Some artists show this in their works, painting, *e.g.*, the roofs of houses red on the sunny side, green on the shady.

The crystalline lens often becomes yellow with advancing age. What effect has this in the perception of colours? We may test it by looking through yellow glass of the corresponding shade. At first every thing looks yellow, but the eye gets dulled by degrees, and things begin by-and-by to appear again in their true light and colour. It is found, however, that a pale blue, or a very small quantity of blue, fails to be perceptible after prolonged experiment. The yellow glass excludes it. Now, the colours of natural objects reflecting light are very much more intense than those in a painting. In looking through yellow glass at the former the small quantity of blue excluded makes no sensible difference in a painting—on the contrary, there is, in some parts, just as much blue as is completely absorbed by the glass, and even in the parts of intensest blue, the quantity of blue excluded by the glass makes itself felt, for it bears a larger proportion to the entire quantity of blue than the blue excluded in the other case did.

Now, a painter whose lens has become yellow will see natural objects almost correctly, but in his picture everything will appear yellowish, and so he will paint it too blue. He does not perceive this, and he will not believe it when told of it, as his own impressions have a stronger force of conviction.

Incorrect perception of form may be demonstrated. A square that appears oblong, *e.g.*, may be measured with a compass. But faults in perception of colour can only be recognised as such from the testimony of a number of persons of normal vision.

An artist in the state referred to, and beginning to paint blue, is said to have changed his style. He thinks he paints in his old style, and has improved the tone of his colours. His early works appear to him too brown. Were his lens suddenly removed everything would appear too blue.

Mulready may be taken as an example. The peculiarity in his later works is produced by an addition of blue. Looked at through a yellow glass these paintings become natural—the violet colour of the face shows a natural red; blue shades become gray, the unnatural glaring blue of the drapery is softened. We may thus see these pictures as he saw them with the naked eye. One subject he has fortunately painted twice; first when 50 years old, and when his lens was in its normal state; again, when he was 71, and the yellowness had advanced considerably. The pictures are both in Kensington Museum; the first one called "Brother and Sister, or Pinching the Ear;" the second, "The Young Brother." The difference in the colouring is very striking, and it almost entirely disappears when the second picture is looked at through the yellow glass. If we look at the first picture through the glass the tone appears too weak; the shadows brown; the green dark and colourless. We thus understand how he became dissatisfied with his earlier works and changed his colouring.

METALLURGY OF IRON AND STEEL.*

(*Concluded from p. 135.*)

IN his sixth and concluding lecture Dr. Percy commenced by recapitulating the former account of the puddling apparatus and furnace, referring, in passing, to the late application of mechanical means to this operation. In speaking of the estimation of the strength of iron, he pointed out the great difference between concussive action and the action of a slow force, and in the materials used for guns, &c., we must calculate from the former grounds. Sir Joseph Whitworth and others had lately experimented on this subject, using gunpowder as the agent to cause the concussive force, and it was thought that gunpowder was, as a rule, the most fitting for that purpose. The more immediate subject of the lecture, however, was

Steel.

What is steel? Steel is *essentially* nothing but iron, containing a certain proportion of carbon. There are a great variety of steels, these varieties depending more or less upon the presence of certain foreign bodies in certain proportions. Taking into consideration the quantity of carbon contained, we may ask, when does wrought iron cease to be wrought iron and become steel? and when does steel cease to be steel and become cast iron? It is a difficult thing to fix the precise lines. We may say that iron containing ·2 per cent. of carbon would be more or less steely, it might be regarded as mild steel, approximating to wrought iron, but capable of being hardened, which wrought iron is not. When we get to 1 per cent. of carbon we find a variety of steels; and at 1·4 per cent. we pass rapidly to cast iron. Steel is a valuable, marvellous metal. It differs as much from wrought and cast iron as many metals differ from each other. It is capable of a hardening process; if steel be heated and then quenched in water, the metal is rendered much harder. The small amount of carbon in the iron does the whole thing, the hardening depending on the way in which the carbon is combined with the iron. The quality of the steel depends especially upon the mode in which the carbon occurs in the iron, and not entirely upon the quantity of carbon. If, after the steel is heated, it be allowed to cool slowly, on acting on the product with an acid and dissolving the iron, a carbonaceous mass remains, but if the metal be cooled rapidly (*e.g.*, by plunging it into water) none of this residue occurs, but the whole of the steel is dissolved by the acid.

Steel is more fusible than wrought, but far less so than cast, iron. It is capable of being welded, is malleable, and can be hammered, rolled, and drawn out into wire and so forth.

Modes of Making Steel.

In the puddling of iron the problem is the separation of carbon. The question arises—Cannot you make steel by that process? Why can't you stop short when you have separated all the carbon except the proportion necessary for forming steel? because in passing from cast into wrought iron and *vice versa* the mass has to pass through the state of steel. In the old method of making pig into malleable iron this ought to occur, and it does.

There are about twenty different methods of making steel on the theory above stated. The most common method of making steel is by

Cementation.

If we take an iron bar and imbed it in charcoal, and then keep it at the temperature of melting copper for ten days or a fortnight, although the iron is never melted, the carbon, by simple contact, will find its way right into the interior of the mass of the bar, and we get "blistered steel." All good steel used in England has been for a long time made by this process. Some suppose the carbon enters the mass in the state of carbonic oxide, for there is always a quantity of air mixed with the fuel. The furnaces are built so as to exclude atmospheric air beyond that which originally exists in the mass of the charcoal. The furnace itself is like a long firegrate with two stoke holes at each end. About it are built two rectangular chests of brickwork, and these are surrounded on all sides by flues, so as to make the temperature as uniform as possible. Around the whole is built a large cone, like a glass-house cone. When a fire is made the products of combustion pass through the openings and surround the converting chests, and by this means a great uniformity of temperature is maintained. The gases then escape into arched chimneys built above of firebrick; a hole being left at each end (which, however, is stopped during the working), through which a man can enter when necessary, the smoke, &c., passing through the flues and by three openings into the outer cone.

At the bottom of the chests is placed a layer of charcoal, then bars of iron on that layer, taking care that the bars are sufficiently short to allow of expansion; then another layer of charcoal, then iron, and so on till the chests are filled. Over the top of the whole is placed a layer of some material which will exclude the air; frequently a substance called "wheelswarf" is employed, being the dust formed by the wear of the grindstones used for grinding steel instruments at Sheffield, and consequently containing fine particles of steel.

The chests are kept heated for about a fortnight, the exact time depending on the kind of steel required; the longer the iron is kept heated the more carbon it will take up. When the proper time has been given the fire is allowed to go down, the chests are uncovered, and the bars are brought out. On these bars will now be noticed strange large blisters, and hence the term "blistered steel." There are diversities of opinion as to the cause of the blisters, but I think they are produced from the action of the carbon as it finds its way into the heated mass, upon the interposed slag, for all iron contains slag, and it is certain that if the carbon comes in contact with slag, some of the oxide of iron must be formed into gas, and this gas produces bubbles or blisters. The steel in this state is heated, worked and drawn out into bars.

* An abstract report of a course of lectures by Dr. PERCY at the London Theatre of the Geological Museum.

The Bessemer Process.

A great feature in this process is Siemens's gas furnace, by which we can obtain a very high temperature. By means of it we can obtain the metal in the form of cast steel—*i.e.*, steel which has been perfectly fused, and, therefore, much freer from the impurities which exist in steel made by the ordinary process. In this process you may see about four tons of steel as fluid as water at one time. A somewhat similar method, as employed by Bessemer, was known in 1722, but in the present process the application is new, and the means of obtaining heat are altogether new, and therefore it possesses a high interest for us.

Bessemer took out his first patent in October, 1855, and at first he had no idea of what he was subsequently going to achieve by it, but he seemed to look upon it as a preparatory process to the operation of puddling. It has, however, turned out to be one of the most remarkable inventions of modern times.

The problem is to eliminate a portion of the carbon from the iron and to convert it into steel, and it is solved by melting the iron and then blowing through it atmospheric air. It appears to be a very simple thing, but it is a very difficult one to accomplish.

The *converter* is ellipsoidal in shape, and made of wrought iron, in several pieces, screwed together. It has a false bottom; underneath it is an empty space into which air is blown. The interior is lined with a mixture of crushed slag and fire-clay, and the lining is dried very gradually. In the bottom is fixed a number of conical pipes, each containing numerous holes, and arranged so as to come flush with the bottom. The converter is suspended on trunnions, and there is a very ingenious contrivance for tilting it up—*i.e.*, lowering the mouth, and erecting it again, the work being performed by hydraulic machinery, or other such power. The trunnion on one side is hollow, and a pipe leads from it into the empty space at the bottom of the converter, from which clay tubes pass into the converter, and through these are forced numerous jets of air. Two converters are usually placed near each other on opposite sides of a circular pit. In the centre of this pit is an arm which can be moved up and down by hydraulic power, and at one end is a lever which can be turned about in several directions very gradually. By means of these converters either wrought iron or steel can be produced at will from the cast iron put into them.

A charge of iron being already molten in a reverberatory furnace (say three tons, but frequently five, and even ten tons, are operated on at one time) at the proper time the converter is tilted, and this metal run into it by a spout of iron lined with clay. The quantity run in is regulated so that it shall not rise up to the lowest twyer opening. While the converter is in this position the blast is powerfully put on—say about 15lb. to the square inch—a contrivance being adopted to allow of this, otherwise the molten metal would run down the above pipes.

The converter is then tilted back again, and now we have streams of atmospheric air rising vigorously through the metal in the converter. The operation goes on pleasantly at first, but at the end of 10 or 12 minutes there is a miniature volcano eruption, and a great roaring flame comes out of the mouth of the converter. In the first furnaces a shower of sparks and pieces of red hot slag and metal accompanied this eruption, but alterations in the form of the furnace have prevented this since. At this period the metal undergoes a remarkable change, and if required the whole of the carbon can be taken out and wrought iron made. The usual process now is to burn out the whole of the carbon in this way, and then at a given time to pour into the remaining mass a quantity of molten pig-iron containing just the proper quantity of carbon to convert the whole into steel. Besides carbon, there is also a certain proportion of manganese, and this has a wonderful effect.

The charge of pig-iron being ready, it is poured in in a molten state, and the resulting mixed mass—steel—is then transferred from the converter to large pans on the lever, which is then carried round, and the molten metal dropped into moulds underneath.

Only certain kinds of iron can be employed in this process—viz., those which are free from phosphorus and sulphur, and unfortunately these kinds are very limited in this country, only that obtained from hæmatite being applicable. The supply obtained from this source is insufficient to meet modern requirements, and we are consequently obliged to import a great deal from Spain. There are no less than 30 or 40 vessels exclusively engaged in this trade.

A small amount of silicon in the iron is thought to be advantageous, inasmuch as by its combination with oxygen it developes a very high temperature, becoming converted into silicon as slag. Sometimes the metal obtained by this process is not so homogeneous as it might be.

The lecturer concluded the course with a few remarks, regretting the short space of time he had been able to devote to a subject of such magnitude, which, to be properly dealt with would require something like sixty, instead of six, lectures.

WRITING MACHINE FOR THE BLIND.

AT a recent meeting of the Royal Scottish Society of Arts a communication was read from Mr. Robert Meldrum, teacher of the blind, Alloa, describing an improved method of corresponding between blind persons. The invention consists of two parts—the upper having the types, with keys and levers for moving them, and the lower containing the paper-moving apparatus. The base of the upper part is a metal disc, with a circular hole in the centre. Around the central opening are arranged twenty-six little hammers, having on their striking surface copper types for embossing the paper. The types are so arranged that they all strike at the same place—viz., on the opening in the disc, and each hammer, after striking, is pulled back to its original position by an indiarubber band. Each of the keys represents a letter, and when any particular key is pressed down the corresponding hammer strikes, and the type makes a mark on the paper, which is stretched on a revolving drum in a drawer below the disc. When one letter is impressed the drum is moved round by a handle in front of the machine, and a plain surface is presented for the next stroke. When a line is finished the drawer in which the paper moves is pulled out one line. The machine is constructed to print Moon's type, but its principle is equally applicable to most others, and especially to Braile's. After the paper had been read the machine was exhibited in operation, and worked very satisfactorily.

CONTACT OF LIQUIDS.

IN a recent note to the Paris Academy of Sciences, M. Van der Mensbrugghe enunciates the following principle: When a liquid of strong surface-tension, and holding gas in solution, is brought into contact with a liquid of feeble tension, there is a disengagement, more or less pronounced, of the gas in the former. This may be shown from a large number of experiments—as, *e.g.*, the following:—1. If a drop of alcohol or ether be introduced into distilled water, contained in a small vessel three or four centimetres in diameter, and about half filling it, and if the liquid be then shaken, a lively effervescence takes place. This effervescence cannot be attributed to air introduced by agitation, for alcohol or ether alone, and water alone, do not give any marked results in this respect. The same experiment may be made with benzine, sulphuret of carbon, creosote, spirit of turpentine, olive oil, linseed oil, colza oil, &c. Similar effects will be produced if a glass rod with a greasy surface be plunged into distilled water, and the water then agitated. A disengagement of small bubbles of gas takes place. If the vessel containing the water be not quite free of greasy matter, small gaseous bubbles form at those parts of the internal surface to which this matter attaches. 2. A drop of oil spreading itself on the surface of distilled water produces a disengagement of small gaseous bubbles, which may easily be observed with a microscope. This seems to be the true cause of the cohesion figures observed by Mr. Tomlinson; which consist in the separation of the film, that has spread out on the liquid surface into a number of parts, which form at first a sort of network, and this gradually breaks up into small discs, which continue to decrease in size, till the disengagement of gas ceases, when they remain unaltered for an indefinite time. The phases of this phenomenon may be watched with a microscope, and it seems to be explained by the liberation of innumerable small gaseous bubbles under the films.

When an oil is kept for a time in contact with water, the surface of separation of the two liquids loses its transparency. This is accounted for by the liberation of small bubbles of gas causing the oil to resinify more or less, and thus become incapable of transmitting light rays. 3. It has been long known that water boils less rapidly the more free it is of gas held in solution. It will be seen from the above that when distilled water is mixed with alcohol, for example, a large quantity of the dissolved gas may be expelled. We have in this, confirmation of an experiment made by M. Kremen. Having added one part of spirits of wine to three parts of water, and applied strong heat, he found the boiling point raised to 109 degrees C., and even beyond it, in proportion as the volatile liquid evaporated.

NATURAL PHENOMENA AND PRODUCTIONS OF THE POLAR REGIONS.*

THE polar year consists only of summer and winter, their limits being determined by the breaking up and re-formation of the sea-ice. The breaking up of the winter ice is sometimes accelerated a month or two, or delayed an equal length of time by circumstances the causes of which are unknown. In August, 1838, Dease and Simpson found the sea about Coronation Gulf a mass of fixed ice, and could only progress on foot along the shore, whilst the following year a month earlier they ran past the same coast with a fresh breeze, a flowing sail, and an open sea. The great mass of the sea-ice does not remain stationary through the winter and melt away in summer, but is in constant though slow motion, mostly in the direction of the lower latitudes, where it is finally broken up and dispersed. Captain Back, in the *Terror*, was helplessly borne along amidst the most frightful commotion of the surrounding ice, from Repulse Bay through Hudson Strait, until liberated after many months in Davis Strait. The wonderful drift of the *Fox* down Baffin's Bay from August, 1857, to April, 1858, by which McClintock was delayed a whole year in his search for the Franklin expedition, was another illustration of the above fact.

The immense floating masses called icebergs consist of fresh water ice formed on the coasts and broken off by the action of the waves. The rocks of ice from which they have been severed are huge glaciers advancing far into the sea. When the buoyant power of the ice overcomes the attraction of cohesion masses break off at the bottom of the sea and rise to the surface in the form of bergs. As they float with only a tenth of their bulk above the water, the rate of movement of the glacier, the distance of its front from the sea, and the depth of the water near the shore, have been made the elements to determine the date at which the first berg will be floated off. If this be the true theory of icebergs, their extraordinary abundance in the Antarctic Seas will suggest large tracts of land in the south frigid zone.

The Aurora stands pre-eminent amongst the atmospheric phenomena of the polar regions. Captain Hall alludes to some peculiarities respecting it not generally known. It was attended by the kind of clouds named cirrocumuli, and the auroral beam illuminated the face of the cloud, proving that it was at play between the cloud and the observer. This writer mentions as the most remarkable feature he ever witnessed the peculiar movement of the clouds overhead, which was by hitches, passing with the wind slowly and then stopping for a few seconds. It seemed as if the clouds were battling with an unseen enemy, but that the former had the greater power and forced their way by steps along the vault above. The observer felt sure the aurora had something to do with it. Dr. Walker, naturalist to McClintock's expedition, also expresses his conviction that on several occasions the aurora was only a few feet above the vapour rising from the sea.

McClintock, Simpson, and Kane, all refer to the connection between the aurora and clouds, and think the former is never seen in a perfectly clear atmosphere. Most observers have negatived the idea of the accompaniment of sound, but Mr. Simpson was convinced of the fact upon what he considered good evidence.

The discovery of the position of the magnetic pole by Sir James Clark Ross claims some notice. Previous calculation had nearly determined its place, and it was most interesting to find as the actual place was neared that the horizontal needle ceased to move and the dipping needle became more and more nearly perpendicular until it showed a dip of 89° 59′, only one minute from the vertical. This was in latitude 70° 5′ 17″ N. and longitude 96° 46′ 45″ W. Fifteen years later the same discoverer made the nearest approach ever effected to the place of the south magnetic pole, determining it to be in about 155° E. long. and 75° S. lat.

The phenomena of cold and darkness during the Arctic winter claim attention. The effect of a fall in temperature to − 50° or − 60° Fahrenheit is shown by the tendency to sleep, and in its worst form exhibits itself in loss of reasoning power, memory and every mental faculty. Dr. Kane narrates several instances of this species of insanity among his men, and was himself to some extent the subject of it. The influence of the long intense darkness is described by the same writer as most depressing.

* Abstract of a paper read by Mr. C. F. Ravis, before the Bristol Naturalists' Society.

Even the dogs were strangely affected by it, and many died, as he thinks, from the absence of light as much as from the extreme cold.

The effects of refraction are particularly noticed by Arctic voyagers. The immense amount of evaporation constantly going on during the summer from the melting of the ice, produces an unusually humid condition of the atmosphere on and near the surface, a state of things eminently favourable to the phenomenon of mirage, of which many very interesting instances are on record. Akin to this phenomenon are those of mock suns and moons, both very common in these regions. These, in combination with halos, are sometimes seen for many hours together, and are attributed to the presence in the atmosphere of innumerable spicula of ice, forming so many minute points of reflection and refraction. They are most common in the winter months, alternating with dense fogs, which for days together conceal every distant object upon the surface of the earth and sea, and quite shut out the glories of the heavens.

The question of an open polar sea has been much discussed during the last few years, and many circumstances have contributed to foster the opinion that such an open basin exists in the vicinity of the north pole. Drs. Kane and Hayes succeeded, the former by one of his sledge parties and the latter in his own person, in reaching an open sea perfectly free from ice in latitude 80° and 82½° respectively, whilst their ships were frozen up 300 miles to the south. Subsequent exploration by a German expedition fully confirms this discovery.

Animal life in the Arctic regions is by no means so scarce as might be expected, except during the depth of winter. In the summer the seas and lakes, the rivers and plains, teem with life. The birds are innummerable, swarming on the sea-cliffs and on the borders of the streams where they arrive in the early summer to hatch and bring up their young, and whence they migrate on the approach of winter to more congenial climes. The marine Mammalia crowd the bays and inlets of the Arctic coasts, and the land quadrupeds wander in immense numbers over the plains, now covered with verdure and bright with summer flowers. The most important members of this order were noticed and their habits briefly described. Of the Whale kind the *Balæna mysticetus* of the Greenland seas, the *Physer microps* or Sperm Whale of the Southern Ocean, the White Whale (*Delphinapterus Beluga*) and the Razorback (*Balæna physalis*) were particularly mentioned.

Of all the Cetaceæ, none is more curious than the Narwhal (*Monodon monoceros*), with its enormous tusk or horn projecting from the snout in a straight line with the body, which has given to the animal its common name of Sea Unicorn. There are, in fact, two tusks, but that on the right side is usually rudimentary. This appendage belongs to the male animal only. It is from 5ft. to 10ft. long, tapering to a point, and with a spiral twist through its whole length.

The Seal is the most valuable of all Arctic animals to the natives, as it supplies them throughout the winter with food, clothing, light, and fuel. The sagacity of the seal-hunter is taxed to the utmost in its capture, as its senses of hearing and smell are remarkably acute. The animal is caught either by watching a seal-hole at which it comes up through the ice to breathe, and by striking it through the head with a spear, or by following the chase upon the open water in the native "kayak" or skin-canoe. The former process entails great privations upon the hunter, who is frequently out for several days and nights at a time in a temperature of — 50° Fahr. The principal species of seal inhabiting the Arctic regions are the Common Seal (*Phoca vitulina*), the Rough Seal (*P. fœtida*) and the Great or Bearded Seal (*P. barbata.*) The seal is carnivorous, feeding on fish, crustaceæ, and water-fowl.

The Walrus or Morse far exceeds in size the largest seal, being sometimes 20ft. in length. It is gregarious in its habits, large numbers being frequently seen lying in heaps upon floating ice. It uses its tusks to aid its movements in climbing or dragging its unwieldy body from crag to crag. It lives on fish and marine vegetation. The hide of the walrus supplies the Esquimaux with the best material for their sledge-lines, the flesh forms a large portion of their winter and spring food, and the blubber is used for their lamps. Both the seal and walrus are known to swallow large quantities of gravel and stones, for what purpose is unknown.

Of quadrupeds the Polar Bear (*Ursus maritimus*) for his great strength, activity, cunning, and ferocity, is pre-eminent. This animal is the terror of all smaller and less powerful tribes, whether terrestrial or aquatic, as he is equally at home on the land, in the water, and on the ice. Exploring parties suffer much from his attacks upon their caches of provisions, which, though constructed with great care and labour, generally fall an easy prey to these tigers of the ice. Captain Hall states, on the authority of the natives, that the bear in his conflicts with the walrus ascends the cliffs and hurls enormous stones upon the head of his prey, fracturing the skull. Most writers agree that he does not attack man except when provoked or wounded, and McClintock says no instance is known to the contrary.

The Glutton or Wolverine (*Gulo luscus*) is allied to the bears, badgers, otters, and mustelidæ. Old authors have told wonderful tales of its climbing trees and pouncing upon the backs of reindeer and elks as they passed beneath. It is no doubt extremely voracious, but modern travellers assert that its attacks upon the larger animals are chiefly made upon them during their sleep, or upon weak and dying deer or young fawns. It is extremely mischievous, and a great pest to the hunters and trappers of the fur countries by destroying their traps for the sake of the bait. Its strength is prodigious. It has been known to disarrange piles of wood among which were trees that had required two men to lift them.

The Esquimaux Dog (*Canis familiaris*, var. *borealis*) is well known. His sagacity in the chase, his patience and perseverance in the sledge-team, and his great speed, render him an invaluable possession to the native inhabitant or the more civilised explorer of the northern regions. Though generally treated with harshness by their masters, and often half-starved, they seldom rebel against human authority. They will attack the bear and every other animal except the wolf, to which they have a great antipathy.

The Wolf is one of the tyrants of the northern parts of the world, and is found in both hemispheres. Its great strength, rapidity of movement and savage disposition, render it the terror of all animals inferior to itself in these qualities. Its strength and courage even after being wounded are the subject of many interesting anecdotes by writers on northern research and adventure.

The resemblance between the wolf and the dog has been noticed by many writers. Cases are on record in which dogs have themselves mistaken wolves for animals of their own species, and have fallen victims to the delusion. Dr. Kane says:— "There is so much of identical character between our Arctic dogs and wolves, that I am inclined to agree with Mr. Broderip, who, in the 'Zoological Recreations,' assigns to them a family origin. Both animals howl in unison alike. Their footprint is the same, at least in Smith's Sound. Dr. Richardson's remark to the contrary made me observe the fact that our northern dogs leave the same 'spread track' of the toes when running, though not perhaps as well-marked as the wolf's."

The Arctic Fox (*Vulpes lagopus*) is found in both hemispheres. It has a fine fur, bluish gray in summer, and pure white in winter. Its habits are gregarious, twenty or thirty burrowing together. It is easily taken in traps and tamed without difficulty. It is said that this little animal hunts with the bear, and "It is certain," says Dr. Kane, "that they are often found together, the bear striding on ahead with his prey, the fox behind gathering in the crumbs as they fall."

Of the few strictly herbivorous animals that inhabit or frequent the Polar regions, the Reindeer (*Cervus tarandus*) takes the foremost place, from its size, its numbers, and its utility to man. The animal itself as well as its habits are too well known to need description. In their migrations they go in large herds. Franklin states that in a short morning walk near Fort Enterprise in the month of October, he saw upwards of two thousand.

The Moose Deer or American Elk (*Alces Americanus*) is the largest animal of the genus. It is higher in the shoulders than the horse, the neck is short and strong, adapted to bear the large horns, which weigh sometimes nearly fifty pounds.

The gait of the animal is a kind of shuffle, and the joints crack at each step with a loud noise. It is said to trip occasionally and throw itself down, by treading with its hind feet upon its fore hoofs.

The Musk Ox (*Bos moschatus*) which ranges over the barren lands of America north of the parallel of 60° is about the size of one of our Highland cattle. Its horns are of a peculiar form, and cover the brow and the whole crown of the head. These animals live on grass and lichens, the country being destitute of wood, except some spruce trees on the banks of the larger rivers. They are not found in the eastern hemisphere, nor in Greenland, Spitzbergen, or Lapland. They assemble in herds of twenty or thirty, and will sometimes attack a man and endanger his life.

Notwithstanding what has been stated as to the annual migration of the deer and other Arctic animals, it is nevertheless doubted by many Arctic explorers whether they do migrate at all. It is certain that several expeditions found even in the depth of winter large numbers of deer in various parts of the frigid zone, and it was the opinion of Parry that only the darkness prevents their being seen all through the winter. What they live on is a mystery, and indeed the animals found at that season are very lean. It seems probable that where migration is easy, as on the Continent of North America, it may be the habit of these animals to seek a more genial climate, from the rigours of an Arctic winter, whilst in more isolated situations they may from the force of circumstances remain permanently on the spot.

FLUORESCENCE.

SOME curious and interesting experiments in this branch of the science of light were recently exhibited at the American Institute by the President, Henry Morton. The subject of the paper was—"Fluorescence," or that action by which rays of the higher purple, or even invisible light, such as produce most strongly photographic action, excite in certain bodies lower rates of vibration, resulting in the emission of light, generally of a red, green, or clear blue colour. The paper was illustrated by a number of striking experiments. Thus, a flash of solution of chlorophyl (a green colouring matter obtained from leaves), which is of an olive green colour, being held in a beam of blue light, appeared to be full of a blood-red liquid. Various solutions colourless in ordinary light were then shown to exhibit the brightest hues when illuminated by the violet rays of the lantern, or those obtained from the electrical discharge of a large coil in rarefied gases. Professor Morton then announced that, in the course of the examination which he had been making of such substances, he had encountered one which he believed to be as yet unknown, and which possessed the property of developing light by fluorescence in a pre-eminent degree. This body was obtained from petroleum, and he proposed to take for it the name "Viridine." The word viridin had been already applied as a synonym for chlorophyl, but was now practically obsolete, and too appropriate to the present substance to be thrown away. The material from which this new body was extracted was given to him by Professor Horsford, of Cambridge, Mass. A large drawing of a flower, with leaves painted seemingly in light umber tints, was then shown and illuminated by electric discharges, when it appeared of the most vivid green. The peculiar fluorescent spectrum of this body, and its relations to the spectra of other substances, was explained, and many other illustrations were exhibited.

THE NERVE OF A TOOTH.

MOST of our readers are no doubt familiar with the phrase, the "nerve" of a tooth, but we imagine that very many of them have only a vague idea as to what is meant by the expression, or rather what is understood by it amongst those versed in Odontology. There is, we think, no more interesting field for the inquiring microscopist—certainly none more replete with "entertaining" objects—than the animal frame. Whether his attention is confined to the construction of the tissues of what are commonly termed domestic animals, or is devoted to acquiring a thorough knowledge of the masterpiece of Creation, the ardent pursuer of this fascinating branch of science is unfailingly rewarded for all his trouble. Take, for instance, the subject of this article and consider how necessary a portion of the human economy are those little instruments by which our food is masticated and prepared for digestion and assimilation by those organs whose especial business it is. And yet how few there are who, if they think about it all, imagine their teeth are worth more than the usual daily brush; how many there are who forget that they have teeth, until, frenzied by a severe attack of toothache, they rush to the dentist's to have the neglected servant discharged or its "nerve" destroyed.

A paper by Mr. T. Charters White, the hon. sec. of the Quekett Microscopical Club, affords an opportunity, and points out the way, of becoming better acquainted with our teeth, and we therefore reproduce a portion of it:—

If a tooth be divided longitudinally the main body of such a section would reveal three different substances surrounding a cavity, which, to a certain extent, partakes of the external shape of the tooth; immediately surrounding the cavity, and constituting the principal bulk of the tooth, we notice a fibrous silky substance, called the *dentine;* capping that part of the dentine which appears above the gum, we see the crystalline, almost insensible *enamel*, designed to protect the highly organised and exceedingly sensitive dentine beneath it; we shall also observe that the dentine inserted in the jaw, and forming the root of the tooth, is clothed with a material of a different appearance to the other two substances—that is called the *cementum*. Of the enamel and cementum, it is not necessary on this occasion to speak, but the important relation existing between the "nerve" and the dentine demands that I should enter more into detail in explaining its microscopical appearance. In looking at a section of dentine under the microscope in a well-developed human tooth, one is reminded of those views of the comparative sizes of the rivers of the world given in some atlases, only here our rivers are all the same diameter and about the same length, and run together in parallel waves. If, for the sake of illustration, we speak of them as rivers, we should say that they arise beneath the enamel by exceedingly fine tributaries, by the confluence of which the main stream is gradually enlarged till, flowing on towards the centre of the tooth, its "debouchure" helps to make up the walls of the central cavity, which is occupied in living state by the so-called "nerve." A closer examination of our metaphorical rivers with higher magnifying powers will show us that they are tapering and undulating tubes, and existing so abundantly in the dentine as to impart to it that fibrous silky aspect which cannot fail to strike the most casual observer. These tubes, which, on the walls of the cavity, measure about the ten-thousandth of an inch in diameter, are occupied in a recent tooth by transparent structureless fibres known as the dentinal fibrillæ, the exact office of which is but obscurely defined, but they may minister to the nutrition and vitality of the tooth, since, when from age or disease these tubes become consolidated, the fibrous structure is replaced by one resembling horn, and, as a consequence, the tooth dies, becomes loose and a source of painful irritation. If a section of the dentine be made in a direction that shall cut across the course of these tubes, each tube will present an irregular aperture, and will be seen separated from its fellows by an almost equal proportion of intertubular tissue. We need not now consider any further the character of the dentine, as I shall have to recur to it when speaking of its relation to the nerve; but what I have laid before you will enable you to understand the meaning of much of the structure it is our especial object to examine in the central or *pulp cavity* of a tooth.

If we take a recently extracted healthy tooth and split it we shall notice that the pulp cavity is occupied by a pinkish fleshy mass about ⅜in. long and one-tenth of an inch wide at its upper and thickest part; it partakes somewhat of the external shape of the tooth, being wide in the upper part, and tapering towards the tooth: this, then, is what is popularly called the "nerve." In physiological parlance it is termed the pulp. The basis of this pulp is composed of areolar tissue, whose interstices are filled with a homogeneous plasma.

A microscopical examination of its exterior will reveal an infinite number of small points, giving to it an appearance not much unlike the cross section of the tubes of the dentine, both as regards size and distribution. Having noticed this much, recourse must be had to compression before we can readily make out the arrangements of its internal structure. Before proceeding to flatten it by pressure it may be withdrawn from its cavity, and allowed to soak in the ammoniacal solution of carmine; let it remain in it twenty-four hours, wash away the carmine fluid, and transfer it to glycerine for a few hours; then put it under gentle, gradual pressure for some few hours more, when it will be rendered sufficiently thin to be easily examined by a ¼in. objective or higher powers.

Commencing our examination at that part of the pulp nearest the apex of the root, we shall notice it entering the foramen of the fang as a fine thread, which though so fine nevertheless conveys the nerve and the artery into the pulp, and gives exit to the returning vein; tracing this thread into the pulp we shall readily distinguish the nerve as a bundle of parallel fibres which, running in together a short distance, divide into two, three, or four fasciculi, and dividing again still give off fibres to every part of the pulp; it is highly probable that these fibres end in loops, but the pressure necessary to reduce the pulp sufficiently thin for observation ruptures the loops, and consequently they very frequently appear to terminate in free extremities; but one fact may be easily demonstrated, namely, their course is always at right angles with the dentinal tubuli. Besides the ramifications of the dental nerve the pulp also contains the branches of the artery and its vein; these are not so easily followed, but in an examination of the pulp of a tooth extracted for severe inflammation in it, the congested vessels were naturally injected, and could be seen as a complicated network without any definite arrangement excepting a loop-like distribution towards the circumference; in some cases the vessels of the pulp, becoming stained by the carmine, will be readily seen with their peculiar transverse nuclei and distinguishable from the areolar tissue, whose nuclei are spindle-shaped. There is one feature in the microscopical examination of this prepared pulp which will not escape observation—it is the curious arrangement of its cortical portion. In referring to the microscopical appearance of the exterior of the pulp, as it appears on first splitting a tooth, I alluded to the comparative likeness presented by it to that of the dentine cut across the tubes, and if that comparison is borne in mind in the examination of this external portion of the pulp, under its present circumstances, we may easily interpret the meaning of this arrangement. The cortical substance of the pulp in its healthy condition consists of a number of oval bodies placed side by side with their long axes perpendicular to the surface of the pulp on which they stand; they are deeply stained by the carmine, which proves that they are endowed with active and growing powers. These oval bodies are termed "Odontoblasts." An examination of an odontoblast, which has been isolated by pressure from the others, will show that it has an attachment by a transparent structureless appendage to something within the body of the pulp, while a similar appendage, proceeding from its distal extremity, penetrates a tubule in the dentine, and becomes the dentinal fibril of Tomes.

The odontoblastic layer of the pulp is so important an element in the life and histology of a tooth that its history deserves a closer examination than the limits of a paper like this can afford; but it may be interesting to show the part it plays in the formation of the dentine.

About the sixth or seventh week of embryonic life a groove is formed in either jaw, at the bottom of which, after the lapse of a few weeks, papillæ begin to rise, and shortly after transverse partitions in this groove shut off and separate each papilla, which then becomes the representative of the future temporary tooth. About the seventh month of fœtal life the ossification of the tooth commences, and the dentine is represented by a cup-shaped scale capping the crown, and ultimately extending down the sides and embracing the whole of the upper surface of the pulp. It is at this period of their growth that the odontoblasts are most active, for they have the development of the dentine before them, and deriving a plentiful supply of nutrition from the plexus of bloodvessels beneath them, dentine is formed through their agency from without inwards, till the pulp being reduced to the size at which we generally see it by the gradual formation of the dentine, the odontoblasts become dormant, but capable of awaking to activity under the influence of certain circumstances of irritation; thus if caries attacks a tooth at a particular spot the tubuli in the dentine, through the fibrillæ in them, become consolidated at an equal distance from the point of attack all round it, and a barrier seems to be thus thrown up against the inroads of the advancing enemy; but unless such a remedial measure as the careful excavation of the carious portion of the tooth and subsequent plugging of the cavity be adopted, barrier after barrier may be thrown up but to be overcome. Even then the odontoblasts of the pulp resist by forming new dentine in its very substance, and it is only when inflammation and suppuration destroy the odontoblasts that this reparative process is annihilated. In some cases of general irritation of the pulp, as where the crown of a tooth is worn through by the grinding down and wear of mastication, the whole of the pulp may be converted into an irregular dentine. Sometimes nodules of ossific matter are found in the meshes of the areolar tissue of the pulp, but these do not partake of the character of the dentine, but are semi-transparent and structureless, testifying to the amount of bone-producing matter in the homogeneous plasma saturating the body of the pulp, but which it is the legitimate office of the odontoblasts to build up as dentine.

There are great and, I fear, almost insuperable difficulties in the way of clearly seeing the termination of the nerve-fibres in the pulp; one can only conjecture at the method in which they end. In some specimens two fibres may be seen running side by side for some distance, and when you expect to see a loop the ends are found separated; this may probably arise by the pressure used to render the pulp thin enough for observation. Some specimens, again, show a very apparent looping of the fibres, but the loops extend round the circumference towards the end of the pulp, they are so large; but in no case have I met with fibres that would lead us to suppose that were they small enough to enter the tubuli that they do so. How, then, are we to account for the painful sensation experienced in cutting into live dentine, unless we suppose that a connection of some kind exists between the tubuli and the fibres of the nerve? The only theory that can be suggested is that the dentinal fibre contained in a tube of the dentine passes out through its odontoblast, and then, becoming fused with the nerve, conveys the sensation to the brain, and we are conscious of the irritation.

I have not found it possible to see this connection between the odontoblast and the nerve fibres, because the re-agents usually employed to render nerves visible, dissolve away the odontoblasts; neither have I, by means of thin sections, been more fortunate, as the proximal caudal appendage of the odontoblast is too transparent and too minute to admit of demonstration, except, perhaps, by the employment of new re-agents; in specimens of the pulp, that after staining with carmine have been teased out with needles, the isolated fibres have had, besides their own coloured nuclei, coloured odontoblasts, with this internal caudal appendage fused into their outer parts. Such may be the general mode of their connection, but I am not clear on that point. Such, then, are a few of the principal elements met with in a microscopical examination of what is popularly termed the "nerve" of a tooth, but in case any one may feel inclined to work out these details for himself, it may be as well to append a few remarks relative to the plans of investigation attended by the best results. The teeth employed have been temporary teeth, removed in a healthy condition, to make room for the advancing permanent set, any others being unsuitable from disease. It is necessary to exercise great care in extracting the pulp from them, as the bone dust from the tooth and impurities of various kinds cling most tenaciously to the odontoblasts, and not only obscure the view of the delicate details, but look unpleasant and slovenly. The plan found to answer best is to file a longitudinal groove round the tooth; then, having washed away all the débris very thoroughly, split the tooth with a pair of wire nippers, when it will come in two and expose the pulp for its whole length, which may be withdrawn by seizing it at its smallest part and tearing it out of the cavity. This will draw out not only the odontoblasts but some of the dentinal fibres attached to them. Another very good plan for observing the relation of the pulp to the dentine is to soak the tooth for a few weeks in the carmine staining fluid, which is sucked up through the foramen of the fang, and being absorbed by the pulp, colours it completely. The tooth may then be decalcified by immersion in ordinary hydrochloric acid, which removes the lime but does not hurt the soft tissues. At the end of a fortnight the tooth may be cut in thin slices, when the pulp will be cut with the decalcified osseous tissue, and the relation will be well shown. I have thus, in these few brief remarks, which fail to do justice to my subject, endeavoured to show you that that which is generally called the nerve of a tooth is in reality a mass of areolar or connective tissue, through which ramify the nerve, vein, and artery destined for the life of a tooth, that its function originally was the formation and building up of the dentine, that its powers in adult life remain dormant, but capable of being aroused under the action of a stimulating influence to develop dentine again, and that it performs an important part in ministering to the vitality of a tooth, as well as constituting a tooth a very delicate sensory organ.

THE STAR DEPTHS.

MR. RICHARD A. PROCTOR, Honorary Secretary of the Royal Astronomical Society, delivered his third lecture on the "Star Depths," at three o'clock on Saturday last. This lecture was specially devoted to the consideration of the laws according to which the stars are distributed. The arrangement of the stars visible to the unaided eye was first considered. Then the lecturer discussed the star-gauges of the Herschels, in which 610,000 stars were counted, the researches of Wm. Struve relating to 31,000 stars, and the peculiarities of stellar distribution exhibited in the lecturer's chart of 324,000 stars. Next the motions of the stars were inquired into as bearing on the same question, and the evidences of star-drift—that is, of a motion of whole sets of stars in one direction—were considered and analysed. Mädler's theory of a central sun in the Pleiades, around which the whole galaxy revolves, was shown to be based on insufficient evidence, as Sir John Herschel had already suspected. As bearing on the subject of stellar distribution the fact was mentioned that in certain regions of the heavens nearly all the stars are of one colour—as greenish white in Orion, yellowish in Cetus and Eridanus, and so on. The aggregation of variable stars in certain regions was also discussed, and the remarkable fact mentioned that with the single exception of the "Blaze Star," which shone out in 1866 in the constellation of the Northern Crown, all the temporary stars have appeared within the Milky Way. The lecturer put forward a theory in explanation of this circumstance. He remarked, in conclusion, on the amazing vitality recognisable within the sidereal system. The lecture was illustrated by nearly 30 photographs illuminated by the electric light belonging to the institution.

DEATH OF AN INVENTOR.

MR. AUGUSTUS SIEBE, Sen., the mechanician and inventor, died at his residence in South London on the 15th ult., at the age of 84. He was born in Saxony, but was taken by his parents at a very early age to Berlin, where he was educated. He was apprenticed to a fine caster, and early evinced great taste both in modelling and chasing. In 1812 he had to join the army, and fought as lieutenant in the Artillery at the battle of Leipsic, where he was wounded. On peace being signed he went to Kiel, where he worked at watchmaking. In 1814, he came to England, and obtained employment as a watchmaker, afterwards as a chaser, and then as a gun-maker. In 1820, having become acquainted with Mr. C. A. Deane, who had invented an apparatus for entering into fires, he suggested to him the practicability of working under water with a similar apparatus, and eventually constructed an air-pump and diving dress, now known as the open dress. Seeing the dangers to which the divers were exposed in using the open dress he afterwards invented what is now known as the close diving helmet dress, by which all danger was removed, and to this he continually added improvements—head piece, the outlet valve, the inlet valve, and the regulating valve. In 1848 Sir Charles Pasley, C.B., who was employed in removing the wreck of the Royal George, requested Mr. Siebe to make a trial of his apparatus, which was done with the greatest success, and eventually it was adopted by the Admiralty for the use of the navy. In addition to this contrivance, Mr. Siebe was the inventor of a great number of mechanical appliances which have found their way into general use.

THE PROGRESS OF GEOLOGY.—COAL-MEASURES AND COAL-SUPPLY.*

(*Continued from p. 142.*)

WHILE the presence of water has determined the early settlement of population, the existence of coal has given rise to exceptional local growths of that population, quite irrespective of the original cause of settlement. The existence of coal has created new wants, developed vast energies, enormous resources, and has established great industries dependent upon it for their maintenance and prosperity. Natural causes, unceasing and ever renewing in their action, maintain our supplies of water in a condition of constant and unfailing operation. They are physical and geological agents, equally in force in the past as in the future of the earth's history. Not so with coal, which is a store of the past, and of which we can look for no renewal. Our coal-measures, great as they are, have defined limits, whereas our wants seem to have no bounds. With the increasing magnitude of the latter our fears of the extent of the former have increased, and have given rise to much speculation and much discussion. At first the estimates of the duration of our coal-fields were little more than guesses; but the subject has of late years been treated in a systematic manner, and in all its various bearings, in the able works of Hull, Jevons, and Warington Smyth.

The area of the exposed coal-measures of England may be estimated at about 2,840 square miles. To these Mr. Hull had added 932 square miles of coal-measures overspread by newer formations; but the investigations of Prof. Ramsay lead him now to conclude that this latter total of unproved coal-measures may be increased to 2,988, to which may be added 153 miles of the Bristol coal field, making a total of 3,141 square miles of coal-measures under the Permain, New Red, and Triassic strata of central and northern England, or of 301 square miles more than the area of all our exposed coal-fields. This branch of the inquiry embraces curious questions of variations in the mass of the coal-measures, in the thickness of the strata, and in the number and persistence of the coal-seams. The extent and magnitude of the faults bounding so many of our coal-fields is also a point of great difficulty, especially when it is complicated by denudations of pre-Permian and of pre-Triassic age; and in this intricate inquiry it must be borne in mind that it is not only a question of superposition and faulting, but one also of removal and replacement, involving a number of important geological problems. Especially is it necessary to distinguish steep old-surface and submarine valley denudations from faults.

The other branch of the inquiry relating to the possible range of the coal-measures under the Jurassic, Cretaceous, and Tertiary strata of the south-east of England, involves questions of a much more hypothetical character, and can, in the absence of positive information, only be treated on purely abstract geological reasoning. Still, it is one essentially within the range of inquiry, and the collateral geological data we possess are sufficient to guide and direct those inquiries. There are two primary points to be determined:—First, how much of the area under investigation remained dry land during the Carboniferous period, and was, therefore, never covered by coal-strata. Secondly, supposing the coal-strata to have spread over a portion of that area, how much of them escaped subsequent denudation? With regard to the first question it is comparatively easy, where the Palæozoic rocks now form the surface, to determine the antiquity of that surface, but where the old rocks are covered by great masses of other strata it becomes very difficult to determine the original conditions.

The great lines of disturbance traversing Central and north-eastern England are subsequent to the Carboniferous period, and the many detached coal-basins separated by the Penine chain and the Derbyshire Hills, together with the Mountain Limestone forming those ranges, are held to be portions of one great Carboniferous formation, which, in its entirety, spread from the south of Scotland to central England, and, probably still farther south. This great Carboniferous deposit was originally bounded on the north either by the uplands of the Scottish-border counties, or, possibly, by the Grampians; on the west by the high lands of Cumberland and Wales; while on the south we find no old exposed land-surfaces of older Palæozoic age until we reach Brittany and Central France. With respect to the deposits going on during the Carboniferous period in this area, Professor Phillips was the first to show that the lower Carboniferous series puts on, as it trends north from Derbyshire, more sedimentary conditions—that the Mountain Limestone there begins to show traces of the proximity to land, which increase rapidly in proceeding northwards—beds of shale and sandstone and subordinate beds of coal gradually setting in in the limestone series, and increasing in importance as they approach the older border land. In the same way the approach to an old barrier-land on the south and west is supposed by Professor Ramsay to be indicated in the overlying coal-measures by the increase in number and thickness of the beds of sandstone in the south of the Staffordshire and Shropshire coal-field, and Mr. Hull connects that old land with the Cambrian and Silurian rocks of Leicestershire.

If such were the case, the question arises, did this form a barrier which cut off the Carboniferous deposits from extending over the South of England, or was it only a partial barrier which in no way prevented the extension southward of the Carboniferous rocks? It has been supposed that during the Carboniferous period a spur from the Silurian district of Wales extended eastward from Herefordshire into central England, dividing the coal-fields of Shropshire and Staffordshire from those of Gloucestershire; and that against this old Silurian tract the coal-measures of South Staffordshire die out. If carried farther eastward it would limit the southern prolongation of the coal-measures of Leicestershire, and then pass under the Oolites of Northamptonshire and the Cretaceous series of Norfolk; and so great an expansion has been given it southward, that it would equally exclude the coal-measures from the area of the south-east of England. We have, however, no sufficient evidence of the continuous extension of these old rocks eastward of Staffordshire. Palæozoic rocks show, it is true, in Leicestershire; but there the coal-measures wrap round them, and the older rocks seem merely to be an island in their midst. At those spots in the southern counties where they have been proved underground, I imagine they were raised by disturbances of a later date than the coal-measures, and did not form part of the land surface of the Carboniferous period. As just mentioned, the older Carboniferous rocks show deeper sea conditions as they trend from north to south, and the same deep sea conditions existing in Derbyshire are found to prevail in the Mountain Limestone of Belgium, while, at the same time, similar slight indications of distant land, in the presence of intercalated shales and imperfect coal, reappear and increase westward in their range into the district of the Boulonnais, in France. There is nothing to show but that the spur of old land stretching eastward from Herefordshire was merely a promontory ending in Warwickshire, round which the Carboniferous sea passed and extended southward uninterruptedly to Belgium and the north of France, and westward to Somersetshire and South of Wales, spreading over all this wide area first the Mountain Limestone and then, in due order, the coal-measures. Of the existence of these formations over the south-western and south-eastern portions of this area we have proof in Wales, Somersetshire, and Belgium. The intermediate area is covered by Jurassic, Cretaceous, and Tertiary formations, which hide from us the older rocks whose position it is our object to determine.

Just as with the disturbance which at a later period caused the Mountain Limestone of the Penine chain to break through the great expanse of coal-measures originally spread over the central and northern counties of England, and brought up to the surface the disturbed and disjointed coal-strata, of which, after subsequent denudation we have the isolated portions remaining in the existing coal-fields, so was the area of Southern England traversed by the earlier axis of Palæozoic rocks of the Ardennes and Mendips, bringing up the coal-measures in like manner along their northern flanks in separate basins and troughs, some of which are uncovered by newer strata, while other basins not exposed on the surface may still possibly exist beneath the newer strata of the south-east of England. They have, in fact, been proved to exist under considerable portions of those newer strata of north-western France and of Belgium, and under some of the older Secondary strata in the south-west of England.

All geologists are agreed upon the age of this great east-and-west axis of disturbance. It took place after the deposition of the coal-measures, and before the deposition of the Permian strata. Its effects, all through its range, are singularly alike. It was not so much a great mountain-elevation, as a crumbling up and contortion of the strata for a breadth of many miles, and along a length of above eight hundred miles. The Silurian and Devonian rocks are thrown up by it into a number of narrow anticlinals, and the flanking coal-strata are tilted, turned back on themselves, squeezed and contorted in the most remarkable manner—the same type of disturbance being apparent whether in Westphalia, Belgium, France, Somerset, or Pembroke. These great flexures have also resulted in throwing the coal-measures into deep narrow troughs, having a length of many miles and a width of but very few.

In France, these disturbed old strata are covered by Jurassic, Cretaceous, and Tertiary strata, and in Somerset by Permian, Liassic, and Jurassic strata; they sink beneath the Oolites at Frome, and reappear in Belgium from beneath the Cretaceous strata. What becomes of them in the intermediate area? It is not to be supposed that a line of disturbance of such great magnitude could have been intermittent. The coal-trough has, in fact, been followed from near Charleroi, where it passes under the Cretaceous and Tertiary strata, to Mons, Valenciennes, and Bethune, a distance of eighty-six miles. Along the whole of this line, the Chalk and overlying beds extend, with a thickness varying from 500ft. to 900ft. around Mons, decreasing to from 250ft. to 300ft. near Valenciennes, and increasing again towards Bethune. At Guines the Chalk was found to be 670ft. thick, and at Calais 762ft. On the other side, the coal-trough of Somerset passes eastward under the older Secondary rocks, which in their turn pass under the Cretaceous and Tertiary strata of Wiltshire; but no attempt has been made to follow coal-measures beyond a distance of six miles from their outcrop, where the overlying strata have been found to attain a thickness of about 450 feet.

The original supposition that the Secondary strata maintained, in the main, their regular sequence, and, to a certant extent, their thickness over larger areas, has long been proved to be erroneous; but we were hardly prepared until lately to learn how rapid the variation in their thickness is. Mr. Hull has now shown that the Great and Inferior Oolites thin out from a thickness of 792ft. in Gloucestershire to 205ft. in Oxfordshire, and the Lias and Trias from 1,090ft. to 400ft. (?); while in like manner the Trias decreases from 5,600ft. in Lancashire and Cheshire, to 2,000ft. in Staffordshire, and 600ft. in Warwickshire. We also know that on the northern flank of the Mendips, the Trias, Lias, and Oolites tail off, although their dimensions in Gloucestershire are so considerable. It would appear that all the Secondary rocks, except those of the Cretaceous series, show a distinct thinning-out in their range southward, which is doubtless due to the existence of an old pre-Triassic land on the south—such as would have been formed by the prolongation of the Palæozoic rocks of the Ardennes and Mendips through the south of England. It has been urged, on the other hand, that this thinning-out is a proof of the existence of a still older land in that area; but as the argument is based on the evidence of rocks of post-Carboniferous age, it is clear that, whether the land were of Cambrian and Silurian, or of Devonian and Carboniferous age, the result, as affecting the Secondary rocks, would be the same.

This thinning out of the Secondary strata has now been proved not to be merely hypothetical. At three points, on or near the presumed line of the old underground range, the Tertiary and Cretaceous strata have been traversed in well-sections, and Palæozoic rocks found to underlie them at once, without the intervention of any Triassic, Liassic, or Oolitic strata. Thus at London the presence of red and gray Sandstones, apparently of Palæozoic age, has been proved under the Chalk at a depth of 1,114ft. Again, at Harwich, and at Calais, strata of early carboniferous age have been found also immediately under the Chalk, at depths respectively of 1,026ft. and 1,032ft. There is therefore reason to believe that the underground ridge of the Mendips and the Ardennes passes in a line from Frome through North Wiltshire, Berkshire, Middlesex, North-east Kent, and between Calais and Boulogne, at a depth beneath the Secondary strata of not more than from 1,000ft. to 1,500ft., while the coal-troughs, which may flank this range on the north would, judging from the analogy of the structure and relations of the same rocks at Mons and Valenciennes, be met with at depths very little, if at all, greater.

To the north of this area it is probable that the thickness of the overlying rocks is greater; but we have no means of knowing exactly. In Northamptonshire the Great and Inferior Oolites and the Lias have been found not to exceed together 880 feet, at which depth the New Red Sandstone was reached; but its thickness was not proved beyond 87 feet; while at Rugby the Lias was found to be about 905 feet thick, below which 136 feet of beds of New Red Sandstone were passed through. Looking at the proved thinning out from north to south of the New Red and Permian strata, there is no reason to suppose that they would be found of any very great thickness in the southern counties. Even immediately to the south of the known coal-fields of the midland counties, the trials for coal have not yet proved any very great thickness of these rocks. It would seem, in fact, that the extensive tracts of Chalk, Oolites, and Trias, forming the substrata of our midland and southern counties, constitute but a comparatively shallow crust filling up the plains and valleys of Palæozoic rocks, the great framework of which stretches apparently at but a moderate depth under our feet, and of which the highest ridges only, such as those of the Ardennes and Mendips, now rise above ground.

It is clear, therefore, that in any search for coal, the relation of the Secondary and the Palæozoic groups of rock to one another being perfectly independent, the latter must be considered entirely on their own internal evidence, and apart from the bearing of the newer rocks covering them and forming the present surface, except possibly in a few cases where old lines of disturbance have proved points of least resistance, and yielded again, as suggested by Mr. Godwin-Austen, to later movements, which have equally affected the overlying formations.

* An abstract of the annual address of the President of the Geological Society.

It was in the north that the conditions fitted for the formation of coal first set in. The common *Stigmaria ficoides* and various coal-measure plants appear at the base of the Carboniferous series of Northumberland, which there overlies conformably the Upper Old Red Sandstone; and productive beds of coal exist low down in the Mountain Limestone series. These disappear in proceeding southward, and the great productive coal-series becomes confined to beds overlying the Millstone Grit.

Of the prolongation of the axis of the Ardennes under the south of England there can be little doubt; nor can there be much doubt that the same great contortions of the strata (which in Belgium placed the crown of the anticlinal arch at a height of four or five miles above the level of the base of the accompanying synclinal trough, to the bottom of which the coal-measures descend, and was the cause of similar folds in the coal-measures of Somerset and Wales) were continued along the whole line of disturbance, and that the preservation of detached portions of the same great supplementary trough is to be looked for underground in the immediate area, just as it exists above ground in the proved area; for the minor subordinate barriers dividing the coal-basins can, I conceive, in no way permanently affect the great master disturbance, by which the presence of the coal-measures is ruled. Whether, however, admitting that the coal-measures were originally present, they have been removed by subsequent denudation, is another question.

(*To be concluded next week.*)

HINTS ON PAINTING.*—V.

(*Continued from p. 88.*)

Gilding.

THIS beautiful art requires our special attention, for it appears to many to be a very troublesome operation to execute well. But it is easily done, as my remarks will show, and a little experience prove. It is best when gilding on carriage or waggon work, where the gold will be protected with varnish, to procure "gold size" ready prepared —English gold size being the best. If not to be had, you can make a substitute by using English varnish and Japan in equal parts. If the gilding is for striping, you should mix a little chrome yellow with it, to be able to see the lines better; but in lettering no colouring is required. Having your job rubbed down smoothly, take a piece of muslin and tie up in it a little whiting to form a "pounce bag;" with this you pounce or dust over every part of the work where the gold leaf is to be put, to prevent the leaf from sticking to the surface not covered by the size. Another method is to wash the job over with starch water: while still another plan is—where dust or starch is not applicable on account of newly varnished work near by—to cut a potato in half, and with the raw surface rub the place desired, leaving the juice of the potato on; this soon dries and forms a thin film, to which the gold will not adhere. Any one of the above methods will be found to answer the purpose, and the coating will wash off clean when the gilding is dry. The surface prepared, take the size and put on the stripes, ornaments, or what not, and allow it to dry just enough to enable you to pass your finger over it without sticking; but if when the finger is placed directly upon it, it is "tacky," it is ready to receive the gold.

For signs, or work which is not to be covered with varnish, we should use oil size, which is made with old boiled oil. The best is that taken from a paint cup in which the paint has settled and left the oil on top. Pour this off carefully and grind into it a little chrome yellow.

To Lay Gold Leaf.

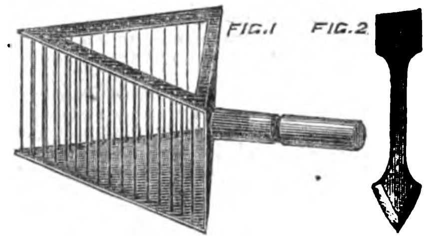
If for scrolls, letters, or large work, take the book of gold leaf in the left hand, and with the forefinger of the right hand lift the first paper leaf, leaving the gold on the opposite leaf smooth; then holding the book close to the work, with the front pointed downwards towards the bottom of the letters or scroll and lightly touch it, rolling the book up and leaving the gold on the letters. Repeat this operation until all the size is covered. Touch any missed spot with the finger tipped with the superfluous gold, and wipe all off nicely with a bunch of cotton. For striping it is better to use a "tip." Place the book on a piece of board covered with cloth, and raising the paper, cut the leaf the desired size with a table knife, the edge of which is perfectly straight and smooth. Then draw the tip across your face or head, to slightly grease it, and lay it on the cut gold; you can then lift and carry it to the size. Thus you can proceed until the striping is completed. Some painters cut the book of gold leaf in strips, and lay the leaf directly from the stripes: practice with either method, and you will find it easy enough. Gold may be shaded with transparent colours, such as asphaltum, ultramarine, lake, carmine, verdigris, Paris green, &c., to suit the taste of the painter.

Bronzing.

Gold bronze is used on carriage parts for striping; and many fine fancy jobs can be done with this powder. The size used for bronze is the same as that described for gold leaf. To put on the bronze, take a piece of plush or velvet, and make a small "pounce" bag, by tying up a ball of cotton. This will take up the bronze, which is gently rubbed over the size. The best quality of bronze is but little inferior to gold leaf, and for striping is better, as it does not consume so much time, and at the same time it is cheaper than gold leaf. To make fancy work with bronze, cut out any desired pattern in paper, and laying it over a nearly dry varnished surface, rub the bronze on through the holes of the pattern. The fronts of the spokes and the ribs of express waggons may be nicely ornamented in this manner. Copper and silver bronze can also be used in this way, and when the three are mixed up in ornaments they look well.

To Remove Old Paint.

There are various methods employed for removing old paint, and I will endeavour to describe them. First there is the hot-iron process. This is done by taking a heavy piece of iron and heating it in a stove or forge, and then holding it close to the work. The paint will blister or soften, and can be scraped off with a putty knife or chisel. A better plan is the furnace process. The furnace is made of sheet-iron and heavy wire; its general form is shown in Fig. 1.



The triangular shape allows it to be held closely to the work on either side. Being filled with ignited charcoal, and a good fire kept up by holding it in a draft frequently, one can with this "burn off" a body very quickly and well.

There is also a patent lamp used for the purpose (p. 124). I have used it, and found it an excellent tool. It is designed to burn alcohol, and makes at the same time alcoholic gas, which is directed upon the flame by a pipe, while the flame is blown out in a long tongue of fire. This lamp is self-acting, and the workman merely holds the lamp in his left hand, directing the tongue of flame upon the desired spot, scraping the paint off as he goes along with the right hand.

Still another process is the potash plan. Dissolve one pound of potash in three pints of water over the fire, then add yellow ochre or some common dry paint until it is as thick as rough stuff. Smear this over the panel with an old brush, and in a little while you can scrape off the paint like old cheese.

After the paint is taken off by the potash process, wash the wood well with soap and water to remove any residual potash, dry off and sandpaper, and then give a coat of clean raw oil. With the furnace or hot iron process, sandpaper smoothly and apply a coat of the usual priming, and proceed as if on new work.

Carriage parts must be scraped, and for this purpose I use a tool, of the shape shown in Fig. 2. It is made of steel (an old file, for instance), the square centre part being ground, and the four square edges are excellent to scrape the spokes, while the ends will be found useful on the carriage part. It is only where an extra job is wanted that it will be necessary to scrape off the carriage part, for we can generally fill them up with lead and get a good substantial surface.

Re-Varnishing.

Old jobs should be rubbed well with pumice-stone and water, the bare wood being covered with lead colour. All spots not bare can be touched up with dead colour; then put on a coat of rubbing varnish. It there be spots yet not coloured properly, they can be fixed for the next or finishing coat. It is generally the cheapest plan to colour the carriage part over and stripe anew, as it is a long, tedious job to touch it up, and never looks well.

To Bind a Brush.

Brushes, when new, should be bound at least one-third the length of the hair, to preserve them and render them better for use. Some painters bind a strong cord round and round to the proper distance, and secure each end to the handle.

But a better way is, to take a piece of strong muslin and wrap one thickness around the hair, then tie a cord firmly around the same as low as you desire the binding to come: then fold the muslin back toward the handle, and fasten it by tacking the margin around the border of the original binding.

This method makes a very neat binding, especially for varnish brushes.

Bleaching Oil.

Pour about as much linseed oil into a shallow earthen vessel as will stand one inch in depth; then pour in six nches of water, cover with a fine cloth, and let the whole stand in the sun for a few weeks until the liquid becomes thick, when it should be poured in a phial and submitted to a gentle heat, after which the clear is to be poured off and strained through a flannel cloth.

The longer oil is kept, it is always the better both in regard to its drying and transparent qualities. To make good nut oil, the skins of ripe walnuts should be peeled off, as it contains an acid which turns it brown. Poppy oil is made from the ripe seed of poppies. It is the best drying oil. The oil of spike, or lavender, is obtained by distilling spike with water; it is very volatile and fine for working with the pencil, or for enamelling. To make a fine drying oil for extra fine painting, take of poppy oil or nut oil one pint, of gum sandarac two ounces, of white vitriol and sugar of lead each one ounce. Boil the whole till the solid ingredients are dissolved, and the mixture is the colour of linseed oil. This oil will dry fast, and a portion of pure turpentine added makes a fine oil for use where the purest white tint is required. It may be mixed with other oils as a dryer, where common drying oil would be injurious to the colour.

Raw linseed oil for carriage work is best, as being more volatile than boiled oil, it strikes into the wood, and forms a hard, resinous filling.

To Transfer a Picture.

Pictures are frequently transferred to painted surfaces or wood, and may be seen on stages, fancy boxes, &c. To transfer a picture, prepare a white ground well rubbed down with pumice-stone and water. Then apply a thin coat of very light-coloured varnish. (English hard drying is good). When this is not quite dry—"tacky," like gold size—damp the picture on the back with clean water, and lay it between some newspapers to remove any water that might be on the face of the picture: then lay it carefully on the varnished surface, pressing it down with a damp cloth, or the finger, until there are no bubbles of air underneath. If there should be bubbles not easily pressed out, prick them with a pin to let the air escape. Then stand the work aside to dry, and when hard, damp the paper, and it can be rolled off by the finger in small rolls, until the picture is left quite perfect on the paint. After this has dried well, a coat of clear light varnish will finish the operation. The same process is used to transfer pictures to glass, and when coloured on the back they look beautifully. Almost any one can do this kind of ornamentation nicely. Try it on a small scale.

Another method is to use Grecian varnish—Canada balsam and turpentine,—but Copal varnish is better where you desire durability; and, besides, every carriage painter has the material always at hand.

* From the "Carriage Painter's Manual." By F. B. Gardner. New York: S. R. Wells.

SOME RECENT IMPROVEMENTS IN ENGLISH AND AMERICAN BOILERS.*

By W. Forsyth Black.

(*Concluded from page 139.*)

THE size of the boiler is regulated within certain limits by the number of units employed in its construction. The units are always of one size, and more can be added at any time without disturbing those previously fixed. The usual, and, indeed, the most advantageous size of the boiler consists of six arched front units and twelve rear units—equal to about 36 horse-power. The effective heating surface of one rear unit, from the top of the base-piece to the centre of the upper chamber, is 23 square feet, which is considered equivalent to about 2 horse-power; and the effective surface of each arched unit above the firegrate level, taking only the inner half of the surface, is 7 square feet, which, from its position, is also considered equivalent to 2 horse-power.

Though larger boilers than this size have been made, they have not been found so easily manageable on account of the firegrate being rather too deep for efficient and ready firing. Consequently, when more power is wanted, it has been found better to employ two smaller instead of one larger boiler.

The boilers were practically introduced in this country by the Isca Foundry Company, at Newport, Monmouthshire, where the first was erected. It was employed to drive machinery which had been previously driven by a Lancashire boiler of 26ft. in length and 6ft. in diameter, with two outer flues of 2ft. diameter, the firegrate being 27 square feet, and the total heating surface 390 square feet. The cast-iron boiler used in its place has eight arched units and fourteen rear units, giving a heating surface of 378 square feet, and the firegrate area is 17 square feet.

The result of a careful trial, extending over ten days, to test the relative consumption of the two boilers, including in each case the fuel requisite to get up steam, was, that the average total consumption of fuel per day was 16cwt. with the cast-iron boiler, and 27cwt. with the Lancashire boiler, the day's work being practically the same for each boiler. The coal used was Monmouthshire small

* Read before the Civil and Mechanical Engineers Society.

steam coal, costing 6s. per ton at the boilers, and the difference of cost in working was consequently very considerable.

Trials made to ascertain the evaporative power and economy of the cast-iron boiler have proved very satisfactory; and, in one instance, an evaporative duty was obtained of 11¼lb. of water per pound of coal. In this case 625¼ gallons of water at 53° Fahr. were evaporated in 3 hours 54 minutes by 560lb. of Ebbw Vale Elled coal, amounting to 11·17lb. of water per lb. of coal, and equivalent to 11·67lb. of water, evaporated from 100° standard temperature of feed; the steam pressure was from 55lb. to 60lb. per inch.

I have been able to obtain minute details of this trial, also of others. The first table gives the particulars of the experiments upon the evaporative duty of the cast-iron boiler to which I have just referred. The general results were that the evaporative duty ranged from 10·15lb. to 11·67lb. of water per pound of coal, calculated at the standard temperature of feed of 100° Fahr., the mean evaporative duty being 10·93lb., and the rate of evaporation per square foot of grate surface per hour ranged from 79lb. to 119lb. of water, the maximum temperature in the chimney flue did not exceed 425°, and the firebars had ¼in. spaces between them.

In a subsequent series of experiments made upon the same boiler by Mr. Joseph Tomlinson, with other kinds of South Wales coals, for the special purpose of testing the speed of evaporation and the evaporative power of the boiler, the evaporative duty ranged from 9·37lb. to 10·15lb. of water per pound of coal, the mean being 9·82lb.; the maximum temperature in the chimney flue was 575° Fahr., and the firebars had ¼in. spaces. The rate of evaporation per square foot of grate per hour ranged from 136lb. to 159lb. of water.

One of these boilers has been working at the City Saw Mills, Worcester, continuously for about ten months, and about five or six months ago it was opened, the interior was carefully examined, and the whole deposit raked out. There was found a small quantity of loose scale and mud in the bottom horizontal tubes 10lb. in weight, and consisting of thin scale of less than one-sixteenth of an inch in thickness; and the interior surface of the cast-iron units was found to be quite clean. Their outer surface, where exposed to the fire, was also found to be quite sound, and the metal uninjured. This boiler, which is of the size shown in the engraving (p. 138), had been supplied with water from the water-works, and had been regularly blown off completely under steam pressure every week, and refilled again at the main; in addition to being partially blown off twice a week to the extent of 2in. of water.

The fracture at the centre of the length of one of the vertical tubes of a rear unit, to which I have referred, did no damage whatever, and in two other cases where fracture took place it was where the last front arched unit is connected with the first rear unit; the result was simply the escape of water from the boiler through the fracture, without any other damage whatever ensuing. This second fracture occurred from a method of construction which was altered after the early boilers for this country had been made. The bottom flanges of the last front unit were at first bolted to the bottom tube of the first rear unit, on each side of the fire, so that the legs were prevented expanding freely sideways; consequently, when the arched tubes expanded under the heat a strain was thrown on the two bottom connections, which caused one of them to give way. On this account the connection of the arched units to the first rear unit is made on one side only of the fire, the legs being thus left free at the other side to yield laterally to the expansion of the arch. Although, therefore, this boiler is not exempt from being injured through ignorance or carelessness, it has been proved with ordinary care in working to be safe, and to be free from any risk of a destructive explosion.

It has also the advantage of an easy and ready replacement of any portion of it being effected without disturbing any other portions, by simply disconnecting the joints at the bottom, and the steam-pipe at the top, of the unit to be removed. Access is obtained for this purpose by removing a portion of the brickwork at one side, opposite to the unit to be taken out, which is then disconnected and drawn out sideways, and the whole process of removal and making good again may be completed in 24 hours. The brickwork setting of the boiler is of very simple description, consisting only of side walls with low cross walls for the support of the separate units.

As the total quantity of water contained in this boiler is small to the extent of heating surface—a range of 9in. in the gauge-glass giving only a capacity of 100 gallons, it is requisite in ordinary working that the water-level and the feed should be attended to regularly at intervals of not more than 20 minutes.

The fronts of the boilers are formed of cast iron. The lining of the door is perforated for the admission above the fire of air supplied through a register in the outer shell of the door. The advantage of such an arrangement for securing thorough combustion of the gases, and for preventing the escape of fuel in the shape of smoke, has long been known.

TABLE I.—EXPERIMENT UPON EVAPORATIVE DUTY OF MILLER'S CAST-IRON BOILER, AT THE ISCA FOUNDRY, NEWPORT. With Monmouthshire Steam Coals.

Date of Experiment.	Description of Coal.	Coal burnt per sq. ft. of grate per hour.	Pyrometer in flue beyond boiler, highest reading.	Actual temperature of feed.	Water Evaporated. Calculated from actual temperature of feed. Per lb. of coal.	Per hour.	Per sq. ft. of grate per hour	Calculated from 100° Fahr. standard temperature. Per lb. of coal.	Per hour.	Per sq. ft. of grate per hour
		lb.	Fahr.	Fahr.	lb.	lb.	lb.	lb.	lb.	lb.
1869.—September 9	Tredegar large coal	7·65	—	70°	10·12	1316	77·41	10·40	1352	79·53
" 16	Ebbw Vale elled............	8·45	—	63°	10·52	1512	88·94	10·83	1557	91·63
November 15	Ditto	8·44	360°	53°	11·17	1604	94·35	11·67	1676	98·60
" 24	Abercarn top	10·32	400°	56°	9·74	1710	100·59	10·15	1781	104·82

1870.—February 5	Ebbw Vale elled............	10·67	425°	45°	10·58	1921	113·00	11·14	2023	119·01
" 22	Tredegar small coal......	9·83	375°	48°	10·52	1763	104·00	11·05	1856	109·21

In these experiments the space between the grate bars was ¼in.; area of fire-grate, 17 sq. ft.

NOTE.—The equivalent evaporation from 100° Fahr. standard temperature of feed is calculated by the Admiralty formula which was employed for the purpose in the Wigan coal trials, in 1866-67, the latent heat of steam at atmospheric pressure being taken at 988° Fahr. Pounds of water actually evaporated $\times \frac{988° + 100° \text{ standard}}{988° + \text{temperature of feed}}$ = pounds of water evaporated from 100° standard temperature.

December 13	Two veins mixed	13·53	4·4	575°	44°	9·56	2200	129·41	10·08	2320	136·44

In these experiments the space between the fire-bars was ¼in., and the fire was not disturbed with the pricker, the shovel only being used for firing; area of firegrate, 17 sq. ft.

As, however, such admission of air is only requisite for a certain time after the application of fresh fuel to the fire, a difficulty has been experienced in the burning out of the lining of the furnace doors. This has been provided for by making the lower hinge hollow, and thus establishing through it an air passage between the ash-pit and the interior of the door. A register or valve is placed in centre of door and by opening and closing this air is admitted as requisite. These doors have been proved to have no tendency to sag, or crack, or warp. By use of such an appliance combustion is improved, the radiation of heat is prevented, and the engine room is kept cooler. A door for the ash-pit is also provided.

That there are many advantages consequent on using these boilers is, I think undeniable; and most important of all of these is the immunity from destructive explosions. There follow economy of fuel and consequently steam at low cost; facility of repair, both as regards the ready obtaining of any part, of rapidity of fixing the same; and, not least, the special and obvious advantages of a number of small and comparatively light parts for easy and cheap transit, by sea or land.

Such are the leading characteristics and details of this novel species of boiler—novel alike from the material of which it is composed, and the manner in which this material is adapted to what at first sight would seem an improper object. As the old Latin saying holds true in things scientific, that "the end is the crown of the work," and when we see that end to a great extent attained, no preconceived notions of unfitness as to the means employed should deter us from examining it in all its details, and determining for ourselves how far success has been achieved.

SUBMARINE TELEGRAPH CABLES.

THE construction and submersion of submarine telegraph cables formed the subject of a paper read before the Edinburgh and Leith Engineers' Society, by Professor Fleeming Jenkin, F.R.S., from which we abstract the following information in connection with a growing industry and an important commercial enterprise:—All submarine cables hitherto laid have consisted of three parts:—1. The conducting wire, generally, if not universally, copper. 2. The insulator surrounding the conductor, generally guttapercha, or some preparation of indiarubber. 3. An outer covering intended to afford protection, and give longitudinal strength. The simplest form of outer covering consists of iron wires laid helically over a jute or hemp serving.

Conductor.

Copper, being the metal which offers less resistance to the passage of the current than any other commercially available, is employed in all but a few exceptional cases. The earliest cables had conductors formed of a solid wire, which has the advantage of occupying less bulk than any strand, and so requiring less insulating material to give the same thickness of coating. This advantage was more than counterbalanced by the brittleness of the solid core, which breaks after being bent a few times, and frequently caused total interruption of telegraphic communication. A strand of three or seven wires is, therefore, now universally used. Messrs. Clark and Bright introduced a strand made of wires of such section as to fit into one another, building a truly circular rope, and thus endeavoured to combine the advantage of the strand and solid wire. Many have been unable to carry this plan to any commercial advantage. The strength of copper wire is given in some books as equal to 60,000lb. per square inch, but the one used in submarine cables is chosen rather for electrical than mechanical properties, and will bear only from 35,000lb. to 39,000lb. per square inch. It elongates from 10 to 15 per cent., or even more, before breaking, so that its full strength cannot be made use of; but this extensibility is a very valuable property, since it insures that the conductor shall not break before the full strength of the protecting cover has been made use of and overcome. A copper strand will bear 1½lb. per pound weight per knot before breaking. It will stretch 1 per cent. with 1lb., and will not stretch sensibly with a weight of 0·75lb. per pound per knot.

Thus a strand weighing 300lb. per knot, such as was used for the Anglo-American cables, will barely carry 450lb., will stretch 1 per cent. with 300lb., and will not stretch sensibly with 250lb.

Great care is necessary in making the joint between two portions of the conductor. A scarf joint is first made by soldering together two tapered and fitted ends. Fine copper wire is wrapped round this joint, which is somewhat inflexible, and solder run round the wire. A second wrapping of fine wire is then given, and left without solder. The solder must be applied with rosin, and not with spirits of salt.

The joint is necessarily less extensible and more brittle than the rest of the conductor, but if from any cause the soldered joint is broken and stretched so as to open, the fine wire maintains perfect electrical connection, being simply pulled out like a helical spring.

Insulator.

Even the best insulators, such as glass and guttapercha, do conduct to some extent. Indiarubber has a somewhat higher resistance than guttapercha, and different preparations differ considerably in their resistances. Indiarubber has been applied in many ways to the conductor. Most commonly tapes of masticated or bottle rubber are wrapped round and round the conductor until the required thickness is obtained. These tapes used to be gummed together by solvents, but this plan was found to cause decay, and has been abandoned. Simple heat has also been applied unsuccessfully; the indiarubber so heated becomes tacky. Mr. Siemens applied the tubes longitudinally, and simply pressed the freshly cut edges together. This did not make a safe joint. Some manufacturers vulcanised the indiarubber, but the material thus formed, although quite homogeneous, absorbed water, was subject to decay, and allowed free sulphur to reach the copper wire. Mr. Hooper's method of applying indiarubber has been the most successful; he covers the conductor with tapes of pure indiarubber next the copper, followed by a coating of oxide of zinc and indiarubber, which he calls a separator. The separator is inclosed in a jacket of vulcanised indiarubber. In the process of baking the core to vulcanise the jacket, a little sulphur passes the separator and slightly vulcanises the pure rubber, which is welded into a perfectly homogeneous mass; the core during this process is heated to 250° Fahr. and baked for four hours; it does not become tacky and is remarkably compact and durable. The joints between two lengths of the insulated core are made with the same materials, and are baked for two hours in a steam-jacket. This is the only application of indiarubber which has been thoroughly successful for submarine cables.

Guttapercha is more easily applied, and its use has been attended with almost invariable success; it is pressed out while warm and plastic through a die round the conductor; several successive coatings or tubes are thus applied till the desired thickness is attained. The first coating is attached to the strand by what is termed Chatterton's compound, being a sort of mastic composed of 1 part by weight of Stockholm tar, 1 part of resin, and 3 parts of guttapercha. Guttapercha will bear about 3,500lb. per square inch of section, but owing to its great extensibility it does not add more than about one-third of its strength to the copper strand. It will stretch 50 or 60 per cent. before breaking, and will bear an astonishing amount of ill usage—such as knotting, squeezing, or stretching, but is easily pierced by a nail or similar sharp tool, or cut by a knife. It becomes soft at the temperature of about 100° Fahr., and after manufacture should never be subjected to a higher temperature than 90° Fahr. The joints are made by heating the two ends of the covered conductor after the copper has been joined, and applying by hand successive coatings of warmed and plastic guttapercha, the separate layers of which are cemented by Chatterton's compound. Much skill and extreme cleanliness are required in making these joints, which were a frequent cause of failure in early cables. If the guttapercha be either overheated or under heated the junction effected is not permanent, the guttapercha at the joints becomes hard and brittle, and shrinks back from the guttapercha of the core, leaving a very visible gap which destroys the insulation. The process is now thoroughly understood, but each joint is made under inspection, and subjected to strict electrical tests after completion. When dry and exposed to light guttapercha very rapidly decays, becoming brittle and porous, but under water it appears to undergo no change whatever. The electric and mechanical properties of the cores of cables laid down twenty years ago are as good as ever. The experience with indiarubber is totally opposed to this. All forms except Mr. Hooper's rapidly change under water. Mr. Hooper's appears hardly so absolutely permanent as guttapercha, but the change observed does not appear to be material. Hooper's indiarubber will bear much greater exposure to heat than guttapercha, and is much more permanent in dry places. Both guttapercha and Hooper's indiarubber absorb some water, but not to such an extent as to be mischievous. Some forms of indiarubber are rendered unfit for use by this absorption, which in pure indiarubber is such that the material absorbs 25 per cent. of its own weight of fresh water.

The completed core has considerable strength. The Anglo-American cables have a core with 300lb. of copper and 400lb. of guttapercha, and this bears without injury ¼ ton quite unassisted by the outer covering; it will stretch 10 per cent. under this weight, and may afterwards be knotted and squeezed without any electrical injury being done. Before the application of Chatterton's compound the copper wire used, after a strain had come on the core, to allow the guttapercha to slip back over it without itself returning to its original length. This forced the copper to buckle, and in some cases brought it through the guttapercha. This can no longer occur. The dimensions of the core are determined by the number of words per minute required to be transmitted, and by the total length of the cable. With guttapercha cores the ratio of copper to guttapercha in pounds weight per knot varies from equality to two-thirds. The smallest core practically used has 73lb. of copper and 119lb. of guttapercha per knot, a more common size is 107lb. copper and 105lb. guttapercha. The largest size yet adopted is 400lb. copper and 400lb. guttapercha for the French Atlantic.

The number of words which a core will transmit is inversely proportional to the square of the length, and when a constant ratio is maintained between the weights of the insulator and conductor, it is simply proportional to the weight of the core per knot. Thus a core of 100lb. copper and 120lb. guttapercha will transmit 20¼ words with the mirror and rather less than 1¼ word per minute with a Morse instrument; if Hooper's material or Willoughby Smith's improved core are used, the speeds would be 24 words and 1·7 respectively.

The Morse is restricted to short lengths of cable, thus 250 miles of the above core would transmit by Morse 27 words per minute, or as much as a clerk can conveniently send by hand; the mirror cannot be read at much more than 30 words per minute; but Sir William Morrison's new recording instrument will receive as fast as the mirror, and leaves a permanent writing which can be read at leisure; with this instrument as much as 120 words per minute may be read if the core will allow it.

Outer Covering.

The core is served with hemp or jute applied wet, and either tanned or saturated with brine; originally the hemp was tarred, but the tar tended to prevent the discovery of faults, sealing up any small aperture temporarily. Sometimes for cables of moderate length several cores, 3, 4, or even 7, were laid up together so as to form with strands of hemp, called worming, a circular rope, which was served like the single core with hemp or jute. These multiple cables of course transmitted independent messages through each core. The served core is commonly protected in cables intended for moderate depths by a sheathing of iron wires laid round in a long helix, so as to give the cable the appearance of an ordinary iron-wire rope. The tube which the wires so laid on forms cannot diminish in diameter, and hence stretches very little more under a given strain than an iron rod of the same weight per knot would do. The diminution of diameter is prevented by the abutment of each wire against its neighbour, so that the soft heart of the cable undergoes no compression. If the wires are laid on with equal tension the strength of the completed cable is equal to the sum of the strengths of the wires which compose it. In the spinning or closing machines, as they are called, the wire is wound on bobbins, which as they revolve round the axis through which the core passes remain parallel to themselves, so as not to put a twist in the wire.

A cable so formed is not spongy, and has little liability to kink, that is, to throw itself into a loop when leaving the hold of the ship in which it is coiled. The elongation of an ordinary iron covered cable with half the breaking weight varies from about 0·5 to 1 per cent., an amount which can never injure the core. While being laid the cable generally untwists slightly, but the elongation from this cause also is insignificant. The iron wire is protected from rust by being galvanised, and still further by being covered with hemp or jute, and a compound of asphalte and silica. A cable covered with good iron should bear 2 tons per pound of iron wire per fathom.

A large size of wire is used for shore ends, to protect the cable against anchors, attrition, and rust; for this purpose cables of from 10 to 20 tons per knot are used. The largest size is generally covered with 10 or 12 strands, each spun of three galvanised iron wires. A cable so made is much more flexible and easily handled than one covered with solid wires. Cables covered with ordinary iron are hardly strong enough to resist the strains to which they are exposed while being laid in depths above 1,500 fathoms; above this, homogeneous iron wires (really a variety of steel) are employed. This material will bear from 50 to 60 tons per square inch. The Malta and Alexandria cable is an example, which differs in nothing from the shallow water cable except in the substitution of homogeneous iron for ordinary iron.

Outer Protection.

For still greater depths recourse is had to a more complex type of cable. Each steel wire is inclosed in a serving of hemp or manilla, the strength of which may be added to that of the steel in calculating the strength of the cable, while the serving adds nothing to the weight of the cable in water. The elasticity of a straight hempen fibre is less than that of most steel, but by choosing the lay of the hemp strands properly, the hemp or steel may be made to stretch so evenly as to give way together, and then the strength of the served wire or cable is found to be actually greater than the sum of the strengths of the compound parts; each part breaks at its weakest point, but these weak points never all occur at the same point in the compound cable, so that we obtain for the strength of the cable the sum of the average strengths of the parts, which is, of course, greater than the sum of the weakest parts. The Atlantic and most other deep sea cables are of this type.

The completed cable is coiled in the works, and on board ship in large circular tanks, with eyes of from 6ft. to 8ft. diameter. On board the Great Eastern the largest tank was 75ft. in diameter, and 16ft. 6in. deep, holding 1,100 knots of cable. The diameter of the tank depends on the beam of the ship. One twist per turn is necessarily put into the cable as it is coiled away. This twist as necessarily comes out when the cable runs up out of the tank. In fact, the one operation is exactly the reverse of the other, and leaves the cable as it came from the spinning machine. The cable as it runs up from the tank is led to the centre, and confined to the centre by large wrought-iron horizontal rings, which prevent the line from lashing out under the influence of centrifugal force.

From the tank it runs in troughs to the brake drum, round which it takes four or five turns. This drum is prevented from turning freely by a brake-strap, which thus puts the necessary retarding strain on the cable.

It is essential that the restraining friction should be constant, a result obtained by the Appold brake. In this arrangement both ends of the brake-straps are attached to one lever in such a manner that when the brake begins to turn it tends to lift the lever and weight hanging from it, and as the lever is lifted it slackens the brake-strap, until the difference of tension on the two ends of the strap is equal to the weight hanging on the lever. When this is the case, the lever is no longer lifted, but remains stationary with the strap, allowing the drum to turn, restrained by a constant friction equal to the weight on the lever (reduced to the point where the strap is attached). If the co-efficient of friction increases the lever will be lifted a little more, and the strap slackened; if the co-efficient of friction diminishes, the lever and weight will fall, tightening the strap; but in any case the retarding force will be simply equal to the weight. After passing the brake-drum the cable dips under a weighted pulley, which rides suspended on a V of taut cable. If the strain increases the rope straightens, and raises the pulley; if the strain diminishes the weight and pulley fall. Thus the height of the pulley indicates the strain. This instrument is called the dynamometer. Lastly, the cable passes over a pulley into the sea.

A cable paid out in air hangs in a catenary curve, but a cable paid out in water lies in an inclined shaped line; the strains in the two cases are completely different. In air the rope meets with no sensible obstacle to its motion, either longitudinally or in a direction perpendicular to its own length; in water on the contrary each foot of the cable meets with an opposition to its motion perpendicular to its length. The rough Atlantic cable, when the ship was going at the speed of six knots per hour, was at an angle of 6¾°, so that the inclined plane was 17 miles long, and each foot of the cable took nearly 3 hours to reach the bottom. Cables of light specific gravity have a small settling velocity, and lie at great length in the water; and if they are also rough, the brake is relieved from most of the strain which would be necessary to lay a cable of equal weight, but small bulk, and smoother surface with the same amount of slack. If no slack were laid there would be little difference between the tension required for cables of different construction, but of equal weights in water. When much slack is laid all cables will be considerably less strained than if laid without slack; and, finally, the faster the ship goes the less slack is required to produce any given amount of relief.

The correctness of this has been amply proved in practice. If in seas 2 miles deep the cable hung in a catenary 12¾ miles long, the weight to be carried would be 8¼ tons, and the strain on the cable 29 tons; while if the cable hung in a catenary the inclination of which to the horizon at the stern was 9° 30′, the length would be 24 miles, the weight 17 tons, and the strain 102 tons, instead of about 14cwt., the strain actually observed for the Atlantic cable when being paid out at the rate of 7 knots per hour, while the ship was going at 6 knots. The motion of the ship even in heavy weather alters the strain very little.

New Form of Galvanic Cell.—K. Kohlfurst has devised an arrangement of a copper and zinc battery, which, he states, will, if used for ringing electric bells, give a sufficient current for a year, at the cost of 1½lb. of crystals of sulphate of copper. A truncated hollow cone is thoroughly varnished inside, filled with crystals of sulphate of copper, and placed mouth downwards in a glass cylinder deeper than itself. This cone has notches round the rim, and has a small hole in the centre of the top. The positive pole is a thick cake of zinc suspended over the face of the cone, cast with a hole in the centre, through which passes a guttapercha covered wire, making the connection with the copper side of the battery. The glass cylinder is then filled with water, when it is evident that the rate of solution of the sulphate depends on the facility with which it is dissolved by the access of water through the notches in the cone, and this taking place at a uniform rate, the electric current arising from the mutual action of the copper and zinc in a solution of a given strength will be uniform also. The strength of the current is said to be increased if instead of water a dilute solution of sulphate of magnesia, or of common salt is used.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, *31, Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

*** *In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

MR. LOWDON "AT SEA"—SOLAR LONGITUDE, &c.—PHOTOGRAPHING THE SUN—SIDEREAL CLOCK—NEW ZEALAND TIME AGAIN!—AND α DRACONIS AS THE POLE STAR.

[4047.]—JUDGING from internal evidence, I should say that Mr. Ralph Lowdon (letter 3966, p. 119) can certainly never have been "at sea"—save, of course, in a very obvious, if figurative, sense—in his life. I have twice read his letter through, to be quite sure that the whole affair was not an elaborate joke on his part; but, having ultimately arrived at the conclusion that he is serious in what he advances, can only express my belief that we have not had a funnier communication in "our" columns for many a long day. In effect, it would appear to be an attempt on Mr. Lowdon's part to supersede the old nautical method of obtaining longitude by "lunar distances," by the terrestrial one of Moon culminators. It is, however, in the details of his suggested method of observation that he shows such a curious want of knowledge of the possibilities of observing on board ship. I have no doubt that the ENGLISH MECHANIC must circulate as largely in the navy as we know it does in the army (and to such an enormous extent in civil life), and I really should be very glad if any Navigating Lieutenant who may read these lines would give us an opinion of an arrangement that involves the examination of the direction of plummets with a microscope (!); the keeping the pedestal "exactly even with these plummets, and thereby upright or perpendicular by an assistant with an even hand" (I fancy that I hear Jack's remarks, made *sotto voce*, while he is being shouted at by the observer to "keep that pedestal perpendicular!"); the use of the "[illegible]," the meridian "lines in the telescope," *et id genus omne!* As for Mr. Lowdon, I would [illegible] of Professor Piazzi Smyth's [illegible], by the aid of the "Free-revolver" stand (an arrangement on the principle of the gyroscope)? and ask him how it is that he does not endeavour to apply that mechanism to his astonishing arrangement? Pending his success in doing so, I fancy that the sextant will serve sailors for a little while longer.

In answer to the string of questions put by "W. H." (in query 11597, p. 131) I may tell him that (1) the Sun's mean longitude signifies his angular distance measured on the ecliptic from the mean equinox. Question 2, as your correspondent will see on reflection, [illegible] form. 3. The longitude of perihelion [illegible] "W. H.") was [illegible] 1, 1872; this increases some 1° 43′ in a century. 4. The mean obliquity of the ecliptic on January 1, 1872, was 23° 27′ 21·36″; its mean annual diminution is 0·476″. Question 5 involves another on my part—"those" what of the Moon?

"X." (query 11640, p. 132) might get a small instantaneous photograph of the Sun; but nothing else with his appliances—or absence of them.

With regard to his next query (11641, same page), the only way which occurs to me as being a feasible one for him to adopt, seems to be to mark a second set of figures on his clock face above the existing ones—*i.e.*, 13 over the 1; 14 over the 2, &c., and so on; and then to shorten the pendulum until the clock beats sidereal seconds.

It is altogether extraordinary to me that people like "J. S." (query 11711, p. 159) will persist in raising—and re-raising—questions which have been discussed over and over again in these columns. He will find the identical one which he puts most fully gone into in letters and communications running through the first half of your thirteenth volume; and the entire subject of longitude and time thoroughly argued in earlier ones.

If, by the "cycle of revolution" of α Draconis, "J. X. T." (query 11716, p. 159) means its return to the position of our pole star, I may tell him that, instead of 400 years, 25,800 years must elapse from the period at which it occupied that place before the northern end of the earth's axis will again point towards it.

"E. L. G." AND CATACLYSMO-MYTHOLOGY.

[4048.]—UPON finding myself accused by "E. L. G." (letter 4011, page 146) of copying exactly "the most sensational line or two from the first preface of (I omit the graceful and thoroughly argumentative adjectives) Bishop Colenso," I at once obtained his book on "The Pentateuch" in order to see whether really there was anything in it to justify your correspondent in making such a charge. Having read the preface carefully through, the only passage which I can find which in the smallest degree would warrant "E. L. G.'s" suspicion is this: "Volcanic hills of immense extent exist in Auvergne and Languedoc, which must have been formed ages before the Noachian deluge, and which are covered with light and loose substances, pumice-stone, &c., that must have been swept away by a flood, but do not exhibit the slightest sign of having ever been so disturbed." Are these the words which I am accused of "having exactly copied with every blunder, as the Chinese copy a worn picture?" Reading on, though, through this same preface of the Bishop of Natal, I have found some words in a footnote which I certainly should have copied, had I had the preface before me. They were uttered by the greatest palæontologist living (if not the greatest who has ever lived), Professor Owen, in 1864, before "The Young Men's Christian Association," at Exeter Hall, when, after speaking of the geographical distribution of plants and animals, he went on to say: "*And such knowledge is incompatible with the notion of the divergence of all existing, air-breathing, or drownable animal species from one Asiatic centre within a period of 4,000 years.*"

I hope that the Geological Society will get over the epithet with which "E. L. G." has essayed to describe them—"a little English coterie and mutual admiration society"—but, doubtless, coming as it does from one so perfectly entitled to speak *ex cathedrâ*, it must be a tremendous discouragement to them; even should it not finally extinguish them altogether.

I am sorry to say that I was never in Auvergne in my life, and am indebted to Scrope, Lyell, Murchison, Mantell, and people of that sort, for my knowledge of it. Those who have been on the spot would be likelier than I, I should think, to satisfy "E. L. G." as to the exact whereabouts of the particular cones which exhibit proof of having remained quiescent since the Pliocene period. He complains that "Lyell and the whole Geological Society" have ignored him for eight years past; but I can scarcely conceive that any English gentleman would be discourteous enough not to answer a letter asking civilly for information, even if the Society (*quâ* Society) declined to give your correspondent a field-night to himself, to show that they were all utterly wrong, and that his was the only original and infallible system.

What the "widely-circulated paper" was in which eight years ago "E. L. G." offered to bet £10 that nobody would find any Pliocene pumice-stone *in situ* I don't know. I should have guessed *Bell's Life* (as its columns generally teem with cognate announcements from people who wish "to back their opinions") but for the fact that I am in some doubt as to whether that lively serial "chiefly circulates among the clergy." At all events, I am content to leave such a mode of [illegible] scientific question to my *bettors*, and shall forbear to instruct my solicitors to sue "E. L. G." whether I find out the exact locality of the cones under discussion or not.

I wait for more light. As far as we have gone we have had plenty of declamation and assertion, but nothing else whatever. We must have encountered comets at various periods, *therefore* deluges must have ensued. There are marks of deluges, therefore we *must* have encountered comets. There seems to me to be a faint resemblance in this to what we used to call the "circulus in probando;" but this may arise from the fact that in the matter of "E. L. G.'s" dicta I walk by sight and not by faith.

THE THEORY OF VISION, AND SPECTRUM ANALYSIS.

[4049.]—I REALLY think that the difficulty of "E. J. D." (letter 3974, p. 160) will disappear if he will consider that his hypothetical "statue of black polished marble" would be illuminated by rays of light coming from every conceivable direction, and that they would certainly, as he says (quoting apparently from some book), "be detached from every physical point of it"—*i.e.*, reflected, I suppose—"in all directions." That "only those rays which enter our eyes can render them (the points?) visible to us," seems too elementary a principle to need discussion here. It would be demanding a trifle too much of any theory to require it to explain how an object could be seen by the aid of rays which did *not* enter the observer's eye. Of course, in the case of black marble a good deal of the light would be absorbed, some irregularly and some specularly reflected; the kind and amount of reflection depending upon the contour of the different parts. That objects do thus send off light in all directions "E. J. D." may satisfy himself by darkening any room by the aid of a shutter, and inserting lenses in three or four apertures cut in it. He will find that each lens will form its own image of a church, tree, or other object in the landscape upon a screen held behind it. A little practical study of the phenomena of stereoscopic vision, too, would, I think, tend to clear up your correspondent's ideas as to the radiation of light from every part of an object. Of course, he does not need reminding that a man viewing his imaginary statue from the north would have a totally different image on his retina from one who regarded from the south: while those among the "vast multitude of persons" who were situated to the east or west of it would see it in an entirely different phase from either. Evidently the rays sent up perpendicularly (or nearly so) from the top of the statue's head, could never enter the eyes of the men down on the plain at all; albeit they would be those by which a man in a balloon would discern it.

It is certainly possible for "R. M. F." (query 11671, p. 158) to conduct some "sort of spectrum analysis with a very small pocket spectroscope." With such a one the spectra of many of the metals and metalloids may be very beautifully seen; and (if the instrument be furnished with a reflecting prism covering half the slit) compared immediately with the dark lines in sunlight. Schellen's "Spectrum Analysis," reviewed in these columns some little time ago, is the standard work on the subject.

HEIGHT OF SEA WAVES.

[4050.]—THE only method of measuring the height of sea waves (for which "A., Liverpool," asks in query 1168?, p. 158) is by eye estimation. From the nature of wave motion, the height above the mean sea level would be one-half of that from trough to crest—*i.e.*, in his own supposed case of a wave 20ft. high in all, its summit would be 10ft. above the sea level.

I have myself, though, seen waves very considerably higher than this. I shall never forget one awful night out in the Atlantic, when I made an effort to estimate such height, and when standing—or rather hanging on—on the poop of one of her Majesty's ships, with my eye 22ft. 6in. above the water-line, I saw huge mountain after huge mountain of water come rushing towards me at least 8ft. above what was visible of the horizon. I have no doubt whatever that every one of these waves was at least 31ft. from trough to crest; and but for the sublimity of the sight, I would express a hope that "A., Liverpool," may never be compelled to endure a similar experience.

COMMUNICATING ROTARY MOTION TO BALL FIRED FROM SMOOTH-BORED GUN.

[4051.]—"PHILANTHROPIST" (let. 3992, p. 129) will be glad to learn that his manslaughtering invention is not likely to prove a blot in his career of philanthropy. The attempt to communicate a rotary motion to projectiles fired from smooth bores has been made in various ways, but (to quote from a letter written to me by the War Department, in 1864) it has been found impossible to obtain "efficient rotation" by such means. My plan was to fire a long bolt, having a hollow screw through its centre, the breech end being, on firing, closed by a shoe or by a suitable projection in the breech. Mr. Cottam, the engineer, told me my bolt would fail, because the projectile must be rifled at the instant of leaving the gun. He invented a bolt with the screw outside, which laboured under the same defect.

If "Philanthropist" could succeed he would gain many advantages. 1. The use of smooth bores. 2. The use of smooth or rifled projectiles *pro re natâ*. 3. Cheapness, &c. Some time after 1864 the *Débats* gave an account of a conical cannon ball invented by the King of Portugal, which appears to have been grooved on the outside. I believe it turned out also a mouse. "Philanthropist's" firework would hopelessly fail, because he could not arrange the direction of his fuses on leaving the gun, so that the rotation might be at any angle to the line of flight, it being quite possible for him with such a ball to shoot round a corner; not to mention the nice state his gun would be in from deposit after a few rounds, as I doubt whether sponging would be sufficient.

M. PARIS.

THE ALCOHOL QUESTION.

[4052.]—ACCELERATED heart-beats may be from rapid oxidation, demanded by too suddenly carbonised and hydrogenised blood, rather than by (as Dr. Richardson suggests) removal of resistance. Our oxygen retention requires all foul topers' expulsion to the woods, so that the production of CO_2 and H_2O, the quick formation of which is essential to their safety, may more rapidly proceed, and contribute more directly to the increase of timber.

Alcohol requirers need ozone, and should work in the garden, or contemplate duty at Southport, where the Fernley Observatory shows ozone in abundance beyond rivalry.

Excess of C and H, from imbibing C_2H_6O, rapidly absorbed and dispersed, paralyses infirmity by overwork, and may it not accumulate molecules obstructive to atomic recombination in capillary network, and to the blood's capillary circulation?

Chloroform's effects are widely different; its chief element Cl (in weight 106·5 to C_{12} and H_1) being inorganic, whilst all alcohol's three elements are organic. Death from chloroform, I suppose, is mainly from over reduced circulation, by alcohol mainly from over rapid; oxygen in both cases too out proportioned by the other elements; the lungs are overtasked, whilst nitrogenic process is retarded or becomes *nil*, alcohol and fat being without it.

Alcohol drinking may suit out-door work, but tea or lemonade better suit for study, for council, for el[illegible] duty, and for work at the desk. Alcohol may be [illegible] spur, but needs caution in its use.

J. BARW[illegible]

P.S.—How do the heart-beats count under i[illegible] of chloroform? Are they fewest during inse[illegible] to pain?

TERRESTRIAL GRAVITATION.

[4053.]—"T. A.'s" last letter (4008, p. 144) illustrates the difficulty of reasoning with one who has taken up the discussion of a subject in advance of his present knowledge. The letter is crowded with mistakes and misapprehensions. Thus the integral calculus is by no means "useless," as "T. A." conceives, but particularly useful in dealing with problems on nearly neutralised attractions. It deals excellently with the case of a particle placed at the middle of one of the circular surfaces of a flat disc, though in this case the attractions are by no means neutralised, as "T. A." supposes, but larger than they would be if the particle were raised above the surface. "T. A." does not seem aware of the fact that a flat disc *is* a cylinder, though every cylinder is not a flat disc. Moreover in the case of a cylinder whose axis is considerable compared with the radius of its base (which seems to be "T. A.'s" idea of a typical cylinder) all the attractive force of the molecules cannot "act in one direction," as "T. A." supposes, "on a particle at either end," nor in anything like one direction. They act, in fact, one half of all the directions possible with respect to such a particle.

But the closing sentence of "T. A.'s" letter causes me to doubt whether, apart from the difficulty abovementioned, I have not done unwisely in discussing this matter at all with him. He refers your readers to the able reasoning in Ganot's "Physics," on "Capillarity" (a subject, by the way, having absolutely nothing whatever to do with "T. A.'s" troubles), and then he adds "those who are desirous of discovering the truth concerning this question are recommended to study Chapter 2 of this excellent work." The idea he wishes to suggest is obviously (I fear) that Ganot is on his side. Now, the *fact* that Ganot is not on "T. A.'s" side is a circumstance which "T. A." *might* have overlooked; but it chances that "T. A." opened this very discussion by pointing to the accepted (or rather known) facts about the attraction of oblate spheroids as involving "a glaring error" repeated in Ganot's book; while in the same letter he described Ganot's work as fairly describing "the present state of physical science as based upon the atomic theory, the material forces of attraction and repulsion being consequently entertained, and as *consequently leading to error*."

Before "T. A." undertakes to exhibit the glaring errors of modern science, and his own superior insight into all truth, he should increase his store of knowledge, but above all he should show a love of truth in his own person, and avoid the *suggestio falsi*, as verging very closely on deliberate untruthfulness.

RICHARD A. PROCTOR.

SELENOGRAPHICAL.

[4054.]—LOHRMANN, describing his crater A, Sec. 1 (Halley), says that on the south side are two clefts, and between them is a great mountain chain coming from Albategnius, with a small cavity in its highest summit. I remark the opposite of this phenomenon where a lumpish protuberance rises from the bottom of the deepest part of the principal cleft as it enters Halley. It has all the appearance of having fallen from the mountain, and is a feature, one would think, that might easily attract the attention of Lohrmann, who, however, does not refer to it. The cleft, which is noticed by Beer and Mädler, extends to Albategnius, the west wall of which it appears to divide longitudinally, and it progressively deepens and widens from that crater to Halley.

A small rill, which I do not find in Schmidt's list, connects two craters W. and SW. of Arzachel.

Schmidt's No. 352, described as having been discovered by Lohrmann in 1824, and not found afterwards, agrees well in position, but not in direction, with this rill, which shows a remarkable parallelism with the above-mentioned cleft, and also with another, No. 358, that runs into Parrot.

Schmidt says of his No. 98, that it was originally discovered in 1824 by Lohrmann, and not seen again until 1865, when Schmidt observed it at Athens. It is situated in four or five degrees of latitude north of the great rill valley of the Alps. I saw it on the 15th of April, and believed I could distinguish another parallel, and close to it, but they were objects of extreme difficulty, as they ran nearly along the line of illumination.

J. BIRMINGHAM.

METHOD OF MAKING A LEFT SCREW WITH A RIGHT SCREW PLATE.

[4055.]—I DO not know whether any of the readers of "ours" can perform the above feat without the aid of a lathe or not; at any rate, as the *modus operandi* was shown me some time ago by a very intelligent journeyman watchmaker, I give it *pro bono publico*. It is as follows:—(1). With an ordinary plate tap a right screw on a piece of good steel wire; (2) file down the two opposite sides of the part that has been tapped until it assumes the form of a flat bar having the thread on its edges, and until it is about one-third the original thickness; (3) heat the tapped end, and, with the aid of a vice, a pair of strong pliers, and great care, give it a twist or two to the left, bringing the right edge over to the left, and *vice versâ*, then temper as usual; (4) with this transformed tap a thread is cut in a plate which will produce a left screw of exactly the same size, pitch, &c., as the original right screw plate would turn out. In small work, when it is necessary to make a right and left screw with identical thread, &c., on the same rod, the above method, with a little ordinary care and not much trouble, will effect the purpose. Of course, in giving the twist alluded to, the wire must not be bent.

A. M. FESTING, F.M.S.

THE SINGER NEW FAMILY MACHINE.

[4056.]—FIG. A represents the under side of the bed and the mechanism for working the shuttle and feed. The bed (80) is ribbed near its edge for strength, and other ribs, with grooves cut, contain the working parts. The bed is fitted with a pair of hinges (shown on the lower edge of engraving) for screwing to the stand. The original Singer machines are made with an upper and a lower horizontal shaft, with large gearing wheels to connect them. The needle-bar and cam act the same in all the machines, the shuttle slides in its race somewhat like the Howe, but driven by a crank instead of a cam. The shuttle is short and thick, but does not make so good a stitch; it is faster than the Howe, and is chiefly used, for its speed, in the slop-clothing trade. It has a wheel-feed resembling the Howe, but like the Howe has recently had a "step-feed" introduced for tailors' work. This machine is driven direct from the treadle by a connecting-rod, or "pitman" of wood, to the crank on the large-toothed wheel of the machine. The Singer machine, unlike the Howe and Thomas, which pull up a firm stitch by positive action, has a spring which governs the stitch, being depressed to form the needle-loop, and on being released suddenly pulls up the thread and stitch. These springs are very unsightly in the original machines, but the action is retained in a neater form in the new family machine herein described.

wears the shuttles much faster, and certainly makes an inferior stitch.

THE SINGER FEED.—A bracket, or feed-guide (72, Fig. A), is screwed to the bed; between these, in a groove, the feed-dog (74) is worked in one direction by the spring 75, for returning after the stitch is made, the same spring also depressing the end of the feed containing the teeth; the raising of the teeth up against the fabric is effected by the longitudinal travel of the feed-lever (61), which has an incline or wedge-shaped end, in contact with a corresponding incline in the plate, or raising-cam (62), adjusted on the bed by its screw. The same feed-lever (61) has also a cross motion, which acts against the end of the feed-dog nearest the shuttle, and at the extreme end of the lever (61). The other end of this feed-lever has an oblong hole, and in this the upright shaft is passed through, and above the crane disc (59) a cam is made to work in the slot, so as to give it the longitudinal and cross motion, not constant, but with a pause to give the time required for the feed-action. This motion is conveyed from the shaft to the feeder by means of a universal joint (69). It is formed by a piece having a groove cut the size to fit the flat lever (61), and to allow a sliding motion longitudinally, by means of a stud passing through a hole in the plate on the end of the bar (65). This piece and stud in one has a nut on the stud to retain it in place (as shown on the end of bar 65); this bar is the stitch regulator, the bed is

FIG. C

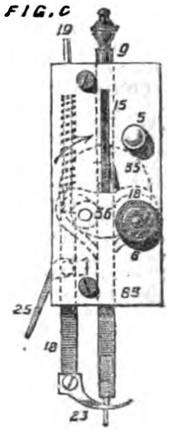

FIG. A

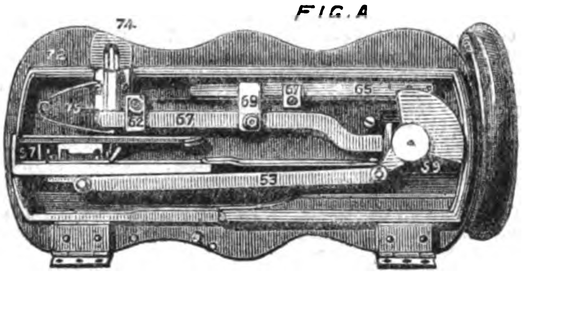

FIG. B

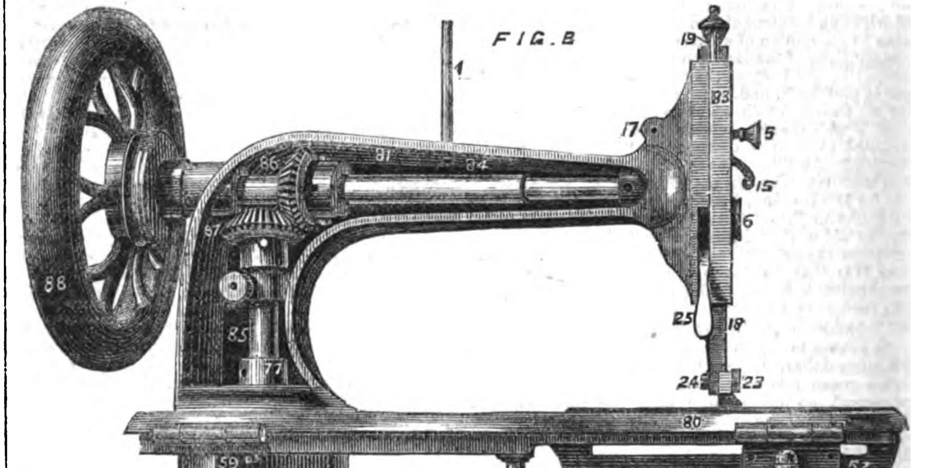


The arm of the machine (81) has a side to it, covering the upper mechanism; it contains the main shaft (84), which has a fly or balance-wheel (88) on its right hand end, a strap descends from a groove on a pulley to the driving-wheel on the stand below. Motion is communicated to the works below the bed by means of a bevel-gear, or toothed wheel (86), fixed on the main or horizontal shaft, and gearing into a corresponding cog-wheel (87) fixed on the top of an upright shaft (85), which works the crank (50, Fig. A and B) to drive the shuttle. A steel crank-stud inserted in the crank fits into the connecting-rod (53, Fig. B), which is kept in place by a washer over the stud, and a pin through the stud to retain it. A similar connection is made on the shuttle-driver. Instead of the Howe mode of sliding the shuttle, it is carried by its round back resting on two prongs, and its face against the shuttle-race on the bed. At 57 (Fig. A) the carrier is shown in the shuttle-race, the shuttle-race slides being partly open to admit the light. The shuttle-race is faced on its (apparent) upper side, and contains the needle-groove. The opposite side is faced also, and a slot cut through it and its back faced. The shuttle-carrier is connected by its back through this slot by two screws, and can thus only travel horizontally when moved by the connecting-rod 53. While the Howe shuttle only travels the actual distance needed to form the stitch, the Singer, and all shuttles worked by a crank, travel a greater distance. This has no advantage; but, on the contrary, the higher velocity and extended friction

grooved to receive it. A plate (67) with its screws, holds it in place, free only to travel longitudinally. A long stitch is made by placing the universal joint (69) near the cam or shaft, and the reverse, of course, for a short stitch. The stitch-regulator bar (65) is moved from above the bed by a thumb-screw, fixed in its right-hand end; when moved to obtain the stitch required the thumb-screw is used to fix it. These parts must be fixed firmly; in addition to set-screws, taper pins are driven hard in the crank, collars on shafts, and cog-gear wheels. If it gets dirty the worker should not attempt to take it to pieces. The parts are so complicated, and all requiring so much fitting and workmanship to accomplish what in other machines is very simple, that its invention would be a credit to a trades' unionist bent on the one idea of increasing the demand for labour. The closest inspection cannot discover a new or better motion than in the Howe class of machine, but it is easy to perceive that the motion obtained by all this complication is limited in range, no pause whatever is given to the shuttle, and carrying, instead of sliding it, is an idea borrowed from some other machine.

NEEDLE MOTION.—Fig. C shows the face-plate (83); the dotted lines, the heart-shaped cam (10), cam-roller and stud (36), and crank disc (35). The arrow indicates the direction of motion, which is towards the operator when sitting at the stand. On turning the cam-roller (or crank), the observer may notice that the action of the heart-cam causes the needle-bar to descend from the top steadily to the bottom; it is then raised about one-eighth of an inch, and remains nearly at rest while the shuttle enters the loop of needle-thread, but descends a little while the shuttle passes through the needle-loop thrown off the needle-eye in the act of rising of the needle-bar. When the shuttle has passed nearly through, the cam lifts the needle-bar quickly. The time of this action, compared with the Howe machine, is inferior for making a good stitch, but far superior for strength, speed, and wear. The defect of having a strong spring to pull up the thread-loop from off the shuttle, instead of the needle-bar direct and positive, makes it requisite to stop often to regulate the tension from thick to thin, or hard to soft, fabrics. The check-lever (15), which pulls up the slack or loop of thread, can be regulated by the check-spring, coiled around a screw placed in the hole for the screw (17), which acts as a pivot for the check-lever, as well as to keep the spring in place. The end of the spring is placed in one of the holes under the screw (17), so as to be weak or strong, according to the work in hand; it looks neat, but is troublesome to adjust, and leaves the machine far behind others in simplicity of adjustment. Testing it, by pulling up a firm stitch in thick cloth, and then in thin paper, shows the thread cutting the paper, and adjusting it to paper shows a slack or loopy stitch on the cloth. This experiment proves that the machine is made to depend too much on the fabric in forming the stitch, an arrangement which is sure to produce an uneven stitch, when the speed is sometimes necessarily too fast or too slow. There is a stop in the needle-bar to force up the spring at the end of the stroke; sometimes it acts properly, at others the spring acts in advance, according to speed and materials. This ever-varying quality is very troublesome, to new workers especially, and its want of simplicity is a drawback to all such machines as work the shuttle by a crank instead of a cam motion. This part will be better understood by comparing it with a cam-shuttle-action machine, to be illustrated shortly, and chosen as the easiest to explain the formation of the stitch, and all the actions of a sewing-machine.

TO THREAD-UP THE SINGER MACHINE FOR WORK.—Place the cotton reel on the wire pin (1), pass the thread through an eyelet-wire in top edge of face-plate, then down under and between the tension-plates or discs (6), then up to the eye of the check-lever (15), pass it through from the front backwards, then down to and through the hole in needle-clamp, and passing into the needle-eye from the front backwards, leaving the thread about three inches through, so as to hold it between the fingers while pulling up the shuttle-thread. The shuttle being properly threaded, and put upon its carrier (57), and the shuttle-race slide closed over, then one turn of the wheel passes the shuttle through the needle-thread loop; as the needle rises, pull up the end of the needle-thread, and draw up the shuttle-thread along with it. The lock-stitch is thus made, by a little practice, as easy as the chain-stitch, provided the operation is fully understood.

DEFECTS OF THE SINGER NEW FAMILY MACHINE.—When the machine has been laid aside, and thus made stiff by dirt, the worker finds the great disadvantage of a complicated machine. It will take a mechanic three-quarters of an hour to take it to pieces, clean, and replace the parts; and to do this more tools are required than are supplied with the machine. The teeth or cogs are liable to be broken off the wheels (86 and 87) inside the arm, and in many ways this machine requires the help of a mechanic, where some machines for similar purposes do not. Many other machines are nearly as complicated and troublesome, and for some it has been found needful to caution the user not to take the machine to pieces. Doing so involves sending it to the mechanic, thus incurring expense and delay. Users will know better in a few years.

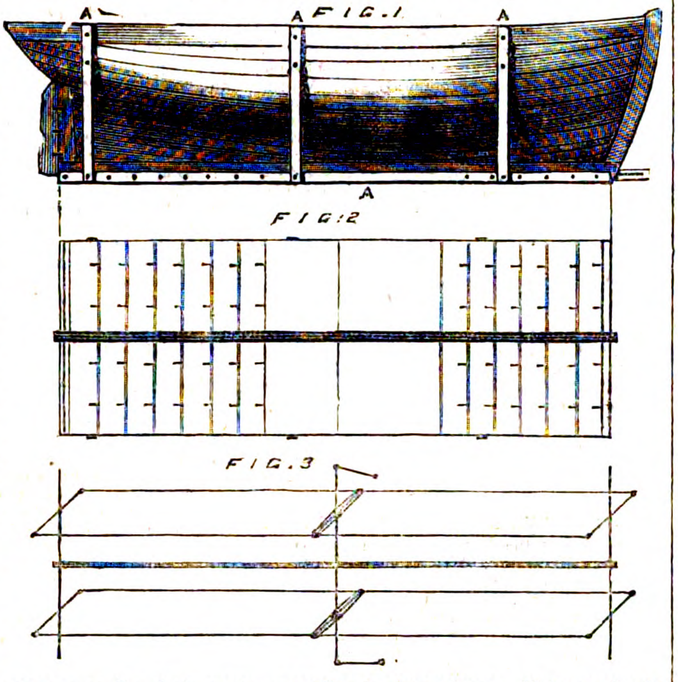
A PRACTICAL MAN.

IMPROVED DIRECTING POSTS.

[4057.]—I HAVE a fellow feeling with "Canis Minor" (let. 3991, p. 123). The fingers of most posts about here having been long amputated, and the letters as undecipherable as Sinaitic Pilgrim inscriptions, would it not be better for the plates to be perforated? There are few nights when a post is not darker than the clouds and to fumble about the raised letters like a blind man, does not impress me with a desire to pursue knowledge under such difficulties. As to the clerk "kept" by the Postmaster-General to hunt newspapers to any one acquainted with the Civil Service such a notion is ridiculous. It is more likely that some favourite of official fortune is paid £800 a year for seeing that a messenger or boy "chosen at once" at £50 stows them away carefully in a "depository" forgotten even by the ubiquitous spider. M. PARIS.

ALLINGHAM'S PROPELLER.

[4058.]—I FORWARD by same mail the *Liverpool Albion* newspaper containing an account of my latest experiment, as exhibited to a large number of professional men, and although all, including the reporter, who was personally unknown to me, came prepared to witness a failure, they were astonished, and the only objection which was put forward was that the invention was in a crude state, which, being translated, means that my means being limited and the experiments having extended over a period of nearly twelve months, I am forced to construct my models principally of tinned sheets for economy's sake, and they are very easily disarranged in rough weather. This apparatus would be invaluable as applied to lifeboats, as it would only require one man to steer, another to start, stop, or reverse the boat, instead of the large crew required at present to row against the storm. It is also applicable to the navy, as being below the surface it is beyond the reach of shot, and leaves the whole hull available where room is so valuable. I inclose drawings of latest designs for attaching to any vessel. Fig. 1, A A A A, represents steel bars as thin as possible, consistent with the size of the vessel, the vertical bars riveted to the vessel's side; the horizontal one on each side of keel carries the blades, and does not project below the keel, so that if aground the vessel would sit up as if supported by legs. The blades as shown in Fig. 2, which represents the boat turned keel up, are ten in number forward and fourteen aft, each blade securely attached by clasps to steel rods which go through the keel from side to side, each blade being just able to pass to upper or under side of frame. Fig. 3 represents the guards separately from Fig. 2 to avoid confusion. These guards regulate the height to which the blades rise or fall, and are capable of being closed or opened at will on port or starboard side, amidships, by means of a lever, worm-wheel, or



screw, according to circumstances. If the weather be fine, open slightly, which gives the highest speed; if stormy head sea and wind, open more, which increases the power as it reduces the speed; if to stop her, close similar to a parallel rule, which shuts all the blades; if required to back her, open to full extent, let the vessel acquire a little sternway, and all the blades would instantly reverse; then up with the guards until required to go ahead again, when on turning her head from the wind the blades would all go back into the original position for propelling ahead. By stopping or reversing one side the vessel may assist the helm to turn more quickly, and, if necessary, she could be steered altogether if any accident occurred to helm. I am perfectly convinced that no steamer could outsail a vessel of this construction in a heavy sea, although she would probably do so in light weather.

JOHN JAMES ALLINGHAM.

KING NUMBERS.

[4059.]—IF "E. L. G." (letter 3990) will refer back to my letter he will see that I did not say that it was king numbers that everybody knew before, but something quite different. I never said a word about king numbers, good, bad, or indifferent, and willingly allow that he has said much about them that I, at least, did not know. What I fail to perceive is the connection of the curious properties of numbers he has been explaining with the question whether the convenience of having what is called the metric system in use would or would not overbalance the cost and trouble of introducing it. It seems to me that the best judges of that are those who have tried both the English and French systems sufficiently long to become familiar with both, and I believe that those who have are nearly unanimous in favour of the change. Is this belief correct? PHILO.

PRACTICAL INSTRUCTIONS FOR MAKING THE PIANO ACTIONS IN No. 368.

[4060.]—HAVING contributed full-sized working drawings of these actions, and a pretty full description of their advantages, perhaps it may be as well also to contribute some instructions which will, I trust, facilitate the operation of making them.

It may, at first sight, seem rather presumptuous for so unpractical a person as the "Blacksmith" must be, to pretend to give practical instructions to small work makers, whose general experience must so greatly exceed his, how they can most easily form the parts of these actions, but it may be some excuse for his presumption that in the construction of them he has been enlightened by experience which they cannot yet possess. So he subjoins a few hints which, in his opinion, even those eminently practical men would do well to bear in mind.

That it might resist the rebound of the hammer from the strings as little as possible I had the sticker O, Fig. 1. made as light as I considered consistent with necessary rigidity. Its section is $\frac{3}{8}$in. from back to front, by $\frac{1}{4}$in. wide. It was made deeper than its width to afford sufficient depth for the oblique hole which receives the projecting piece. To make it wide enough for that hole to be bored in it, the upper 2in. of its length was reinforced by cheeks formed of two slips of good beech wood, one-tenth of an inch thick, one being glued on each side. For this purpose I know no better wood than beech, well-selected; no doubt good Spanish or Cuba mahogany would answer, but beech is stronger, cheaper, and, I think, holds the glue better, and for the latter reason I prefer it to hornbeam, which I first employed, and I don't think any much cheaper method than this of forming the sticker will readily be devised. Should it be desired to make the sticker capable of being disconnected from the butt on the French system—which I greatly prefer—probably the most facile and cheapest plan will be to glue one cheek in its place, then glue on the rectangular projecting piece required in lieu of the cylinder P, and when quite dry to plane the sticker in a suitable matrix to its required thickness, after which, the right-hand slip or check being glued in its place, the projecting piece will be well secured between the two cheeks, but it would greatly strengthen the connection of the parts if two (about No. 24) soft copper wire rivets were inserted below and one through the rectangular projecting piece, employed in lieu of P, whose section may be $\frac{1}{4}$in. × $\frac{3}{8}$in.

There is no necessity to make the lower end of the sticker into a cylinder. If tapered for a trifle more than half its length until its end is but $\frac{1}{4}$in. square, it may then have its edges planed off and thereby its end rendered octagonal, which answers quite as well, always assuming it to be glued in the centre of the cloth or felt disc at its bottom, and that it does not touch the hole in the rail in any of the positions into which the hammer carries it during performance.

Should it be determined to attach the damper to the butt in this sticker action, Fig. 1, which, as it saves fully $\frac{1}{2}$oz. in the weight of the touch, is a thing I should certainly do myself were I able to conceive it possible I could ever become foolish enough to be tempted—(qy., by the evil one)—to have a piano with a sticker action finished for me. I much prefer, however light the sticker be made, for the escapement, if any escapement be allowed, to be at the hammer butt. It is obvious that the forked portion of the butt must not extend far below the hammer centre, at least the last half inch of its length—it should be made about $\frac{3}{8}$in. longer below the centre—must be filled in solid, and have a hole bored in it into which the damper wire can be screwed. Of course it would be possible to mortice the butt cheaply by suitable machinery, and leave its lower part solid for the insertion of the damper wire; but, considering small work makers do not usually possess mortising machines whose scale is suitable for such small work as making the butts of pianoforte hammers (sooth to say, I greatly doubt if one such machine exists); also considering that they seem to think it is their mission to do everything they well can do (and sometimes something more) with the circular saw, I presume they will prefer making these forked butts with a circular saw (say) $\frac{1}{4}$in. thick, which is the space between their prongs, and to fill up the lower half-inch of their length by glueing a piece of hard wood (say) hornbeam, beech, or Cuba mahogany, between them. It might be preferable for the grain of this piece to be at an angle of about 30° with that of the butt, because the glued joint would be quite as strong, and it would hold the screwed portion of the damper wire better than any wood can whose grain is parallel to the hole which receives it. It would be a further improvement to leave that portion of the butt which is more than five-sixteenth's of an inch below its centre wire, the same depth from back to front as its upper portion, which receives the hammer shank, because this will not only afford larger surfaces to be glued together, but also room for a couple of soft No. 24 copper wire rivets, one in front of and the other behind the damper wire, thereby greatly increasing the strength of the butt at an inconsiderable cost.

It will be observed I have designed the butts in both actions, Figs. 1 and 3, so that the holes which receive the hammer shanks are bored parallel to the backs of the butts. This, which is by no means essential, was intended to facilitate correct guidance while boring those holes. As merely glueing the joint between the arms C C, which carry the counter weights D D, and the butts could not be relied on for endurance, [illegible] shown, by dotted lines, glued wooden dowels, [illegible] through the butts from their backs into th[illegible] for connecting the parts securely. The same [illegible] apply with equal force to the joint between th[illegible] and vertical portions of the hopper H in Fi[illegible] securing this joint I have also thus shown two wooden dowels, about five thirty-second's of an inch in diameter. These must, of course, be inserted sufficiently to the right and left of the centre of the hopper to allow room for the check wire descending between without touching them.

As the only means provided in Fig. 8 of regulating the distance of the hammer from the strings—and the parallelism of the damper to the strings—is by bending the damper wire, it will be found needful to facilitate those regulations by employing a somewhat thinner, or at least a softer, material than hard brass or iron for the damper wire. I found moderately hard drawn copper—a well stretched piece of copper bell wire, for instance—and soft brass wire preferable for this purpose, because its form was very easily altered by a tool with two nicks, one of them being at its end and the other at its side. The regulation did not require much time to effect with this tool, which is easily made.

As it is quite notorious that all pianoforte makers are so far advanced in civilisation as to have all (intellectual) things (if not their worldly wealth) in common, and no trade secrets from each other, and that they also are willing to co-operate intellectually for their mutual benefit, also, as the practical reader must long ere this have become quite convinced the writer is totally ignorant of all practical details, he "wery 'umbly" suggests that Mr. Schucht, and others of your practical correspondents who must necessarily know so much more about small work making than he possibly can, would oblige by suggesting better methods of constructing the different parts of these actions than his very limited experience has enabled him to carry out.

THE HARMONIOUS BLACKSMITH.

HOW WE SEE A DISTANT OBJECT.

[4061.]—"E. J. D." (letter 3974) infers that, because only the rays which enter our eyes render objects visible, "two distinct sets of rays must proceed to each of the spectators, that is, one for each eye." "E. J. D." should know that the eyes only catch proportionately to their size the rays in contact with their surface, which impinge on them neither more nor less than on every other object in space at an equal distance and equally unintercepted. The illuming ether is evidently that elastic as to need no atomic prisms for secondary reflection, it rebounds on all sides as balls inflated with hydrogen so thrown might aid towards exemplifying, each rebounding from contact with the other, rays extending till increased crossing rays finally divert them all. Astronomers may know at what distance combustion, or an unintercepted star, becomes invisible by distance; the law, or fact, may be learned. The great wonder is the enormous myriads of ultimate ether atoms that by variety of impingence force delineate with such nicety every distance, shape, tint, and magnitude that we behold.

We easily see the rate of reduction of light rays on secondary reflection, when we behold our face at the glass, with the light first falling on our face, and then compare it with the reflected face when we turn, so that the direct rays first impinge on the mercury, and then rebound to the face before they return, and rebound again from the mercury in the variedly modified impingements that present to us the picture of one's-self.

J. BARWICK.

[4062.]—"E. J. D." (let. 3974, p. 120) supposes a large statue of black, polished marble to be set up upon a plain, and seen by a vast multitude of people. How, then, he asks, is it that each individual of that multitude receives a distinct image of that statue? "E. J. D." seems to think that he would not be able to see it unless rays of reflected light were proceeding from every part of the statue in a direct line to his eye, but I do not think that to be at all a necessary condition. In the first place, how do we discern that the statue is black? Is it not because a great portion does not reflect any rays of light to the spectator's eye? No number of rays of light, be they few or many, can convey to the eye the idea of blackness—pure blackness is the absence of reflected light. Having perceived that the object is black, how do we perceive that it is a statue. I submit that it is because we see the black non-reflecting contour of the object standing between us and certain objects in the background which do reflect light, such as distant hills, clouds, &c., and we see that this black contour is that of a statue. But if no part of that statue reflected any light to the eye of the spectator it would appear against the background as a flat, black silhouette, without the appearance of roundness or modelled form. How, then, do we perceive this roundness and form? We discern this from the high lights—those points on the statue whence the rays of light are reflected in accordance with the well-known law of the equality of the angles of incidence and reflection,—and it is to be noted that this reflected light is white light. The mind combines these two facts; the non-reflecting condition of a great portion of the statue, and the position, form, and size of these high lights, and a correct perception is obtained of a black statue. If "E. J. D." will take a black bead, and place it on a sheet of white paper, he will perceive that the greater portion of the bead appears of an intense black, reflecting no rays of light whatever to his eye. He will also perceive the high light, a small speck of light which is reflected to his eye in accordance with the usual law mentioned above, and that it is so reflected he can easily test by moving to one or the other side of the head, when he will perceive that this speck of high light will appear to follow in the same direction as that in which he moves. If he were to photograph this bead lying on the paper he would find that the sensitised plate was not acted upon by that portion of the bead which appears black, clearly proving that from thence proceed no rays of reflected light; but it would be acted on by the light from the paper and by the high light of the bead, and if from this negative a positive were printed it would give a correct representation of the bead on the paper.

BOBO.

[4063.]—IN reply to Mr. Barwick's letter (3973, p. 120), I beg to state that he has not touched on the main point which I have put forward, particularly in my last letter (3974, p. 120), so I shall not at present allude to any of the statements in his letter. I would beg to refer his attention to my last (3974), and will now try and explain the point on which I want information. I presume he agrees in the theory of light, which I have quoted, as to our seeing distant objects by pencils of rays emanating from every part of the object to the eyes of the observers, no matter how numerous the observers may be, or where placed, so long as the object is in view. Sir Isaac Newton perceived the difficulty, and he ascribes the reflecting power to the principle of repulsion, remarking that what appears to our senses smooth and polished are found, when viewed through a microscope, to abound with inequalities. If, therefore, the power which produces reflection did not act at some distance from the reflecting surface, these inequalities would prevent the rays from being reflected with so much regularity as we find they are. This theory seems to me to reduce all rays to a sort of general specular reflection, and cannot (as far as I can perceive) explain the distinct pencils of rays on the present theory of light.

Again, I am at a loss to know how any object can provide all those rays to meet the requirements of a great multitude observing any object at the same time, for it is calculated that the best of mirrors reflect little more than half the light they receive. Thus we have the theory of repulsion upset, for by that the mirror ought to reflect the whole of the light it receives. Now to the point. From what cause do those innumerable pencils of rays proceed from every physical part of an object to the eyes of the numerous spectators (and as the theory states) in right lines, and converging to points before they enter the eyes? If Mr. Barwick adopts the theory of repulsion, how does he get over the specular reflection it would be likely to cause? Why do those pencils of rays converge to points before they enter the eye, and what is the inherent power in any object causing them to do so? Suppose an observer sees an object at three feet distance, he does so by this pencil of rays. The object is stationary, but the man retires from it, and we are to believe that for the most trifling change of position a fresh pencil of rays must flash from the object before he can see it; and in the case of a multitude constantly moving, the number of pencils of rays required to be thrown off the object would be innumerable. But to make the matter more difficult, these rays must all converge to a point before they enter the eyes of the spectators. Mr. Barwick will now, I hope, understand the nature of the information I require, and I shall now expect that he will answer the above questions in detail. I must have full proof in every case.

E. J. D.

REVOLVING PUDDLING FURNACES.

[4064.]—IN the last impression but one of the ENGLISH MECHANIC, it is stated that "Mr. Danks's patent for the revolving puddling furnace is contested." While giving Mr. Danks all credit for the energy he has shown in this matter, beyond this he has no earthly claim whatever to the invention. In 1853 Mr. Walker took out a patent for the "revolving puddling furnace," and most certainly Mr. Walker's furnace requires more consideration than it has yet received from the English ironmasters.

Next to Mr. Walker we have the revolving puddling furnaces of Mr. Tooth. This energetic gentleman's patents were taken out in 1859, 1860, 1861 and 1864. On the other hand, the first patents taken out by Mr. Danks are of very recent date—viz., 1869 and 1870. He has since taken out two other patents, dated 21st December, 1871, and 9th April, 1872. His specifications, however, are not yet filed in the patent office.

On comparing the inventions of Messrs. Walker and Tooth with those of Mr. Danks, it is difficult in the extreme to discover what the latter claims as new in his patents. In my humble opinion Mr. Danks is a mere copier of the inventions of the above-named gentlemen. Let us hope that Mr. Danks's claims on England for this invention will not be classed among the other items in the "Alabama claims."

During the late great Exhibition in Paris considerable agitation prevailed in England in reference to the great progress made in the manufacture of iron at Mr. Schneider's works in France. When this subject was investigated, all these so-called French "improvements in the manufacture of iron" were to be found recorded in our patent office, as the labours, of hard-working, but sadly neglected scientific men in England, which foreign ironmasters had adopted. In the present state of our intelligence it would appear that the scientific discoveries of the sons of England must first be adopted abroad and re-patented here before such discoveries can be appreciated in this country. This is a sad state of things, but so it is. We have numerous scientific institutions in England, but these, so far from rendering any aid to the development of scientific discoveries, or in any way assisting the inventive genius of the nation, are utterly worthless, in fact, little better than *egotistic shams.*

G. S. (Civil Engineer.)

EXTINCT VOLCANOES.—VII.

[4065.]—BESIDES the volcano of Jorullo (letter 3883, p. 66), so recent in its origin, Mexico contains other five, Orizaba, Toluca, Tuxtla, Popocatepeil, and Colima. What is rather remarkable is that these five, together with Jorullo, all lie nearly in a straight line, running east and west. The tracts of country which these volcanoes have desolated with their lava are called by the Mexicans the Malpays. The most remarkable of the mountains is Popocatepetl. Although it has long remained in comparative quietness, it was very active at the time of the Spanish invasion under Cortes. Of the first approach of the Spaniards to this volcano, and of the attempts made by some of them to climb to the top, Mr. Prescott, in his "History of the Conquest of Mexico," gives the following graphic account:—

"We are now passing between two of the highest mountains on the North American continent, Popocatepetl, 'the hill that smokes,' and Iztaccihuatl, or, white woman; a name suggested, I think, by the bright robe of snow spread over its broad and broken surface. A puerile superstition of the Indians regarded these celebrated mountains as gods, and Iztaccihuatl as the wife of her more formidable neighbour. A tradition of a higher character described the northern volcano as the abode of the departed spirits of wicked rulers, whose fiery agonies in their prison-house caused the fearful bellowings and convulsions in times of eruptions. It was the classic fable of antiquity. These superstitious legends had invested the mountain with a mysterious horror that made the natives shrink from attempting its ascent, which, indeed, was from natural causes a work of incredible difficulty. The great volcano, as Popocatepetl, was called, rose to the enormous height of 17,852ft. above the level of the ocean, more than 2,000ft. above the monarch of mountains, the highest elevation in Europe. During the present century it has rarely given evidence of its volcanic origin, and 'the hill that smokes' has almost forfeited its claim to the appellation, but at the time of the conquest it was frequently in a state of activity, and raged with uncommon fury while the Spaniards were at Tlascala; an evil omen, it was thought, for the natives of Anahuac. Its head, gathered into a regular cone by the deposits of successive eruptions, wore the usual form of volcanic mountains, when not disturbed by the falling in of the crater. Soaring towards the skies, with its silver sheet of everlasting snow, it was seen far and wide over the broad plains of Mexico and Puebla. This scene is enough to stir the young student up to diligence and duty, and to consider the omnipotent hand that formed such stupendous objects—the first object the morning sun greeted in his rising; the last on which his evening rays were seen to linger, shedding a glorious effulgence over its head that contrasted strikingly with the ruined waste of land and lava immediately below, and the deep fringe of funereal pines that shrouded its base. The mysterious terrors which hung over the spot and the wild love of adventure made some of the Spanish cavaliers desirous to attempt the ascent, which the natives declared no man could accomplish and live. Cortes encouraged them in the enterprise, willing to show the Indians that no achievement was above the dauntless daring of his followers. One of the captains, accordingly, Diego Ordaz, with nine Spaniards and several Tlascalans, encouraged by their example, undertook the ascent. It was attended with more difficulty than had been anticipated. The lower region was clothed with a dense forest, so thickly matted that in some places it was scarcely possible to penetrate it; it grew thinner, however, as they advanced, dwindling by degrees into a straggling stunted vegetation, till, at the height of somewhat more than 13,000ft., it faded away altogether. The Indians, who had held on thus far, intimidated by the strange subterraneous sounds of the volcano, even then in a state of combustion, now left them. The track opened on a black surface of glazed volcanic sand and of lava, the broken fragments of which, arrested in its boiling progress in a thousand fantastic forms, opposed continual impediments to their advance. Amidst these, one huge rock, the Pico del Fraile, a conspicuous object from below, rose to the perpendicular height of 150ft., compelling them to take a wide circuit. They soon came to the limits of perpetual snow, where new difficulties presented themselves, as the treacherous ice gave an imperfect footing, and a false step might precipitate them into the frozen chasms that yawned around. To increase their distress, respiration in these aërial regions became so difficult that every breath was attended with sharp pains in the head and limbs; still they pressed on, till, drawing nearer the crater, such volumes of smoke, sparks, and cinders were belched forth from its burning entrails, and driven down the sides of the mountain, as nearly suffocated and blinded them. It was too much even for their hardy frames to endure, and, however reluctantly, they were compelled to abandon the attempt on the eve of its completion. They brought back some large icicles—a curious sight in those tropical regions—as a trophy of their achievement, which however imperfect, was sufficient to strike the minds of the natives with wonder, by showing that with the Spaniards the most appalling and mysterious perils were only as pastimes. The undertaking was eminently characteristic of the bold spirit of the cavalier of that day, who, not content with the dangers that lay in his path, seemed to court them from the mere Quixotic love of adventure. A report of the affair was (I believe) transmitted to the Emperor Charles V., and the family of Ordaz were allowed to commemorate the exploit by assuming a burning mountain on their escutcheon. The general, not being satisfied with the result, two years afterwards sent up another party, under Francisco Montaño, a cavalier of determined resolution. The object was to obtain sulphur to assist in making gunpowder for the army. The mountain was quiet at the time, and the expedition was attended with better success. The Spaniards, five in number, climbed to the very edge of the crater, which presented an irregular ellipse at its mouth, more than a league in circumference. Its depth might be from 800ft. to 1,000ft. A lurid flame burned gloomily at the bottom, sending up a sulphurous steam, which, cooling as it rose, was precipitated on the sides of the crater. The party cast lots, and it fell on Montaño (I believe) to descend in a basket into this hideous abyss, into which he was lowered by his companions to the depth of 400ft. This was repeated several times till the adventurous cavalier had collected a sufficient quantity of sulphur for the want of the army."

The more tranquil state of the volcano in modern times having rendered the summit no longer so difficult of access as it was in those days, the ascent has been several times achieved, twice in 1827, and again in 1833 and 1834. The crater is now a large oval basin, with precipitous walls composed of beds of lava, of which some are black, others of a pale rose tint. At the bottom of the crater, which is nearly flat, are several conical vents, whence are continually issuing vapours of variable colours, red, yellow, or white. The beds of sulphur deposited in this crater are worked for economical purposes. Two snowy peaks tower above its walls. Not less magnificent in its proportions is the volcano of Orizaba, which is nearly of the same height as Popocatepetl. It was very active about the middle of the sixteenth century, having had several great eruptions between 1545 and 1560, but since then it has sunk into comparative repose. This mountain was ascended by Baron Müller in 1856. A first attempt proved unsuccessful, but by passing a night in the grotto, near the limit of perpetual snow, he was able, on the following day, after a toilsome ascent, to reach the edge of the crater. A yellow crust of sulphur coats in several places the internal walls, and from the bottom rise several volcanic cones. The soil of the crater, as far as I could see, was covered with snow, consequently was not at all warm. The Indians affirmed that, at several points, hot air issues from crevices in the rocks. Although I could not verify their statement, it seemed to me probable, for I have often observed similar phenomena in Popocatepetl. There are several of the West Indian islands of volcanic origin, and three of them, St. Vincent, Martinique, and Guadaloupe, contain active volcanoes. The most remarkable is the volcano of Morne Garou, in St. Vincent, the eruptions from which have been particularly violent. In 1812, the ashes which it threw out were so great in quantity, and projected to so vast a height, that they were carried to a distance of two hundred miles in the teeth of the trade wind. From Mount Pelée, in Martinique, there was an eruption in August 1851. La Laufriere, the volcano in Guadaloupe, is said to have been cleft in twain during an earthquake. Its activity has long been in a subdued state, but it is remarkable for its deposits of sulphur.

RALPH LOWDON.

PSYCHIC MANIFESTATIONS.

[4066.]—PERMIT me to point out the suspicious resemblance between the performances of the "painting medium" (noticed at p. 58) and the "sleeping preacher" of James I.'s reign. In his sleep, so-called, Dr. Haydock preached good sermons with a good voice, and quoted Hebrew; while, when he was awake, as there was good (?) evidence to show, he knew no Hebrew, and stuttered badly. He used to preach before numerous fellows of the Oxford colleges, whom he completely deceived. He was next taken up to Court, and preached there before the King; but James forced him to "ingenuously confess and acknowledge that this use of my nocturnal discourse, seeming to be in a deep and sound sleep when indeed I was waking, was from the beginning a voluntary thing," &c. This confession was made April 27, 1605. What a pity we have not another James I. to make Mr. D—— make a little confession in 1872!

HEDERA.

P.S.—There is an account of this man at p. 338 of Disraeli's "Miscellanies of Literature," and a fuller one in *Chambers's Journal* for Feb. 17, 1872, p. 99.

DR. CARPENTER AND PERSPECTIVE.

[4067.]—OF course no one conversant with perspective would think of disputing "E. L. G.'s" axiom, that on a vertical plane all really vertical lines must be projected vertical, and no tower not tapering can have its picture tapering at all, whether its height be 100ft. or 100 miles. This is indisputable. But a curious question arises, and if it will not be considered trifling with the subject, let us suppose that there should be a tower built, say, ten miles high. How could M. Paris possibly represent it as it would be noticed by his eye? In the first place, in order to see the base of the tower he would have to look straight before him, level with the plain on which the tower stood; but in order to see the top he would have to look right up over his head, nearly into the actual zenith, and as his eye roved over the tower from summit to base, and from base to summit, it would appear to bend over him in a curve. I think it would be rather difficult, not to say painful, to make a sketch of the tower as it really appeared. Of course I am supposing that the tower is not very distant from the spectators, say, a quarter of a mile.

BOBO.

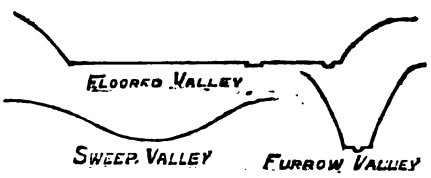
ONE PROOF OF THE DELUGE.

[4068.]—"P. SANTALINUS" (let. 3968, p. 119)—if we pass over the mis-statements of the former parts of that letter (which should be compared with his last query 9389, p. 489, and my reply, p. 514)—asks in the last sentence for some phenomenon unaccounted for, and unaccountable, by causes now in action, or without a cometfall. Now, in total ignorance what spot or country on earth "P. Santalinus" may inhabit, I can only lay, perhaps, nine to one that he is within a walk of such evidence. It is most probable that he cannot stir a mile, and very probably not step out of his door, without standing on ground whose form defies all Lyellian theory to account for, being such as the "causes now in action," never could form either in 60 million or 60 billion years (to say nothing of the 60 *thousand* of "F.R.A.S.," let. 3960). Probably, 99 hundredths of our *habitable* earth surface belongs to this category, but as the remaining hundredth includes the most fertile and therefore populous lands, and in some cases whole degrees in width of them, I must bear in mind the possibility that P. Santalinus *may* dwell where he might have to take whole days' journeys to reach the following evidence. This would be so if he dwells, for instance, in Alexandria, Calcutta, Venice, Amsterdam, or New Orleans. From any of those cities, to reach the traces of cometfall, or facts inexplicable without it, he must either go down a shaft or boring to some considerable depths (which, strange to say, are recorded by Lyell, but no other author I know of), or else he must go, perhaps, some hundred miles away; in fact, leave the alluvium. Alluvial land is the work of "causes now in action," and so are fore-shores and glacier moraines, and moreover, all precipices or cliffs, and banks that are as steep (or nearly so) as their material would stand durably in an embankment. All these kinds of surface the present actions, volcanic and atmospheric, are adequate, between them, to produce. But these alone are they *tending* to produce anywhere, and had they continued, or were they to continue a very long time uninterrupted, perhaps even the "sixty thousand years" of "F.R.A.S.," they would reduce the whole of existing land to these forms. There would be no other dry land than—

1. Lava streams.
2. Cinder cones.
3. Alluvial flats.
4. Embankment—steep hill-sides.
5. Cliffs and peaks, or aiguilles.
6. Blown sand-hills.
7. Moraines.

Of *undulating* and gently sweeping hill and vale, which P. Santalinus must well know to constitute *a majority* of all present land surface, there would, in a certain amount of time, remain not an acre. For the causes "now in action," instead of, as the Lyellists dream, anywhere *making* this kind of surface, are everywhere *unmaking* it, and through all historic time have been *diminishing* its amount! A few experiments with clay or dry mud, or a little observation either on a sandy tidal shore, or on fresh heaps of nearly any soil, exposed to all kinds of weather, suffice to prove this.

But coming to the globe's surface, regarded as a whole, P. Santalinus will allow that all the land is divided into a certain number of valleys. On whatever spot a drop of rain may fall and run, it will reach the sea by one ordained path, so that every square foot belongs to some particular valley, and the division between valley and valley is but a mathematical line. Now valleys, in this broadest sense, constituting our whole world, are divisible first into the *floored* and *unfloored* ones. The valleys of main streams, of nearly all that have names, or that are marked on common atlas maps, are, for most of their length, floored with alluvium or flat ground, rising *lengthwise*; indeed, parallel with the river's course, but level *across* at any point, like the stage of a theatre from side to side. The width of floor may be not half a mile, or many miles, and in approaching the sea such floors widen, or else several run together, and form whole alluvial countries, as Bengal, Lombardy, Holland, or the English fens. But the minor vales, all whose streams have no names (or none on ordinary maps), and in some strata (as chalk) ramify for miles and miles without a vestige of stream, and which make up the majority of every country's area that is not *fen*. These have, for most of their length, no alluvium; they may be called *unfloored*, as the Fleet or Holborn Valley, through the heart of London, and that of Marylebone (properly Mary-bourn) crossing its West end. Now, these are to be distinguished—as, indeed, the major sort are; but I speak here of the unfloored vales, because it is only in them that the distinction becomes glaring and impossible to ignore—into those whose cross section is a wavelike curve, finely rounded off, convex beyond or above the place of steepest fall on either side, and concave between these points, and those whose section is a mere V, a furrow or ravine, with banks of equal gradient from bottom to top. These last I will call *furrow*-vales, and the former *sweep*-vales, using the word "sweep" as short for "curve of contrary flexure," for which there hardly seems any other single English term (equivalent to the French *accolade*) for the word "ogee," used in building, is so gross a perversion of *og ve* itself, already totally perverted in France (for in old French its sole meaning was "groin rib," and in modern its sole meaning is "pointed arch"), that it should be abandoned, as now, in both languages, a mere source of confusion. Observe that the uniform slope of the furrow valley nowise renders it less picturesque or varied in curvature than the sweep valley, for as the stream or bottom is never straight, the banks have no plane portions or any resemblance to a railway cutting. Each necessarily forms in *plan* a succession of sweeps or contraflexures, every protruding part being convexly conical, and every recess part of a hollow cone. The straightness, as opposed to the swelling curves of the sweep valley, belongs only to the engineer's cross section of each.



Now, it is simply impossible to form sweep valleys by any length of exposure to "causes now in action." A heap of fine clay, loam, mortar, exposed to a single shower, will be furrowed with miniature gutters, gorges, and even, in the lower parts, model floored valleys, with their alluvial flats; and if they extend to the shore of a pond, you may even see the process of *delta* forming. In one hour of thunder-showers you may see, by means of an upset waggon load of soil, the entire history of a continent acted in miniature; and study it as if the mound were the Abyssinian table-land, the chief rill the Nile, and minutes were centuries. All effects of "*atmospheric* denudation" and *alluvial* deposit will be accurately reproduced; but nothing like a *sweep* valleylet, not even of the above dimension, an inch wide; nor can any length of rain exposure begin the least tendency to such sweeps and undulating forms. On the contrary, the perpetual action is to *deepen* and *lengthen* each furrow once begun, to lengthen them backward or upward into the heart of the mound, and multiply their upper branchlets; *deepening* and *steepening* every furrowlet wherein there is no deposit of alluvium going on, but *widening* none, so that all the decaying (or non-alluvial) surface is growing ever more rugged and more furrowed, and *less* like ordinary habitable hill and vale. It may lose, indeed, bits of sheer precipice, by their wearing down, as Shakespeare's Cliff has done; but loses also, and without recovery, all gentle gradients, which are progressively steepened, by erosion from their feet, and reduced to the steepest angle the material can assume (in rainy air). The only *widening* that the weather can effect in any ravine is that which may be seen in descending the gorge below any ancient waterfall. Just below the fall the sides are vertical (if not overhanging), not having had time to be weathered back by landslips into their permanent form of banks. Thus, of the six miles of gorge made by Niagara, the upper mile, next the fall, is a walled rectangular groove; but each furlong further down, being older, has less and less cliff, more and more slope (of slipped brow above and *débris* below), till, at Queenstown, the cataract's *original* place, where it began its work (not Lyell's "30,000 years," which plenty of *his own* observed facts contradict, but, as any real inquirer will find, only *five* thousand ago), there remains no cliff, but banks as regularly gradiented as the cleverest railway work; and such they must remain (except for cutting back of more tributary furrows) if "causes now in action" go on uninterrupted for ever—no undulation, no sweep-vale, for there are no causes in action to smooth off into any such form.

All this Niagara process we may see rehearsed in one hour, any fine day, on a shore of fine sand that a rill of fresh water crosses to reach the low tide. In sand but slightly damp, it will cut itself a channel, with one or more inch or two-inch Niagaras, quickly eating their way back, from the sea or wet sand, across the damp or drying, to the dry or to high-water mark. Your two-inch Niagara leaves, at any moment, its last-cut yard or two of channel between a pair of two-inch precipices, as vertical or overhanging (for in two inches damp salt sand can even stand overhanging) as those whereby Canada and New York State frown at each other across the last mile of roaring passage that their continents' outpour has hewn itself. But a few yards nearer the sea these curious sand-steps, especially if a shower has fallen, will have become slopes, and the rill's channel (if it has swollen and shrunk again) be a model of (say) Upper Egypt, a floored valley between regular level-topped steeps, bounding the deserts on either hand; the shrunken rill winding across its wide flat floor, alternately close to the foot of one steep, and anon across to the foot of the other, as if they played shuttlecock with it, but often having minor branches, canals of Yussuf, close to both. Now, when the tide has risen and washed over all this, but not till then, it will make something like a gentle sweep-vale, like those of the Fleet, Mary-bourn, &c., that the northern half of London covers.

No causes now in action, neither Plutonic nor of Jupiter Pluvius (the only two acting on land), have any tendency to make sweep-vales, but are unmaking them. Hence Lyell has to bring in Neptune, but also in vain, as a far superior geologist, Colonel Greenwood, has repeatedly shown in editions of his work on "Rain and Rivers," only he has *not* shown that these can account for the majority of the surface. He has well explained what they *can* do, and exposed the inconsistency and muddle wherewith Lyell drags in continually both Pluto and Neptune unwarrantably and uselessly to account for things purely of Jupiter Pluvius his sole work. Moreover, Mr. Scrope has, by Lyell's own admission, excluded from central France (a most typical and immensely evidential *diluvial* region) any visit of Neptune proper, any sea overflow, sweep, or *horizontally* acting deluge, since, at least, Eocene times. The French geologists, at least, have long begun to see that chief of the enormous denudation which has moulded the present lands can *neither* have been *subaërial nor submarine;* the two between which Lyell (with his shadows) and Greenwood, his stout and seemingly now sole opponent, may fight for ever, both being equally unable to account by continuous actions for what is the work and monument of an *astronomical catastrophe.*

Observe that the more any district has had of "subaërial denudation," the less has it of undulating ground, or the most common character of surface. This common character of sweep vales is *most* developed, and most exquisitely carried out, upon deserts, or the districts having either least rain or no streams; if we may trust published surveys, in the waterless deserts bordering Egypt, or here in England on Salisbury Plain, on which it remains doubtful whether the autumn review can be held, because it is by far our most waterless district. Professor Smyth notes as unaccountable this most elaborately valleyed moulding of the African *rainless* hills; but the rule applies universally, the fewer springs the more beautifully and distinctly water-moulded the surface. On the other hand, no land historically of known age, alluvial or volcanic, or upheaved in historic time from a sea, has anything but *ravines* or *gulleys*, no vale or approach to anything like undulating ground. And the districts *most* like such new lands, or like weathered heaps of our own making, are those exposed to the greatest yearly rainfall. I will only name, as a striking case, the eastern end of Jamaica, probably also the last of any mountainous tropical island which meets the brunt of the constant trade winds and condenses their vapours, in this case of Jamaica, into two or three fathoms of rain-fall per season. Its name signified "Land of Springs." You will nowhere find, I believe, less undulating ground. For the space of a moderate English county, scarce an acre inclined at between 2° and 30°, or, in short, between alluvial flat and the steepest bank that will stand, for these two kinds of ground constitute all to the exclusion of original (*i.e., deluge-moulded*) surface. A view will have undulating *lines* or *horizons*, of course; these being the ridges or water-partings between valley and valley. But all these are as sharp as a house-ridge; too narrow even to make a foot-path, for the slopes, universally of one angle, about 35°, simply ascend from every stream or alluvial floor edge to that height in the air where they will intersect the like slope from the next other stream or flat, so that if you had a model of merely the alluvial flats and lines of stream, you could proceed to build up in clay a perfect model of all the country, and find the exact height of every square yard without seeing it!

That is simply a bit of *totally weathered* country, or the state to which weather is tending to bring all the earth, and to which the present course of things left long enough would infallibly bring every square mile—as, indeed, Colonel Greenwood has well shown. But how much of existing land is thus fully weathered? Probably not a hundredth. Now, on the remaining ninety-nine of all habitable land (except alluvium), there is literally *not one acre* whose form the Lyellian geology or "causes now in action" can account for. Every acre in our five zones, that is *not modern*, that cannot be historically traced to an origin within these fifty centuries, has been plainly *under a cataract*, which is not a cause now in action. E. L. G.

RADIUS OF SURFACE OF OBJECT-GLASS.

[4069.]—I feel I am much in Mr. Vivian's, "Orion's," and Mr. Oldfield's debt, but should like to inform them how matters are with the object-glass. I took my own made eyepiece (power 130) down to a friend's 5in. equatorial, where it defined about equal to his own. But with my own glass it does the following:—On looking at a small white paper disc on a black board, a faint bluish ray is seen on two sides of the disc, perhaps more correctly it resembles a bluish white double secondary image. With a shorter focus colour is seen at quarters of the circle. It defines the moon well with the above power—only a slight doubleness on edge. But it is with Jupiter that I have most to complain of, he darts out two elongated rays top and bottom; this destroys all belts, but his satellites are all seen unless they come too near this formidable ray. This interesting phenomena turns round with the object-glass, not with the eyepiece. I should like to ask Mr. Oldfield are any object-glasses made with one lens fast in its cell, the other slightly movable by screws across the path of its optical centre? I am doing this with mine. I am also aware of an error of about a 200th part of an inch on the edge of the flint lens. We are told by Barlow, in his "Manufactures," that this optical centre is the all-important matter; also some reflection of candle flames, seen in and through that, are impossible conditions. My own definition of a lens is a piece of glass or a disc of glass cut absolutely true off a cylinder of small material; its edge would then be equal thickness, also its centres opposite. Would Mr. Oldfield be so kind as to give us the complete recipe and method of using a cement polisher, as in his reply (11090, No. 364) it might be useful to many? He will see from this I am still lost in the blue rays.

W. H. Cash.

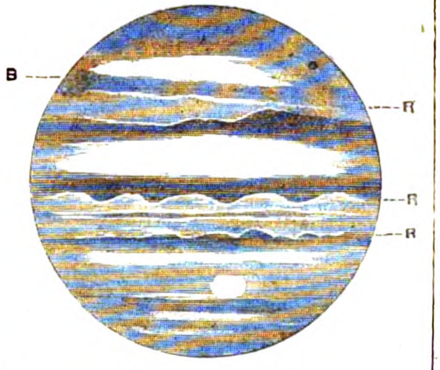
UNANSWERED QUERIES.

[4070.]—In the English Mechanic of 11th February, 1870, I asked for some information as to the working of Mr. Taylor's apparatus for screw-cutting—one of which I had just procured—and the method of cutting medallions in the lathe. Our sheet anchor, the author of "The Lathe and its Uses," has been deaf to the call, and Mr. Taylor offers but small inducement for parties at the antipodes to purchase the apparatus, as he persistently declines to explain its method of working. With reference to the medallions, I find in your issue of 16th September, 1870, that "J. L." has come to my assistance by publishing a sketch of a machine for this purpose. He has also politely sent me, by last mail, a photograph of some exquisite bits of eccentric turning, including medallions, but, unfortunately, his description is too meagre to be of any practical use. Bergeron, in the "Manuel du Tourneur," gives drawings of a machine for turning medallions—so arranged as to make the copies of the same size smaller or larger than the originals, with a description so full and minute that he who runs may read. I should feel much obliged to "J. L." if he would favour us with drawings and descriptions of his apparatus as minutely as Bergeron, or as fully and distinctly as Mr. Plant, described the geometric chuck in your pages, on 4th November, 1870. He should remember that a lathe with two mandrils is a *rara avis* with amateurs, and requires some explanation. I am inclined to think that a simpler method of turning medallions might be adopted, but I shall reserve my views on the subject till "J. L." favours us with a fuller description of his *modus operandi*. I thank him much for what he has done, but will thank him more for what he has still to accomplish. There are no secrets in art since the English Mechanic has become the medium of intercommunication with amateurs in all quarters of the globe.

John Rae.

ECLIPSES OF THE SUN AS SEEN FROM JUPITER.

[4071.]—As the eclipses of satellite 4 are of rare occurrence, I append a true sketch of the planet, and the shadow of satellite 4 at the beginning of transit, on March 14, 1872, as seen with a good 5¼in. refractor. The shadow of the satellite is given to the most prominent marking observed on the said evening, for the sake of making future observations with the same instrument. The general hues of the planet were brilliantly brought out, so as to render the observation somewhat interesting. Two large belts of ochreish colour, with a dark belt between them, were seen south of the equator, represented at R R; likewise at R, north of the equator. As the shadow was traversing the planet's disc, a some-



what remarkable occurrence took place: the large polar belt seemed to unite with the dark belt south of the bright belt at B, happening somewhat about 9.45 minutes after transit. At the end of transit of shadow of satellite 4, the bright belt (B) covered several degrees of the planet's disc, which, at the beginning of transit of shadow, was scarcely visible. Ralph Lowdon.

THE LINK-MOTION.

[4072.]—The dispute as to the originator of the link-motion is, I should think, finally laid at rest by the recent presentation of a testimonial to Mr. Howe, subscribed by 200 persons who should be intimately acquainted with the facts. The testimonial, which consisted of a gold watch and chain (the former of which was engraved with Mr. Howe's name and a representation of the link), a purse containing 200 sovereigns, and last, but not least, an illuminated address on vellum, was presented to Mr. Howe at the Angel Inn, Chesterfield. After the dinner the chairman, Mr. Smith, of the Sheepbridge Ironworks, said:—That all inventions might be considered to be divided into two parts, the idea and the method of carrying it into execution, and he did not believe that in any one patent that existed, that the idea and the working it out were not traceable to two brains. It was the case with the steam-engine; all knew very well the pretty picture of Watt as a child watching the tea-kettle, while at the very time steam-engines were already at work—rude and clumsy, no doubt, but the steam-engine was a fact before Watt was born. Still, Watt took up the idea and made it a practical success. The real practical use of the link-motion was to make use of the eccentrics of the engine to reverse the engine. No doubt that idea first struck Mr. Williams, but the way in which he attempted to carry it out would never have done, and if he had been left to it, it never would have been carried out. Here the man of genius and execution steps into the field. He says, "The idea is there, but it is of no use; the idea is a good one; can I make it of use?" He takes up the idea, but goes to the other end of it and works it out. Mr. Howe in reply, said that the matter had passed over so long that he did not expect to get any further recognition than he did when he received 20 guineas from Robert Stephenson and Co. Mr. Stephenson had come to his bench where he was working, and seemed to have some doubt whether the link-motion would turn out well or no; but he said a present would be made him, and some time afterwards he received a cheque for 20 guineas, which he put in the bank, and which formed part of the money which brought him from Newcastle to Claycross. Mr. Howe then referred to the plans which had been previously tried to meet the object of the link-motion, and remarked that the original draught he had made of his plan was on the table, as also the wooden model he had made the day after drawing the draught. He also read some letters written in 1843 upon the subject, and stated that the first accurate description of the link-motion appeared in the *Practical Mechanic* in 1846. In that year he made a design for applying the link-motion to winding engines, which he believed was the first time that was attempted, and in the latter end of that year he came to Claycross, and Mr. Binns set him to design some small winding engines for iron-stone pits. He applied the link-motion to them, and found it so successful that they had used nothing else, and he believed that there was no other gear that would meet the requirements. He then referred to the attempt of Mr. John Gray to claim the link-motion, and the trial which resulted in his defeat, and passed on to say that he thanked them heartily for the testimonial.

I think it may be said that the dispute is now satisfactorily settled: it is not claimed that Mr. Howe originated the idea, but he was the man who turned it to account, and if the honours are to be divided he certainly deserves the lion's share. Crude ideas are formed in many minds, but the master mind is that which utilises them. G. J. H.

ERRORS IN POPULAR WORKS PROFESSING TO DESCRIBE MUSICAL INSTRUMENTS.

[4073.]—I lately purchased Hiles' "Dictionary of 12,500 Musical Terms," which, certainly, is a very big shilling's-worth indeed, and would be very cheap, even at a higher price, if more nearly complete and accurate. Probably, so far as regards musical terms, accuracy is the rule of the work, and, after all, this is far more important to the musical student than any errors of commission or omission concerning instruments of "mvsick." Nevertheless, considering the writer is far from being the only person who feels an interest in the said instruments, both ancient and modern—as the present collection at South Kensington Museum, and that which is now being formed for exhibition in the forthcoming international display, testifies—he feels justified in commenting on Mr. Hiles' clever, if not quite accurate, catalogue.

About forty years ago I had the pleasure of seeing and hearing what was then alleged to be a new instrument of the double reed class, termed alto fagotto. This "faggot" of hollow sticks was shown to me by the late Mr. Bainbridge, the inventor of that pleasing instrument then so popular with the fair sex, the double flageolet. The tones of the alto fagotto, or tenor bassoon, whose compass extended, if I am not mistaken, down to tenor C, were remarkably firm and full, in my opinion quite equal to any sounds of the same pitches which it has been my good fortune to hear from its big brother even when the latter was blown by a Denman or a Baumann, and this is saying a good deal for their quality. It was, indeed, a very effective solo instrument, and put the chalumeau of the clarionet quite to shame; but I find Mr. Hiles has omitted the alto fagotto from his list, unless, indeed, it appears under the titles of Courtal, alias Dolcino, alias Tenoroon, for after all, the alto fagotto may be only the instrument formerly known by those appellations with a new name, which, *for commercial purposes*, at once converts it into a new instrument of "mvsick," just as the old harmonicon—one of the earliest of the free reed species blown by the mouth—has, by the addition of a pipe to enter our mouths, and finger keys like those of the flute, become the modern "angelophone," which musical angel, by the way, is also omitted from Mr. Hiles' catalogue.

That one of the very first words in Mr. H.'s catalogue "The Harmonious Blacksmith" would look at should be harpsichord need not "very much surprise" those of his friends who remember he formerly possessed no less than three examples of that old-fashioned instrument, for which be yet has an old man's old-fashioned fancy. Mr. Hiles' description of this ancient predecessor of the pianoforte is singularly inaccurate. He says, "it had sometimes two rows of keys, the sound (qy., its sounds) were produced by a plectrum (qy., by plectra), a statement about as accurate as saying the sounds of the pianoforte are produced by hammers instead of by its strings and soundboard when its hammers cause them to vibrate. He adds, "the keys were sensitive to the slightest touch, which is true enough if *waste* touch is meant, and, what is not true, that however lightly the key was put down, it—query the key—produced a sound whose intensity could be varied only by moving—query the sound on the performer's hands—from one set of keys to the other, or by moving certain "stops," whatever the word stop may mean as applied to a harpsichord. Mr. Hiles adds, "the single harpsichord had two unisons—I presume he means two unisonous strings—and the double harpsichord two unisons and an octave (string).

From what I have quoted, it may be inferred the touch of the harpsichord was remarkably light, but the very contrary is the fact. The only workman I ever knew who was what would now be termed a harpsichord finisher, assured me he was accustomed to regulate quill plectra until, for a drawing-room instrument with light touch, an old-fashioned copper penny piece weighing an ounce would just cause each plectrum to pass the string. More powerful instruments were regulated to what he called three "'arfpence and tuppence," the "tuppenny" touch being the limit of weight in harpsichords for domestic use, but his beau-ideal of a concert harpsichord was the one that perished in the fire which consumed old Covent-Garden Theatre, all the plectra of which he regulated to three original George the Third penny pieces. Now, when it is considered that an ordinary harpsichord, with two unisons and an octave string, has three plectra which have to be raised simultaneously, I think it probable Monsieur the conductor at old Covent Garden found three times three ounces—in other words, a nine ounces' touch—tolerably, or rather intolerably, heavy, and it must have convinced him that his occupation was no sinecure. The heaviest touches in modern pianos very rarely exceed three ounces (one third of this); and the touches of many modern German grands, are only from two to two and a quarter ounces. The latter exceeds the weight of most pianos made during the last century, so it is not much to be wondered at that the writer—when a good little boy, which, alas, is some few years ago—was told by a rather old-fashioned teacher he ought not to play on the piano because its keys descended so easily that it would certainly spoil his touch for the harpsichord and organ. *Cæteris paribus*, the loudness of a harpsichord or piano will be in proportion to its weight of touch; so we need not be very much surprised that Fanny Burney agreed with old Kirkman in thinking the pianoforte of their time was but a very poor affair, and not to be compared with the harpsichord for a concert instrument, although its weak sounds were rather pleasing for the performance of mere chamber music. "I rayther guess" things have changed" pretty considerable" since lively Fanny's time, both in music and literature. "Evelina" would be voted very slow indeed compared with Miss Braddon, not to mention "Ouida."

Mr. Hiles' statement that a single harpsichord had but two unisonous strings is simply a mistake. No doubt some of the very earliest examples had but two, and perhaps not much, if any, greater compass than four octaves. They were, indeed, little else than double virginals or spinets; but the compass was extended to nearly five octaves about two centuries ago. Not to mention the productions of the Rucker family, a fine example of which is in the possession of Mr. Hullah, and was used by him in his illustrations to the Cantor lectures, reported in the ENGLISH MECHANIC about three years ago, I may remark the only single harpsichord ever in my possession, dated 1774—viz., the one formerly the property of Madam Catalini—had the super-octave string and four rows of jacks, including the lute "stop." Nay, John Harris, in A.D. 1730, patented "a newly-invented harpsichord which might be performed on either one or two unisons, or two unisons and one octave together; or the 'forte' and pianos, or loud and soft; and the contrary may be executed quick as thought, and also double basses by touching single keys." My celestina harpsichord has two ranks of keys; it is dated 1778, and has, of course, the super-octave string; but, like the single harpsichord, it has but sixty keys. Probably our ancestors, in their remarkable wisdom, considered it impossible to distinguish a semitone whose pitch was between FF and GG. My modern harpsichord, dated 1790, the most modern I ever saw, excepting that in the possession of Mr. Chas. Salaman, has the F sharp between those notes, and a beautifully made Venetian swell. The weight of its touch was at one time 10oz.; but had it possessed another string sounding the sub-octave, I suppose its tone would not have satisfied me until its touch had been increased to from 12oz. to 15oz., when all four strings were plucked simultaneously. Capital practice for strengthening the fingers.

I have read that Handel possessed a large harpsichord with not only two unisonous, but also with super and sub-octave strings, thereby extending its compass to seven octaves. Probably the "large" one he devised to his friend. The "Rucker" in South Kensington Museum, contributed by Messrs. Broadwood, has but three strings, consequently, if it ever was Handel's property, which seems very doubtful, it can hardly be the "large" harpsichord be devised to his friend. Probably this, like most of its contemporaries, has perished, and many remaining examples of ancient musical instruments will perish also unless *conservative* principles (in relation to them) become more prevalent.

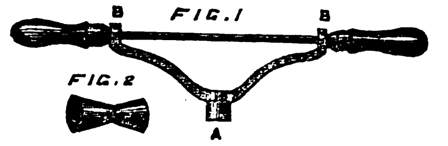
THE HARMONIOUS BLACKSMITH.

THE PIANO-QUATOR OR TETRACHORD.

[4074.]—HAS "The Harmonious Blacksmith" seen the piano-quator, and heard it properly played? if not there is a treat in store for him. This instrument, under a new, but to my mind an ugly name, tetrachord, can be seen at Stead's, in Piccadilly; I forget the number. Referring to the harmonicon, the finest instrument or instruments of this kind I ever heard, were performed upon by the brothers (3) Richardson, who were giving concerts here and in the provinces some years since, and termed by them the "Rock and Steel Band." I well remember the effect it had upon me the first time I attended their concerts. From memory, I consider the frame of this instrument was about 25ft. feet long, on which were laid roughly cut pieces of rock, similar in appearance to the stone used by mowers to sharpen their scythes with. These brothers performed at the same time (each occupying his proper portion in the scale of compass of the instrument), by means of small wooden mallets, one in each hand; in fact, the middle occupant had a double-headed one. With astonishing facility, expression, and point they rattled out the overture to "Zampa," Schuloff's "Carnival of Venice," Jullien's "British Army Quadrille," &c.; even the drum was well imitated. The steel portion of this instrument was on the same principle as the harmonicons now made, but much longer, and wider in scale. I should think the CC note was quite 4ft. long. DISC.

SIMPLE WAY OF FITTING BICYCLE HANDLE.

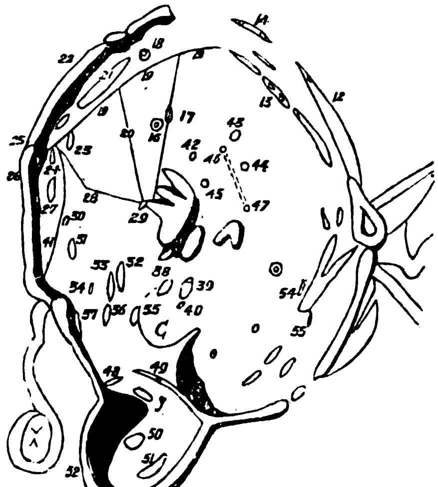
[4075.]—As the time for bicycle-riding is again coming on, I wish to place before the readers of the ENGLISH MECHANIC a simple, easy, and efficient method of fitting their bicycle handles, which will keep them tight, and prevent them making a noise. Make, or get made, the iron handle A, leaving two round bosses at BB, through which drill two ⅜in. holes. Procure a piece of good ⅜in. round iron, and draw out a tang on each end on which to fix your timber handles, which you can best do by boring a hole right through handle, and letting iron tang through it, and secure at



end with a thin brass or iron nut, which can be filed to shape of handle when finishing. Screw about an inch near each end of ⅜in. iron rod, where it runs through the two bosses BB, with the gas thread for ⅜in. iron pipe, and get a ⅜in. iron pipe socket. Fix in lathe, and turn two cones as in Fig. 2, cut them off, and having first coned or rimed out the holes BB, place in your ⅜in. rod, and screw up the two cones on the outside so as to compress or spring in the handle slightly, and let the cones fit rather tight on the spindle. Fix on your handles and finish off. You will find you will have a tight, well-fitting handle, and one which will not annoy you with that shaking, rickety noise so common in bicycle handles. FRANCIS J. B.

GASSENDI.

[4076.]—IN the ENGLISH MECHANIC for January 26, p. 487, you kindly inserted one of my sketches of Gassendi, with a description of markings situated chiefly on the eastern portion of the floor, while the west was covered with shadow. I now send you another sketch of the same crater, with a description of details contained chiefly on the western portion of the floor, so that these two sketches will complete each other as far as they go. To prevent crowding, and also to lighten, as far as possible, the work of your engraver, I have not lettered or numbered those markings which have received a designation in my sketch of January 26. I beg, therefore, the reader to refer to the description there given for objects not described now.



I observed Gassendi on April 19, 1872, from 8h. to 12h. p.m. The air was rather good, especially about midnight. At times—far too short, indeed—the whole of the floor seemed as if covered with gravel, so numerous were the markings. Had this lasted, it would have been impossible to give a sketch or a description of them, on account of the superabundance of markings. It reminded me of that fine region situated S.W. of the wedge-shaped valley, only the markings were the miniature of these. 16 is Schröter's N. crater. 17 is a cleft emerging from behind digit *a* (see sketch of January 26). It directs its course due S., passing at a short distance E. of crater 16. Just S. of this crater, where No. 17 stands, the cleft seems to be enlarged. This is the marking I spoke of in my letter of Jan. 26. The cleft 17 meets cleft 19 where it ends. 18 is the S. crater of Schröter. 19 is a cleft emerging from the shadow of the west rampart just now. Its general direction is S.S.E., forming a very obtuse angle near crater 18. It runs along the N.E. foot of mountain 22 and ridge 21. From the point where cleft 17 meets cleft 19 to the end I have seen other branches on March 2, 1871, but none of them were visible on this occasion. 20 is a cleft emerging from mound 29 just west of digit *a*, and, with a direction S.S.W., meets cleft 19 where it ends. 21 is a ridge between cleft 19 and the S.W. rampart. 22, a mound N.W. of 21. 23, a mound near the junction of clefts 19 and 28. 24, a mound near the emerging point of cleft 19. 25, a peak just shining out of the shadow of the W. rampart. So is also 26. 27, a mound situated on a high ground, round the foot of which runs cleft 41. 28 is a cleft branching (I think) from cleft 19 between the two mounds 23 and 24. It turns slightly towards the east, then towards the north-east, until it reaches a point west of 28. Then it runs in a straight direction towards peak 29. 41 is another cleft emerging from nearly the same point as 28 (I think). Its general direction is N., with a gentle curve, and ends in the shadow of the W. rampart. Among other clefts, Schmidt gives 17, 19, 20, and 28; but 41 does not seem to be the same as his 7, which I did not see on this occasion, though, I believe, I saw it on Sept. 20, 1870, and shown in that bad sketch of mine. 30 is a very small hillock east of cleft 41. 31, a mound also east of cleft 41. 32 to 39 are mounds of various forms and sizes. Among these, 35, 38, and 39 seem to form the west and south rim of ring G. Mound 39 has a minute hillock on its south end. 40 is a minute peak within ring G. 42, 43, 44, and 45 seem to be Phillip's four mounds. If so, there are two others in this neighbourhood (46 and 47), connected between them by a very low ridge, more visible as a streak of light than for its height. 48, within the opening of the "Spoon," a mound. 49, on the south border of the "Spoon," is a bright peak. 50, the central peak, and 51 a short ridge in the "Spoon." 52 and 53 show a double ridge on the N.W. border of the "Spoon." Towards the end of the S.E. border of Gassendi 12 there is a bright peak; two others are found at 14, and three on the interior ridge near 13. 54 and 55, two mounds.

Has it been observed that digit *b*, or the middle one of the central mountain, is much brighter than the two others? On one occasion, not very long ago, I found it as bright as crater 16 and mountain γ of Beer and Mädler, though smaller.

BROWNING'S MOUNTAIN, between Aristarchus and Herodotus.—This object is shewn as a crater in my sketch in the ENGLISH MECHANIC of May 12, 1871, p. 180. I have again and again looked at this object, when opportunities have offered, with the view of correcting my sketch in case I found it to be wrong; but I have never yet felt really convinced this object is not a crater.

During my present observation, after I had finished with Gassendi, I turned my telescope on Aristarchus. The streak of light west of Herodotus was, at that moment, the terminator here. Its shape was well defined. It forms a portion of the S.W. border of Herodotus, is thick on the top, and the west slope is nearly perpendicular. Is it not possible that the angle this surface presents to the rays of the rising sun might account in part for its early brightness? The T-shaped valley shown in my sketch was seen almost in perfection. The right-hand side horizontal branch was running right through the rampart into Herodotus, while the opposite side extended as far as the foot of the exterior eastern slope of Aristarchus. These objects, however, arrested my attention only for an instant, and I carefully examined Browning's Mountain. At once I said: If this is a mountain it is double. In fact, I saw two bright peaks close one to the other, with a black space between them. While considering this, it came to my mind that this object was looking very much as a craterlet in very early illumination; the west point of light answering to the western outside slope, while the east point of light represented the eastern interior slope, with the dark shadow of the western ridge between them. I ended my observation with the impression that my sketch is true. I do not write this, however, to defend my sketch, but rather to ask observers to examine this object, because, when I think of the far superior experience of Mr. Browning, and also of the larger aperture he observes with, notwithstanding all I have seen, I feel rather doubtful of the truthfulness of my sketch of May 12, 1871.

Jumet-Hainaut, Belgium, C. GAUDIBERT.
April 24, 1872.

COLLIERY EXPLOSIONS AND THEIR PREVENTION.

[4077.]—I HAVE just noticed that "King Coal" (let. 3994, p. 124, No. 369 of the ENGLISH MECHANIC) makes this remark: "If 'Arley Mine' is acquainted with any method whereby the large 'goaf' of a colliery can have the gas always removed and made safe, he will be conferring a benefit to humanity by explaining it, because (as I said before) this has been the great problem hitherto unsolved by mining engineers."

I beg to inform "King Coal," "Arley Mine," or whomsoever it may concern, that I have recommended the following plan for rendering "goaves" less dangerous, in a prize-essay sent into Lancashire two or three months back.

"Goaves," and all disused places which cannot be conveniently ventilated, should be firmly built up with bricks and mortar; but there should be an opening at the top (or roof), connected by a wooden or metal tube or conductor, open at each end, with the main or some other sufficient air-course, with the open outlet pointing in the direction of the "up-cast" shaft, and entering such air-course near the roof. In a favourable state of the atmosphere, it is probable no gas would issue from this tube; it would be condensed and driven back by the atmospheric pressure; but when the barometric pressure is low, the gas would expand and deliver itself quietly in the very place where it should be—viz., near the roof, and in the rapid air-course, whence it would be swept out of the workings. If this air had to pass over a furnace (I advocate the fan in preference), it would be advisable to make a cavity in the roof where the gas is delivered, and at dangerous times set a powerful jet of water (this has reference to a plan I proposed more than thirty years ago, to bring down the carburetted hydrogen in solution, by means of jets of pure water) from a tripod to play continually upon it. This would absorb the greater part of the gas, and take it to the "sump" to be lifted harmlessly to the surface. WILLIAM PEARSON.

Brampton, West Melton, Rotherham.

[4078.]—THE prevention of explosions is, I fear, impossible; a great diminution both in their frequency and in their fatality is quite within our reach if we render it much more costly for mine-owners to enforce than to neglect the precautions necessary for comparative safety. The proposed Mines Inspection Amendment Act will, if passed, do this in part by rendering all coal-owners and managers of mines liable to penalty when it is proved that certain precautions directed by the Act to be observed have been neglected, unless such owners or managers prove that they have adopted all reasonable means for enforcing their observance. I think the law should go a step further, and render the owners who have neglected, or allowed to be neglected, any precautions directed by law to be observed, liable to pay limited compensation to those who may be injured, who could not have been injured if such precautions had not been neglected; and I contend that such liability would be beneficial not only, though chiefly, to pitmen so injured and to their families, but also to all mine-owners who carefully observe the precautions upon which their pitmen's safety depends.

"King Coal" (letter 3994, p. 124) very fairly asks me if I know of cases in which injuries done to the paid servants of a company have been compensated. I do not, and it is, I think, a grievous hardship that paid servants are not entitled to compensation; but that is not the precise present question, though closely connected with it. There are stronger reasons why servants injured by the neglect of a specific precaution their employer is by special law directed to observe, and which is well known to be essential to safety (such as the sufficient ventilation of a fiery mine), should be sheltered from destitution than for securing compensation to all servants for injury arising from all causes, some wholly unexpected and unforeseen. I contend that whosoever by his act or neglect injures another, or allows him to be injured, should, unless he can show he has taken all reasonable precaution to prevent such injury, be liable to pay compensation to the person injured, whether he be his paid servant or not; but that *à fortiori* should he be so liable if the cause of injury be that which the employer alone can control (*e.g.*, the ventilation of a mine), and one which it is his express duty to control.

If the coal proprietor mentioned by "King Coal" at p. 124 had been liable to compensate men injured in consequence of his mine being badly ventilated, he dare not have let them run the risk he did.

PHILO.

EARWIG IN EAR.

[4079.]—Two queries which I have answered relating to stings and needles in the body bring to my recollection another annoyance which possibly may have occurred to some one of your numerous readers, but it is likely will be considered by many of them as mythic. I allude to an earwig entering the ear. I know of one instance, besides, which drove the sufferer into a half-frantic state; but having myself experienced a similar visit, may say that it is a most unpleasant situation, the sensation being that of iron claws scratching your inmost nerves. Now, as it is likely none of your readers would wish to await a reply on the subject while such a tenant was in residence, I will answer the query what to do in anticipation (*i.e.*, if you will permit me to bring tobacco-smoking again into your pages). Charge a pipe with strong tobacco (never mind the nicotine), get up a good light, then apply the mouthpiece to the ear, and blow through the bowl. There will, of course, be a good smoker wanting to assist in this performance, who may be considered active, but the passive will be transferred from yourself to the earwig. It may be asked what became of the earwig. I can only say that he was dead in a moment, and dropped out of the ear unexpectedly some months after, enveloped in a shroud of wax. I felt nothing of him after his decease.

SUFFOLK AMATEUR.

CO-OPERATIVE SOCIETIES.

[4080.]—HAVING given "F. C. S." a perfectly straightforward, definite, and practical solution for the problem that he says has baffled him, and a solution which, tried or not, differs from him and his "society," let me remind him, in having *never failed*, I should not be led away into the paths (tried or untried) of contemptuous, knowledge-scorning, social nescience, and pride of ignorance, nor think another line called for, save to correct "Loach" (let. 4030, p. 149), who fears that, whether any society pay a steward or secretary in the way I defined (p. 666), or keep the elaborate ledger of "Philo," the result will, "in a pecuniary point of view, be equally unsatisfactory." Now, he might surely discard such fear if he had merely read *how* my secretary" was to be paid—namely, not at all *until unless* their pecuniary results (or those of any member paying him) *are* satisfactory. His pay is together contingent on such results—to follow (not precede) them—and be exactly proportional to them, and this in each man's case individually, so that, for the very same year's or quarter's work, some members may owe him much and others nothing. A secretary paid anything before the store has "succeeded"—*i.e.*, before any members have made ascertainable saving, would not be "E. L. G.'s" "secretary" (steward is the term I prefer); so that "Loach's" fear involves a contradiction in terms.

Being thus obliged to add this, I may add that of course the storekeeper must (as "Loach" says) make good the "unknown quantity" or "leakage" of "F. C. S." (p. 148). It is simply ridiculous to talk of a keeper not undertaking the whole responsibility of this, and considering it in his bargain whether paid by salary or fees. Who else can possibly share it?

As for "E. L. G.'s" "check-system," I never professed to suggest any new one, having heard no complaints of the ordinary tin checks, but merely alluded to them as well known. The absurd payment of shopmen by mere time salaries *must* give way to uniform fees per parcel; but I never proposed it should do so at once. The best practical plan might probably be to bargain with every shopman on this understanding: that his full salary lasts but the first half year. At the end thereof, competitive tenders to be invited from him and others that have similarly served, to find the lowest fee per parcel that one will contract to take with three-fourths of this salary. Then, after a year, another tendering to determine what fee will suffice with half the original salary. Six months later, a similar tendering for the increased fee to go with only one-fourth of the first salary; and at length you would stop this, and begin to pay by fees alone, which is the ultimate goal.

The eleemosynary element, any help unpaid for, is the fatal leprosy that will poison with its touch, we must fear, every English working-class effort. The particular store that has occasioned this discussion is truly most unlucky, and its members to be pitied. I can only hope some or one of them may read the ENGLISH MECHANIC for himself, and if any such will refer to "Philo's" letter (No. 3166, Vol. XIV.), and (comparing it with whatever it attacks, as let. 3044) just bear in mind that one is, in their secretary's view, chimerical and "pernicious" (p. 149), and the other "an admirable letter," their main obstacle to satisfactory results will not be difficult to recognise.

E. L. G.

HONEYDEW.

[4081.]—HAVING in a previous number written upon this subject, I may, perhaps, be permitted to add a few remarks. In the first place I think it a great mistake to mix up what we call in this country honeydew with productions like the gums, sugar grains, and, above all, manna. In the course of the summer many of us will doubtless look out for honeydew, and I venture to predict that whether on limes, beans, hops, or roses, they will never find any on the upper surface of the leaves which are not overhung by others, and further, that if they pay attention they will see the aphides discharging little globules of viscid and transparent fluid for which the ants patiently wait, patting the backs of the aphides with their antennæ one after the other, as if to feel the state of the aphides. When there are no ants this sweetstuff falls on the leaves or ground below. Officinal manna is supposed to be an exudation, not an animal excretion, and the result of a puncture. I do not say it is impossible for it to exude naturally, for on my vine-buds I have noticed large crystals of sugar. The aphides do not feed on honeydew, if only for the reason that they protrude a sucking tube into the parenchyma.

M. PARIS.

PRESERVING AUSTRALIAN MEAT.

[4082.]—I HAVE intended for some time past to send you an account of the whole process, but cannot at present find it. In the first place what is called a 4lb. tin weighs gross 5lb. and more, the overweight depending more upon the weight of the tin than anything else, so that a 4lb. tin contains 4lb. and a 6lb. tin contains 6lb., and all sizes generally a few ounces more, of cooked meat (in most cases without bone), and some fat and a little jelly. That is my experience, and I have turned out some scores of tins. As regards preparation: Each tin has put into it a certain quantity of meat, then the lid is soldered on, a hole being first made in the centre. The tins are then placed in a bath of strong solution of chloride of calcium up to about two-thirds of their height. This bath is then heated to its boiling point, which is many degrees higher than that of boiling water. When all the steam and air have been expelled from the tin through the hole in the lid, a drop of melted solder is dropped over the hole, which is thus hermetically sealed, and the tin rendered perfectly airtight, the small strip of tin soldered under the lid catching any drop of solder which falls through the hole, and preventing it from mixing with the meat. The only fault I find with the meat is, its being somewhat overcooked, owing, I myself believe, to the heat inside the tins, during the progress of cooking, being too great. Improved processes are, however, being adopted. Each case, on being landed at the quay, is opened, and any tin found with convex ends is put on one side as unfit for sale, and the contents used for manure. The convexity or bulging out of the ends of the tin shows that the meat, owing to some fault in the process, has decomposed, and formed a quantity of gaseous matter in the tin. J. L.

P.S.—The cost of "tinning" the meat has been 3d. per pound on the 2lb. tins, and of course less on the larger sizes.

VERDE ANTICO.

[4083.]—I HAVE wondered whether my apparently simple queries as to verde antico and working in gold and silver would ever be answered. At length "Proven" (let. 3978) has noticed my communication, although not affording any direct information as to the oxydizing of the bronze.

I can only repeat that I have seen frescoes on the walls of Pompeii representing female figures with brooches and bracelets of a *green* colour, and I recollect in one of the recently excavated dining-halls in the palace of the Cæsars at Rome a fresco of a male athlete, wearing a snake bracelet, the colour of which is most decided, and as fresh as when first painted. It evidently represents bronze, and, had the original not been coloured with verde antico, would certainly not have been painted green. Besides this, many of the most exquisite bronzes in the Museo Borbonico at Naples were found, not in the earth, but in urns, hermetically sealed by the Vesuvian ashes and mud, so that the only air that could have acted upon them was that contained in the urn during 2000 years.

Would there be no way of so oxydising the mass of bronze before casting as to produce a green homogeneous metal which would take a fine polish?

"Proven" wishes to know how I work. I generally make my first models of the antique objects in lead—wire and plate, riveting when necessary—so as to be pretty sure, by a comparison of the specific gravity of the article, how much silver or gold I shall require to work up. My silver I have hitherto got from the Mint in ingots ready alloyed, 13 fine, but I would much rather make it myself from the fine metal. The gold I buy fine, of course, and indeed all the gold articles I have made were copied from fine originals. Some were so large and costly that I reduced them in copying—but it is impossible to produce any very elaborate work in soft fine gold, and the antique are more remarkable for their wild and original design than for the beauty of their execution.

The twisted snake bracelet is an easy and satisfactory ornament, the fine gold wire—about No 8 or 7—being drawn from the middle through decreasing holes in the plate so as to taper it away to nothing at each end. Three of these are then twisted into a cable, and a rough snake's head and tail beaten out of their ends on the anvil. The bracelet should be about ten inches long at least, to go once and a half times round a lady's wrist. It is perfectly pliable, and can never break, and if nicely made looks exceedingly savage and handsome.

I should very much like "Proven" to recommend me a tolerably exhaustive treatise on working the noble metals, as I really know very little about the art, but just try and imitate as well as I can what I see—much, I suppose, in the rough-and-ready way adopted by the ancients.

I would repeat the queries as to alloys and the composition of bronzes which I asked in my last (p. 560, Vol. XIV.).

If "Proven" will try and work in a pair of old long white gloves, already used for balls and parties, previously, however, tightening the first button on the wrist to make them fit close, she will not have to complain of her hands. When working at a furnace, or forging a large piece of metal, she will, of course, wear a thick pair of gauntlets.

Has "Proven" had any experience in the use of the spirit blowpipe recommended by "H. B. E." in 3999? I learnt soldering at Rome, from one of the principal goldsmiths who excel in that branch, but it is most difficult to use the blowflame like a pencil, as is done by those artists in fixing minute pieces to large ones.

The solder used by the Roman jewellers for their best work is as follows: 2 parts silver, 1 part copper; 1 part of this to 2 parts fine gold. Flux: borax and water. This solder suits 18 carat gold. To solder fine gold, use 18 carat gold and the same flux, but the heat required is much greater. Clean from borax by boiling a few minutes in sulphuric acid and water, equal parts.

"I do hope "Proven" will help me, as a sister interested in the same delightful work.

Stockholm, April 23. ETHEL.

INFLUENCE OF COLD ON VEGETABLE GRAINS.

[4084.]—THE explanations of "A. B. M.," for which I thank him, do not make this matter much clearer, and I can only reiterate the opinion that the conclusions of M. Duclaux are erroneous. The facts are merely these: Seeds of certain plants are exposed to cold, and because these germinated when seeds of the same kind preserved from the influence of cold did not, M. Duclaux thinks that exposure to a low temperature has an influence on the germinating powers of the seeds. On the contrary, I contend that there is something radically wrong in the experiments. Ripened and selected seeds certainly do not require seventy-six days to germinate when submitted to the requisite temperature (as those under discussion were); this fact is patent to all who have had any experience in the matter, and the wonder really is that any of M. Duclaux's seeds germinated at all. I presume the method of sowing was exactly similar in all respects, so that all I can conclude is that they were allowed to dry after swelling, the surface mould became caked, or some of the seeds were sown too deep, and so failed to germinate. What would be thought of a gardener who only raised eight out of eighteen thoroughly good seeds in one case, and only two out of thirty-six in another? Certainly further experiments must be made before anything reliable will be obtained.

I hope "L. C. E." will speedily make the amende honorable for his unfortunate letter, for he must now see that scientific experiments and researches, even those from which erroneous conclusions are drawn, are, by their very nature, of value; for the facts remain, while the errors of one explorer are but lighthouses to direct the steps of future discoverers. No one has said much for the microscope; but how "L. C. E." can say that that instrument has done little or nothing for science and humanity passes my comprehension.

SAUL RYMEA.

CASTINGS.

[4065.]—IN casting by the *forma perduta* method the mould is made of "due mattone, uno gesso," *i.e.*, two brickdust, one plaster of Paris, made into a thick cream, which is allowed to dry, and the wax is then melted out. This composition will not, of course, bake into a brick, and when heated enough to melt the wax out it becomes exceedingly friable, and must be handled with the utmost tenderness. My other occupations have prevented me testing this mixture personally, but, as I mentioned before, it is used in Italy, though the "Tripoli" is doubtless preferable. But if "Faber" is addicted to this kind of thing, he can make mixtures for himself, bearing in mind that crucibles are made of either fire-clay and sand, or plumbago and clay, and a little practice will soon obtain him a perfect non-porous mould. As to the wax, the red wax sold in Long-acre by artists' colourmen as "modelling wax" is, of course, the right kind to model with, but, unluckily, it is mixed with things which will not run out clean when the mould is heated, and though blowing through it and pouring quicksilver in and out are practised, I find nothing but wax comes thoroughly away. But it requires skill to model in beeswax alone, as it is too sticky, and it must, indeed, be remembered that skill in modelling is specially called for in this mode of casting. If you don't finish very fine and get a sharp cast, you must put it into the hands of a chaser, in which case it is better to have your work cast in sand. But then your metal casting will be finished by some one else than the original artist, which is, in fact, the objection.

PROVEN.

USEFUL AND SCIENTIFIC NOTES.

The Metrical System in Austria.—The law rendering the metrical system compulsory in Austria and Hungary has just been promulgated. The standard metre is a glass rod, which has a length of 999·99761 millims, at the temperature of melting ice. The standard kilogramme is a crystal glass cube, the weight of which in vacuo is equal to 999·9978 milligrms. (both standards having been made according to the great platinum standards at Paris). The new system is to be in full compulsory force from Jan. 1, 1876, but in all official works the new system will be required to be adhered to on and after Jan. 1 next.

Prehistoric Races.—The United States exploring party in Colorado have discovered many ruins of the communal houses once occupied by the prehistoric people of that country. Several of these houses stood upon the cliffs overhanging the canons, and many others were found in valleys amongst the mountains to the west. Stone implements, pottery, basket-ware, and other articles were found buried in some of the ruins. A tribe of Utes were found on the Kaibab plateau who still make stone implements, and Major Powell, the leader of the expedition, had an opportunity of witnessing the manufacture.

Dyes for Leather.—According to Herr Springmuhl picric acid gives a good yellow without any mordant; but it must be used in very dilute solution, and not warmer than 70° Fahr., so as not to penetrate the leather. Aniline blue changes this colour to a fine green. In dyeing the leather, the temperature of 85° Fahr. must never be exceeded. Aniline green is well adapted for dyeing leather, and its application is quite simple, a concentrated aqueous solution being employed. The leather is brushed off with a solution of sulphate of ammonia in water, and the dye solution applied at 95° Fahr. Care must be taken, however, by rapid manipulation, to prevent the dye from penetrating through the leather. By the addition of picric acid, the bluish shade of this dye stuff is modified to leaf green, and it becomes faster; but the picric acid must not be added to the colour solution; it must be applied to the leather before or after the dying with aniline green.

The Velocity of Wheels and Shafts.—Professor A. E. Dolbear suggests a simple and effective method of determining the velocity of rotation of wheels and shafts. Upon the face or upon the periphery of the rotating objects he fastens smoked paper, and this he touches with the point of rubber which is attached to one branch of a vibrating tuning fork, having a known rate of vibration; the fork is to be so held that the direction of its vibrations will be at right angles to the line of motion of the shaft. By counting the number of undulations made on a given extent of the smoked paper the speed of rotation is at once indicated. Thus if the fork makes 100 vibrations in a second, and one vibration is recorded on the smoked paper in a space covering one half the circumference of the wheel or shaft, or two vibrations within the entire circumference, it is evident that the rate of rotation is fifty revolutions per second. By this simple and easy method the velocity of rotation of gyroscope discs and of all kinds of shafts and wheels may be readily ascertained.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[10414.]—**Retrievers.**—I am sorry to differ from "Hedera" in his advice upon training retrievers, but, as an old sportsman, and a very successful breaker of dogs, I should say by no means let a young dog, that is intended for retrieving game, play with or carry a stick. Teach him to fetch a soft ball or glove, and if he shows any disposition to be hard mouthed, cover the ball with a hedgehog's skin, and again with the skin of a rabbit or bird. A tender mouth is most essential for a retriever. I had one that would carry hens' eggs.—MOUNTAINEER.

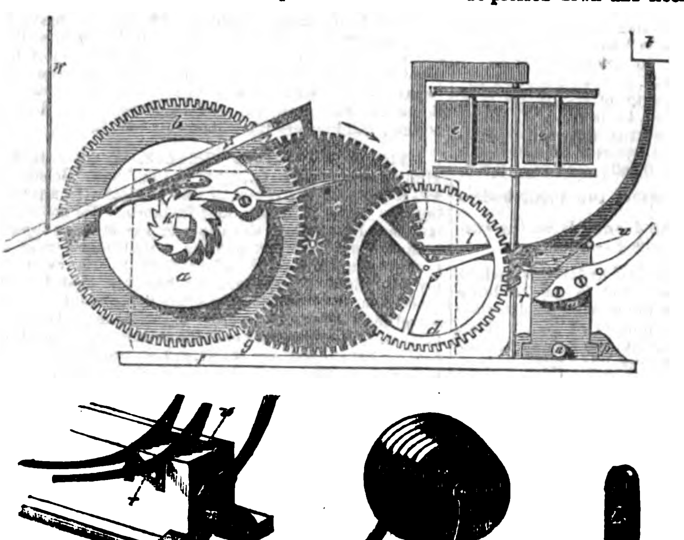
[10617.]—**Watchmaking and Isochronism** (U.Q.).—The reply of "Anglo-America" on this subject is meaningless nonsense. Isochronism as applied to horology, means unequal vibrations in equal times.—WEST CORNWALL.

[10954.]—**Circulation of the Blood.**—I do not doubt that "F. R. C. S." is a very good teacher of anatomy and physiology, for many high authorities in those sciences hold the same opinion that what is called the suction power in the chest favours the return of blood to the heart; but some are of the contrary opinion, and it is a question rather of hydraulics than of physiology. No doubt if an opening were made into the chest, air would be forced in by the excess of atmospheric pressure, and so also would blood, by the same excess of pressure, be forced from the rest of the body into the chest, were it conveyed in rigid tubes; but the veins are very flexible, and become quite flat when not distended with blood, just as the hose-pipe of a fire-engine does when the m-n stop pumping. No pressure on a flexible hose-pipe can possibly increase, and if it be in excess of the pressure of the pump it must diminish, the flow in the hose-pipe; if there is to be any suction whatever the pipe must be rigid enough to resist the excess of external pressure, or the pipe will be flattened just as veins are when the flow of blood into them is checked from behind, an experiment which any one may try by tying a bandage round his arm, when the superficial veins below the bandage will become full, and those above it empty, just as a soft hose pipe when trod upon will become fuller between the pump and the foot, and empty beyond it.—PHILO.

[11008.]—**Tilt Hammer** (U.Q.).—Mr. Fennell has entirely misunderstood the action of the tilt hammer used in the manufacture of steel, &c. In the machine engraved, the hammer would be lowered as gently as it rose, and the effect would be little beyond that due to its dead weight. The fulcrum or fixed axle of a tilt hammer is generally near the tail end, which is raised by the action of a wheel having two or more large teeth, which depress the tail as they revolve, and permit the hammer to escape suddenly and fall by its own weight as many times during each revolution as there are teeth on the wheel.—A BARRISTER.

[11008.]—**Tilt Hammer** (U. Q.).—If Mr. Fennell will look his sketch over on p. 128, I think he will agree with me that the hammer would not work with the eccentric motion as shown—first, because the hammer would not reach the anvil, because the eccentric has too great a diameter; and second, the hammer would not drop sudden enough, it would follow the circumference of the eccentric all through the revolution, and consequently fall as gently as it rose. There are several kinds of motion that might be used, but I should say use the cam with two, three, or four tappits on, to suit the number of blows you require of the hammer for one revolution of the shaft; shape of tappets more this style .—GOUX.

[11031.]—**Model of Church.**—Herewith drawings of mechanism to play wedding chimes and two tunes on eight bells every time a penny is dropped into the model. The bed of the machine is a brass plate *f*, having another plate *g* fixed perpendicularly to one edge of it. This latter supports the arbors of the wheels and barrel at one end, their other ends being supported by separate standards *h*, screwed on plate *f*. Plate *g* is drawn with dotted outline to shew *a*, the barrel containing spring, on which driving wheel *b* is fixed. The ratchet and pawl, *k* and *i*, and end of driving-wheel arbor, squared for winding, are outside of plate *g*. The wheel *b* drives the barrel, a long brass cylinder, to one end of which is affixed the wheel *c*, driving-wheel and pinion *d*, and fly-wheel *e*, by means of an elongated screw on the shaft. The wings, *e e*, of the fly are made to turn stiffly on their axes, so that the rate of speed may be adjusted. The hammers and bells are fixed to a movable brass block *m* (shown separately below) which slides by means of the rod *n* (which must be carried outside the model), so as to bring the hammer-tails against different rows of pins, and change the tunes. The hammer-rods *l*, bearing hammers *t*, are hinged in slits in the block *m*, at distances of one-third of an inch, having springs *r* to make the strokes, and a stop, *u*, to make them rebound after striking. The hammer-tails must be so adjusted as to be pressed down and liberated by the pins on the revolving barrel. The bells must be placed close together without touching each other on a rod fixed to the bars, *o o*, fixed at each end of the block *m*. If clock bells are not used it would be well to drill the bell handles, and carry out this arrangement as far as possible. The diagram of surface of barrel shows the arrangement of pins, which should not exceed one-sixteenth of an inch in length) for three different tunes — viz., "Wedding Bells," "Minstrel Boy," and Prayer from "Der Freischutz." These may be altered at will by shifting the lock *m* one-ninth of an inch. In fixing pins in barrel attach the diagram to the surface thereof, and drill through the dots. The whole is started and stopped by the rod, *v*, the inner end of which, bent inwards so as not to touch wheels *b* or *c*, is bent perpendicularly downwards, slides along the edge of barrel until the tune is finished, when it drops into a hole made in its track, and stops the motion. On the outer end of this rod (which is kept up by the spring *x*) is a small tray, on which the penny dropped in, guided by a tin shoot, strikes a blow which starts the machine, and then drops to the bottom of the tower. By means of the wire, *w*, which "Modeller" had better keep under his own control, the bells may be started without the denarial contributions. Finally—by means of those seductive, not to say, silvery, arts, which "Modeller" probably knows how to use, he may get much of this gear second-hand from a clock-maker. — HENRY NEWMAN.

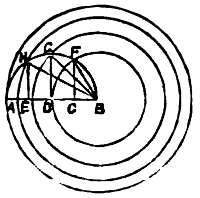


[11196.]—**Drowning** (U. Q.).—The reason why a human being, when drowning, alternately rises to the surface and sinks towards the bottom of the water is as follows:—When he falls into the water, if it is not of great depth, he goes to the bottom; but on account of the air in the lungs rendering the specific gravity of the body lighter than the water, he immediately rises again to the surface. The efforts made by him to maintain himself at the surface diminish the quantity of air in the lungs, and he again sinks, but soon rises again; and this alternate rising and sinking may occur several times. With every expiration the specific gravity of the body is increased; the powers of sensation and voluntary motion rapidly diminish, and the body settles at the bottom.—F. A. EDWARDS.

[11286.]—**Blacking Gun Barrels.**—There is no book on this subject as a specialty that I am aware of. Several recipes have appeared in back numbers; if "B. & J." cannot find them I will see whether I can.—E. M.

[11293.]—**Colour Blindness.**—There is, I believe no remedy for achromatopsy or Daltonism. The colour blind are taught to distinguish the colours just the same as we teach a child that the colour he sees reflected by grass is green, and so on. There are, of course, colour sensations they cannot receive, and to that extent the accuracy of their perception of colour is defective, for they soon learn to distinguish between the colour sensations peculiar to their abnormal vision. —SAUL RYMEA.

[11294.]—**Dividing Metal Disc.**—I send a demonstration as requested by Mr. Tonkes, on page 126, of diagram given on page 78:—Let A B = $\frac{12}{12}$ = unity of the quantity (to be divided). Put A C = a, and C B = b. Then by the equation to the circle and (Euclid I., 47) F B = $\sqrt{ab + b^2} = \sqrt{b(a + b)} = \sqrt{b(1)} = \sqrt{(b)}$. Similarly G B = $\sqrt{\text{D B}}$, H B = $\sqrt{\text{E B}}$, A B = $\frac{12}{12}$. Now, as circles are as the squares of their radii, therefore the circles to the radii F B, G B, H B, A B, described from the common centre B, are as their squares C B, G B, H B, A B, respectively, that is as the fractions $\frac{3}{12}, \frac{6}{12}, \frac{9}{12}, \frac{12}{12}$, and by successive subtractions the remainder 3 in every case is found. N.B.—In the geometry of fractions, the squares of fractions appear less than the fractions themselves.—THETAMU, Horsham.



[11305.]—**Bakers' Ovens.**—There are several patented ovens which, I believe, are better than the ordinary form; perhaps some one who has had experience will give the information. There is a "pyrometer" specially constructed for taking the temperature, being inserted through a plate by the side of the door. It has a dial on the outside face, so that the heat is read at any time.—E. M.

[11312.]—**Boiler.**—The best boiler is undoubtedly one of those recently patented, like Miller's in the last number. But "One in Trouble" says that his boiler is to be 30ft. long by 7ft. in diameter. If so, it should have two flues, 2ft. 3in. in diameter, and the rule for calculating the strength of the plates is T (thickness) = P (pressure per sq. in. in lb.) × D (diam. in inches), divided by 2 k, k varying with the description of iron: thus for best Yorkshire double riveted it is 7,800, best Stafford ditto, 6,200; ordinary, 3,700. The formula is $T = \frac{PD}{2k}$. Whether two small boilers would be preferable will depend entirely on the surrounding circumstances of working.—E. M.

[11313.]—**Setting Lathe.**—If I understand aright F. Humes's query—viz., an easy way to set the lathe mandril exactly in a line with the moving headstock—the readiest method is to drive a piece of wood, which is as long as the bed of lathe, into the hole in nose of mandril, or into a chuck. On revolving this, see that the centre at its end agrees with your moving centre; if so, the mandril must be truly in line with the moving centre.—A., Liverpool.

[11324.]—**Salt Damp in Walls.**—"Barbaros" kindly suggested to test the crystalline fur that exudes itself upon the wall-surface for saltpetre rather than salt. I have done so, but have not succeeded in detecting it. Nor can I discover any cause, such as the presence of liquid manure about or near the wall affected. The house is situated about a mile from the sea-shore, whence I know that sand is sometimes got for building with. It is used because of its cheapness as compared with the cost of carting pit-sand seven miles. I, therefore, think it not unlikely that this part of the brickwork was set with mortar made from that source. Perhaps "Barbaros" or some other of your talented correspondents would suggest some application that would chemically combine and form a barrier in the substance of the plaster.—W. M.

[11324.]—**Salt Damp in Walls.**—Let "W. M." try a strong solution of alum in water put on hot as a wash for his salted walls.—SUFFOLK AMATEUR.

[11329.]—**Electro Deposition of Iron.**—I do not clearly understand what "Puck in a Hollow" wants to know. His query is headed as above, but he talks about solid articles in copper.—E. M.

[11359.]—**Casting Brass Solid.**—Don't use the sand so wet.—GOUX.

[11378.]—**How to Kill Beetles.**—Get a suitable vessel—a large-mouthed pickle bottle—and put into it a few bruised laurel-leaves and warm it before the fire or in the sun to bring out the strength. Keep it corked when not in use. Any animal living in that for five minutes must have a constitution like a steamboat.—W. FRENCH.

[11380.]—**Sand for Casting** is a misnomer. The substance used is a species of loam called sandy or founder's loam. It possesses a certain amount of adhesiveness, and is of very fine grain. It is used without any preparation.—SUFFOLK AMATEUR.

[11386.]—**Crystals in Gas Tar.**—As Mr. Bottone says, these were probably naphthaline; he is, however, wrong in stating that this substance is used in the preparation of artificial alizarine, which is prepared from anthracene ($C_{14}H_{10}$). From naphthaline a body termed chloroxynaphthalic acid is prepared, which is somewhat analogous to alizarine, and is used in dyeing, giving fine shades of scarlet and orange.—ETHYL.

[11390.]—**Brown Hat.**—Take about three ounces each of fustic and madder, tie in a muslin bag and put in an earthen vessel (pipkin) containing two quarts of cold soft water. Having cleaned the hat with soda and water and well rinsed it, while wet put it in the vessel and let all simmer for about two hours. Drain the hat dry and gloss to taste with hot gum arabic; after pressing, another coating of gum may be given it. If the colour when dry is not sufficiently dark, add more madder and reboil.—REDIVIVUS.

[11398.]—**Sting of Bees** and all venomous bites are best treated with ammonia, or in its absence soda. Hartshorn and oil is a good form of application.—SUFFOLK AMATEUR.

[11423.]—**Surgery.**—Without pretending to any particular surgical knowledge, it seems unlikely that the presence of a fragment of a needle in the finger should be of much greater consequence than the fact of its causing some annoyance, unless severe inflammation were present. When a boy I had a needle broken and about half of it left in me; it entered about the bottom of the breastbone and caused some annoyance for about a fortnight, after which I felt nothing of it for some two or three years, when a hard lump gathered inside the knee, from which by pressure the piece of needle was extracted. As in the present instance, the effect of the presence of the piece of needle seems to show itself on the opposite side of the finger to that at which it entered; it will probably make its exit by that road, and Nature assist by a small gatheri g. The hard point of the needle may possibly be then felt under the skin, when a pointed pair of tweezers would do all that is wanted. —SUFFOLK AMATEUR.

[11428.]—**The Violin** alluded to is probably genuine. Thomas Smith was a maker (pupil of Peter Wamsley) of stringed instruments (his violins are supposed to be rare) from 1756 to 1766. He used a brownish red spirit varnish; occasionally labelled his violins as Steiners. They are of no particular value.—SUFFOLK AMATEUR.

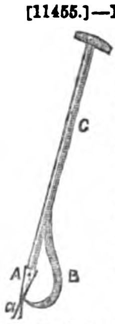
[11438.]—**Lemon Marmalade** can be made in the manner described for orange in No. 368, p. 107. For vegetable marrow preserve cut off the peel of the vegetable marrows, and scoop out the seeds. Boil the fleshy part left with sugar as in ordinary jam making. Some candied peel, cut in thin slices, added during boiling, will improve it considerably.—J. L.

[11442.]—**Old Wives' Science.**—I am sure my kind friends, "E. L. G.," "Wee Pet," and "Science," will forgive me if I revert to this subject. In answering the question in the first instance, I did not mention that I had made any experiments on the subject, because I always prefer quoting a well-known man to requiring my readers to place faith in the results of my own trials. It so happens, however, that I have made a series of rather exhaustive experiments, under a broiling Italian sun, in order to satisfy myself on this subject. My mode of experimenting was doubtless rough; but the average result was so unmistakable as to lead me to the conclusion that the direct rays of the sun have no perceptible influence on combustion. My method was this. Into an open brazier (basket) I introduced a given weight of coke, with a given quantity of wood, &c., to insure ignition. Fire was then applied, and a small copper, containing three litres of water, was suspended over the brazier at a distance of about 15 centimetres. The time at which the fire was lighted, and the water put on, &c., was carefully noted. The time required to raise the temperature of the water to 100° Cent. was also noted. After repeating this experiment, first in the full glare of the sun, and then in the shade of a high house, on more than twenty different occasions, with wind, and without wind, I found that no appreciable difference was noticeable in the time requisite to cause the water to boil. With regard to "E. L. G.'s" experiment of causing paper, &c. to inflame in the focus of a lens, I can only say that I have never failed in causing the paper to burst out into flame, provided it did not rest on anything. As to the effect of the actinic and heating rays (*id est*, the extreme violet and red), I have always succeeded in igniting phosphorus with these, though I failed with the pure yellow. Indeed, if these have any effect, so far from exercising a retarding influence, it is only consistent with reason to expect that the contrary should obtain. If "Wee Pet" and "Science" will consider for a moment, they will easily perceive that while the sun's rays are shining on the fire, the temperature of the fire is also raised in exactly the same proportion as that of the air on which the sun is likewise shining; hence the current of air is relatively the same in both cases. As to Dr. Brewer's statement that the heating and actinic rays are "detrimental to combustion," I need only say that it is contrary to fact. Many cases of chemical combustion are known, which only take place under the influence of actinic rays. I may mention as an example the detonation of a mixture of hydrogen and chlorine, when exposed to the highly actinic rays of the magnesium light.—S. BOTTONE.

[11442.]—**Old Wives' Science.**—One fact is worth a bushel of argument. I have fairly tried the effect of the sun shining on a fire, and it does not put it out or cause it to burn low. The room in which I tried it has two fireplaces at the same end of the room, and the draught equal in both. The two fires were lighted at the same time, and by adjusting the blinds the sun was allowed to shine full on the one fire, and the other fire was in a deep shade. The two fires were watched, and, contrary to the expectations of several persons present, both the fires burnt up equally well, and were left untouched till they were both nearly out from want of fuel.—SHU FLY.

[11450.]—**Adjusting Equatorial.**—ERRATUM.—Kindly permit me to correct an error in my reply (p. 154). Instead of "north declination at the instant of transit," read "altitude above the north point of horizon." The other two lines may be cancelled as inferential nonsense. The N. P. D. should have been the co-declination of star + refraction. The S. P. D. = 90° + declination − ref.—THOMAS BUCHANAN.

[11455.]—**Daisy Extractor.**—I think this will do for "F. T. S. S. D." (sketch enclosed). A is a socket having a forked end; a B, a piece of stout hoop iron at the back for a leverage; C, any kind of handle to which the hoop-iron and socket are fixed. Use it as you would a spade. The hoop-iron prevents marks on the turf.—W. H. M.



[11461.]—**Reviving Black Cloth.**—The following will be found very good for reviving black cloth, and may be useful to A. Despoire:—Strong ammonia, 1oz.; water, 4oz.; turpentine, 2oz.; good black ink, 4oz.—TIP.

[11472.]—**Plaster of Paris.**—There are few amateurs who know how to gauge (mix) plaster of Paris properly, although it is so simple. If "C. B. B.'s" plaster had been good, and he had used it properly, the result would have been satisfactory. This is the way to gauge it. Put into a basin the quantity of clean water you require, and shake the plaster into it with your hand, scattering it over the whole surface as fast, but no faster than it will sink, and when the water will soak no more plaster, stir it up quickly with a brush whose size should be in proportion to the quantity of plaster. If you require to fill in a mould, or to make a mould of a medallion, dab it in with the brush. This is as clear as I can make it on paper.—W. FRENCH.

[11475.]—**Artificial Butter.**—The fat or oil is heated in a shallow vessel until it begins to fry, the action of which is owing to the violent evaporation of the water contained in the fat. After this is all driven off, the fat becomes still hotter, but it is absolutely necessary that the heat shall be so regulated as not to be pushed to the boiling point of the fat itself, but a few degrees below it. A temperature of about 300° Fahr. is required, and a little water should be cautiously sprinkled from time to time upon the fat while at that temperature, after the water that it originally contained has frizzled away. The process is continued until the purification is completed, and the hot fat is then strained, and if the process has been properly conducted it is found to be pure, colourless, and tasteless, besides becoming smooth like butter. Invented by M. Dubrunfaut and M. Charles Fua during the siege of Paris.—J. L.

[11482.]—**Algebra.**—If "our" correspondent "Thetamu" imagines he has solved the equations in question 11482, he is dreadfully mistaken. The equations contain four unknown quantities, to obtain the values of which four equations must be used. "Thetamu" only uses the first three, and then instead of the fourth he makes an unwarrantable assumption amounting to the following:—That certain auxiliary quantities (n and d) which he has introduced are whole numbers. There is no warranty for this in the given equations, except so far as it can be derived from the fourth equation, of which he makes no use. Any one could solve the equations in the way he has done (if that can be called a solution), by simply observing that 12 + 2 = 14 and 8 + 3 = 11, and then trying whether the values of 12, 8, 3, and 2, satisfy the other equations. But that is not solving the equations, but guessing at them.—A NEW SUBSCRIBER.

[11498.]—**Re-Scaping Old Verge Wheel.**—B. James wishes to know how to "file up" a balance-wheel I presume. First examine the teeth to see that none of the points are bent, then put on screw ferrule, put the wheel in the turns, and top the ends of the teeth true with a slip of water Ayr stone sloped off flat at the point. Take the wheel out of the turns and with ferrule still on, rest it firmly on your cork in the vice while you are filing the backs of the teeth. This must be done with a fine balance wheel file. Let the file rest well on the tooth, but more on the ends than on the middle part, as in the latter case your file is likely to act just below the point, which gets so thin that the end of the tooth bends over instead of coming to a point, and you file on wondering why it is you make no progress, unaware that the tooth is doubling over until, perhaps, you have gone so far that the tooth is spoilt. This is a common error with young beginners. The tooth should be filed more obliquely than across, and as the back of the tooth is a curve you may prevent the file from pressing too much on the middle part of the tooth by filing more or less in the direction of its length. The burrs left by the file may be stoned off in the turns. Use oil on the stone both for topping and removing the burrs.—WEST CORNWALL.

[11499.]—**Zymotic Diseases.**—I beg to thank "F. R. C. S." for his answer to my question on p. 130. I did not christen the diseases, as he is, of course, aware. For my part, I would suggest "zymoid" as far preferable. Why Dr. Farr should have selected some infectious diseases for his zymotic class, and have left others quite as "leavening" out in the cold, is, I believe, what no medical man can understand. But is not all our medical nomenclature in a pitean state? In an official medical report now on my table, I find the same part of the colon called *cœcum, caput cæcum, caput cæcum coli*, and *caput coli!* the cœcum proper being, moreover, the vermiform appendix. *En passant*, I would remark that it is very odd that from all the heaps of medical statistics published at great expense to the country, almost for the sole benefit of unprofessional members of the two Houses, not a ray of light has ever, so far as I am aware, illumined the dark maze of the etiology of diseases, or, I might add, their connection. I once attempted to show how we should proceed by means of parallel curves, and stumbled upon the undoubted fact that a certain disease now causing much agitation in the country had been mixed up by pardonable errors in diagnosis with a very innocent one. The answer to my question lands us in more difficulties. I assume that it is not due to mere chance that people do not contract zymoid diseases frequently again, and I also swallow dutifully the assertion that every particle of our bodies is, after the lapse of a few years, and although we grow visibly wrinkled and worn, replaced by a brand new one. If this brand new particle has to be leavened, the leaven must either be the disease (say small-pox), or else the leaven of something left by the disease, which serves as an antidote. Now, it seems to me, in the first case a person must be always having small-pox in some part of his body, and he would, therefore, be a chronic focus of infection. The new particle, moreover, must undergo, on its arrival, inoculation with the leaven of, perhaps, a dozen other zymoid diseases, and although the old opinion that two or more such diseases cannot exist at the same time in the body is now abandoned, yet to have to suppose this miserable "new boy" to undergo at once measles, whooping-cough, scarlatina, small-pox, and, perhaps, yellow fever, is a "facer." In the second case, when the leaven is the leaven of the result of the disease, secondary leaven, it seems obvious that then we should be able to inoculate with it, and by transfusing the blood of the leavened into a person who has not had the disease, we should leaven his body so as to ward off an attack far more effectually than we now do by vaccination. There is another remark I should like to make. If a disease is unlikely to recur from having effected some change in the body, it must have added something to the body, have altered something, or have removed something, and that being so, the health of the person must undergo some alteration permanently or for years after an attack of these zymoid or zymotic maladies, and there are strong grounds for supposing such to be really the case. The subject is one of intense interest, and I do not think practising medical men are the best to handle it. They must speak with the vulgar, although thinking, perhaps, with the wise.—M. PARIS.

[11516.]—**Veneering.**—"Joiner" should purchase No. 331, where he will find a lot of information on veneering and French polishing.—J. L.

[11516.] —**Veneering.** — Doubtless some cabinetmaker will answer the first part of "Joiner's" query, but as to the second part, he can fill in the grain by rubbing well in plaster of Paris, mixed into a thick paste with water, after that rub down with middling fine glass paper, then oil with linseed oil, rub that off dry, and proceed to polish. Make a rubber of flannel and wet it with polish (which he can buy ready to use), and cover the rubber with a piece of soft linen rag, and rub in the wood by working it about in a circular direction, not stopping long on the same place; he will have to touch the rubber outside of the rag with linseed oil to make it work easy. When he has got the grain well filled he can add a little methylated spirits with the polish for a little while, increasing the quantity of spirits each time. Finish by using spirits alone in a clean rubber, like the other. Be sure and keep the work smooth all through the process with very fine glass paper.—F. J. GODDEN.

[11524.]—**Pitch of Roof.**—The pitch of a roof is the height of the meeting point of the rafters above the level of the toe or foot of the rafter in proportion to the span—viz., supposing the span or distance between the rafter feet is 18ft., and the height is 4ft., the pitch would be called a two-ninths pitch, if 4ft. 6in. it would be a quarter pitch.—BRAHE.

[11540.] — **Preserving Tub Butter.** — If the butter is well made and pretty well salted, it ought to keep good for six to twelve months, but should be kept cool, in a cellar, out of reach of the sun, and the tub kept filled up with brine. The best time to buy butter for keeping is in the autumn. Butter made in hot weather never keeps well.—J. L.

[11554.]—**Pedestrian Tour.**—1. August, September, or even later, is the most popular time; July is generally too hot. 2. The lake air is relaxing, therefore light clothing, and a waterproof to roll up and strap on the back, is the best. The most important part of a pedestrian's outfit is his boots—they should be broad-soled, and as old as is prudent, so that they may not break into holes. 3. Opinions differ widely on this point. Some people prefer to carry all their luggage about with them, on their shoulders. I think, for two, the best plan is to have a portmanteau to hold a pair or two of trousers, three flannel shirts, a couple of night-shirts, three or four pair of undarned woollen stockings, &c., each; this might be sent to some "centre of operations," from which, or to which, the "jubilants" might work, carrying with them in the hand a light black bag to hold a night-shirt, a piece of soap, brush and comb, &c. When the centre is to be changed, send the portmanteau by coach or train, and walk up to it again, so *ad infinitum*. 4 and 5. See 6d. guides at any bookstall.—HEDERA.

[11558.]—**Refuse Paint.**—Paint skins, scrapings of kegs, &c., can be worked up by melting (boiling) them over a slow fire. This is best done out of doors, as the smell is very offensive. Let "W. T. M. D." put his skins in an iron pot, adding half a pint of raw linseed oil to about four or five pounds of skins, according to their dryness. Boil them till all are dissolved, which he will ascertain by stirring frequently. When the skins are all dissolved, take them from the fire and thin down to about the consistency of milk (it will thicken again as it cools), and strain the dirt from it, and he will find he has some good material for common work, especially if mixed with a little fresh paint.—CALLEN.

[11560.]—**Annealing Steel.**—Heat it to redness, and cover with slacked lime; let it stop till cold.—GOUX.

[11571.]—**Virginia: Its Climate and Soil.**—If "E. R. E. A." will apply to J. W. Harrington, Esq., 114, Cannon-street, London, I think he may obtain the information required.—AMERICUS.

[11686.]—**Cement for Fixing Glass Letters.**—A thick solution of marine glue in wood naphtha will answer perfectly if colour is no object. But the glass must be chemically clean, and this is not always easy. The least trace of soap or grease will spoil the adhesion of any cement. Try soda or ammonia, followed by whiting and water, clean cloths, and plenty of rubbing, and let the cement dry on the letters till the surface just begins to be "tacky" before you apply them. Many excellent recipes fail on a first trial, from the omission of some minute precautions which the sender has failed to mention for fear of taking too much space. I have found this especially the case in the answers to queries in "our" columns.—J. L.

[11589.]—**Dry Steam.**—The superheated steam in this case, I should think, must be decomposed into oxygen and hydrogen.—J. L.

[11593.]—**Lime-juice and Glycerine.** — Both "J. L." and "A. P. S." are quite out; neither of their recipes will make the article, which is really a weak soft soap or liniment of glycerine, and they have entirely left out the most important element of soapmaking, the alkali. The only materials necessary are glycerine, carbonate of potash, and lime-water, scented by essence of lemon.—MAYLAND.

[11595.]—**Starlings.**—I will describe to "Rara Avis" my cage. It is 22in. long, 12in. wide, 18in. high, outside measure. The base is of bay mahogany ⅝in. thick, and 3in. deep. The wires are set ⅝in. from centre to centre, bright tinned. The thin is No. 6 wire gauge; the upright and cross supports, of No. 14 wire gauge, are at 4in. and 9in. up from the woodwork. Across the top are five supports; to centre one the handle is attached. The wires are neatly lashed to the frame or supports by very fine tinned wire, and it makes a very smart cage. The side door is eight wires wide, and slides up as far as the first horizontal support. The end door is eighteen wires—*i.e.*, the whole width, and slides up to same bar, where it can be held with a hook. This is to give access to the food box, which is movable and made of wire, and wood bottom also; two tin cans fit into it for food and water. The shape is like a lean-to greenhouse; so when you shift it to clean and renew, this end door is dropped until food is brought. For a bath I use a white crock dish (made to order), 5in. × 3in. × 1½in. deep. Never let this go dry, the starling revels in water. This makes it necessary to have the drawer made of zinc, say ⅜in. deep. I have no seed drawer, just plain all round, and only two perches. I consider this the smallest cage allowable for starling, thrush, blackbird, cardinals, and Virginian nightingales, if you wish to keep their plumage from damage. A very pretty rustic looking cage can be made by making the uprights of dark wood, and using peeled osiers instead of wire, but still keeping them a good ⅝in. apart. Take them from the nest about the time you see them able to stand or approach the old ones to receive food. The cloth should be put over the cage at lesson time only; leave it on for half an hour after drill. The first few days they will want their food given them by hand; roll it like elongated pills, and not too dry; be liberal with hard-boiled egg amongst your scalded pea flour. Put a few bits on the edge of the cage, and give them their peck over these pieces, it's a good hint to help themselves. I omitted to include a few of the very small garden snails in shell as part of food in my communication, query 10947, page 645, No. 363, to which I refer "Rara Avis." The only hint that occurs to me is, that if "Rara Avis" intends to make his own cage, he should get a few needle points from an ironmonger, such as are used to fix gilt slips upon drawing-room walls. Take his compasses and mark off his centres on a strip of hard wood, say 6in. long and ½in. thick, drive the points through the marks up to the head, then screw on a back, like a hair-brush; he can thus mark off quickly any amount of cage stuff for the insertion of his bradawl.—JOE.

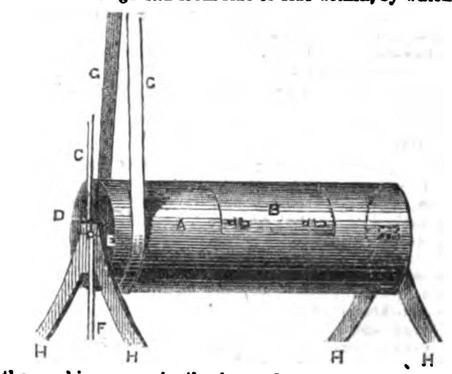
[11599.]—**Lint**—is made from old linen by means of a rather heavy knife, not too sharp, worked by the hand so as to partially cut through the linen, and then raise the cut part up on the surface, so as to make it very soft and velvety on the side operated upon.—J. L.

[11600.]—**Analysis of Water.**—The best work for your purpose is Sutton's "Handbook of Volumetric Analysis," a new edition of which has lately been published. To effect an analysis of a water in the way there described requires several titrated solutions, considerable practice, and a good practical knowledge of chemical manipulation. In my opinion a gravimetric estimation is far preferable, and though it occupies more time the results obtained are free from the sources of error which frequently obtain in volumetric analyses. Our chemical knowledge of the organic impurities in water is at present very small, and the methods employed for distinguishing the injurious and non-injurious bodies of this class are not at all satisfactory. One great point is to ascertain whether the water is contaminated with sewage of any kind; and if nitrites or nitrates can be detected in any considerable proportions, it is in almost every case an indication that noxious matter of this kind is polluting the water. Some waters, however, may contain nitrates without having received any sewage at all, and on the other hand, a water may be highly contaminated and yet not contain any nitric acid, because the oxidation of the nitrogenous matters has not reached its last stage. The presence of ammonia, or of bodies yielding ammonia, by treating with suitable reagents, is also to be regarded with much suspicion when occurring in a potable water. On this point see Mr. Wanklyn's papers on the "Ammonia Process." Dr. Angus Smith has shown that in many cases the amount of common salt in a water may afford useful indications as to whether sewage is passing into a stream or not. The use of permanganate of potassium for determining the relative purity of water has been often recommended. Its use, however, is open to many objections and fallacies, because the purple colour is destroyed by many innocuous substances.—ETHYL.

[11606.]—**Organ Pipes.**—The proper size of hole for tenor C open diapason is ⅜in., and graduate up to 3-16ths of an inch for upper F; if a wood pipe stopped, a foot having a ⅜in. bore ought to be used and graduate up: it is usual to get the feet first, and bore holes to fit. The cutting up is generally guided by the pressure of air; but if cut up a fourth of the width of mouth the stopping at foot will accommodate fancy of operator.—PROFESSIONAL ADVISER.

[11607.]—**Ebonising Wood.**—First procure an ordinary slate and hold it over the gas, lamp, or candle, until it is well smoked at the bottom, scrape a sufficient quantity into French polish, and well mix; then polish your article in the ordinary way. If there are any lumps gently rub them down with your finger, and apply another coat.—ARCHER.

[11608.]—**Boiling by Steam.**—"A. W. B." might possibly take a hint from the following:—Sixteen years ago a factory was built in this country for the manufacture of oils and manures from fresh fish, which had to be boiled in their own liquor by steam without contact with it. One of the machines used for cooking the fish revolved twenty times a minute by means of a driving-strap. This machine consisted of two drums, one within the other, resting horizontally upon two beds. A flange ran from side to side within, by which



the cooking mass in the inner drum was turned over and mixed at each revolution. The steam required for heating played between the two drums, and was applied at the side from the boiler. The machine was supplied with fish by means of a door which closed hermetically. When once hot this apparatus, with a pressure of 30lb. of steam, would cook a ton of fish in ten or fifteen minutes. The fish thus cooked resembled thick gruel, every bone being quite clean and disjointed. The same kind of machine placed upright instead of horizontally, and which was stationary during the process of cooking, baked the fish instead of boiling them. A drum, B door, closed with two keys, C steam pipe from boiler to supply heat to drum, D cock to turn steam on or off, E cock to turn off condensed steam, F pipe for escape of condensed steam, G driving strap, H beds supporting drum.—ROBT. A. WHITELOCKE.

[11608.]—**Boiling by Steam.**—There must be an additional boiler to generate steam, which many would consider a mere waste of money and fuel with such a small quantity as fifty gallons, though it may be necessary to try such a mode in "A. W. B's." case. If he cannot allow the entry of the steam into the mixture boiled by an opening near the surface of the contents, another opening for a condensing pipe being formed beside it for the escape of superfluous steam, though somewhat above the inlet pipe, by which the mixture would be constantly stirred without an attendant, "A. W. B." may send the steam through a hollow jacket around the boiler in the same way, the opening for the exhaust pipe being formed at the bottom; but this arrangement has not so many advantages as the other, and a mechanical contrivance, which will easily suggest itself, may be necessary to stir the contents of the inner boiler. One boiler may be placed inside the other, as in the pot for boiling glue, with the fire underneath, which is the simplest arrangement.—RAT-TAT.

[11610.]—**Defective Battery.**—I beg heartily to thank "Sigma" for his kind and prompt answer, and wish to add that the vibrating contact breaker does not act: there is neither shock nor vibration. Not having a galvanometer I am unable to test the coil in the way he kindly suggests.—G. F. L.

[11614.]—**Gums.**—In reply to "Meneleus'" query on p. 132 of your valuable paper, the MECHANIC, I beg to recommend him the following test of gum resins, they are all soluble in spirits of wine and trustworthy:—Olibanum, ant, thus, or incense, known in Palestine as arbor thurifera; galbanum, the bubon galbanum of Linnæus; scammony, gamboge, gum assafœtida, myrrh, euphorbia, aloes, ammoniacal gum, benzoin. —JOHN LE BAS.

[11615.]—**Teeth.**—Tincture of iron and quinine does not tend to loosen the teeth, but it certainly makes them decay. Before taking the medicine, chew a piece of gum arabic, and distribute it over the teeth with the tongue, then take the medicine and rinse your mouth out with solution of carbonate of soda. This is the only way in which you can preserve the teeth from such medicine. Tincture of myrrh and alum, separate or combined (diluted, of course), are capital things to tighten the teeth with.

[11616.]—**Engraving.**—Nitric acid, one part acid to four of water is generally used.—JOHN LE BAS.

[11618.]—**Deadening Sound.**—Let "Wickliff" set another partition of boards, a few inches, three or four, from the present one, and fill the interval with sawdust, packed together a little, as each board is nailed on, of course beginning at the bottom. This is effectual, if properly done.—H. O'B.

[11619.]—**Electrical.**—The following hints may be useful to "F. T. Z.":—(1) A Leyden jar should be well warmed and freed from dust before attempting to charge it. (2) A good connection should exist between the outer coating and the earth, and between the inner coating and the brass knob projecting from the jar. Let "F. T. Z." charge his jar with (say) ten sparks (which will be sufficient, if they are what he describes them), and then let him take the shock through himself. My first trial with a Leyden jar terminated in a similar failure, owing to there being no good connection between the outer coating and the earth. A Leyden jar should be made of as thin glass as possible.—T. SMITH.

[11620.]—**Capturing Moths.**—The method of making sugar for capturing moths is thus: 1 pint of old ale, 1lb. of coarse sugar, and 1lb. of treacle simmered together; it must not boil; when cold add three tablespoonfuls of rum, and when the fruit-trees are in blossom, a little essence of almond may also be used. Take the mixture into the fields or woods just about dusk, and with an ordinary paint-brush, lay it on in patches on the trunks of trees, then return in about twenty minutes with a lantern, and you will find the moths sucking the sugar. This is best used from May to September, but for some species, such as piniperda, instabilis, &c., you may begin as early as March. Dark warm nights are the best for sugaring, bright moonlight ones being comparatively useless.—EDWARD SUTTON.

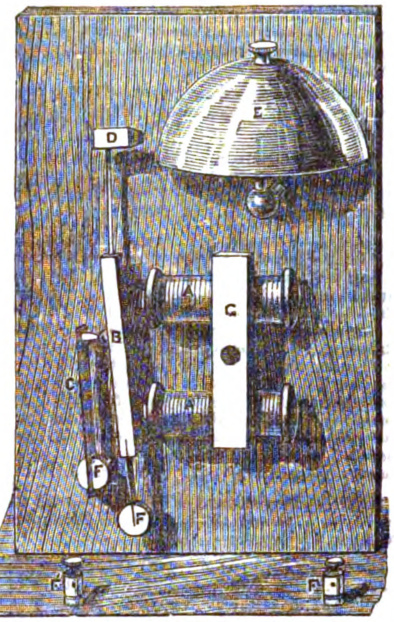
[11620.]—**Capturing Moths.** — Apparatus required: A jar, a small bottle, small paint can and brush, moderate size, a bull's-eye lantern, a small entomological clap-net, about 3ft. long. The use of the above: In the jar get 1lb. of the thickest treacle to be got; in the bottle get a quarter of a pint of best rum. When about to proceed to business put one-third of the treacle in the can, and the small bottle of rum in your pocket with the brush and lamp, take up your net and can and march to the happy hunting-grounds. On your arrival light your lamp and pour one-third of the rum into the can with the treacle, well mix with your brush, then paint the trees, railings, &c., with the above compound (about one tree or rail in twelve yards is sufficient) in patches about 6in. or 8in. square, but don't put on too thick, or it will run down the tree. The results of the above proceedings are similar to what takes place in gin palaces on "human insects." They taste, rather like it, get too much and can't get away, and so fall an easy prey to designing humanity. When the victims are arrived, which won't be long, I can assure you, they may be easily taken off with thumb and finger, or, better still, get some one to hold your lantern, and hold your net under them with one hand and knock them into it with the other, and kill in usual way—viz., a sharp pinch under the wings. The time to use the above is at night, from the middle of May till the end of October, weather permitting. The best places are woods, coppices, &c.—W. LA W.

[11621.]—**Killing Roots of Trees.**—Bore your holes and then fill with a strong solution of sulphate of copper (blue vitriol).—ETHYL.

[11621.]—**Killing Roots of Trees.**—With a 1in. auger bore a hole from outside to centre, inclining downwards, and fill full with saltpetre, plugging with a short plug.—J. WRINKLE.

[11624.]—**Bell Pianette.**—This instrument consists essentially of a number of steel tongues, varying in length from 1½in. to 6in., one extremity of which is screwed on to the sounding board, while the free end is struck by a hammer actuated by ordinary pianoforte action. No dampers are required. Each tongue will require tuning by filing up to pitch.—S. BOTTONE.

[11626.]—**Electric Bells.**—If Thomas Whalley will examine the diagram, he will have some idea how electric bells are made. A A are coils containing about five layers of wire, No. 18, covered with silk or cotton, but silk is best; in the centre of each coil is a core of soft iron, the discs at the ends are composed of brass. The wire should be wound on in one direction, that A and A may produce opposite poles. B is an armature of soft iron connected to F by means of a spring. C is also a stiff spring which makes and breaks contact with B. Near to B and C are projections tipped with platinum. One end of the wire, from the coils, is connected to F; the other end to the binding screw F, and a separate bit of wire joined to F and F. It will be seen



that, when the batteries are attached, B makes rapid oscillations, when the hammer, D, strikes the bell E. If any definite number of rings are required, the ends of the coil wire must be connected to the binding screws, and the battery current turned on and off by means of a commutator. The coils, &c., are fixed on to a vertical board, and may be inclosed in a box, except the bell and hammer.—J. THOMPSON.

[11629.]—**Skeletons.**—If "Hedera" lives on the sea-coast let him moor the animal securely where the crabs can have access to it and they will do the work he requires. If not, let him place it in the vicinity of a large ants' nest.—MOUNTAINEER.

[11632.]—**Debility.**—Before adopting homœopathy try the altera-tonic system, as advocated in the *Anti-Lancet*, to be had of any large chemist. I tried homœopathy for indigestion (and its result, gout) for several years with no effect; but I was at once relieved under the altera-tonic treatment, and have had no gout since I adopted it, although I have had many warnings of its approach, which a few pills quickly dissipated. I know a patient under homœopathic treatment for tumour who is obliged to take these pills *sub rosa* for constipation, which the former medicine does not relieve. Allopaths think they can cure by the administration of an unlimited number and quantity of drugs and counter drugs; homœopathists by the finding of a medicine suitable for each separate malady, and for that only. This seems to me an absurdity, and there is also the awkward possibility of the patient dying while the experiment is being made. The *Anti-Lancet* is opposed to allopathy, homœopathy, hydropathy, &c., many cures being recorded of the victims of each of the above systems. It goes to the root of the matter by proving that nervous debility is the one sole cause of all disease, and having logically demonstrated this, the arguments advanced in favour of the remedies advocated are equally conclusive.—AMATEUR.

[11636.]—**Desert of Sahara.**—Whilst attending a course of lectures on "Physical Geography," delivered at the London Institution by Professor Huxley, I was given to understand that there are two large tracts of land whose levels are considerably lower than that of the sea. The first of these lies to the south-east of the Caspian Sea, and the second consists of a considerable part of the Sahara Desert. Each of these is about 400ft. below the sea-level; and each abounds in shells and chalky matter, which clearly proves that at one time or other they must have formed the bed of the ocean. In the latter also the learned Professor showed that extensive pools of salt water were to be found.—UNDERGRADUATE.

[11638.]—**Silkworm Disease.** — "Muscardine," the disease peculiar to silkworms, and which a few years ago played such havoc among them throughout Europe, is a fungus growth upon the body of the insect. It is induced by overcrowding and bad ventilation in the cells or boxes in which they are kept. There is no cure when once the attack has commenced, but a good preventive has been found in sugar given as food. A still better is plenty of fresh air and fresh food.—H. G. W.

[11639.]—**Rock Inscriptions.**—I do not think there has been so much neglect in reference to the Sinaitic inscriptions as "H. E. H." and "E. L. G." imagine. Prof. Beer, of Leipsic, published, in 1840, a number of these inscriptions transcribed in Hebrew letters. The style and tenor of the inscriptions was found to be almost universally identical. They uniformly read thus: The salutation of so and so, son of so and so, or remember so and so, son of so and so ("British and Foreign Evangelical Review," 1871, p. 347). Since then other collections have been made, and have been made the subject of a good deal of discussion. It seems, however, to be pretty well settled that they are of Nabatéan origin, and that the limits of antiquity which can be given to them, are either the two centuries before or two centuries after Christ.—A. D. H.

[11644.]—**Mending Copper.**—"M. B." does not state what kind of copper he wants to mend. If a copper furnace, rivet a patch on, and then close the seams as close as possible. Make a paste of red lead and the white of an egg, and rub well in the seams and on the rivets inside the furnace with a piece of white sandstone. If for a cooking copper, you must braze a piece in; but you cannot braze it if it has been tinned. —APIARIAN.

[11645.]—**Bees: Managing Old Stocks.**—I cannot understand why your old stocks should die, unless the queen is dead; then the bees mostly die when they have eaten all the honey. I generally, in the autumn, get the bees from the country people, when they put them down, and unite them to my stocks. This makes them stronger in the spring. If you do this you must secure one of the queens, or it will cause fighting, and your stock will be destroyed. I have done several, and only had one that fought. If all the hives you use are bar hives you can easily feed by taking a comb out and filling with liquid food and put back where most of the bees are. If queenless, get a piece of comb with honey, eggs, and brood in. Fit it in your bar, and put it in the queenless hive (I should advise you not to do this until next month). The bees will soon form a queen out of one of the eggs. I have known bees to remain in a straw hive for six years. Three years is long enough for them to remain in before putting them down, or the comb becomes very black.—APIARIAN.

[11647.]—**Cabbage Plants.** — Transplant into richer soil any which have not now "run up;" feed them with weak liquid manure twice or thrice a week. If a plant has started it is too late to remedy. Pull up all such, and boil them for table.—AMATEUR GARDENER.

[11647.]—**Cabbage Plants.**—To prevent running to seed slit the stalk through the centre under the leaves and put a small wooden peg through.—J. WRINKLE.

[11647.]—**Cabbage Plants.**—Whenever "Anon" notices the plants going to seed, let him pull them up and put others in their places. The running to seed proceeds from a premature growth of the plant; they also run to seed in dry weather if they are not properly attended and watered. Plants that will run to seed are very easily noticed when they are put in. If, at the part of the stalk where the leaves ought to sprout out thickly, there is a gap, "Anon" may at once lay aside that plant as useless.—BED OF STONE.

[11651.]—**Analysing Ash of Cane Sugar.**—By treating the sugar with sulphuric acid you will convert all the bases present in the ash into sulphates. The ash of sugar generally contains chlorides, carbonates, silicates, phosphates, sodium, magnesium, and small quantities of other bodies. In all probability your ash would also contain sulphides arising from the action of the carbon on the sulphates. As the ash varies in composition it would not be possible to calculate the altered weight without knowing the exact quantity of each ingredient in the ash. Sugar is not very difficult to incinerate unless it is very impure. Have you tried inclining the crucible till it is nearly horizontal, so as to create a current of air in it? I presume that you are working in a platinum vessel; if you are using porcelain you will find more difficulty in getting sufficient heat.—ETHYL.

[11653.]—**Carving.**—I do not know whether A. H. Cooke means fret-cutting or really wood carving, but if he has not yet tried the former he will find it very interesting, and after a short time will find himself fully repaid for his pains and expense. I bought my tools and learnt the art in Germany, where fret-work is much cultivated by the middle classes. I have since bought a set of tools in England for a friend, but am not so satisfied with them. I fancy for a set of tools—viz., saw-frames, saws, drill, patterns, and wood (nut wood is the best to commence upon)—he would pay about 15s. to 20s., according to the amount of wood. The drawing shows how the wood can be the better sawn by placing it on the corner of a table, and

FIG. 2
FIG. 1

screwing the same on the table at A, by means of Fig. 2. The Fig. 1 can be easily made out of a piece of deal about ½in. thick. The object of the round hole at B is when he comes to a tender part it can be rested so that the piece is not so apt to snap off. The above is an invention of my own, which I find very useful.—C. COLMAN

[11654.]—**Cleaning Violoncello.**—Use turpentine to clean, but do not polish by the application of anything except a soft rag, and light but brisk rubbing. It is probable you may experience a little difficulty in removing the accumulated rosin between the *f* holes ...

se, carefully apply spirits of wine, but do not let it remain on the instrument long enough to attack the varnish. For the inside get a handful or two of barley (corns) warm, and put them through the *f* holes and shake the instrument, at the same time turning it in all directions; when finished, empty through the *f* holes.—DISC.

[11657.]—**Thorough Bass.**—"L. M. F." should procure Hullah's "Grammar of Musical Harmony" (3s.), with the accompanying course of exercises, 1s. (Longmans and Green). He should commence with the first chapter, reading it through several times, then work out on a music slate the exercises to that chapter, copying them when correct into manuscript music-book. —HARMONIC CHORD.

[11658.]—**Power to Drive Crown Printing Machine.**—A quarter horse-power engine is of no practical use, they are always getting out of use, and are only patronised by amateurs. Any engine below one horse-power a workman would not accept at a gift to use in his own workshop. There is a printer not far off driving his machinery by an engine of 7in. stroke and 2¾in. diameter, about one horse-power, and this printer says that he could not possibly do with a less. He only drives one machine at a time. The boiler is a vertical one of 3ft. by 2ft. This is the size that I think would be suitable. Quarter horse-power is not to be thought of.—P. W. H. J.

[11660.]—**Lead Pipes.**—"Flactem" can convey the [illegible] his greenhouse in lead pipes, but they will not last [illegible] so long as iron tubes; besides, iron can be laid [illegible] which is to be taken into account in laying gas tubes. Your gasfitter will tell you the size pipe necessary for the number of lights you purpose having, and also its price per foot.—FRANCIS J. B.

[11660.]—**Lead Pipes** (or "compo") are best for gas, and more so under ground, if not likely to be interfered with by digging, &c. Cost from 3d. to 6d. per foot, according to size of pipe.—J. L.

[11661.]—**Photography (Background).**—A simple and efficient background may be made in this way: Procure a square (at a draper's) of 9 or 10 quarter gray calico sheeting (say, about 2½yds.), make a light frame of deal, exact size, well fastened at the corners, and upon it nail the calico with stout tacks and plenty of them. Let the cloth then be coloured with a distemper gray wash, which will neither rub off nor reflect the light, and you have a cheap and efficient screen. A dull lead is a convenient colour, as it suits for any complexion or any shade of dress. Let your sitter be (say) 3ft. or even more in front, so that the screw be entirely out of focus, and then the texture of your background will not be apparent in the picture. I used such a frame for years, and found it to answer well, and, being light, I could lift from my hall where it stood to two hooks in the yard. I had no glass house, being only an amateur. The cloth tightens on the frame after drying from the white-wash brush, so that there can be no unsightly wrinkles. —SENECIO.

[11665.]—**Brown Ink.**—1. A strong decoction of catechu. The tint may be altered by the cautious addition of a little weak solution of bichromate of potash. 2. Sepia prepared from the cuttle fish. This may be obtained at any artists' colourman.—A BARRISTER.

[11667.]—**Carbon Points.**—These are generally made of graphite or plumbago, as being denser and better suited for the purpose than charcoal. I do not think they are dear; any philosophical instrument maker would know the price.—PHILANTHROPIST.

[11675.]—**Solder for Britannia Metal.**—10 tin, 5 lead, and 1 to 3 bismuth.—A. M. FESTING.

[11675.]—**Solder for Britannia Metal.**—I find no difficulty in soft soldering any metal with the aid of Baker's solution, or spirits of salts and resin.—A. LIVERPOOL.

[11676.]—**Lemonade Syrup.**—To every pound of sugar add 12 fluid ounces of lime-juice, add a few drops of essence of lemon, and dissolve with the aid of heat; 1oz. of the syrup to a tumbler of aërated water. This is A 1.—OPALINE.

[11683.]—**Height of Sea Waves.**—The assumption during all the experiments made many years ago by Dr. Scoresby and Mr. Scott Russell was, that the proper level of the sea was midway between the highest and lowest points of the waves, and, I believe, that more modern experiments on tidal levels show very little, if any, discrepancy.—A BARRISTER.

[11684.]—**Pressure on Cork of Bottle.**—The pressure on the cork will be greater when the bottle is upside down, as the cork will, in addition to the gaseous pressure, have to bear a column of (say) 6in. of water (33ft. of water gives 15lb. to the inch, about).—PHILANTHROPIST.

[11684.]—**Pressure on Cork of Bottle.**—The pressure on the cork of a soda-water bottle is = the elastic pressure of the gas + the weight of 1in. or 1½in. of liquid; if suspended cork downwards it would be = gas pressure + the weight of (say) 6in. of water; if resting on cork it would be = to gas pressure + 6in. water − weight of bottle and contents.—A BARRISTER.

[11686.]—**Cement for Fixing Glass Letters.** —A thick solution of shellac, in methylated spirits, waterproof. Having used this I can recommend it.—OPALINE.

[11686.]—**Cement for Fixing Glass Letters.** Try the following cement. Powdered orange shellac [illegible] alcohol 2oz. Place the containing bottle in a warm place. Agitate frequently until all the lac is dissolved. Apply cold. This will resist wet, and will cement strongly metals, wood, porcelain, glass, &c.—S. BOTTONE.

[11687.]—**Speeding Machinery.**—The number of revolutions of two pulleys or wheels are inversely as the diameters or circumferences; in the case of pulleys is the thickness of the belt added? (as the neutral axis, or part of the belt which is neither compressed nor extended, is in its middle). In the case of wheels the diameter or circumference of the pitch circles are taken, practically adding the depth of a tooth to the diameter of the uncut part of the wheel would give this pretty nearly. The number of teeth in the wheel in driving shaft should bear to the number of teeth on wheel of machine the proportion of 135 : 50 or 27 : 10, and the diameter of the pitch circles be in this ratio. Further information if desired.—PHILANTHROPIST.

[11691.]—**Tidal Mill.**—I think Poncelet's undershot water-wheel (with curved buckets) would be the best; it is superior to the ordinary undershot wheel, as the water loses almost all its velocity before leaving the wheel; however, as the tide changes, reversing gear would be needed. (I described a kind of screw on p. 403, Vol. XIV., which rotates in the same direction, whether the water passes up or down through it; I do not know, however, if its *modulus* is satisfactory, as compared with other wheels.) A screw revolving against water produces good results, but does it follow that water rushing against a screw would do the same? I should like some information on this myself. I think that tide mills are not sufficiently used in this country. In Germany the rapid current of the Rhine is utilised to drive floating mills; why should strong tides not be used also? As to the flux motor, I saw it in the Exhibition, but as a horse-power is 33,000 units of work in a minute, or more than 500 cubic feet of water raised 1ft. high in the minute, or upwards of 90,000 cubic feet of water to fall 1ft. in three hours, as the machine does not act constantly, the size of the dam—and the consequent expense—seems an objection.—PHILANTHROPIST.

[11693.]—**Defective Feed Pump.**—"An Engine Driver" cannot take "ours" regularly or he would have noticed the same query answered one or two numbers back. Very probably the pump is keeping him in hot water from it being allowed to become hot.—A., Liverpool.

[11694.]—**Green Fly.**—Use Gishurst's compound; to be obtained, with directions, from any respectable nurseryman. It is extremely effectual.—S. BOTTONE.

[11694.]—**Green Fly.**—Why is the conservatory too large to be smoked? Mine is 27ft. by 14ft., by an average of 9ft. high, and I find a pound of tobacco paper, price 8d., amply sufficient. Choose a calm evening, close up the conservatory tight, the plants must be thoroughly dry (I do not even water the roots on the smoking day), then set a lighted candle end on the floor, invert a 6in. or 7in. flower pot over it, on this set another pot upright, taking care the drainage holes correspond, in the latter shred the damp tobacco paper, and when all is going on well leave it shut up till morning, when you must ventilate well and syringe copiously. The third or fourth evening after smoke again, this will finish off the insects half killed by the first operation. The inverted pot must be raised a little to admit air. I use a broken one.—HAMMER.

[11694.]—**Green Fly.**—If "H. T. C.'s" conservatory is really of such dimensions that tobacco fumes are useless, he must try syringing with tobacco-water. Under similar circumstances I should remove every plant that was removable, and clean off every aphis I could find. If the conservatory had been cleaned properly last autumn, he would not now be troubled with an "army of spiders of every shape and description." He must clean it down now, or else clear the plants out and fill the conservatory with chlorine, or sulphur fumes.—SAUL RYMEA.

[11695.]—**Succession Duty.**—"C. P." can make himself quite comfortable about the legacy duty: the people at Somerset House will not let him go to sleep. The probate duty has, I suppose, already been paid; if not, that will be £30 if the entire sum left by will does not exceed £1,500. The legacy duty of 1 per cent. is calculated on the gross value of the property, which "C. P." must get valued for the purpose, or run the risk of making a false declaration of value.—SHU FLY.

[11701.]—**To Mr. Knott.**—In reply to M. Gaudibert's query (p. 159) I beg to say that I have measured ζ Cancri twice this season with the following results:—Feb. 2, P = 166 52°; Feb. 20, P = 166 93°. On each occasion the distance was estimated about 0·6"—a value which may, perhaps, be a little too small.—GEORGE KNOTT.

[11702.]—**Curry and Rice.**—I am not an Indian, but during my residence at Milan, famed for its "Risotto alla Milanese," I learned that the only requisite to obtain rice grains firm and dry consists in having the water quite boiling, and after having introduced the rice, allowing it to boil only ten minutes, when it must be immediately strained through a wide-meshed sieve. After seasoning, if found too hard, it is again placed in the saucepan (without water), and while on the fire constantly stirred. The following is a good recipe for curry:—Pale turmeric ½lb., powdered cumin 2oz., powdered coriander 4oz., black pepper 2oz., cayenne pepper 1oz., Jamaica ginger 2oz., carraway seeds 5oz., cardamoms 2 drachms. All these must be well ground and mixed.—S. BOTTONE.

[11703.]—**Ink Powders.**—Aleppo galls 4oz., sulphate of iron 1½oz., gum arabic 1oz., lump sugar ½oz. all quite dry and in powder). Mix and divide into three packets. A pint of boiling water poured over one of them produces in a few hours a pint of excellent ink. If used for copying it may require a little more sugar, say, ½oz. to the pint.—A BARRISTER.

[11704.]—**Rats.**—Undoubtedly oil of rhodium is the best; you can buy it wholesale at 6s. per ounce; if too dear, use oil of aniseed and oil of verbena, of each equal parts; add a few drops of oil of rhodium.—OPALINE.

[11704.]—**Rats.**—Oil of aniseed is said to attract rats.—SAUL RYMEA.

[11708.]—**Gas Burners.**—Gas burners are usually marked round the top with a series of rings, each corresponding to 1ft. per hour.—A. M. FESTING.

[11708.]—**Gas Burners.**—The burners in ordinary use consume from 3ft. to 5ft. per hour. Those constructed for cannel gas about 20 per cent. less than those for common gas.—A BARRISTER.

[11710.]—**Cleaning Oil Painting.**—Years ago I recollect being told that one of the most effectual ways of freshening an oil painting was with the finger and saliva, but I cannot vouch for the truth of the statement.—A. M. FESTING.

[11714.]—**Test for Sugar.**—Into a cold solution of the sugar add a few drops of tincture of iodine, if it contain starch a blue colour will be the result; for chalk add a few drops of sulphuric or muriatic acid, effervescence will ensue.—OPALINE.

[11715.]—**Testing Acetic Acid.**—"Aceticum" will easily test the relative purity of commercial acetic acid, by ascertaining if it does or does not precipitate nitrate of silver (in the first case it would denote the presence of hydrochloric acid), or if it does or does not precipitate nitrate of barium (in the first of latter cases it would denote the presence of sulphuric acid). Acetic acid may sometimes contain traces of sulphurous acid. In that case add a few drops of nitric acid to the liquor, and see if, after having boiled for a few minutes, it precipitates nitrate of barium.—F. T.

[11715.]—**Testing Acetic Acid.**—The only acids with which it is usual to adulterate this are the sulphuric and sulphurous. The former is used for the weaker acids and the latter for the so-called "glacial." The presence of the former may be detected by means of a solution of barium chloride, which, if sulphuric acid be present, gives a white precipitate, proportionate in amount to the quantity of sulphuric acid present. If there is reason to suspect that sulphurous or hydrochloric acids be present, the addition of a few drops of a solution of silver nitrate will immediately clear up the doubt, by affording a white precipitate, if such be the case.—S. BOTTONE.

[11719.]—**Gut Lines.**—If for fishing, are made from the silk receptacle of the silkworm, and cannot be obtained from sheep-guts, which are used for the manufacture of lathe bands, catgut for musical instruments, &c.—A BARRISTER.

[11724.]—**Discharge of Water over Weirs.** —I think this is mentioned in some of Weale's Series. In the case of a hole, the well-known phenomenon of the contracted vein occurs, and the actual discharge is considerably less than the theoretical. The formula $v = \sqrt{2gh}$ may be used, a large deduction to be made for fluid friction. Further information if desired.—PHILANTHROPIST.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "West Cornwall" has answered 10617; "A Barrister," 11008; "Goux," 11008; A. F. Edwards, 11196.

QUERIES.

[11730.]—**Artificial Gum.**—Will any of the readers of "ours" kindly oblige me with a good recipe for making a cheap artificial gum, suitable for suspending colouring matter in, which will not precipitate?—J. Wrinkle.

[11731.]—**Hair Wash.**—I have for some time past been in the habit of using a solution of camphor and borax as a scurf wash. I do not, however, find it to answer. The camphor is never wholly dissolved; may this be fairly set down as the cause of its inefficacy? Can any reader recommend another preparation?—Excelsior.

[11732.]—**Temperature of Ice and Water.**—One kilogramme of ice and three kilogrammes of water at 79° C., are mixed in a closed vessel, the sides of which are supposed to be impervious to heat. What will be the temperature of the water after the melting of the ice (latent heat of water = 79°)? As several different solutions have been obtained, I venture to ask for a correct one.—W. N. Oswad.

[11733.]—**Cotton Spinning.**—Could any of your readers recommend a work upon cotton (practical) spinning in all its processes, with calculations for the same?—Sufferer.

[11734.]—**Engine Counter.**—Mr. William Tonkes will remember some time ago answering me the question how I would work my engine counter (situate 150ft. from engine) with electricity. (1) Will he kindly give me a little sketch how I am to make the necessary connections? (2) Will No. 10 galvanised iron wire do? (3) Should I insulate the wire? (4) Will one wire do, making an earth circuit, or would Mr. Tonkes prefer two wires? (5) Where shall I place the battery in connection with the engine and the counter (the oscillation of the counter pendulum is 1in.)? (6) How shall I arrange the mechanism to work the counter in the most efficient manner? (7) Shall I use two Bunsen cells?—Der-sunthal.

[11735.] — **Gilding on Glass.** — Can any correspondent instruct me how to perform the process of forming the diamond pattern, and of writing and gilding on glass, such as we see on the backs of glass nameplates, shop facias, &c.? The cross lines forming the boundaries of the diamonds, and the stars at the intersections of the lines, look as if the gold were burnished, but the diamond shapes look like dead or frosted gold. I fancy the latter appearance is produced by light etchings of the glass by hydrofluoric acid, if so, what should be the strength of acid used?—T. L.

[11736.] — **Extracting Iodine from Seaweed Ashes.**—I should be obliged to any reader who could inform me how to extract iodine from the ashes of seaweed.—J. R.

[11737.]—**Fairbairn's Ventilating Buckets.**—I should like information on Fairbairn's ventilating buckets for water-wheels (they promote the escape of air and admit of the buckets being readily filled with water). What modification is made in the hydraulic ram when intended to raise water to many times the fall? What is the practical limit?—Philanthropist.

[11738.]—**Cyanide of Potassium.**—Can any one tell me anything about this substance? Is it as poisonous as arsenic? What is its antidote? The saucepan containing my gold bath has all round the outside a quantity of brown settlement of some kind, is this cyanide? or what is it? Is it dangerous to live in the room in which cyanide baths are kept?—Dentiste.

[11739.]—**Economy of Fuel.**—I am using two boilers, each 30ft. long by 8ft. diameter, and 7lb. pressure, for producing steam, used solely for heating (by injection) hot-water vessels. Would there be any economy in fuel, by making use of a more modern boiler and using steam at 45lb. or 50lb. pressure, either with or without a reducing valve? I know it is admitted that something like 50 per cent. less coals would be used, if the steam were for engine purposes.—X. Y. Z.

[11740.]—**Potash Salts.**—Is there any ready means of estimating the quantity of actual potash in the compounds sold to farmers as fertilisers, under the names of kainit, potash salts, and saltpetre refuse? Their actual value depends on the potash they contain, not the soda (which we can obtain cheaply in dirty salt). The manure dealers talk of sulphates, muriates, and nitrates of potash; but I see no way of checking their representations easily available to a farmer, through not knowing how to disentangle the soda, though I can see my way to get both alkalies into a nitrate. How do the saltpetre refiners expel the soda?—Hammer.

[11741.]—**Boot and Shoe Making.**—I should like to know how the permanent black shining and glossy appearance is produced which is to be seen on the soles of new shoes, for I find that when I apply the heel ball to new soles, it always comes off when the shoes have been worn a few days in wet weather. Should the soles be quite wet or should they be quite dry when the heel ball is applied? and how hot should the heel ball iron be? An answer to the above would be a favour, and some useful information about boot and shoe making would confer a favour.—James Lonsdale.

[11742.]—**Painting Iron Bedstead.**—I want to paint an iron bedstead white and gold. Would some reader kindly say if the smooth iron will take white paint? How must I mix white paint that will not turn a yellowish shade? How must I do the gilding without using gold leaf?—Suffirer.

[11743.]—**Humea Elegans.**—I have some seeds of this plant. Would some subscriber give directions for growing some good specimens? Will they grow without artificial heat? What compost should be used?—H. A.

[11744.]—**Shorthand.**—I am in the habit of taking notes of lectures and meetings. Could any reader tell me of a system of shorthand, that is a near approach to ordinary writing? I have tried Pitman's, Taylor's, and other systems, but find the angles and straight thick and thin lines awkward after a hard day's work; and I have little leisure for studying. I have little doubt but that some of your readers use a contracted form of ordinary longhand.—Wood Sawyer.

[11745.]—**Watch Keys.**—I am anxious to know how the neat square holes in watch keys are made. Are the sides of the key supported and the holes punched?—Ethyl.

[11746.]—**Coil Construction.**—I have a coil of the following description: — Primary, 3 layers No. 16. Secondary, 5 layers No. 30 cotton-covered wire. Primary insulated from secondary by guttapercha tissue. Each layer of secondary insulated in same way. Hammer vibrates on core. Can I strengthen this coil without the use of more wire, and how?—Zeta.

[11747.]—**Canoe Voyage.**—I contemplate going for an excursion in my canoe, now building, this summer, so would be very grateful to any of your numerous readers who can give me any valuable hints, on either the management or outfit, or where to go, in England or Ireland; but most likely I shall choose the latter.—Afloat, Liverpool.

[11748.]—**Artificial Manures.**—I should be glad of information respecting the use of chemical salts, &c., in promoting the growth of plants; more particularly as regards nitrogen, phosphorus, and sulphur compounds. Information upon this subject will, no doubt, be interesting to other of your readers as well as—Guano.

[11749.]—**Cementing Iron in Wood.**—Will any kind friend inform me how I can fasten the screws in the knobs of dressing glasses? I have great bother with them frequently.—F. J. G.

[11750.]—**Circular Saw Driving.**—Will any one kindly tell me how I can fix the mechanism of the simplest kind to drive a small circular saw about 12in.? In fact, tell me all about it. I have a small wooden lathe.—F. J. Godden.

[11751.]—**Bugs, Lice, and Parasites.**—Can any of "ours" tell me if there is any herb or preparation which is prophylactic against fleas, bugs, and lice, *et hoc genus omne*? I have frequently to be in contact with unclean people, and have been sadly plagued by carrying home more than I bargained for. I have been told wormwood is useful. Is it so, and are there any other prophylactics?—M. A. B.

[11752.]—**Meerschaum Pipe.**—Can any brother reader inform me how to remove the black colour from a meerschaum pipe (produced by a solution of caustic), without injuring the real colour?—F. G. C.

[11753.]—**Crucible for Quartz.**—Can any correspondent inform me what kind of crucible is used to crystallise such a refractory substance as quartz? I am aware what salts are used to reduce quartz. An answer will oblige.—John Le Bas.

[11754.] — **Polishing Diamond.** — I have a small diamond which has been made too hot under the blowpipe, and got a coating on the surface which takes away its brilliancy. I believe that there is a process by which this formation can be easily removed, without the trouble of repolishing. I have tried various chemical means, but failed, and shall be much indebted to be informed through your valuable columns what I am to do.—Chas. Perks.

[11755.]—**Tempering Charcoal Iron.**—Would any of your readers say if it is possible to temper charcoal iron? and, if so, how it is done? If it cannot be tempered, is it possible to harden a ⅛in. or ⅜in. rod through and through? I do not mean to case harden the outside only. Can malleable cast metal be tempered or hardened through the same size of rod?—W. G. L.

[11756.]—**Power of Water-wheel.**—Will any of your numerous correspondents have the kindness to inform me the horse-power of a water-wheel 14ft. in diameter, and 22in. wide, the depth of buckets 9in., having an iron axle and rim, the other parts of wood, supplied by a reservoir 40 yards long, 7 yards wide, and 2 yards in depth; the water runs through a pipe 100 yards long, and takes 90 seconds to run through, and runs out in two hours in thrashing corn. When the water is allowed to run 4 hours, 6 hours, or 8 hours, what is the horse-power of the wheel? Also what is the best tap or a plug at the bottom of reservoir to prevent leakage?—Water-wheel.

[11757.]—**Boring for Coal.**—Would any of your readers advise me as to the best and most economical method of boring for coal?—J. H. B.

[11758.]—**English Mechanic Colony.**—Is the idea of forming a colony to settle in Tasmania—that was being got up by "Alexandra"—given up? Would "Alexandra" or any one else, please give me any information about it?—Americus.

[11759.]—**Oil Painting.**—I have an old flower piece, apparently of the English school, signed "Gregory." Can any subscriber say who he was, and at what time he flourished?—Shu Fly.

[11760.]—**Soldering Jewellery.**—Will some practical hand please say how the common gold jewellery is hard soldered? what kind of solder is used? and how is the article protected when applying the heat? I think the silver solder is too hard, as I often partially melt the job before I can get it to run.—New Pivot.

[11761.]—**Magnetism.**—In the course of a series of lectures on "Magnetism" delivered here (Liverpool) on the 22nd and 25th April, by Prof. Barrett, two experiments were tried, in order to show the change caused by magnetisation in the capability of iron to conduct light and heat. The first experiment proved conclusively that heat is conducted by magnetised iron, quicker in a direction transverse to the polar axis, than in one parallel to it; whilst the same iron in its ordinary state conducts heat equally in all directions. The second experiment proved the increase of transparency of iron when magnetised, and was accomplished in this wise. A beam of limelight was cast on a screen, passing (the light) through a tube filled with water, holding in suspension minute particles of oxide of iron. On an electric current being passed round the tube, thus producing magnetisation, a great increase in the quantity of light transmitted was apparent. Now the beam of light was passed along the axis of this semi-transparent magnet; but in the preceding experiment it was proved that heat (which is similar to light in kind, though differing in degree of intensity) is conducted faster through iron transverse to the polar axis, than parallel to it. What I want to know is this. Would not the action of the transmitted beam of light be much more apparent if it had been sent across instead of along the polar axis of the semi-transparent magnet? Perhaps some will feel sufficiently interested to try this experiment and report results.—Conatus.

[11762.]—**To take Honey from Bees by Using Chloroform.**—Will some brother subscriber kindly inform me what quantity of chloroform is required to take the honey from a hive of bees?—W. T. B., Belper.

[11763.]—**Watchmaking.**—What kind of tool is generally used for putting new cylinders in small Geneva watches? I think the Geneva turns are too heavy. Would the English turnbench do better?—New Pivot.

[11764.] — **Scrubber for Gasworks.** — Could any reader inform me how to make a scrubber for a gaswork—the size is to be 4ft. × 10ft.—and how the pipes are put inside?—Gasfitter.

[11765.]—**Astronomical.**—A tyro in star gazing will be much obliged by the following query being responded to through the English Mechanic:—On what days of the current year will the first point of the respective signs of the zodiac cross the meridian of Greenwich at midnight nearly?—C. A. S.

[11766.]—**Piano in Canada.**—I have (purchased in Canada) a 7-octave cottage piano, by Holdernesse and Holdernesse, of London. Will the "Harmonious Blacksmith," or other expert, tell me if there is any way of attaching additional bracing to make it more capable of being kept in tune, as the great extremes of temperature here, with the dry stove heat in winter, render it difficult to keep a piano, especially of cottage style, in good playing order. Also the bass notes sound somewhat wiry and harsh. Is there any remedy for this? I believe that there is a mode of "needling" up the face of the hammer to soften the tone. The action of the instrument is apparently quite new and unimpaired. I may add that I can handle tools as well as most amateurs, so could possibly add any bracings necessary myself.—H. E. K., Toronto.

[11767.]—**Horsehair.**—Horsehair, after having lain in water for a certain time (indefinite), twists and twirls about in all directions, sometimes swimming straight on, like an eel, at other times twisting itself into numerous knots around a piece of stick or straw, and as quickly untwisting itself. Is the above owing to galvanism?—A Subscriber.

[11768.]—**Cheap Filter.**—I have made a cheap filter in the following way:—I have filled the hole in the bottom of a flower-pot with sponge, then placed a layer of charcoal, then a thick layer of gravel, and on putting the water in, it ran from the sponge in a stream, instead of dripping. Is that of any consequence? if so, how can it be altered?—H. D. W.

[11769.]—**Tricycle.**—Will some kind reader inform me whether I could have a tricycle made that would be of service to me and many others who are unable to walk? I have spent money on a four-wheel which is useless to me, as it is very heavy and clumsy. My ideas through reading some ten volumes of "ours," are that a machine might be made very light (say 50lb.; after the style of one you sketched some three or four years ago, belonging to J. Hastings, with description. I propose a strong wooden frame, very light, with two wooden levers outside of frame to drive cranks attached to hind wheel, guide by feet in front, indiarubber tires all round, hind wheel to move going down hill, with levers still, a small wooden frame under frame behind, with long wooden lever to brake on ground. This brake power is used about here to two-wheeled trucks laden with fruit. A long wooden lever is attached under the truck, and rubs on the ground behind, so as to cause any amount of brake power by raising the handle and throwing the weight of the load on the lever behind. I don't want to go ten miles an hour.—J. H.

[11770.]—**Magnetic.**—I have a compass which I considered did not indicate with sufficient precision the position of north and south. Supposing the magnetism had exhausted itself, I thought to renew it by rubbing it with a horseshoe magnet, but on replacing it I found that it would not act at all, but stood anywhere, just where placed. How is that? and how can I remedy it?—H. G. W.

[11771.]—**Varnish.**—How can I make a varnish that will be flexible when dry, on calico or kid?—Apiarian.

[11772.]—**Black Lacquer.**—There is a black used by painters called black lacquer, for blacking chimney pieces, ash-pans, &c. Could any one inform me how it is made, and particulars about it?—Apiarian.

[11773.]—**Cleaning Plain Blue Silk.**—Can any contributor assist me by giving a recipe to clean plain blue silk, that is not greasy but dirty? My husband says the English Mechanic is the only publication from which I can get the information.—A Mechanic's Wife.

[11774.]—**Caulking Boats.**—Can any reader kindly inform me the best material for caulking boats, and how to make it?—Boatman.

[11775.]—**Tugboat for the River Wye.**—Can any reader tell me the best method of ascertaining the velocity of a current over a weir, and of calculating the horse-power of an engine which would be capable of driving a steamer against a given velocity of current? I wish to build a tugboat for drawing empty barges up the river Wye. The draft of water must not exceed 18in., nor the width of the vessel 8ft. amidships.—G.F.G.

[11776.]—**Commercial Geography.**—Will some one, who is acquainted with the requirements of the Cambridge Local Examinations name a text book, in which commercial geography receives full and reliable treatment? The examiners complain in their last report that "scarcely a candidate answered with any degree of accuracy a simple question on exports and imports."—Glenbogie.

[11777.]—**Postage Stamps.**—Having collected a large number of used penny postage stamps, I should be obliged to any one who could tell me of a use to put them to.—F. A. E.

[11778.]—**Sweeping Machine.**—Will some reader of the MECHANIC kindly tell me how I can make a chimney-sweeping machine, to clean chimneys with very sharp curves? or is there any machine in use that would suit me? I also wish to know if there is anything that will prevent Portland stone from vegetating.—SWEEP.

[11779.]—**Photographic.**—Will "Iodide" kindly send his further promised communication on enlargements and resinised paper.—LEX.

[11780.]—**Machinery for Cutting Envelopes.**—Would any correspondent kindly describe the machine or machinery used in cutting and making envelopes of various sizes? Does it require a different cutter for each different form and size? What gums are used and how prepared before being applied?—TIP.

[11781.]—**Lathe Query.**—I beg to thank Mr. Smither for his kind description of hook tools on p. 516, Vol. XIV. I have carried it out, and they answer very well. I should be still more indebted to him if he would describe the following:—1. A parting tool. 2. A beading tool; there is a sketch of one on p. 557, Vol. XIV., but I want to know how it is to be ground, what sort of grindstone it requires, &c. 3. The best way of cutting ferrules either iron or brass in the lathe, as I think it will be a better way of cutting them than with the saw or file. I have no doubt the answers will be useful to others as well as to—J. S. E.

[11782.]—**Band.**—I wish to form a band of English concertinas and some other instrument. Which would be the most suitable instruments along with concertinas?—DUET.

[11783.]—**Molten Lenses.**—Supposing I have a large plate of crown glass, and am acquainted with its optical properties, and then melt it until extremely liquid, and afterwards immerse therein a platinum mould whose inner surfaces are turned true to the curves which would be required if the same plate of glass was ground. The mould being overhead would fill with glass, and its respective portions being firmly held together would separate the inner glass from the outer. After also making a lens of flint glass on the above principle, and after carefully annealing the two, would they not act together just the same as if they had been ground? If not, kindly show what would have arisen to prevent them.—ALPHA.

[11784.]—**Restoring the Colour of Marble Mantelpiece.**—Can any correspondent inform me how to renew the colour of a marble mantelpiece, the upper slab of which is stained, apparently by coal smoke?—J. L.

[11785.]—**London Blackbeetles.**—Can any of your correspondents impart (from experience, not from hearsay) an effective plan for getting rid of the London variety of blackbeetles? Past experiments prove that they thrive and fatten on red lead wafers, phosphorus paste, and the like, and utterly despise such futile contrivances as traps of stale beer, treacle, &c. A thirst for discovery has lately seized them, and they have taken to exploring the upper rooms of my house—bedrooms, baths, &c., and hold nightly mass meetings on the staircase. Are the present resources of science adequate to repel such an invasion?—J. L.

[11786.]—**To "J. K. P."**—Will "J. K. P." be kind enough to inform me if he has allowed in the distance from centre of lathe mandril to centre of screw for a pinion on mandril and stud pinion to gear from?—DIGBY.

[11787.]—**Electric Signal Bell.**—To MR. TONKES.—Having made an electric signal bell upon the plan described by you a few weeks back, I find that when the current is broken the armature still remains attached to the magnet; and if I place it so far off that the spring will overcome it, the magnet has not sufficient power to attract it. If you would kindly tell me how to remedy this I should be greatly obliged.—H. G. N.

[11788.]—**Bunions.**—A friend of mine will be truly thankful if any of your learned friends can give a perfect cure for a bunion, not any appliance with a hole, but anything that will disperse it or absorb it, as walking down Welsh mountains caused the same, not tight boots.—DER MOND.

[11789.]—**Effect of Temperature on Ale.**—I am a brewer, and the ale I brew is very satisfactory in mild weather, but when I send it out in very cold weather, and the temperature of the ale gets low (say to under 50°) it goes very dull, and if the heat is raised again it comes bright. Can any of your kind correspondents give me the reason of this? I think it is because my water is very hard. If it is so, I should like to know what to do to it to prevent the above effect in cold weather.—W. A. N.

[11790.]—**Photography.**—Will some practical photographer help an amateur in a fix? I find the greater portion of my negative, after developing and fixing, marked across in diagonal lines exactly in the direction the surplus collodion was poured off the plate. Whilst pouring the collodion from plate I keep it rocking backwards and forwards. I thought, perhaps, collodion was too thick, so diluted it with alcohol, but the difficulty still exists. To precipitate silver from waste washings I am told to throw in some common salt, but I cannot learn about how much. The plan I thought of adopting is this: I have a cask capable of holding about four gallons, with a tap about half way up. I purpose filling this with washings of prints before toning (how much salt shall I then add?) and next day drawing off and throwing away all the upper part. In what form will the silver be precipitated? Will it still be held in solution at the bottom of cask? and how am I to know it has all left the upper water? How many times may a positive fixing bath be used? If many times, how am I to know when it ceases to act? if only once, what quantity will be suitable for (say) two dozen cartes? If a negative requires ten seconds' exposure in the studio, how long would the same require to be exposed in open air?—CAMERA.

USEFUL AND SCIENTIFIC NOTES.

Detecting Cider in Wine.—The adulteration of wines with cider can easily be detected by filtering and adding ammonia in excess. The apple juice will immediately deposit crystals on the side of the test tube. Genuine wine sheds a pulverulent deposit which does not adhere to the glass, and is devoid of a crystalline structure. Acetic acid will dissolve either of these precipitates. The deposit from the cider consists of flat crystals with parallel sides; that from wine shows star-shaped formations. The treatment with acetic acid shows the presence of lime and phosphoric acid in both cases, the quantity of lime in the wine being minute.

The Prizes of the Painters' Company.—The educational movement on the part of some of the London guilds is a good sign, and has not come too soon. The Painter Stainers' Company, as it was anciently called, was one of the first, in a comparatively small way, to offer medals and premiums for works connected with "the art and mystery of painting." The subject for which they offer rewards to decorators, artisans, apprentices, and others, is described as "alto-relievo and decorative painting," and the prizes, three in number, are—1. The Company's silver medal and freedom of the Company; 2. The Company's silver medal; and 3. The Company's bronze medal. These rewards are open to any under the age of thirty years, engaged in the trade, and residing within a radius of twelve miles from the Company's Hall. The specimens must be sent in between the 18th and 25th of May. It is to be hoped that some good work will be elicited. The Company do not ask for design, as the programme says the subjects may be copied either from an antique bust, cast of ornamental grouping, decorative moulding, or otherwise.

The Royal Society Soiree.—The first, which will be the only soirée for the present year, was held on Saturday evening last at Burlington House. The show of objects was all that could be desired, although there was no novelty of intense importance. In the philosophical group there were many things of interest—notably, in the first place, Lord Lindsay's photographs of the late solar eclipse, two of which were shown stereoscopically with admirable effect. At the same table were several new and important instruments by Mr. Browning, of which we may particularly mention a telespectroscope for viewing solar prominences, in which a ray of light is sent four times through compound prisms. The crystals of gold, silver, and other metals shown under the microscope in actual formation, by Dr. Gladstone, were very interesting, as was also the experimental decomposition of water and of iodide of ethyl by zinc in intimate conjunction with a more electro-negative metal. The trace-computor invented by Mr. Francis Galton deserves mention. It is applied at the Meteorological Office to obtaining from the curves of the dry and wet bulb thermometers the vapour tension of the atmosphere. By the cross wires of two micrometers being brought severally on these curves a pointer is compelled to take up such a position on a curved template as to cause the pricker of the instrument to record perfectly the vapour tension, which otherwise could only be obtained by means of complicated tables. A maximum thermometer of extreme delicacy, with index divided into tenths, so as to record to the one-hundredth of a degree of Fahrenheit, was contributed by Mr. G. J. Symons. Its range is from 65° to 85°, and it is calculated to withstand in service a pressure of three tons to the square inch. A simple hydrometer for obtaining the specific gravities of woods was shown, revised by Professor A. S. Herschel; it consists of a floating ring, to which the index is attached, and the bars of wood, cut to definite lengths, are simply immersed through the centre of the ring, when the gravity can be read off at once on the scale. Amongst the other interesting objects in this group were Mr. Napier's electro-magnetic light coin rejector; the Rev. A. Rigg's differential air-pressure gauge; the drawing of a curve from actual analyses illustrating the accuracy attained in the standard fineness of our British coinage, by the chemist to the Mint; a chart of 324,198 stars, by Mr. Proctor; Thomson's testing instrument for telegraph cables, &c.

CHIPS.

The very best way to clean a stained steel knife is to cut a solid potato in two, dip one of the pieces in brick dust (such as is usually used for knife cleaning), and rub the blade with it.

Repeated spectroscopic measurements made last year by Professor Zöllner and Vogel, in Germany, show that the velocity of rotation of the sun on its own axis is at the rate of 660 miles an hour.

According to the Abbé Moigno, in *Les Mondes*, a violent thunderstorm at Rosano (Italy), some weeks ago, was accompanied by a fall of pebbles, varying in size from a small cob-nut to a large-sized pigeon's-egg.

Annealing Steel.—Wm. Hamilton Hey (4013) will excuse my correcting his somewhat loose statement that heating steel to dull red in forge and allowing it to cool gradually in the ashes will make it soft enough for all practical purposes, as when I have finished this note I shall place a piece of red hot steel in common sawdust, and when cool it will be far softer than by the other method.—A., Liverpool.

ANSWERS TO CORRESPONDENTS.

*** All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, April 30, and unacknowledged elsewhere:—

J. B. Ward.—Wm. Whiteman.—R. Pearson.—E. Davis.—H. G. Nash.—Rev. G. S. Nichol.—Francis and Co.—T. C. H.—D. C. L.—D. H. Harvey.—S. H. Nash.—Wm. Brown.—E. S. Hunter.—John Dutton.—R. F. Fairlie.—Charles Fletcher.—A Jovial Fellow.—William Lea.—Joe. Waters.—G. W. Pagemont.—J. W. Buck.—W. Botton.—Hughes and Co.—C. A. Ball.—Rat-Tat.—Lancashire.—Cherryeater.—F. N.—F. A. Buffham.—Zeta.—P. W. H. J.—Bleaching Powder.—Ariel.—Bed of Stone.—Paddy.—S. W. Burnham.—Anglo-Celtic.—W. E. Lee.—Ralph Lowdon.—C. H. B.—T. P. Barkas.—C. Glasgow.—No. 170.—Amrotet.—M. A.—Go Ahead.—Adolescens.—Lancashire.—J. M. Taylor.—F. C. H.—Sholto Douglas.—T. T. Greg.—A Country Printer.—H. W. R.—W. F. R.—Ethyl.—M. Paris.—Albiereo.—3rd City.—A Novice.—Philanthropist.—Rudex.—J. C.—F. R. A. S.—Z.—W. R. Birt.—A., Liverpool.—E. G. L.—Senecio.—Fred. Harris.—T. C. H.—Rusticus.—G. J. C.—Jennings.—Petty Curry.—O. N. C.—Chronometer.—E. J. N.—Country Tinker.—V.—J. L.—Brake.—A Subscriber.—Musical.—Excelsior.—Workman.—Thetamu.—Not Proven.—W. H. B.—Samuel Kempling.—Perry.—Ricardo.—R. M. Hatch.—S.—Dexter Keen.—J. Starling.—Henry Page.—S. Bottone.—Wm. Tonkes.—W. L. G.—H. T. N.—Rev. W. White.—Artillery Captain.—Pattern Maker.—C. W. H.—F. A. Edwards.—S. H. L.—A. Cazala.—William Botham.—J. B. Cooke.—Dr. G. Goyard.—R. A. Proctor.—C. A. Bull.—John Rae.—C. H.—Delves.—Watts.—One Afflicted.—An Official.—An American.—An Upholsterer.—O S.—Clerk of Works.—Jackson and Shaw.—L. E. Redditt.—H. S. J.—A. M. C.—V. B.—Americus.

Communications which can only appear as advertisements to hand from J. L. A., Subscriber from the First, G. Baylis, A Nainsmith, M. W., J. P., Curious, W. T. B., Bradfordian.

FITTLE.—Have patience. If not answered, it will appear in the list of unanswered queries in due time.

GLASGOW.—Consult indices, and you will find in back numbers how to construct a telescope.

S. B.—Consult indices, and you will find in back numbers the best way of cleaning old coin. We cannot repeat questions for the benefit of occasional readers.

G. CHOUTER, W. DREW, E. ARMISTEAD, PRO RATA, see "Hints to Correspondents," over Replies to Queries.

ASTHMA.—The article referred to was merely a note bringing the subject before the medical profession. The author has not published a book on it.

AN OFFICER.—Another correspondent has this week put a question on the same subject. If answers to it are not satisfactory, write again.

E. L. G.—Yours on "Ventilation" next week, which must conclude the controversy.

DUPED.—If the maker of your Pulvermacher's chain will not answer your letters or give you any information, we must also decline doing so.

E. S. S.—We have laid down a rule to which we shall adhere at all hazards, and that rule forbids us to insert trading or commercial queries save as advertisements.

WEST CORNWALL.—A printer's error.

G. H. B.—We do not know of any work on bookbinding. You will find plenty of information in recent back numbers (especially Vol. XIII). Bookbinding is not an art. There are a few facts, termed the *modus operandi*, the rest is skill which comes of practice.

W. H. M.—The information you ask for about scientific meetings for the week is given in the *Athenæum*, the *Society of Arts' Journal*, the *Daily News* on Mondays, and other papers.

B. C. HULMER.—The treatise has not been published in a separate form. For second query write Trübner and Co., Paternoster-row, London.

PRIMROSE, S. MASON & CO., and R. W. E.—Your queries are advertisements. See "Hints to Correspondents."

H. C.—Works on telescope have been mentioned in our pages again and again.

W. C.—The reason why the query was not inserted was that a similar one was inserted and answered a few weeks before.

W. M. FLINDERS PETRE.—See our reasons in the last and preceding numbers for termination of controversy on the metric system.

PHAROS.—Inquire of a newsagent.

PARTONIAN SCHOOLBOY.—Answered by others.

PAUL GILL.—If the controversy on the decimal system were not terminated, your letter would certainly appear; but there has been too much passion and prejudice imported into the controversy to justify its continuance at present. If, at any future time, a discussion on the question be recommenced, we hope it will be considered on its merits, without linking it with the vices or the virtues of the French Revolution. We believe the decimal system will ultimately prevail for the same reason that we believe in the "survival of the strongest."

A READER.—Good food, and plenty of exercise for your first two requirements. A course of gymnastics will aid in acquiring your third, if you are naturally of a robust habit.

H. AXON and J. B.—Consult a medical man.

P. G., W. C. B., Edgar David, J. Guthrie, J. B. P. Darlington, E. L. E., J. L., One in a Fix, Emigrant, and Touchweight, are referred to indices to back vols.

F. WELLS.—The whole process of lead burning was given in Vol. XII., pp. 211, 356, and 406.

T. CRAWFORD.—For cement for aquariums, see p. 593 Vol. XII. Second query is an advertisement.

ANXIOUS INQUIRER.—We suppose you mean the telegraphic department of the postal service. Write to the Superintendent of Telegraphs, Telegraph-street, E.C.

A. F.—A description of the Leclanché cell will be found on p. 568, Vol. XII., No. 310; see also p. 616, No. 313. You ask for a good work on electricity, magnetism, &c. Have you read Mr. Sprague's articles in the ENGLISH MECHANIC?

H. B. E.—For information on water velocipedes, see p. 75, Vol. IX.; p. 121, Vol. X.; and p. 69, Vol. XII. We cannot at present speak definitely as to what we shall do with the mechanical inventions at the International Exhibition.

BARNES RICHARDS (Penzance).—We know of no published guide or handbook to advertising, but some such a thing is wanted, as there is much deception daily practised by canvassers and others. Advertisers have, however, to thank themselves in a great measure for it. They will follow each other like flocks of sheep into journals that have little or no circulation, and neglect journals of wide circulation. There is, for instance, a scientific journal published in London which has not one-twelfth of the circulation of the ENGLISH MECHANIC, but it has twice the number of advertisers. Some will ask, why is this? Because the said journal pays men an enormous percentage to canvass for advertisements, and those canvassers, not being very scrupulous in the statements they make, manage to throw dust in the eyes of advertisers, and so victimise them.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING APRIL 23, 1872.

1123 W. R. Renshaw, Kidsgrove, Staffordshire, for improved means and appliances for puddling iron.

1124 H. Stephens, Breage, and J. Harvey, Wendron, Cornwall, for improvements in crushing, dressing, and refining tin and other ores, and in apparatus employed for these purposes.

1125 P. Ironside, Lambeth, for improvements in machinery or apparatus for raising and lowering carriage steps.

1126 T. N. Palmer, Dalston, for an improved method of and apparatus for producing motive power. A communication.

1127 F. A. Harrison and C. Priestland, Birmingham, for improvements in attaching door and other knobs to spindles.

1128 H. Glaysher, Newport, Isle of Wight, for improvements in marine engines.

1129 G. Hepburn, Liverpool, for improvements in governors for steam and other engines.

1130 B. J. B. Mills, Southampton-buildings, for improvements in the manufacture of sheet iron. A communication.

1131 D. McC. Smyth, Orange, U.S., for improvements in sewing machines.

1132 C. S. Venables, Essex-road, Islington, for improvements in pianofortes.

1133 J. R. Taber, Southampton-buildings, for improvements in artificial breasts for ladies' wear. A communication.

1134 D. Dubbin, Lewisham, for improvements in self-acting stands for beer or other casks.

1135 W. R. Lake, Southampton-buildings, for improvements in the manufacture of iron bars, plates, sheets, or slabs. A communication.

1136 A. V. Newton, Chancery-lane, for an improved mode of and apparatus for preserving animal and vegetable substances. A communication.

1137 A. R. Duncan and J. Macnaughton, Edinburgh, for improvements in breech-loading fire-arms. A communication.

1138 G. Clark, Craven-buildings, Drury-lane, for improvements in shoes and boots.

1139 E. Edwards, Southampton-buildings, for improvements in steam traps. A communication.

1140 B. J. B. Mills, Southampton-buildings, for improvements in apparatus for the extraction of oil, fat, or resin from vegetable or other solid matter by chemical agency, and the recovery of the chemical employed. A communication.

1141 F. Alekan and I. Alekan, Paris, for improvements in screw studs for shirts, cuffs, and similar purposes.

1142 W. H. Hacking and T. Hacking, Bury, Lancashire, for improvements in machinery for folding and measuring woven fabrics.

1143 J. S. Christopher and J. F. Lackersteen, Lombard-court, City, for improvements in propelling vessels.

1144 J. W. Harper, Stowmarket, for improvements in the arrangement and construction of hammock-beds, more particularly applicable in tents.

1145 W. E. Newton, Chancery-lane, for improvements in distilling apparatus. A communication.

1146 J. Peris, Middlesborough, for improvements in reverberatory and other furnaces.

1147 S. Barlow, Oldham, for improvements in apparatus for the prevention of accidents upon railways.

1148 H. J. H. King, Glasgow, for improvements in apparatus for feeding wool, cotton, or other fibrous materials to carding or other machines.

1149 J. L. Norton, Ludgate-hill, for improvements in the construction of walls, ceilings, and floors of buildings and other structures.

1150 S. Sorby, Denham, Uxbridge, and J. C. Richardson, Maidenhead, Berkshire, for improvements in multiple furrow ploughs.

1151 J. L. Norton, Ludgate-hill, for improvements in the manufacture of blocks and slabs for building, paving, and such like purposes.

1152 S. Crighton, Manchester, for improvements in apparatus for regulating the feeding of machinery employed in the preparation of cotton and other fibrous materials.

1153 C. Jackson, Birmingham, for improvements in sewing apparatus.

1154 W. B. Robins, Shepherd's-bush, for improvements in hand pumps or syringes.

1155 E. F. Goransson, Sweden, for improvements in apparatus for obtaining motive power.

1156 G. Holcroft, Manchester, and J. F. Lackersteen, City, for improvements in apparatus for separating metals from their ores or other admixtures.

1157 T. C. Fidler, Emberton, Bucks, for improvements in the construction of suspension bridges and iron arches.

1158 J. Broel, Westbourne-terrace, Middlesex, for improvements in apparatus for lighting and heating.

1159 C. Catlow, Lancashire, for improvements in looms for weaving.

1160 S. Brooke, Yorkshire, for improvements in carding engines.

1161 B. Graham, Batley, Yorkshire, for improvements in apparatus for preparing wool or other fibrous substances for feeding carding engines.

1162 H. Warry, Parkstone, Dorsetshire, for improvements in various beverages.

1163 H. A. Dufrene, South-street, Finsbury, for an improved process for the preservation of textile fabrics from the destructive effects of wet or moisture. A communication.

1164 R. Griffiths, Rhual Isaa Mold, Flintshire, for improvements in the construction of steam ships or vessels, and in screw propellers.

1165 J. Davey, Cornwall, for improvements in the construction of turn-wrest ploughs, parts of which improvements are also applicable to steam ploughs.

1166 P. Rosier, Paris, for improvements in apparatus for emptying or exhausting the conduct or supply pipes of cisterns and similar structures as a protection from frost or other damage.

1167 J. Campbell, Founders court, City, for improvements in the mode of getting at the external bottom of ships and vessels for the purpose of cleaning, repairing, and overhauling them.

1168 G. Halfe, Stockport, for improvements in machinery for winding yarn.

1169 G. L. Shorland, Manchester, for improvements in grate backs for increasing the efficiency of sham register and other firegrates.

1170 J. Edge, Bolton-le-Moors, Lancashire, for improvements in boilers or steam generators.

1171 J. Barrow and C. J. Crosfield, Liverpool, for improvements in utilising certain saccharine syrups, and in apparatus employed therein.

1172 B. Ramsden, Leeds, for improvements in steam boilers.

1173 S. Kay and T. Kay, Stockport, for improvements in feeding bottles, parts of which are applicable to other purposes.

1174 R. Wilson, Manchester, for improvements in hydraulic machinery or apparatus.

1175 W. R. Lake, Southampton buildings, for an improved machine for filling metallic boot-heel shells with wood or other materials. A communication.

1176 W. R. Lake, Southampton-buildings, for an improved process of treating animal and vegetable fats or greases for the purpose of obtaining stearine and oleine therefrom. A communication.

1177 J. Hawker, Chard, Somersetshire, for improvements in steam road locomotive or traction engines, parts of which improvements are applicable to portable engines.

1178 T. J. Smith, Fleet-street, for improvements in Jacquard machinery. A communication.

1179 M. Rowlands, Pontypridd, Glamorganshire, for improvements in coke ovens and in the means of charging the same.

1180 F. G. Fleury, Southwark, and A. Tylor, Newgate-street, City, for improvements in water waste preventers or apparatus for controlling and arresting the flow of liquids.

1181 A. F. Ragon, Upper Westbourne-terrace, Middlesex, for a new or improved case for railway and other tickets, fitted with a memorandum paper or advertisement sheet. A communication.

1182 H. Bytheway, Pontypool, Monmouthshire, for improvements in annealing boxes, pots, or pans, used in tin works.

1183 C. H. Aston, Birmingham, for improvements in connection with spiral spring mattresses and frames, and spiral springs used in connection with frames, bedsteads, couches, and for other upholstery purposes.

1184 H. C. Briggs and D. R. Ramsay, Saltburn-by-the Sea, Yorkshire, for improvements in steam generating and heating apparatus to be used in connection with rotary or other puddling furnaces.

1185 W. D. Scott, Glasgow, for improvements in governors for motive-power engines.

1186 G. Davies, Manchester, for improvements in the construction of stereopticons. A communication.

1187 A. McGregor, Lancashire, for improvements in the construction of machinery for reaping and mowing.

1188 R. Shaw, Higher Walton, Preston, for improvements in drawing frames used in the preparation of cotton and other fibrous materials.

1189 M. Doubelt, Grosvenor Hotel, Middlesex, for improvements in the means and apparatus for the transmission and registration of telegraphic despatches. A communication.

1190 J. H. Teal, Tennessee, U.S., for controlling, regulating, and shifting the packing of pistons working in cylinders, as in steam, air, and water engines, air and water pumps, and other machines, while the same are in motion.

1191 N. P. Stockwell, Regent's-street, for improvements in embroidery and tuck-marker attachment for sewing machines. A communication.

1192 W. B. Thelwall, Upper Holloway, for improvements in the construction and method of actuating colossal and other figures of men, monsters, and animals for stage purposes.

1193 E. J. Hill, Pimlico, and J. L. Clark, Westminster Chambers, for an improved boat-lowering apparatus.

1194 S. H. Stevens, Crowan, and T. Williams, Helston, Cornwall, for improvements in machinery for reducing tin stuff and other partially pulverised ores and substances.

1195 W. W. Laddle, Buckinghamshire, for an automatic pulp save all.

1196 J. Pickles, Bramley, Leeds, for improvements in the machinery or apparatus employed in puddling iron.

1197 G. R. E. Fairholme, Roxburgh, Scotland, for improvements in household fire-escapes.

1198 S. Johnson and A. Johnson, Leicester, for an improved plumb rule and level.

1199 J. Hunt, Bolton, for improvements in apparatus for winding thread or yarn upon pirns or bobbins.

1200 J. F. M. Pollock, Newtown, Leeds, and J. Mitchell, Bradford, for improvements in kilns.

1201 L. Fontana, Paris, for improvements in the treatment of certain substances employed for some surgical and therapeutical applications.

1202 W. R. Lake, Southampton-buildings, for an improved burner for lamps and other illuminating apparatus. A communication.

1203 H. B. Barlow, Manchester, for improvements in apparatus for cooling wort and other liquids. A communication.

1204 F. H. A. Heyer, Leather-lane, Holborn, for an improved press for printing and copying.

1205 W. Ferry, Southampton, for improvements in cistern filters.

1206 T. J. Smith, Fleet-street, for improvements in the manufacture of buttons. A communication.

1207 G. Little, New Jersey, U.S., for improvements in electric telegraph apparatus and in circuits employed in telegraphing.

PATENTS SEALED.

2806 W. McKenzie and C. A. Cameron, for improvements in the manufacture of solidified tea and coffee.

2809 J. F. M. Pollock, for improvements in machinery for compressing bricks, tiles, and other similar articles.

2813 J. Petrie, for improvements in valves of steam engines.

2815 E. T. Hughes, for an improved liquid meter.

2816 J. Sellers and E. Hopkinson, for an improved machine or apparatus for effecting calculations, applicable to weights measures, time, and money.

2823 G. A. Vivien and P. C. Vivien, for a novel chemical composition for the preservation of wood, metal, and other substances.

2833 J. F. Wanner, for improvements in the ornamenting of garments, and of silk, woollen, and other fabrics.

2836 T. K. Mace, for improvements in hats.

2837 H. Stapfer and J. Sinclair, for improvements in apparatus for withdrawing or discharging ale or other liquor or liquid from casks or receptacles, and for raising the said ale, liquor, or liquid to a higher level.

2842 P. Lecloux, for an improved double balanced bolt or fastening for windows, shutters, folding doors, and other like purposes.

2843 J. J. Turner, for improvements in constructing the wheels of railway and tramway rolling stock.

2844 W. T. Sugg, for improvements in apparatus for distributing fluids and liquids.

2847 E. T. Hughes, for improvements in hydro-meters.

2851 W. R. Lake, for improvements in sewing machines.

2861 W. McAdam for obtaining motive power by the rising and falling of tides and in the machinery or apparatus employed therefor.

2862 W. Symons, for improvements in the construction of the framework or hull of ships and vessels.

2870 H. G. Lawson, for improved mechanism for transmitting power.

2872 H. G. Lawson, for improvements in harvesting machines.

2878 W. Pidding, for improvements in mechanism to be attached to wheeled vehicles to form a railway therefor.

2884 F. W. Webb, for improvements in locomotive engines and railway breaks.

2911 W. R. Lake, for improvements in metallic packing for the piston and valve rods of steam and other engines.

2923 R. Winder, for improvements in steam ploughs.

3037 W. Bayley, for improvements in roller blind furniture or apparatus.

3177 A. V. Newton, for improved machinery for printing from types.

3355 E. Entwistle, for improvements in railway signals.

3357 G. Evans, for improvements in the manufacture of asphalte or composition adapted for paving and other similar uses.

60 G. Lewis, for improvements in ploughs.

283 H. W. Ripley, for improvements in colouring fabrics.

412 T. Cockshott, for an improved method of laying sub-marine telegraph cables in connection with shipping in different rivers, harbours, and seas, and other places.

480 C. D. Abel, for improvements in moulds and cores and in mould and core linings and facings for metal castings, and in materials employed therefor.

563 W. C. Church, for improvements in steam engines, parts of which improvements are applicable to hydraulic rams and pumps.

593 J. Quick, sen., J. Quick, jun., and A. Cooper, for improvements in signal lanterns or lamps.

595 G. Westinghouse, jun., for improvements in pneumatic apparatus for working brakes and communicating signals in railway trains.

2839 W. Onion, for improvements in machinery or apparatus employed in the manufacture of looped or knitted fabrics.

2841 D. Wilks, for improvements in apparatus for collecting, receiving, and holding all animal refuse and manufacturing the same into manure without nuisance, particularly applicable to the collecting, deodorising, removing, and utilising human excretions and other animal matter of large towns.

2848 L. Hornblower, for improvements in the construction of walls, partitions, floors, and roofs of dwelling-houses and other buildings.

2859 S. Alley, for improvements in wheels for steam and other carriages.

2869 R. A. Wright, for improvements in apparatus for fastening purposes, especially applicable to the fastening of railway and other carriage doors.

2877 W. H. Chase, for an improved animal trap chiefly designed for catching rats and mice.

2893 G. Green, for improvements in apparatus for separating ores and other materials.

2932 J. H. L. T. Portner, for improvements in sewing machines.

2979 J. Jordan, for improvements in steam boilers and in arrangements connected therewith.

3011 A. Maw, for improvements in machinery or apparatus to be employed for the working of screw presses.

3013 A. P. Tronchon, for improvements in the construction of counters for cabs, carriages, or other vehicles.

3043 J. H. Johnson, for improvements in solidifying petroleum, schist, and other oils and their volatile essences employed for illuminating purposes, and in the purification and liquefaction of such solidified oils and essences.

3099 J. I. Sands, for improvements in the means of and apparatus for locomotion, applicable to steam carriages, also to traction and other locomotive engines, and to steam road rollers.

3178 J. H. Johnson, for improvements in artificial dentures and in bases for the same.

3183 A. M. Clark, for improvements in apparatus for reefing and furling ships' sails.

128 A. Lee, for improvements in apparatus to be applied to pipes used for heating buildings by steam.

253 B. J. B. Mills, for improvements in seal locks.

345 W. R. Lake, for an improved wood pavement.

346 W. R. Lake, for an improved machine for packing and securing blocks laid for paving and for other like purposes.

354 W. Betts, for improvements in capsules, and in apparatus to be employed in their manufacture.

355 W. Betts, for improvements in machinery or apparatus for capsuling bottles and other like receptacles.

371 F. Taylor, for improvements in the construction of bedsteads for invalids.

477 O. C. Betchell, for improvements in treating or preparing certain waste substances so as to render them useful as compositions for lighting fires.

494 F. Hills, for improvements in the treatment and utilisation of sewage and the manufacture of manure therefrom.

531 W. R. Lake, for improvements in breech-loading fire-arms.

561 F. A. Gatty, for improvements in printing and dyeing cotton fabrics.

603 W. Weldon, for improvements in treating and applying dilute chlorine.

624 G. H. Smith, for improvements in metallic alloys, and in their application to iron surfaces for preventing the corrosion of the same.

659 J. Sullivan, for improvements in chamber vessels.

679 W. R. Lake, for improvements in railway rails.

The English Mechanic
AND
WORLD OF SCIENCE AND ART.

FRIDAY, MAY 10, 1872.

ARTICLES.

THE ENTOMOLOGIST'S HOLIDAY.

WITH the increasing warmth of the now rapidly strengthening spring many of our numerous insects are putting on the holiday garb of their ephemeral existence, and beginning to quit their winter haunts for the scene of their short, but too often mischievous career. Their ardent admirers, the Entomologists, who may be considered as their devoted friends, though probably regarded by sundry species of butterflies and moths as their inveterate enemies, are also on the *qui vive*, and are diligently preparing their paraphernalia for the coming campaign. The Lepidopterists and the Coleopterists — the moth-hunters and the beetle-catchers—are setting in order their nets and their killing-bottles; examining their cabinets for vacant spaces and noting down the species wanting. As soon as the warmer nights set in they will be out on foraging expeditions, searching for the beautiful ornaments of the woods, the coppices, and the fields as ardently as astronomers examine the markings on the moon or the rings of Saturn. Entomologists, however, have an advantage over the astronomers; for while the principal objects of interest to the latter are only to be seen at night, the enthusiastic insect-collector may pursue his hobby at every hour of the twenty-four. We are not concerned to defend our friends from the charge of cruelty which may be brought against them by ultra-sensitive minds, so long as they capture moths and butterflies for a higher purpose than the mere pride of exhibiting their achievements; for even Tennyson's sweet-hearted young lady "whose light-blue eyes were tender over drowning flies," would, we imagine, offer but a feeble opposition to the utter destruction of every thing termed a "moth." As a matter of fact, however, the study of Entomology in all its bearings is a subject of the first importance to the farmer and the practical horticulturist, if the truths which it teaches are rightly read, and the knowledge gained turned to account in a scientific manner. This, it is true, involves a knowledge of the life-history of the insects from the egg to the perfect state; but as this is not to be acquired in a day or in a year, but only by patient and unflagging observation, we have thought it probable that if a taste for collecting the more beautiful specimens of the insect world could be infused, the contemplation of them might lead to a desire to be better acquainted with the different phases of their lives, and so, step by step, to a knowledge of the humbler denizens of our cultivated fields, which though less attractive to the eye are often far more destructive in their operations. Science, we know, should be pursued for its own sake; but science, with too many, means flashy experiments and attractive sights, without which but little attention can be obtained for even the most entertaining and instructive subjects. It is, therefore, with an ulterior object that we lay before our readers a few hints for the capture and preservation of moths and butterflies—viz., in the hope that at least a moiety of those who may endeavour to make a collection will pursue the subject further, and turn the knowledge so acquired to scientific purposes.

The net forms the most important part of an entomologist's equipment, and there are as many designs for this implement as there are days in the week. The one most commonly used, however, and the most serviceable for beginners, consists of a light steel ring, jointed so as to fold up into small compass for convenience of carrying, and provided with a handle, which may be made to screw on when wanted for use. But a more easily made and just as serviceable form is the cane-net, which consists of a tubular Y or T shaped piece made of sheet brass or tin plate, into the arms of which the ends of the cane are secured, while the leg forms a socket for the insertion of the handle. There are also the clap-net, the umbrella-net (a folding net patronised by many), and a net with a handle about 20ft. long, supposed to be necessary for capturing some species. Possibly the best material for the "bag" of the net is grenadine, but this is rather expensive; book muslin answers all the purposes of beginners, and is generally used. Some lepidopterists prefer a black-coloured net for night work, as the insects can be more readily distinguished; but white should always be preferred to green for day work. The bag should be made tapering, with the seams outside; about three-fourths the length of the collector's arm; and if the ring is of steel it should be covered with thin leather. A collecting-box is not absolutely necessary, but it is at all times convenient. It should preferably be made of zinc in order that the cork may be damped—a very requisite operation on a hot summer's day. With the box, a number of pins should be carried (No. 10 is the most useful size) for pinning the captures to the cork, and a number of pill and ointment (chip) boxes, previously strengthened by pasting strips of thin calico around the joints, and with four or five small holes in the bottom. Some method of killing, or at least stupefying, the captives is essential, or on returning home after a long day, many will be found to have nearly knocked themselves to pieces and irretrievably damaged their beauty. For this purpose there is nothing better than the cyanide bottle, the mode of preparing which has been described in these pages. It is merely a tolerably wide-mouthed bottle, on the bottom of which a layer of cyanide of potassium is spread and covered with a thin stratum of plaster of Paris. When the plaster has set, three or four pieces of blotting-paper are laid on it, and a good tight-fitting cork, sealing-waxed at the top and upper part of the sides, completes the killing apparatus, which will last nearly the whole season if kept cool and properly corked. If the collector is without a killing bottle, or wishes to stupefy a specimen confined in one of the chip boxes, it is only necessary to dip a very small piece of blotting-paper in a solution of the cyanide, and drop it into the box; but this will require a pair of pincers, or miniature tongs, in order to hold the paper. A bag or basket of some kind is almost a sine-quâ-non if we would return with our treasures uninjured—a fisherman's basket, which can be instantly detached from the shoulder-straps answers very well. These will about make up the complement of the necessary apparatus for an ordinary daylight excursion when Lepidoptera are caught on the wing or "settled;" but if the night-fliers are sought, which are generally captured by "sugaring," one or two "weapons" of a different kind will be found requisite. The first is, of course, the sugar itself. Opinions vary as to the *best* compound, but the tyro will find the following probably as enticing as any:—Boil equal parts of treacle and "foots" with sufficient beer (stale will do) to make the mixture work well with a brush, neither too thin nor too thick. Place this in a bottle or the regulation sugaring tin, and just before starting to lay your traps mix with it a small quantity of rum—not too much, or the moths will fall off and be lost in the grass or underwood. Begin to sugar as soon as "dusk" has fairly set in, choosing trees with rough bark at intervals of nine or ten yards, and putting on a narrow streak about a foot from the ground up to the height of the face. Where there are no trees, bushes, thistles, and the flowers of ragwort and umbel-bearing plants may be tried, tufts of grass, and even good-sized stones. The sugaring performed, the would-be collector must trim his lamp and see there is no scarcity of oil. A lantern with a piece of plate-glass for a window is better than a bull's-eye for "sugaring," but there should be a cover for it and a strap so that it may be hung round the neck or carried in some way so as to leave both hands at liberty on an emergency. As a rule but little difficulty will be experienced in securing moths at "sugar." They may be boxed-off on the tree, tumbled into the cyanide bottle, or netted in the usual "sugaring" net. This latter is made Y-shaped or V-shaped, by securing steel wires into a socket of the requisite form, and connecting the ends by a piece of flexible wire or stout string, or, indeed, any material that will yield to the shape of the tree-trunk when pressed against it. It should be of a size convenient for supporting it by pressing with the leg against the end, so that both hands can be used for boxing or bottling, while any insects that fall are received by the net. A catching and pinning box is used by many, which is constructed as follows:—A wooden or very stout cardboard tube, at least 2in. in diameter and about 4in. long, is covered at one end with a piece of strong network (fine brass wires secured in holes at the sides and crossed would, perhaps, be an improvement), and about half an inch from the other end a slit is cut transversely for half the circumference, in which a circular piece of tin, zinc, or cardboard can be slipped so as to close the tube; a piece of cork, of nearly the same diameter as the cylinder, to which a short rod is attached, completes the apparatus. The method of capturing with this consists in placing the end of the tube over the moth, which flies to the netted end; the disc is then slipped through the slit, the cork piston inserted into the tube, and, the disc being withdrawn, the cork is pushed towards the netted end, by which means the moth is easily pinned through one of the meshes and drawn out with the cork.

We think we have now mentioned all the "weapons" necessary for a fully-armed collector, and we have left ourselves but little space to speak of the *modus operandi* of the art. As to giving any description of the species to be sought after and prized, it would be useless here, as a great deal, of course, depends on the nature and general characteristics of the hunting-grounds within reach of the entomologist. In and near London, Epping Forest is probably the best spot, especially those parts which, some distance from the "line," are beyond the usual range of the army of collectors who visit that locality. All woods are likely places, particularly in parts where trees have been felled and clearings made; so are parks, with their old trees and young plantations; hedge-rows, ponds where there is abundance of vegetation, chalk and gravel pits, and for some species of night-fliers the gas-lamps or the windows of an illuminated room. Just as in other pursuits of life, the collector who works with his head, and saves his legs and arms until their energetic use will really assist him, is invariably the most successful; a knowledge of the habits of the various species, the time and manner of their flight, the plants they frequent, and the various other minutiæ of the art, is of course of great assistance, but much of this can be acquired from manuals specially devoted to the subject, and a little practice teaches more than volumes. The enthusiastic tyro who has been rushing about all day, and, perhaps, succeeded in capturing half a dozen butterflies, which he has utterly spoilt by his rough treatment, is apt to be disappointed when he examines the "bag" of a more practised friend, who has merely pitched on a likely spot and waited his opportunity

There is, however, one method of capturing many species of Lepidoptera which requires but the minimum of time and patience. This is hunting the sallows in the spring and the ivy in the autumn; for when in bloom their visitors very rarely leave till they have recovered from the effects of the absorbed nectar, and so fall an easy prey to the collector. For this purpose a hooked stick, a shallow net, a bull's-eye lantern, and an umbrella or a sheet, are the principal requirements, with, of course, the usual boxes and killing-bottle. Having ascertained the whereabouts of the bushes, choose an evening free from wind, and with the net carried a little below and in front of the lantern examine the bushes. The moths being intoxicated frequently fall into the net directly the light is brought near them; and, if not, a gentle tap with a stick on the branch will insure the capture of the victim. For branches out of reach the umbrella is held open underneath and the moths gently shaken off the bush; or a sheet may be placed around the roots where the ground is suitable. Warm dark nights, with a light steady wind in one quarter, will, however, rarely fail to yield a goodly number of moths at sugar, and even moonlight nights are not always barren of game. Great care, is, of course, necessary in removing the captive from the net; but by the exercise of a little skill, without excitement, a very few trials will make the tyro proficient. The net must be so held that the moth cannot fly out, and a lidless box being taken in one hand is passed into the net and over the moth and grasped by the other hand from the outside. The free hand is then at liberty to take the lid and carefully slide it between the top of the box and the net, and so the insect is captured without damage. Such are some of the rudiments of the art. The names and characteristics of the numerous species can, of course, only be [illegible] from voluminous works and catalogues, or [illegible] collections; permission to view is general[illegible] by nearly all Entomologists, and nothi[illegible] calculated to infuse the spirit of emul[illegible] good look at an extensive and well-[illegible]

In these columns we should not have space to mention even the names of all the British Insects, but we may at some future time give some hints on setting and arrangement. In the mean time, we hope those who may "collect" will not rest satisfied with mere admiration of the beauties of their captures, but will endeavour to acquire a knowledge of their life-history and of their purpose in creation.

NOMINAL HORSE-POWER.

IN an article on the rating of steam-boilers, which appeared on p. 28 of our last volume, we drew attention to the desirableness, indeed, the necessity, of adopting a general and well-understood rule for estimating the horse-power of steam-boilers. A very large number of purchasers of steam-engines and boilers are uninitiated into the mysteries of calculating the power which those machines are capable of developing, and being utterly at a loss to comprehend the formulæ employed by mechanicians in estimating this power are easily deluded by designing manufacturers. We do not wish to insinuate that makers as a rule are in the habit of deceiving unwary purchasers, but, like most other businesses nowadays, there are manufacturers of engines and boilers who do not hesitate to represent their goods as being capable of accomplishing an amount of work which on trial it is found impossible to obtain with the surrounding conditions. There is, it is true, some little excuse for this method of conducting business on the part of the makers, for so long as there is no recognised rule for ascertaining and stating the power, the seller may say that it is no part of his duty to inquire under what circumstances the buyer intends to employ the engine and boiler he purchases. They may be capable of indicating the power stated when worked at the requisite pressure and piston speed; but it frequently happens that this part of the calculation never troubled the purchaser, and as the seller did not choose to enlighten him, he speedily finds himself disappointed and considers himself deceived.

Nominal horse-power is at the present time a mere name, possessing no definite value—being, in reality, rather more delusive than instructive. The rule laid down by Watt, calculated for a steam-pressure of 7lb. per sq. in. did very well for the purpose at the time, before the steam-engine had reached its present development, but it is quite inappropriate now that the average pressure is something like 49lb. on the sq. in. Still, if Watt's rule were generally adhered to, the expression "nominal horse-power" might not be so unmeaning as it is, because it would be easy to find out exactly what was intended, but the method of calculating the nominal power varies in different parts of the country and with different descriptions of engine. According to the Admiralty rule the square of the cylinder's diameter in inches is to be multiplied by the piston-speed in feet per minute, and the product divided by 6,000; but on the Clyde and in the North of England, where large numbers of engines are made, a nominal horse-power is reckoned for every 30 circular inches of piston area, counting both high and low pressure cylinders; while on the Thames 17 or 20 circular inches of piston are taken to represent a nominal horse-power. Again, the Royal Agricultural Society, in order to guide the farmers, adopted 10 circular inches as the standard in estimating the power of portable engines —a rule generally accepted by the makers and universally employed in rating that class of engine. Besides these, there are numerous other rules, giving results which differ from one another, and affording anything but an accurate idea of the power actually to be obtained.

Indications are not wanting that a remedy for this state of things will shortly be proposed which will possibly receive the sanction of authority, and so settle a vexed question. Towards this desirable solution of an acknowledged difficulty, Mr. J. Macfarlane Grey, M.I.M.E. and N.A., contributes an able paper (to the *Nautical Magazine*), and though it is devoted to a consideration of the question as it affects marine engines, there is also much in it which pertains to steam-engines generally. After pointing out that the Board of Trade should insure reliable information as to the power of the machinery in emigrant ships, he proceeds to lay down the principles on which the power of the engines should be estimated. The primary source of the power being the fuel, the rate at which that can be consumed is the first element of the sum. This Mr. Grey puts at one ton of steam coal a day per foot of furnace width, irrespective of length of bar. After calculating the quantity and the power of the steam thus produced, he proposes that the nominal horse-power of the marine boiler should be taken as 20 horse-power for each foot of furnace front. Turning to the engine, he proposes that 10 circular inches of piston area should be taken as a nominal horse-power, counting only the low-pressure pistons in compound engines, which corresponds to 14lb. effective pressure, and a piston-speed of 300ft. per minute. It will be observed that Mr. Grey proposes to reckon only the low-pressure pistons, a point on which he differs radically from the custom adopted in the North. His reasons for this we give in his own words:—"The high-pressure cylinders do not add to the power of the engine. A horse is no higher because you have used a stepping-stone to get on his back; the stone is not added to the height of the horse. So with the compound engine; the high-pressure cylinder is only a stepping-stone dividing the work to be done, but not adding to it. To include all the cylinders may or may not be a convenience in the buying and selling of engines, but in a rule for horse-power it introduces confusion, and I apprehend that, even commercially, the high-pressure cylinders have no more claim to be included than the surface condensers, or any other adjunct distinguishing a type of engine."

In order to ascertain the "nominal indicated horse-power" he proposes to add together the nominal horse-power of the boiler and that of the engine, and the formula comes out thus—

$$\text{N. I. H. P.} = \frac{D^2}{10} + 20\ F$$

where D^2 is the sum of the squares of the diameters of the cylinders, divided by 10; to the product, 20, multiplied by the width of the furnaces in feet, is to be added, and the result is said to agree very closely with the *average* indicated power, when there is surface condensation. With the jet condenser $17\frac{1}{2}$ F is to be substituted for 20 F. Mr. Grey also gives formula for ascertaining the power when the expansion and pressure form portions of the calculation.

So far as marine engines are concerned, therefore, the prospect is fairly satisfactory, for it only remains for some of the principal persons concerned to accept Mr. Grey's proposals or improve upon them to induce the Board of Trade to make regulations with which we imagine the majority of marine-engine builders would readily agree. This portion of the matter, however, is surrounded with difficulty in connection with land-engines; for though one of the Engineering Societies might be induced to publish a rule which would answer all requirements, it would not be able to enforce its observance, although, as a matter of fact, of course, obstinate makers would be in the hands of the buyers, who could refuse to purchase of those builders who declined to adopt what would doubtless become an almost universal system of rating. It may be remembered that in the article previously mentioned it was stated that the Committee of the Franklin Institute regarded their report as a preliminary one, and solicited the results of investigations from all parts of the civilised world. There is, therefore, an excellent opportunity for one of the mechanical societies of this country to join with the Franklin Institute in establishing a rule which would be recognised at least in all English-speaking countries.

As a matter of fact, whatever formula may be adopted for this purpose, it cannot be accepted as the true measure of the capability of any engine—the power actually indicated in working can alone be deemed satisfactory; nevertheless the advantages of a commercial unit of measurement are so self-evident that it is worth while inquiring whether there is not some way of stating the power developed under certain circumstances which shall be accurate for the given circumstances and be readily calculated for altered conditions. Thus, as suggested by *Engineering*, whose remarks on this subject we print on another page by way of corroboration, if an engine were rated and sold as "80 C. H. P. (60·5·400)" which would mean that it was "calculated" as capable of exerting a power of eighty horses under steam of 60lb., expanded five times, with piston speed of 400ft., a definite idea of its capability would be furnished, and the purchaser would be enabled to ascertain what its power would be under the special conditions of his own requirements. There will be little difficulty in framing simple rules by which to determine the "calculated indicated horse-power" with as near an approximation to accuracy as those of Mr. Grey given above.

The "rating" difficulty is, however, more easily solved with marine engines, for the simple reason that boilers and engines can be reckoned, as one machine, the sole duty of the former being to supply the latter; but, as a rule, boilers employed in workshops have to supply steam for other purposes than driving the engine, such as heating, washing, steaming, &c., and hence the necessity, if the rule depended partly on the size of the boiler, that the "rating" should specify the elements on which it is constructed. Some recognised unit of measurement is certainly wanted, as much for the security of the buyer as the credit of the seller.

THE SUN AND TERRESTRIAL MAGNETISM.

THE nature of terrestrial magnetism is but imperfectly understood; and the thoughts of physicists are much engaged upon it. In a recent research by Professor Osborne Reynolds, a theory is ennunciated, according to which the earth's magnetism is produced by electrical influence from the sun. His reasoning, briefly stated, is as follows:—

If an electrified body be placed near a moving conductor (such as an endless metallic band), it will induce a charge in the latter. This charge will remain opposite the electrified body, and the effect will be the same as if a current were moving in the conductor in an opposite direction to that in which the conductor moves.

Suppose, instead of an endless band, we have a steel or iron top spinning opposite the electrified body, the electricity induced on the top will have the effect of a current passing once round the top of each revolution. And this effect will be a magnetising of the top, the position of the poles depending on the direction of the top's motion, and the kind of electricity induced. The production of such a current was proved experimentally. On a glass cylinder 12in. long, and 4in. across. were fixed strips of tinfoil parallel with the axis. These strips were 6in. long and $\frac{1}{4}$in. wide, and were separated from each other by the two-hundredth of an inch, except in one part, where there was a wider interval, and the strips on each side of this were connected by a commutator with the wires of a galvanometer. The cylinder was then made to rotate rapidly before the conductor of an electrical machine. The galvanometer needle was deflected at times as much as 20°; the direction of deflection depending on the direction of motion, and the nature of the electricity induced. This, then, may be taken as proof that a magnetising current would be produced in the steel top, in the case previously supposed.

Now, the direction of the earth's magnetism has a close relation to the earth's shape. But as we know it is not in any way the cause of this shape, we may suppose that the figure of the earth, and the rotation which causes the earth to keep this figure, has something to do with the production of magnetism. There must be some influence at work, which, along with the earth's rotation, results in magnetism. What is this influence?

Many things show that the sun has some connection with magnetism. If, then, we seek this influence in the sun, we cannot suppose it to be the result of the sun's heat, or light, or attraction. But, if the sun were charged with negative electricity, it would seem (reasoning analogically from experiment) to result that the earth would become magnetic, the poles being as they are.

The only other way in which the sun could magnetise the earth would be by magnetism of its own, the sun's poles being opposite to the earth's poles. Now, this magnetism in the sun might be caused by rotation of the latter under inductive action from the earth and planets. The direction of rotation being the same, the electricities opposite the magnetism would also be of the opposite kind. Thus the sun would act by both causes. Connected with the foregoing research are some interesting observations Professor Reynolds has made on the nature of the solar corona. From photographs of the eclipse of 1871 a very clear idea is obtained of the appearance of the corona. The distinguishing features of it are chiefly these four:—

1. Its rifts and general radiating appearance.
2. The crossing and bending of rays.
3. Its self-luminosity, as spectroscopic observations have shown.
4. Its changing and flickering character.

Now Professor Reynolds was enabled to obtain a very striking imitation of this appearance by electrical action, and in the following manner:— He caused electricity to be discharged from a brass ball placed in the centre of a partially exhausted receiver, and supported by a brass rod coated with indiarubber, this rod being in connection with the machine or coil. It was negative electricity that was discharged into the globe, and it probably discharges itself on the inside of the glass, inducing a corresponding charge on the outside. Using a large coil and exhausting the receiver down to half an inch of mercury no corona was seen; the air was gradually let in and a variety of appearances followed. At first it seemed as if a mass of bright serpents were twining and untwining round the ball, then these were transformed into the branches of an oak, and then a faint corona appeared among the branches like a radiating envelope, while, as the pressure increased, the oak branches gradually faded away. The diameter of the envelope was about three or four times that of the ball, and it was strikingly similar to the solar corona in those features of the latter above referred to. It was best seen when the pressure was about 4in. In one point this corona differed from the solar corona. The shading off of the light in the latter is much more rapid than in the former; but if it were possible to make the pressure vary in the receiver this difference might be done away with.

In this way, then, according to Professor Reynolds, the theory of an electrical influence in the sun receives further confirmation.

THE WAVE-MOTION OF THE SEA.

IN estimating the motion of particles in the mass which forms a wave, there are two things, according to Captain Cialdi (in a recent work on the subject), which are not generally taken into account. One is, the motion of particles, which, being cooled at the surface through evaporation, descend, from increased specific gravity, giving place to others which are less dense. True, in the case of waves, there is a continual mixing and friction of the molecules, and the cooling is less than on a calm sea. Still, the phenomenon is not to be neglected, as the wave-surface is not always in a state of overturn, and the particle's motion in the wave is affected by this other. The second is, the extent to which the molecules are affected in a vertical direction by the action of a strong wind blowing continuously. It is known that such a wind will produce a horizontal current, varying with the depth and with the force of the wind, but it is found the wind produces an effect at depths considerably below the mass of water which is set moving horizontally. Thus it has been proved that waves break up the material at the bottom at a depth of 200 metres in the ocean, and of 80 metres in the Mediterranean.

Most of the writers who have treated of waves have taken for their example those circular waves which arise from the fall of a body into a liquid; but waves of this kind are hardly to be compared with the long parallel waves produced in the sea by wind which strikes the surface at an angle of about 18°. In the former case molecular forces and elasticity have a large influence, while the external action of wind has no place. In every case in which the wind strikes the waves, the arrest in development of the undulating mass must have important influence. The action of wind, therefore, and the reaction of the bottom of the sea, should be especially studied by those who would explain wave action satisfactorily, and the results, from experiments made on a small scale, are often falsified by what we find in the operations of Nature. In the present case, a direct study of these operations is more productive than the study of artificial phenomena.

The wave, in its normal state, may be regarded as consisting essentially of two planes equally inclined. A floating body, rising on one of these planes and descending on the other, is (by the law of gravity) retarded and accelerated in such a way that if no other force were acting, it would remain at the same point, without partaking of the wave's motion of propagation. But, practically, it is otherwise. The curved surface of a ship's hull receives a series of shocks from the rising motion of the waves, and (supposing the molecules of the wave do not rise in circles) the horizontal components of these tend to push it forward in the direction of propagation. The force resulting from these shocks is, however, far from imparting to the ship the speed with which the waves move. For waves to attain a great height or velocity, there must be a considerable extent of surface and depth of water. It is on this account that the waves of the Mediterranean are less high, voluminous, and rapid, than those of the ocean. In the open and deep sea, the dimensions and motion of the waves are generally in proportion to the velocity, inclination, and extent of action of the wind, and follow its direction; but when it becomes very furious, the height and volume of the waves diminishes sensibly. When, however, the wind is of long duration, of force not excessive, and acts on a large extent of surface, the size and speed of the waves continue increasing.

Near the coast, the progress of the waves is very much retarded and altered by the obstacle which the bottom presents, and also by the materials with which they become more and more charged as they near the shore.

We may further notice that the undulation caused by tempest in a given place is not the effect of the immediate action of the wind in that place, but arises from rupture of the equilibrium in circumjacent columns of water, and the transmission of shocks from these. For this reason, sailors are often able to know of a storm in the neighbourhood some days before it comes, and so prepare for it. In the same way the continuance of waves after the wind has fallen arises from the fact that the wind has not yet ceased to trouble the sea at a distance. As a force loses its intensity in course of transmission, the horizontal propagation of sea waves diminishes in proportion to distance from the origin, so that the sea may be calm near at hand, while large waves agitate it a considerable distance off. The height of a wave should be measured, from the bottom of the hollow, not from the ordinary surface. The distance from summit to summit is the wave length.

Wilkes, in 1839, made a careful measurement of waves on one occasion when the sea appeared regular and the waves of a great height. This was his method:—The schooner *Seagull* was sailing in the wake of the brig *Porpoise*, and distant from her by about two waves. Their relative positions did not seem to vary, and they were sailing eight knots an hour. Casting the log from the *Porpoise*, Wilkes observed that the clip, when on the top of the nearest wave, was 380ft. distant, or one-sixteenth of a mile, and the *Seagull* on the top of the next wave, twice as far, or one-eighth of a mile. The time taken by a wave to come from the *Seagull* to the *Porpoise* was, on an average, thirteen seconds. This gives 26½ miles per hour for their apparent progressive motion. For observing the height, Wilkes chose a moment when the *Seagull* was in a hollow, and the two crests were in a horizontal line with his eye, this line cutting the *Seagull's* mast at a certain height. His observation gave 32ft. as the wave height. Various observations have been made of wave height. The captain and officers of the *Inconstant* on one occasion saw waves that, as they showed, must have been more than 23·46m. (77ft.), and waves have been known to reach the top of Eddystone Lighthouse 32·48m. (about 106ft.). In estimating the motion of waves, it is to be remembered that the atmosphere exercises the pressure of an elastic force of about 2,000lb. on each foot of the wave surface, and this must be added to the weight of water forming the wave. From a series of experiments made by Mr. Walker, at Plymouth, the following inferences are made:—1. The speed of waves is retarded in proportion as the water becomes shallow, and depth facilitates wave action. 2. The speed of waves does not depend on their height. 3. The experiments made on a large scale seemed to confirm the result obtained by Mr. Scott Russell in another way—viz., that when the depth of the water becomes equal to the height of the wave, the latter breaks and becomes a wave of translation.

Among the waves observed were some moving 46ft. per second; these were wide apart and of short height. Their destructive effect on masonry was, nevertheless, very great, while certain other waves, which were higher and in closer succession, and moved 41·8ft per second, were much less destructive. The effect being as the square of the velocity, we may calculate what should be the height of waves which, moving at the rate of 41·8ft. per second, would have an equal effect with waves 27ft. in height, and moving 46ft. per second (27ft. having been the height of those observed to move 41·8ft. per second). Thus $41{\cdot}8^2 \times 27 = 46^2 \times x$, whence $x = 22$.

The height of waves in the Mediterranean has been estimated by W. Smith as in general from 4·27m. to 5·49m. (14ft. to 18ft.).

SECONDARY BATTERIES.

IF the mode of production of voltaic electricity has of late engaged much attention, the means of accumulating and transforming such electricity are not of less interest; just as, in mechanics, the question of accumulating and transforming motive force gives abundant material for inventive skill.

M. Planté has studied the subject for many years, and after careful researches on the polarisation of metals, he has constructed his secondary battery (recently described in *Les Mondes*), the results obtained from which are truly surprising.

It is well known how the Leyden jar discharges, in one strong spark, the sum of electricity it received from the electric machine. M. Planté connects a somewhat analogous apparatus with the voltaic pile. Two plates of lead (20in. long by 8in. wide), are rolled up in spiral, being separated from each other by a few strips of indiarubber. This spiral is placed in a jar containing acidulated water, and having a guttapercha cover, on which are fitted binding screws connected with the plates. Twenty such elements are placed in two rows of ten each, and charged from the primary battery, which consists of two Bunsen couples. By means of a commutator of peculiar construction, these secondary elements may be connected either for quantity or for intensity. When the elements are joined in series, an electromotive force equal to thirty Bunsens is obtained, giving a current by means of which platinum wire may be fused.

In the secondary couples, the chemical action generating the current is the reaction of hydrogen on peroxide of lead, the current from the primary pile having caused decomposition of the water, oxidising one of the plates and developing hydrogen on the other.

By the above arrangement, the quantity of electric work from the direct action of the primary pile is transformed by condensation. The case is somewhat similar to that of a hydraulic press or crane. In a pile driver, *e.g.*, a heavy body raised by degrees to a great height, by a series of successive efforts, is then left to itself, and gives back at once the greater part of the work thus expended on it. So, when, after charging, the secondary circuit is closed, the sum of the accumulated chemical actions caused by the primary current is given out in the form of a very intense current of short duration. The effect, when the couples are joined for quantity, corresponds to the fall of a very heavy mass raised a small height; when joined for intensity, to the fall of small mass raised to a great height. It is not difficult to see how these secondary piles may become of important use.

PRESERVING WOOD.

THE following are the conclusions arrived at by Herman Haupt, C.E., after an elaborate investigation as to the best means of preserving wood from decay, which we extract from *Van Nostrand's Magazine*:—

1. That so long as the cells of wood are occupied by air and moisture, no preservative solutions can be introduced, and the expulsion of air and water must be the first step in any effective process for preserving timber from decay.

2. That water can be expelled by a long-continued application of heat, but air only by expansion in a vacuum, and the combination of heat and vacuum will secure the most rapid expansion both of water and air.

3. The preservative fluid must be introduced while the cells are empty, consequently the process must be carried on in vacuo.

4. That no pressure, however great, applied externally to the surface of timber, can force any fluid into the interior so long as air or water is contained in the cells. When air alone is present there may be penetration to a limited extent, superficially, but water is practically incompressible. If, however, the pressure is applied at one end only of a log, as in the Boucherie process, a fluid may be forced through and exude from the other end.

An apparatus to fulfil the conditions which, from the preceding discussion, appear to be essential to success, must be founded on a process similar to distillation in vacuo. It must consist of at least two vessels—one a receiver corresponding to a retort, in which the material can be placed and subjected to the action of heat; the other a condenser, in which all escaping vapours can be condensed and the vacuum maintained during the process in both vessels.

The condenser may be of much smaller capacity than the receiver; they should communicate by pipes furnished with stopcocks, and both be supplied with thermometers, vacuum gauges, and pumps.

As an illustration, suppose wood is to be impregnated with dead oil or any other fluid. The receiver must be filled with the wood to be operated on, the door closed air-tight, and the air expelled from both the receiver and condenser.

The expulsion of the air may be effected in various ways.

1. Steam may be admitted at one end to drive out the air at the other end; the subsequent condensation of the steam should leave a vacuum, but, in the experiments of the writer, this plan has been only partially successful.

2. The air may be exhausted by an air-pump, but a perfect vacuum cannot in this way be secured.

3. The vessels may be filled with water and the water removed by a pump below the level of the bottom into which the water flows. This should remove all the air excepting that which escapes from the cells.

4. As the atmosphere supports a column of water 33ft. high, pipes may lead to a tank at a level about 40ft. lower, where the location is favourable, and thus by filling the vessels with water and opening cocks to allow the water to flow by gravity into the tank, a very perfect vacuum could be produced. This arrangement would be particularly favourable for maintaining a vacuum in the condenser; a pipe in the condenser could throw jets of water in spray from numerous fine perforations, and the water would consequently flow into the tank 40ft. lower, maintaining a constant vacuum without the aid of pumps. This object can be accomplished in almost any locality by placing the condenser at the top of a building or on trestle work.

Assuming that a vacuum has been created and provision made for maintaining it during the whole process, the next step will consist in the application of heat, which may be done most conveniently by steam-pipes introduced in the receiver. The length of time during which the timber must be subjected to the baking process will depend upon the dimensions of the logs, and can only be determined by experiment.

It is obvious, however, that the circumstances are favourable to the most rapid evaporation possible; the temperature can be regulated at pleasure, and the removal of pressure by vacuum will give a very low boiling point. As the vapours pass over they will be immediately condensed.

Should the vacuum become vitiated by the escape of air from the cells, it may be improved by the use of an air-pump. The condition of the vacuum will be indicated by the gauges.

When sufficient time has been allowed for the wood to dry thoroughly, cocks must be opened connecting the bottom of the receiver with a tank of dead oil, at a lower level. As a vacuum exists in the receiver, the atmospheric pressure will force up the oil and the timber will be immersed in the fluid. When the immersion has continued a sufficient length of time, which also must be determined by careful experiment, cocks may be opened at the top of the receiver to admit air. The oil not absorbed will immediately flow back to the tank from which it was taken, the air pressing upon the exterior of the cells, which are partially filled with oil while a vacuum exists in the interior, will force the oil before it, and thus coat in its progress the interior of the cells. It is probable that in this way a sufficient amount of dead oil may be introduced into the cells to prevent fermentation and decomposition, while still far below the point of saturation, and the process may prove rapid and economical.

Instead of admitting air in the manner proposed to expel the oil from the receiver, it is possible that better results may be obtained by allowing the oil to remain until it becomes heated by the steam coils, and the vapour collecting at the top expels the oil and penetrates the pores.

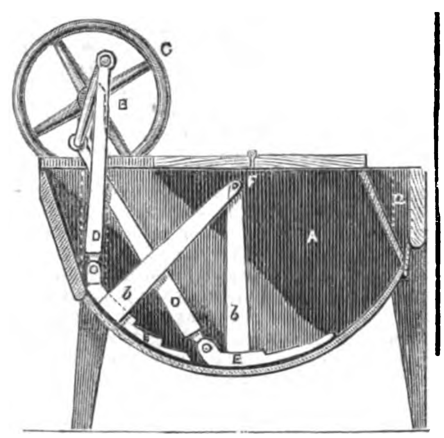
Too much oil might be introduced by this mode of treatment, and it is probable that the introduction of air, followed, perhaps, by a second bath of oil to close the cells superficially and exclude moisture, would give the best results. All these and other questions that may arise can be promptly settled by experiment, and in no other way.

This process of drying in vacuo would be well adapted to the rapid desiccation of fruits, vegetables, fish, meats, &c., with a view to preservation. The writer does not claim that he has solved the important problem of preserving timber from decay. Before he could satisfy himself or others, a series of continued experiments with suitable apparatus would be required; but it will not be considered egotistical to assume that, in several months of experiment, something has been learned. He is satisfied, at least, that none of the ordinary processes will preserve wood economically, and there is, in his opinion, no surer avenue to success in any investigation than the study of failures and their cause. He has witnessed too many failures to be sure of anything until it has been proven, but believes that in the processes indicated there are strong reasons to expect success.

A NEW WASHING MACHINE.

An improved washing machine has been patented by Mr. Key, of Union City, Indiana, of which the figure and description will be found sufficiently explanatory.

The general contour of the tub, A, is indicated in the cut, the bottom being of inverted arched form, and made of zinc or other suitable material. The ends of the tube are straight, and at one is a partition shutting off a small space, *a*, to permit the facile attachment of a wringer when desired. The legs at one end of the tub extend above the top thereof, and have bearings in their upper extremities for a double-cranked shaft, B, carrying a balance-wheel, G, itself furnished with a crank-pin or wrist, whereby the working parts of the apparatus are actuated. Each of the cranks



on the shaft, B, actuates one of the rubbers, E, through the agency of a connecting-rod, D. The rubbers are each made wide enough to extend nearly one-half the width of the bottom of the tub, and are formed with longitudinal slits, and are notched or shouldered on their upper surfaces as clearly indicated in the engraving. They have rigidly attached to them the arms, *b*, pivoted, at F, to a cross-shaft in such manner that the rubbers, when in motion, swing in a path corresponding to the curvature of the bottom of the tub. It will be seen that the rotation of the crank-shaft, B, gives a vibratory movement, alternately in opposite directions, to the rubbers, E. This works the cloths or fabrics to be cleaned repeatedly over and over, alternately expelling the water from them and allowing them to again absorb it, thereby securing the removal of the dirt.

THE STAR DEPTHS.

Mr. Richard A. Proctor, Honorary Secretary of the Royal Astronomical Society, gave his fourth lecture on this subject at the Royal Institution last Saturday afternoon at 3 o'clock. After giving a sketch of the history of the discovery of nebulæ, he discussed the researches of Sir W. Herschel into the great cluster in Perseus. He showed that Herschel's belief, that in examining this cluster with higher and higher telescopic powers he was passing farther and farther into the profundities of space, could not be correct. (He mentioned incidentally that Herschel was in his 79th year when he adopted the plan of estimating stellar profundities by the telescopic powers necessary to effect "revolution.") If Herschel was right then his observations indicated that the remotest parts of the cluster were nearly 30 times as far away as the nearest (Herschel's own numbers are as 344 to 12); but in that case the true shape of the cluster is that of a long cone (a figure compared by the lecturer to the pointer he made use of), whose axis is directed exactly towards the solar system. This is utterly incredible on *à priori* considerations; but, moreover, a star-group of so remarkable a shape would have no dynamical stability. Mr. Proctor said that he considered it as absolutely demonstrated that this wonderful double cluster is, in fact, "what it looks like," that is, a double system in which stars of a great many orders of magnitude are included. He added that he believed that as Herschel gave up in 1802 (notwithstanding the text-books) the principle of star-gauging which he had adopted in 1785, so he would have given up the principle he adopted in 1817, had he lived to apply to his observations the test of careful analysis. But he was already exceedingly old, and it was well known that for several years before his death he was incapable of prolonged or profound study. The lecturer passed then in review the various orders of nebulæ, quoting a singularly apt passage from Tennyson (in the first edition of the "Palace of Art"), where the poet laureate speaks of

> Regions of lucid matter taking forms—
> Brushes of fire, hazy gleams,
> Clusters and beds of worlds, and beelike swarms
> Of suns, and starry streams.

He discussed the laws according to which the nebulæ are spread over the heavens, showing that these laws suffice to demonstrate that the nebulæ belong to the stellar spaces. Passing thence to the gaseous regions surveyed by the Herschels, he propounded the unlooked-for theory that the more widely ranging regions of nebulous light could be better recognised by the unaided eye than with the most powerful telescope, and described the method by which he was about to test this opinion. He described the observations by which Dr. Huggins had shown many of the nebulæ to be gaseous. Passing thence to the consideration of the Magellanic clouds, and of the various orders of nebulæ seen within these objects, the lecturer pointed out that the evidence adduced by Sir John Herschel sufficed to demonstrate that these nebulæ at least were far within the limits of the sidereal system, being included in the same space with stars of the ninth and tenth order of magnitude. The lecture closed with remarks on the variability of certain nebulæ.

Upwards of thirty photographic illuminations were exhibited by means of the electric lamp. The lecturer promised to exhibit among the illustrations next week a chart showing all the stars visible to the naked eye *over the whole heavens*, properly distributed throughout as respects richness. In this, the closing lecture of the series, he will also present a synoptic view of all the theories of the stellar universe hitherto propounded, including the theory to which he has been led by his own researches.

RECURRENT VISION.

Professor Young has adopted this name for the following optical phenomenon:—

In the course of some experiments with a new double-plate Holtz machine, belonging to the college, I have come upon a very curious phenomenon, which I do not remember ever to have seen noticed. The machine gives easily intense Leyden jar sparks, from 7in. to 9in. in length, and of most dazzling brilliance. When, in a darkened room, the eye is screened from the direct light of the spark, the illumination produced is sufficient to render everything in the apartment perfectly visible; and what is remarkable, every conspicuous object is seen twice at least, with an interval of a trifle less than one quarter of a second—the first time vividly, the second time faintly; often it is seen a third, and sometimes, but only with great difficulty, even a fourth time. The appearance is precisely as if the object had been suddenly illuminated by a light at first bright, but rapidly fading to extinction, and as if, while the illumination lasted, the observer were winking as fast as possible.

I see it best by setting up, in front of the machine at a distance of 8ft. or 10ft., a white screen having upon it a black cross, with arms about 3ft. long and 1ft. wide, made of strips of cambric. That the phenomenon is really subjective, and not due to a succession of sparks, is easily shown by swinging the screen from side to side. The black cross, at all the periods of visibility, occupies the same place, and is apparently stationary. The same is true of a stroboscopic disc in rapid revolution; it is seen several times by each spark, but each time in the same position. There is no apparent multiplication of a moving object of any sort.

The interval between the successive instants of visibility was measured roughly as follows:—A tuning fork, making 92¼ vibrations per second, was adjusted so as to record its motion upon the smoked surface of a revolving cylinder, and an electro-magnet was so arranged as to record any motion of its armature upon the trace of the fork; a key connected with this magnet was in the hands of the observer. An assistant turned the machine slowly, so as to produce a spark once in two or three seconds, while the observer manipulated the key.

In my own case, the mean of a dozen experiments gave 0·22" as the interval between the first and second seeing of the cross upon the screen, separates results varying from 0·17" to 0·39". Another observer found 0·24" as the result of a similar series.

Whatever the true explanation may turn out to be, the phenomenon at least suggests the idea of a reflection of the nervous impulse at the nerve extremities, as if the intense impression upon the retina, after being the first time propagated to the brain, was there reflected, returned to the retina, and from the retina, travelling again to the brain, renewed the sensation. I have ventured to call the phenomenon "recurrent vision."

PHOTOGRAPHY FOR THE UNINITIATED.*

(Continued from p. 91.)

HAVING led you through the various steps required in the production of the negative, we have at last reached that portion of our operations known as printing—silver printing. The negative, as you know, is the reverse of the object in nature from which you made it; in other words, white is black, and black is white; this fact following in greater or lesser degree throughout the shadows and feebly lighted portions of the view made. Just in the proportion in which you have secured this fine grading from absolutely clear glass in deep shadows to absolute opacity in positive high lights, and have secured the intermediate grades of opacity, is your negative a good one. From a good negative a good print can easily be made by following any of the formulæ suggested by the many writers who practise our art; but from a bad negative no yet discovered formula will make you a good print. You might as well attempt to build a chimney 100ft. high upon a poor foundation, and have it stand plumb, as to make a good print from a negative deficient in good qualities; both are bad from a bad foundation. I shall not, in this part of the process of picture-making, offer to you any new formulæ, but, as in those given you for negative work, simply call to your notice to formulæ which, by practice, I know to be good.

Albumen Paper.

Of this there are very many brands; all are at times faulty, all are liable to vary. Whether such is due to the paper alone, to the albumen and salting used in same, or to the conditions of atmosphere under which it is albumenised, or to its subsequent place of storage, or more or less to all, are questions not now important to consider. In purchasing, always require the paper to present, upon holding between you and the light, an even body, free from wave lines of uneven albumen; also, an evenness of gloss when viewed across the surface; also, a freedom from spots, small and black, in the body of the paper.

By reference to p. 561, Vol. XIII., you will find that I named one 8 by 10 deep glass dish for silvering paper. To suit this dish you will have to cut your albumen paper 8 by 10, which will give you two prints. To cut paper handily, I advise you to have a board made 2ft. square, upon which to lay the whole sheet, albumen side up; upon it lay a pattern 8 by 10 of cardboard, and around it pass a sharp knife. If you lay half a dozen sheets upon a board, one upon the other, and then turn the face of the upper one down, you can cut with great rapidity, and avoid touching the albumen face with the fingers, a point always well to guard against.

Silvering Solution.

For this I will give you several formulæ:—

No. 1.—Water, 20 fluid ounces; silver, 800 grains; nitrate ammonia, 40 grains; alcohol, 1¼ fluid ounces.

No. 2.—Water, 32 fluid ounces; silver, 1,125 grains; muriatic acid, 40 drops.

Shake this well, and finally render it slightly alkaline with liquor ammonia. After using three or four times, add a few drops of acid, and neutralise with ammonia.

No. 3.—Water, 19 fluid ounces; silver, 4 ounces; liq. ammon. conc., 12 drops.

This will render the solution of silver cloudy, with a heavy brown precipitate, which allow to settle, and from off which decant the clear solution, to which add—Alum, 10 grains; after shaking well, add—Water, 29 fluid ounces.

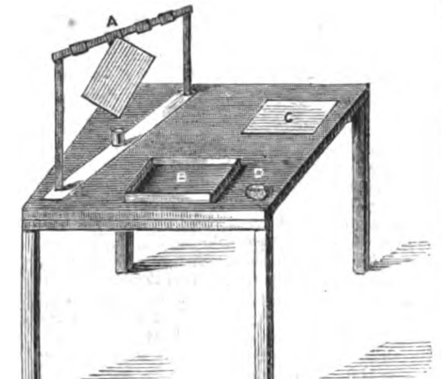
Either of these formulæ work well. The first (No. 1) I have used for years; it is simple and effective. The second (No. 2) is known as Hugh O'Neil's: it works to a charm. The third (No. 3) is Anthony's alum bath, and is better than either 1 or 2, in that it preserves the paper after silvering, and is in other respects equal to any bath within my knowledge. Neither of these baths will materially discolour with papers generally in use; the little they do can be easily removed by placing them in the sunlight for a few hours, and filtering.

In making up your silver solution, first determine how much you require by measuring the capacity of your dish when filled one inch deep. Always filter the bath before using, and have at least half an inch of solution in the dish. Some paper discolours the bath badly. Such I should not bother with; there is plenty which does not.

Silvering.

Pour carefully into a dish the silver solution, avoiding air-bubbles; draw down the buff shades of your room, or light the gas, as bests suits you. This work may be done in a moderately lighted room, for the paper is not sensitive to such light while wet. At your left hand arrange a wooden rod, forty-two inches long and three-quarters of an inch square, upon which, nine inches apart, glue pieces of cork half an inch thick and square. Support this wooden rod sixteen inches above the table, so that under each freshly-silvered piece of paper you can place a small glass to catch the drops of silver. Immediately before you is the glass dish with the silver solution. At the right of it is placed the paper you have cut, also a pin-cushion well supplied with good quality of medium pins, the kind that do not double and bend when stuck into anything harder than butter in hot weather.

This sketch will serve to explain the arrangement of your table when silvering paper. A the frame, with corks glued on the wooden rod 9in. apart, upon which I have placed one piece of paper; under it a



glass to catch the drops of silver. B is a glass dish. C is paper cut and ready for silvering. D is a pin-cushion. Now let me try to explain just how to silver a piece of paper. First, I will sketch a sheet of paper as it lays before us face down, and mark it with letters in each corner. Bend up a small corner at D at right angles to face, so as to better take hold of it in removing it from the silver, and so that this little corner may be kept dry, through which to stick the pin. Now take hold of paper with left hand at corner A, and with right hand at corner D; keep left very low and right very high as you place it on the silver, so that the bend in paper may be as close to corner A as possible; let this rounding or bent part first touch the solution; keep the finger holding the paper at A as near the solution as you can without touching, and hold well over to left side of dish, lowering slowly and steadily the right hand; thus the contact of the paper will be diagonally across the sheet, and will expell to right side of dish all bubbles that may incline to form. Bubbles, if formed at all, will most likely be at first point of contact close to A. Carefully lift at A with a small glass rod, and remove any that may appear, lifting the paper half its length from this end for examination, and immediately do the same at D end.

After the paper has lain for from one to one and one-half minute, lift it at corner D by the bent-up portion with left hand, stick through it a pin, and raise slowly and steadily from the solution to wooden rod, where you will fasten it upon the first cork, albumen side out. After all four corks are filled, proceed to remove paper from cork one to dark room for drying.

You will observe that the paper as pinned to the cork has curled or twisted; corner B and C have turned inward. On the lower corner, which is A, soak off with a piece of blotting-paper any drops which may be clinging thereto, and stick on a small piece of same paper to absorb any more that may pass down while drying. Next remove the pin from corner D, and put it into corner B; carry it into the dark-room and hang it up to dry. The object in removing the pin is to stop the curling in the same direction as it started. After the paper has nearly dried, the pin should be removed from A and placed in C. This will prevent twisting to a great extent. After your paper has become bone-dry, which, if the day is good, will be within an hour, you will require to treat it to a dose of ammonia before printing. This operation I will leave until my next.

* From the *Photographic News*.

AERONAUTICS.

THE result of the experiments with the apparatus for obtaining the data of the fundamental principles of aëronautics which we alluded to as in course of construction in our article on this subject on p. 373 of Vol. XIII., were reported at the recent meeting of the Aëronautical Society. The experiments were carried out at Messrs. Penn's Engineering Works by the Experimental Committee appointed by the Council of the Aëronautical Society of Great Britain to determine the relation between the velocity of the atmosphere and its pressure upon plane surfaces of varying dimensions and degrees of inclination. The instrument and experiments were made by Mr. Wenham and Mr. Browning. Mr. Wenham, in the absence of the latter, explained the nature of the instrument used. The experiments were considered to establish a law that the lifting force of inclined planes, carried horizontally through air, was increased in the direct ratio that the sine bears to the length of the plane, or the height of the incline to the base. Thus, if, instead of stating the angles in degrees, they said "one in ten," or "one in three or four," as the case might be, this would at once express the proportion in which the lifting force exceeded the resistance. The average of all the results was very near to this, making a little allowance for the surface friction of the plane through the air. At 45° the two forces were equal; above that, the proportions were in inverse ratio, as the lifting force was less than the direct. It had been stated that the resistance of wedges or cones through the air was diminished directly in the ratio that the height or diameter of the base bore to the length of the cone. The experiments did not confirm this, but showed the resistance to be less in proportion as the angle became more acute. The Chairman, Mr. Brook, and a few others made some remarks, and a vote of thanks was given to the Messrs. Penn for the assistance they had rendered in making the experiments. Mr. Head read a paper "On Flight," the object of which was to show that it was possible for man to fly through the air if a proper machine were made for that purpose. Mr. Head seems to have come to this conclusion from observations on the flight of birds.

THE WORTHLESSNESS OF BEEF-TEA.

THE experiments of Gustav Bunge lead him to conclude that the common opinion, that beef-tea and extract of meat are as valuable articles of diet as tea, coffee, or alcohol, is totally unfounded; that the refreshment they give is only due to their warmth and pleasant taste; and that their chief value is that they enable a person to take with appetite a larger amount of dry or tasteless food than he could otherwise do. The statements of Liebig, that the addition of some meat-extract to vegetable food increases its nutritive value, and that the extractive matters of meat, and especially creatine and creatinine, are the materials for muscular work, have been disproved by Voit and Meissner; and the idea that beef-tea and meat-extract were beneficial on account of the salts they contain is an unlikely one, as these salts are already present in excess in ordinary food. It has been said, however, that they did good by acting as stimulants, like coffee, tea, and alcohol; and this seemed to be confirmed by the experiments of Kemmerich. He found that small doses of meat-extract quickened the pulse, but large ones produced paralysis of the heart and death. This action on the circulation he attributed to the potash-salts contained in the extract, as the ash alone produced the same effects as the quantity of extract from which it had been got. As Traube, Gultman, and Podkopaew, found that potash-salts slackened the pulse but never quickened it, and as Kemmerich's experiments on man gave an indefinite result, and the only animals he used were rabbits, Bunge investigated anew, in Professor Schmiedeberg's laboratory, the action of meat-extract and of potash-salts on man, dogs, cats, and rabbits. On taking himself, or introducing into the stomach of a dog, a quantity of meat-extract mixed with flour, and containing 5 or 6 grains of potash-salts—a quantity sufficient to kill two rabbits—he found that no effect whatever was produced on the pulse or temperature. Large doses of meat-extract first quickened the pulse and then paralysed the heart. The quickening does not seem to be due to the potash-salts, but to their i troduction and to the distension of the stomach; for the author found that muzzling the animal, introducing a tube into the œsophagus, and distending the stomach with water, all quickened the pulse. When a solution of salt or sugar was used instead of water, the quickening lasted longer, because the fluid was more slowly absorbed and the distension less quickly removed. Extract of meat, deprived of five-sixths of its potash-salts by means of tartaric acid, caused death—not like the potash-salts by paralysing the heart, but probably by desiccating the tissues. Sodium-phosphate has a similar action. This is diminished by injecting water subcutaneously after the sodium-phosphate has been introduced into the stomach.

Potash-salts injected subcutaneously into rabbits quicken the pulse by causing pain, but they do not alter either the number or force of the heart-beats in dogs or cats, either when given subcutaneously, by the mouth, or by injection into the blood, except when given in fatal doses, and then they lessen them both in number and force. They have little action on the temperature or on the blood-pressure.

The poisonous action of potash-salts has been much exaggerated. When injected almost directly into the heart through the jugular, a very small dose will cause death by cardiac paralysis; but very large doses are required when administered subcutaneously or by the mouth. Bunge reckons the amount of potash-salts taken daily in potatoes by many Irish labourers at 100 grains. It is probably impossible to produce cardiac paralysis in man by potash-salts introduced into the stomach, as the large quantity necessary would be ejected by vomiting.—*British Medical Journal.*

THE PROGRESS OF GEOLOGY.—COAL-MEASURES AND COAL-SUPPLY.*

(Concluded from p. 168.)

It has been urged as a fatal objection to the discovery of coal in the south-east of England, that the coal-measures become unproductive and thin out under the Chalk, as they range from Valenciennes towards Calais, and, therefore, that the coal-trough or basin ends there. It is perfectly true that the coal-measures do thin out between Bethune and Calais, but not in the sense of their dying out owing to their deposition near the edge of a basin. In that case, each seam, each stratum, would gradually become thinner and disappear; but such is not the fact. None of the beds of the Belgian coal-field are thick. The average does not exceed 2½ft. At Valenciennes it is the same; whereas M. Burat states the mean thickness of the beds actually increases westward of Bethune to more than 2½ft. With respect also to the extreme end of this basin, the lower beds there brought up correspond with the bottom beds of the Hainault basin, where the lower 650ft. consist of unproductive measures. The thinning-out is, in fact, due to denudation, just as the Bristol coal-field thins out at Cromhall to resume in the Forest of Dean, or the coal-field of Liége thins out at Nameche to resume at Namur in the great field of Charleroi and Mons.

The deterioration of the coal in the small coal-field of Hardinghen, near Boulogne, has also been adduced against the occurrence of workable coal in south-eastern England, but Mr. Godwin-Austen has shown that this Hardinghen coal-field is one of those small local developments of coal-bearing strata intercalated in the Mountain Limestone, and is of older date than the great Belgian coal-field. It has, therefore, no bearing on this part of the question.

Another objection to which much weight has been attached is that the coal-field of Bath and Bristol forms an independent basin, cut off both on the east and on the west by ridges of Millstone Grit and Mountain Limestone, so that there is an end of the eastern extension of the coal-measures. This is quite correct as far as regards the western edge, and is probably the case on the eastern, although as the edge of the basin is there covered by Secondary rocks, some uncertainty still exists about the disposition of the Palæozoic rocks under them. Admitting, however, the basin to be complete and isolated, that is no proof that the older Palæozoic rocks prevail exclusively to the east; for the coal-measures of the Somerset basin maintain their full development to the edge of the basin, and are there cut off by denudation, and are not brought to an end by thinning out. They form really part of a more extended mass, of which we have there one fragment; while on the west another portion exists in the Welsh basin, and another in the newly discovered small basin of the Severn valley.

This last basin is entirely covered by the New Red Sandstone; and as the Welsh basin is bounded on the east and the Bristol basin on the west by Mountain Limestone, the same argument as the one above might have been used to show the impossibility of coal occurring in this intermediate area.

But the fact is, it is the very nature of this great line of disturbance to have minor rolls and flexures of the strata at, or nearly at, right angles to it, and so causing breaks in the coal-trough, which would otherwise flank it without interruption; thus the Aix-la-Chapelle coal-field is separated by older rocks from that of Liége, which is again separated by a ridge of Mountain Limestone from that of Hainaut. So in the case of south-western England, we have the several basins of South Wales, Severn Valley, and Bristol, separated by tracts of Mountain Limestone and Old Red Sandstone, the extremes of the intervening belts of older rocks being two miles at Nameche and eighteen miles in Wales. These barriers are clearly only local, and the division of the coal-measures into separate basins appears to be their ordinary condition along this great line of disturbance. The length of the two known portions of the axis included between Pembrokeshire and Frome, and between Calais and Westphalia, is 472 miles, and in this distance we find eight separate and distinct coal-fields. The combined length of these eight coal-fields is about 350 miles, leaving about 122 miles occupied by intervening tracts of older rocks; so that nearly three-quarters of the whole length is occupied by coal-strata. I consider that a structure which is constant (so far as the axis of disturbance can be traced above ground) is, in all probability, continued under ground in connection with the range of the same line of disturbance; and I see no reason why the coal-strata should not occupy as great a proportionate length and breadth in the under-ground and unknown as in the above-ground and explored area.

With respect to the possibility of denudation having removed the intervening coal-measures, enormous as the extent of denudation must have been previous to the deposition of the Permian strata, we cannot admit its exceptional action in this case. Denudation has removed from the crest of the Mendips a mass of strata possibly equal to two miles or more in height, and from that of the Ardennes as much as three or four miles, and it has also worn extensive channels between many of our coal-fields, so that the power of such an agent cannot be denied. But it is a power of planing down exposed surfaces rather than of excavating very deep troughs. Notwithstanding its immense planing-down action on the Mendips and Ardennes, deep troughs of coal-measures are left flanking their northern slopes.

We have alluded before to the great length and narrow width of the Belgian coal-fields. That of Liége is forty-five miles long, with a mean width of less than four miles, whilst that of Hainaut and Valenciennes is 119 miles long, with a width scarcely greater. The presence of lower Carboniferous rocks under Harwich, and the wider range north and south of the Bristol coal-field, renders it possible that the trough in the intermediate area may have a greater expansion than in Belgium; but we have nothing else to guide us, unless it be that the lateral pressure in the intermediate ground was probably less than in the Ardennes and the Mendips, where it has exercised its maximum elevatory force. In that case the coal-trough in this intermediate area would be less compressed and more expanded; so we might consequently here look to find larger coal-basins than either those of Somerset or Liége. The position of these basins I am disposed to place farther north than Mr. Godwin-Austen, and should therefore look for them not in the valley of the Thames, or on the line of the North Downs, but under South Essex, Middlesex or Hertfordshire, Oxfordshire, and North Wiltshire.

The strata on the south side of the Liége coal-field rise abruptly against highly inclined and faulted Devonian rocks, and on the north side they rise at a less angle beneath Cretaceous or Tertiary strata. In the Hainaut coal-field the overlying strata have a greater extension. Under these strata the coal-measures are succeeded by the Mountain Limestone, and then by Devonian or Silurian strata; but with one or two limited exceptions their outcrop is hidden by the newer strata which stretch uninterruptedly northward over the rest of Belgium. The Palæozoic strata have, however, been met with near Brussels, under Tertiary strata, at a depth of about 600ft. and at Ostend at a depth of 985ft. of which 682 consisted of Lower Tertiary strata, 210ft. of Chalk, and 93 of coloured marls. It appears, therefore, not improbable, that the Tertiary and Cretaceous strata of all Belgium may repose directly on a floor of Palæozoic rocks; and as there is reason to suppose that all these rocks have a strike parallel with that of the Ardennes, folds in the strata may bring in some under-ground coal-basin or basins in parallel lines to the north, in the same way that small troughs of coal-measures are brought in again in the Ardennes to the south of the great coal-trough.

We may, I think, look for a prolongation of this old Palæozoic surface of highly inclined, contorted, and faulted rocks at no very great depth under the same Wealden, Chalk, and Tertiary area of the south of England. For, although the old Palæozoic surface descends rapidly from about 300ft. above the sea-level in the Boulonnais to 1,030ft. below it at Calais, it rises at Ostend 47 higher than at Calais, and crossing the Channel, it is found at Harwich within a few feet of the same depth as at Calais, from which it is eighty miles distant in a northerly direction. Passing westward from Calais, we find the Palæozoic rocks under London (105 miles distant) 102ft. higher than under Calais, and 106ft. higher than at Harwich. Allowing for irregularities of the old surface as evinced by the well at Crossness, near Plumstead, which was still in the Gault at a depth of 944ft. or some 14ft. below the level of the Palæozoic rocks at Kentish Town, we may still consider that in the area between these three points, and possibly throughout the south-east of England, the Palæozoic rocks will probably be found not to be more than from 1,000 to 1,200ft. beneath the sea-level.

Projecting the line another 100 miles westward, we reach the neighbourhood of Bath and Frome, where the coal-measures are, as before mentioned, lost at a depth of about 450ft., beneath Liassic and Jurassic strata. In the intermediate area between that place and London no trial-pits and no wells have been carried to a depth of anything like 1,000ft. beneath the sea-level. The deepest well with which I am acquainted is one near Chobham, in Surrey, through Tertiary strata and Chalk to a depth of about 800ft. or of 550ft. beneath the sea-level.

There are, however, in all this area certain indications of the proximity of old land and of pre-Cretaceous denudation, in the presence of quartz and Lydian pebble-stones, accompanied by secondary rock fossils in the Lower Greensands of Surrey, and in the like old rock pebbles, with the addition of slate pebbles, in that formation in North Wiltshire; while the banks of shingle, Bryozoa, and sponges of the same age at Farringdon, point to still and sheltered waters, probably of no great depth, and to adjacent dry land. Again, on the north of London, we have in the Lower Greensand of Buckinghamshire and Bedfordshire shingle beds consisting almost entirely of fossils derived from Jurassic strata, with a remarkable collection of larger quartz, quartzite, and other rock-pebbles, derived probably from the old Palæozoic axis.

On the south also of the great Mendip and Ardennes axis coal-strata may possibly be found just as they are found on both sides of the Pennine chain; for in either case the measures are cut off and broken through by these chains of hills. In South Wales certain folds of the older strata seem to render it probable that the coal-measures may pass under the Bristol Channel, forming a trough which prolonged eastward would pass along the south side of the Mendips. Trials in the latter area, have, however, shown that the New Red Sandstone, Lias, and Oolitic series attain an infinitely greater thickness than on the north flank of that range, so that it is not likely that the coal-measures would lie at a less depth than from 1,500 to 2,000ft.

In this country the newer strata, overlying the Palæozoic rocks on our presumed anticlinal line, have been sunk through, without result, in the lowest beds of the Wealden at Hastings to a depth of 486ft.; in the upper beds at Earlswood, near Reigate, to a depth of about 900ft.; and, on the presumed synclinal line of Carboniferous rocks, through Chalk at Chichester, to a depth of 945ft., and at Southampton, through Tertiary strata and Chalk to a depth of 1,317ft.

To the south of all the area we have now described, there existed during the Carboniferous period, the ranges of the older Palæozoic strata of the Hunsdruck and Vosges—of the old crystalline rocks of Central France, fringed on the east and north with small outlying coal-basins of the old Palæozoic rocks of Brittany—and of the Silurian rocks of South Cornwall—forming the old land-surface, fringed by the great coal-growths subtended northwards through Northern France, Western Prussia, Belgium, and England, to the Silurian uplands of Central Scotland on the north, and those of the Welsh and Cumbrian highlands on the west, and possibly to those of the Scandinavian hills on the north-east. After the formation and consolidation of the coal strata, the southern area of this great Carboniferous basin was then subjected to that remarkable disturbance which, for a distance of above 800 miles, exercised that excessive lateral pressure by which the older underlying strata were squeezed and forced up into the series of sharp anticlinals forming the axis of the Mendips and Ardennes, while portions only of the Carboniferous series were preserved from the denudation which followed, in deep synclinal troughs flanking the main axis. The central and northern portions of the great Carboniferous basin, which were not raised by this disturbance, were then overspread by strata of the Permian series; after which the northern section of the original coal area was traversed by that other great disturbance at nearly right angles to the former one, by which fresh portions of the coal-measures were brought up in our central and northern counties, still leaving other deeper-seated portions to be afterwards covered by Triassic and Jurassic strata.

At a much later period the emerged southern area of Palæozoic rocks, including the westward prolongation of the great coal trough of Belgium, or portions thereof, was submerged and covered over by the several formations of the Greensands, Chalk, and Lower Tertiaries now forming the surface of the south-east of England.

The trials to discover these possibly productive coal-basins must necessarily be attended with considerable uncertainty. We shall have to feel our way. Of our hope of their ultimate success I have

* An abstract of the annual address of the President of the Geological Society.

given you the reasons. Nor could such trials near London scarcely fail of some important results; for, even if we did not hit at first upon the coal-measures, it is probable that the Lower Greensand would at some spots be reached, so that the inestimable additional benefit of a large and steady supply of pure water might also be obtained, and, with proper care to prevent undue interference, might be maintained for all time.

ON EARTHQUAKES AND VOLCANOES.*

By AUGUSTUS LE PLONGEON, M.D.

1. What is the Cause of Earthquakes?

THIS is a question of more than ordinary importance, since it has occupied the minds of philosophers in all ages, in all countries. It is a question that has been much debated in academies and other temples of learning. And still it remains a puzzle to the learned men of our modern times.

The ancient philosophers seem to have been far ahead of us in this particular, as in many other branches of knowledge; for while they were able to predict days—nay, months—in advance of the occurrence of our mother earth's convulsions, and warn their contemporaries of the impending danger, those possessed of the greatest scientific attainments in our age, are unable to recognise the premonitory symptoms and announce to the world the time when, and the place where an earthquake is to take place—notwithstanding they can read in the atmosphere all the meteorologic perturbances which occur, and prognosticate the storms and other phenomena which these changes foreshadow.

Many are the theories, quite antagonistical some of them, that have been launched on the vast ocean of speculation. All of them, no doubt, more or less plausible, resting on some scientific fact or other, have met with opposition. All have been impugnated, proved inaccurate and faulty. None has unveiled the hidden truth; and the mighty problem stands yet unsolved.

Facts are certainly not wanting to serve as milestones on the road of inquiry. And the laws that govern every phase of the phenomenon, well known to the wise men of our days, if properly applied, will cast their bright light, and illuminate the darkness that hangs over it.

Geology teaches us that, from epochs lost in the deep abyss of time, the earth has quaked; and natural philosophy, together with the discoveries of vigilant scrutinisers in the arcana of nature, have told us of the laws that govern these various manifestations of its wonderful vitality, and taught us that motion is life, and life is for ever and ever.

Why, then, it may be asked, are the causes of earthquakes yet a mystery? Simply because we have entered on the study of these phenomena, surrounded by the preconceived ideas, the prejudices, and bias, either scientific or religious, that had been inculcated in us by the teachings of our predecessors, instead of stepping into the sacred precincts of the great temple of nature, our minds free and unshackled from all prepossessions, ready to receive the revelations of the mighty arcana with candour and good faith.

I do not pretend to be wiser than any of the learned men who have investigated the subject, for I am the last among the worshippers of science. But having studied the phenomena in the midst of the terrible convulsions that have shaken the American Continent to its very basis, of late, and applied the different facts that I have observed during many years' residence in countries subject to earthquakes, to the touchstone of the natural laws that govern their manifestation, free from all undue bias, either scientific or religious, I have tried, from my observations, to draw all possible reasonable and scientific conclusions.

It is the result of patient and careful investigations that I humbly submit to your criticism in this cursory article, with the hope that it will meet with your approbation.

I have said that:—"The Ancient Philosophers were acquainted with the Cause of Earthquakes." This might be considered a bold assertion on my part, if I had not their writings and those of the historians of antiquity to back me up.

We all know that the wanton destruction, by fire, of the 700,000 volumes of the library of the Temple of Serapis, has deprived us of the knowledge of the scientific truths discovered by the wise men of antiquity. The few works, however, that have escaped the fanatical wrath of the ignorant Mahometan chieftain, and the deplorable hastiness of the Roman general, manifestly show that the philosophers of old had indeed given their earnest attention to the study of the very question we are about to elucidate; and that, owing to their diligent inquiries, and their knowledge of the laws that govern the phenomena, they had discovered some of the causes, if not all, of the earthquakes. We read in Philostratus, that Anaxagoras, who was thoroughly instructed in the science of the Egyptians, foretold the falling of stones from heaven, and that there should be an earthquake, in consequence of the mud which he perceived on the surface of the wells.[1]

Marcellinus[2] asserts the same thing, and so does Diogenes Laertius. Appellonius gave it as his opinion that the earth was composed interiorly of a mixture of bitumen and sulphur in a constant state of incandescence, and when a current of air penetrated the chinks and caverns, a fire was kindled, a flame was produced that burst out from the mountains, and streams of liquid fire; this being the cause of volcanoes and earthquakes.[3]

Jamblicus[4] tells us in his "Life of Pythagoras," that Pherecides, merely by testing of or looking at the water drawn from a well, advised the inhabitants of Samos to put themselves in safety, for they were threatened with an earthquake, which, in reality occurred.

Pausanias,[5] in his "Itinerary of Greece," whilst pretending that the earthquakes are phenomena produced by the anger of the gods, enumerates, however, the signs by which they are preceded and foreshadowed. Among these he mentions the water in the wells becoming turbid and emitting fetidity.

Pliny the Elder,[6] in his Natural History, after speaking at length upon the subject of earthquakes, endeavours to imagine means to prevent the phenomenon, and gives it as his opinion, that to some extent it might be hindered by boring very deep wells in the countries where they are of frequent occurrence.

This same author, in another chapter[7] of the same work (and Cicero,[8] in his "de Devinatio," concords with him), says that Anaximunder foretold to the Lacedemonians, not only an earthquake, but also the falling of the summit of the Taygetus, a mountain of Lacona. The event confirmed his prediction.

In the thirteenth century, a monk, in order to oblige the Emperor Andronic to recall from exile the patriarch Athanasius, threatened him with divers plagues—with an earthquake among them. The earthquake really occurred in Constantinople within three days after the prediction.[9]

The illustrious Buffon,[10] speaking of the proofs of the theory of the earth, relates that at Bologna, in Italy, in the year 1695, everybody saw with great surprise the waters becoming turbid four hours before an earthquake.

Agathino Longo,[11] in an historical and physical memoir on earthquakes, asserts that an identical phenomenon took place a few days previous to the earthquake that was felt in Sicily during the month of February, 1818.

Does not Mr. Cadet de Metz,[12] in his Natural History of Corsega, tell us that, after having observed during the month of December, 1782, very dense sulphurous vapours covering the plains of Calabria Citeriore, he came to the conclusion that an earthquake was near at hand, and he predicted the catastrophe which took place at the beginning of 1783?

And, lastly, did not Senor Vidanre,[13] a learned Peruvian, on hearing certain subterranean noises of a peculiar character, predict, four months in advance, the earthquake that destroyed a part of Lima, in 1818?

And I, myself,[14] predicted six months in advance the terrible earthquake that on the 13th of August, 1868, laid to the ground the strongly built city of Arequipa, and many others in the southern provinces of Peru.

Will you reject the testimony of so many writers and historians? Will you say with Cicero: The thing is impossible? No, I am sure—for as a scientific man you know that the arcana of nature become unfolded to our gaze more and more every day; you know also that every day some of the laws that govern its phenomena are discovered, and that nothing is impossible to the human mind in the scope of discoveries and scientific investigations.

Impossibility is the by-word of ignorance, unknown among us, the worshippers of science.

2. That the Centre of the Globe we Inhabit is not Liquid Fire

is generally admitted by most of the scientific men of our age. It does not enter within the limits of a cursory article like this to enumerate all the facts that can be adduced to prove that it is most probably a compact mass of metals and minerals, with a rather thin crust of oxides to cover it. I say thin, comparatively, of course. But to prove it I will merely speak of the heat that has been observed to exist in the different strata where man has penetrated; I will try to show that this heat is simply superficial and influenced altogether by different causes than central fires.

It is a fact demonstrated and proved that electro-magnetism is the active agent that produces all the phenomena of life that takes place at every moment of time before us, continually changing and producing new beings and new species of being. I consider that electro-magnetism is the life of this immense living body on which we exist as parasites; and that in the same manner as heat is developed in the human body through electro-magnetism's agency, which causes the blood to flow rapidly, and circulate with force, throughout the entire system, producing thereby a continuous friction in each and every of its parts, engendering what is termed animal heat—this being greater where there is greater affluence of circulating fluid, and therefore a greater friction—so also are the same electro-magnetic agents the source of the internal heat of the earth. How far this internal heat reaches towards the centre, is unknown, and will most probably remain unknown for ever to man.

The laws of nature are as simple as they are immutable. When studied, we find that they act alike in all things, advancing from the simple to the complex. We find nature very economical of the means employed by her to produce her creations, and most prodigal in the variety of those.

Let us take her for our guide and proceed from the simple to the complex.

The science of electro-magnetism is a comparatively new one, which will eventually lead to great discoveries, and give us the explanation of many phenomena that to the present day have remained unexplained.

The heat seems to augment progressively as we descend towards the centre of the earth. But the progression is not constant. At places the heat increases rapidly, at others very slowly. This difference has for a long time puzzled geologists. At last they have come, not to a definite, but an approximate conclusion, by admitting that the heat increases 1° for every 27 metres; Beudant pretending, however, that it augments 1° for every 33 metres, on every point of the globe. But such is not the case, for there are, perhaps, not two places, even in the same locality, where the heat is the same at the same depth.

However, for the sake of demonstration, let us admit it is so, and that the heat increases progressively 1° for every 33 metres we approach nearer to the centre of the planet. What will then be the consequence? At 3,000 metres the heat will be sufficient to cause the water to enter into ebullition. At 20,000 metres, the supposed thickness of the crust of the earth, all silicates will melt. At 80,000 or 100,000 metres, all metals, even the most refractory, will be in fusion; the diamond volatilised.

As the semi-diameter of the earth is 6,366,000 metres, the heat at the centre will then sum up the prodigious amount of 250,000° of heat. Think of it—250,000°. Can you imagine such heat and not be yourself volatilised instantaneously?

Can any man with common sense ever believe such nonsense? Why, Beudant himself is surprised at the awfulness of the offspring of his own science; his pet frightens him, for in his "Course of Natural History" he tells us: "That if anything is capable of astonishing any one, it is that no more catastrophes should take place in our days on the surface of our planet, particularly when we consider the enormous disproportion which exists between the diameter of the melted matter and the crust of the earth, which is only 20,000 metres. This thickness is but very small when compared to the terrestrial radius, which is more than 6,000 kilometres. On a globe of 1 metre it would be represented by 3 millimetres approximatively. That would not be the thickness of a sheet of paper on one of our ordinary terrestrial globes."

These are, verbatim, the words of the savant geologist. Yet there is another thing that astonishes me more than that; it is that a man of his acknowledged science, if he calls himself sane, can possibly cherish and seriously advocate such an idea, now that we are perfectly conversant with the laws which govern the expansion of gases, and those which regulate the march, attractions, and gravitation of celestial bodies; and Mr. Beudant knows, certainly, as well as ourselves, that only a temperature of 12,000° is required to volatilise all and everything known to man on earth. If his theory was true, at 320,000 metres under our feet there would be nothing but gases floating on an immense furnace of 230,000° of heat to expand them more and more, and a very thin shell of 20,000 metres to contain them and resist the immense pressure caused by their increasing expansion.

Who, in the name of common sense, will admit of such an absurdity? There is no central fire; there

cannot be. What does the science of the skies tell us on the particular? Listen!

We all know that the astronomers, in order to calculate the course of the celestial bodies, are obliged to know exactly their weight and volume. They, of course, had to determine that of the earth, in order to compute its motions in space, and its relations with its other companions and co-travellers. Their computations have been so accurate that they can determine the exact time of the apparition of comets. When eclipses, conjunctions, &c., are to take place, by the astronomical observations, taken four or five thousand years ago by the Chaldean and Egyptian priests; by those of the ancient Chinese astronomers, as that of the eclipse of the sun, mentioned in the "Chou-King," which took place during the ninth month of the year 2159 B. C., all of which within the last century have been proved perfectly correct. We have come to the knowledge that no variation whatever has taken place, in the volume of the earth at any rate, from those remote times to our days. If the planet had contracted, as some pretend, the rapidity of its rotation would have necessarily increased, and such is not the case.

(*To be Continued.*)

EXPEDITIONS TO THE NORTH POLE.

A CORRESPONDENT of the *Daily News* writing from Frankfort-on-the-Maine, sends the following information on this interesting subject:—

According to advices from Stockholm the projected North Polar Expedition, under the control of Professor Nordenskiöld, is almost ready for sea, and Swedish geographers entertain great hopes of success for the new undertaking. The expedition will have on board, I am informed, besides Professor Nordenskiöld, Lieutenant Palander, of the Swedish navy, who has already had some experience in Polar exploration, having accompanied the Swedish Expedition of 1868; also a physician, a physicist, and several other savants, who will accompany the expedition for the summer, returning from Spitzbergen in the autumn; making in all, with the crew, twenty persons. The principal object of the expedition, which is not expected to return before the summer or autumn of 1873, is to reach the Pole from high latitudes by means of sleighs drawn by reindeer—an enterprise in which the German geographer, Dr. Petermann, of Gotha, does not place much faith. The expedition will take with it from Gothenburg a portable house, of nine rooms and kitchen, which is to be put up on the Seven Islands, in 80° 38" northern latitude — the most northern point, I am informed, at which an expedition has ever wintered in these regions. Great importance appears to be attached by Professor Nordenskiöld to the cargo of fifty reindeer, which he will ship from Norway, together with the necessary fodder and a number of Lapps to attend them. The scientific mission of the expedition is as follows:—

During the autumn the expedition will take soundings eastward of Spitzbergen; the eastern part of Spitzbergen is to be thoroughly surveyed; a series of continuous meteorological and magnetic observations for the space of an entire year are to be made; pendulum observations for determining the oblate form of the earth, refraction observations, besides a series of careful observations of the abundant animal life found in the Polar Ocean in these high regions. The scientific gain, it is expected, will be exceedingly valuable. The chief object will, however, be to attempt in the spring of 1873, after pushing as far as possible northward by vessel, to proceed by sleighs drawn by the reindeer in the direction of the Pole, and if possible to reach that point. In this attempt Professor Nordenskiöld casts overboard Dr. Petermann's idea of an open ocean extending to the Pole. Lieutenant Payer, of the new Austrian Expedition, has also expressed the view that Nordenskiöld's idea of reaching the Pole by sleigh is not to be thought of. But the Swedes place great confidence in the leader of the expedition, who is undoubtedly an energetic and skilful man, well acquainted with the North Polar regions, whither he has already made no less than five voyages. The Nordenskiöld Expedition has the support of the Swedish Government. I think it is to be regretted that the Germans do not greet it more warmly, though the feeling is very comprehensible where national rivalry is at play.

Dr. Petermann and the great majority of the German geographical societies have given their entire support to the new Austrian Expedition, which is to sail from Bremerhaven about the end of June, and which Dr. Petermann greets as "the greatest event in the history of modern Arctic explorations." The object of the Austrian Expedition will be the farther navigation of the ice-free ocean which they met with last summer to the east and north, and the exploration of the Arctic Ocean to the north of Siberia. The plan of the voyage is as follows:—

The expedition being provisioned for a period of three years, the first winter is to be spent on Cape Tscheliuskin, the most northern promontory of Asia; during the second summer the exploration of the Central Polar Ocean is to be continued, and an effort made to reach the Pole; the second winter will be spent on the new Siberian Island, and the third summer will be employed in reaching Behring's Straits and an Asiatic or American haven. The Austrian expeditionary vessel is a three-masted schooner, 118ft. long, 25½ broad, 13½ deep, provided with an effective engine of 95 horse-power, and coals for forty days.

There are several other North Polar Expeditions in preparation. A certain Count Wilczek, who has already given 30,000 florins to the Weyprecht-Payer Expedition, has chartered a small vessel, and intends to accompany the Austrian expeditionary vessel as far as the most northern coast of Nova Zembla, taking with him provisions for the larger vessel. Dr. Petermann also reports that two Norwegian steamers of the seal fishing fleet—Captain Jensen of Drummen, with the steamer Cap Nor, and Captain Svend Foyn, an enterprising whaling captain, with his steamer, will proceed, after the fishing season is over, in the direction taken by the Austrian Expedition, and make explorations in the Siberian ice-sea (the Polynia), of course with an eye to future business. France, too, is bestirring herself, and a certain Gustave Ambert issues a circular, declaring his intention to take an expedition in the same direction as the Payer-Weyprecht one. This expedition was to sail from Havre in April. Ambert has in view not only scientific but "practical results, the acquisition of new lands, the discovery of new fishing grounds," &c. Another French explorer proposes to get at the North Pole by way of balloon. He has not yet hit upon a plan of getting back again, however, with the news of his discovery, in case his gas gives out, it being very doubtful how he will procure a fresh supply so far north. The American Expedition, under Messrs. Hall and Bessels, will proceed from the American side, after wintering, and attempt to reach the Pole in the course of the present summer. Thus the great international race for reaching the North Pole has again commenced in earnest, though America has certainly got a good start. Captain Koldewey, the leader of the former German Expedition, has also a scientific voyage in view, which, however, creates little interest in Germany, whose sympathies and material support have been directed by Dr. Petermann in favour of the successful Austrian voyagers of last year, Messrs. Payer and Weyprecht.

FALSE HAIR.

FALSE hair appears as necessary in the United States as in this country, and the following particulars extracted from the *Commercial Bulletin* (U. S.) will afford some little insight into the business done in this commodity:—

Formerly, as ladies grew in years and their hair became thin, a false "switch" was procured, and combined with the growing hair to repair the ravages of time. Great care was taken to conceal the fact that false hair was worn, and it was only to her most intimate lady friends that the fact was whispered even. But now all this is changed. Nineteen-twentieths of all the women in the country who make any pretence to dress wear false hair or some artificial equivalent, and the lady who, no matter how luxuriant her tresses, should presume to appear in society without supplementing their natural growth with "rats," "mice," "switches," "bands," or some other specimen of the wigmaker's handiwork, would find herself so hopelessly in the minority, and so laughed at by all, from her dressing maid to her most intimate friend, that resistance would be impossible, and surrender at discretion imperative.

Where the Hair Comes From.

The hair which adorns the heads of our belles and matrons comes mainly from the heads of the peasant women of France, Germany, and Italy. The hair buyer, supplied with sundry stores best calculated to captivate the rural eye, travels from village to village, seeking out those whose wealth of hair gives promise of a handsome price in the Paris market, the great centre of the hair trade, and drives the best bargain he can in obtaining it. Sometimes the price is paid in money, but more generally in finery of various kinds, such as ribbons, cheap laces, trinkets, &c., a trade in which the buyer realises a handsome profit both ways, and the seller parts with the adornment which Nature has provided for almost worthless ornaments which she will soon tire of and throw aside.

Having completed his purchases, the buyer takes or sends the hair he has collected to the broker, who buys it at a price which pays the buyer well for his trouble. It next goes into the hands of the merchant, under whose supervision it is cleaned with meal, sorted as to length and colour, and put up in packages weighing from one to four ounces, each consisting of hairs of uniform length and colour, but not all the product of any one head.

How Hair is Ruined.

Strange as it may seem, the hair which grows upon the heads of our fashionable ladies has no commercial value. Through much crimping, curling, and dosing with various hair "invigorators," "restorers," pomades, &c., it not only becomes variegated in colour, but hard and brittle, rendering it wholly unfit for use in the manufacture of hair work. Indeed, it is found that the more people "take care" of their hair, the more they injure it, while those European peasants who let Nature take its course, and seldom even comb their hair, produce the finest and most delicate article.

Its Value.

In the shape in which the buyer brings it in from the country, this hair is worth about 30 dols. per pound, in gold. After it has been sorted, the different lots vary in value according to length and shade, from 1 dol. 50c. to 100 dols. per ounce. Indeed, it is almost impossible to set a limit to the outside price of choice lots of long hair of desirable shades, for so difficult are they to obtain, and so urgent is the demand from parties with whom money is a secondary consideration, that the fortunate holders can set their own price and be sure of a customer. "A switch of very light gray hair," said a dealer, "thirty-six inches long, and weighing five ounces, is worth 1,000 dols., and can rarely be found at that price."

Substitutes.

In a country like ours, where fashion is a law to the poor as well as to the rich, it has been necessary to provide some cheap substitute for human hair, in order that factory and shop girls, and others of slender means, may vie with their wealthier sisters in the adornment (?) of their heads.

For this purpose, several substances are in use. The first material applied to this purpose was jute, which, after passing through several processes, is reduced to a long and glossy fibre which, in general effect, closely resembles hair, and which, owing to its comparative cheapness, rapidly came into general use. By means of dyeing, it was produced in all possible shades, and was eagerly bought in the shape of "switches," "waterfalls," &c.

Its Injury to the Skin.

In the process of adapting jute to this use, *nicotin*, the essential principle of tobacco, and corrosive sublimate, a most deadly mercurial poison, are used. It is also rendered exceedingly brittle, and breaks as easily as spun glass. The small particles find their way through the air to the scalp, and, their edges being ragged from the combing process, act like so many poisoned barbs, which, entering the pores and being held in place, introduce the poison beneath the skin, and cause irritation and ulceration. It is owing to this that the idea became current that the jute contained animal parasites that bored into the skin and laid their eggs beneath it. The most careful examination has failed to discover any vestiges of animal life in jute, but the little barbs we have spoken of have been distinctly seen protruding from the pores of the scalp, and the sores they produce give every evidence of being the result of mercurial poison.

Linen and Cotton.

A more recent and harmless substitute for human hair is found in fine cotton and linen thread, dyed to the proper shade and sized to give it the requisite gloss, and then made up into the various forms in which it can be used. Switches of this material are sold at retail for about one dollar each, a price at which a very handsome profit is probably realised by the dealer.

Silk as a Substitute.

Probably the best substitute for human hair yet introduced is silk fibre. Its fineness and strength render it peculiarly suitable, while its brilliant lustre adds to its resemblance to the real article. It is used both alone and in connection with real hair, especially in those cases where a switch just sprinkled with gray is required. To produce this effect, dark hair and gray silk fibre are taken in unequal proportions, varying according to the shade desired, and woven together, the result being with difficulty distinguished from a combination of real hair, yet costing, owing to the immense price of long gray hair, a moderate sum comparatively. Bands and braids are also made of silk, the exposed portion only being of this material, and the filling of jute or "combings."

The Extent of the Trade.

Formerly hair work was sold only in a few of the leading hair-dressing establishments. Now large and expensive stores are devoted to its sale in the large cities, nearly every dealer in fancy articles keeps some of the grades of so-called "hair goods," and in every country store neat cardboard boxes, containing switches, *chignons*, and other head gear, are offered for sale. So long as fashion holds its present course, every woman in the land nearly is a customer, and thus an enormous bulk of business is done, paying handsome profits to all engaged in it. At first the percentage of profit was extremely large, but competition has reduced this materially. But the volume of business has increased in a like ratio, and the sale of hair and hair work continues to be exceedingly profitable.

PERFORMANCE OF A LOCOMOTIVE.

THE following extract from a letter, detailing the performance of one of Baird & Co.'s (U.S.) locomotives, will be read with interest:—

"Engine 422 has been taken into the shop for repairs, and as her performance has been an extraordinary one, you will, I am sure, desire to know some of the particulars of her career thus far.

"She was placed on the road on the 17th day of October, 1867, and ran until the 14th day of May, 1871. During the whole of this time she hauled fast and heavy passenger trains over Middle Division, and made the wonderful run of 153,280 miles, losing only three trips, which was during November, 1869, to have six new flues put in and to clean the mud out of the waist of the boiler. She also lost six round trips in May, 1870, getting in a larger tank, to enable her to make the run from Altoona to Harrisburg (112 miles) without a stop.

"This, however, was no fault of the engine, and should not be counted against her.

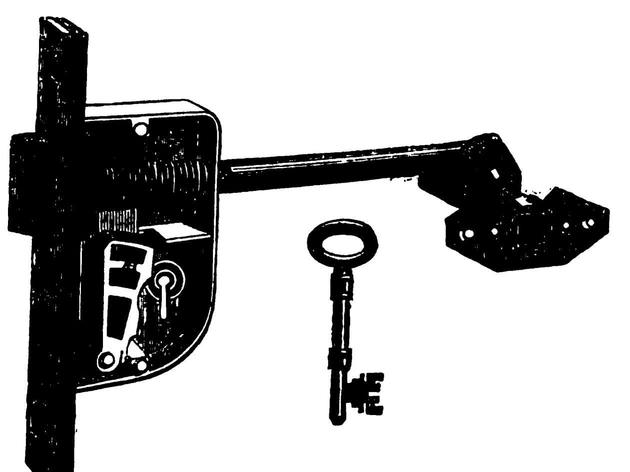
"As an offset against the nine trips lost, she made 11½ extra trips between Altoona and Harrisburg.

"The total cost for repairs up to the time she was laid off amounted to 3,727·06 dols., or 2·44 cents per mile. Our book account makes these amounts somewhat greater, but I have deducted all items not actually running repairs, such as the new tender, cost of applying air brakes, etc., which, although under our system of accounts are necessarily charged to repairs, actually do not belong there.

"When Engine 422 was taken into the shop, she was reported as run down in the working parts, but uniformly so; all the bearing surfaces being smooth and good, and her general condition being better than is usual with engines taken in for repairs. The cost of placing her in thorough repair is estimated at 1,262·73 dols."

SAMELS' PATENT STANDARD LOCK.

THERE are one or two features in the new "Standard" Lock, recently patented by Messrs. Samels & Co., well worthy of notice. The illustration given will readily convey an idea of the principle adopted. The working parts of the lock are confined in a small case readily inserted in a door without weakening it by making the large mortice necessary for most of the locks now used. The rod of the latch works in a hole easily bored with a common auger, and may be of any length, allowing the handles to be fixed as far as desired from the edge of the door. The construction of the lock is very simple, but yet affords greater security from violence than that given by many other locks.



The principal advantages derivable from its use are notably the great saving of time required for fixing, the effectual securing of the handles from lateral play, and the prevention of any wearing away of the woodwork by the action of the square spindle, by means of the bearing, which extends through the whole thickness of the door.

Yellow Solder.—The Prussian Society for the Promotion of Industrial Advancement at Berlin offers as a prize a silver medal or its value, and the sum of 1,875 francs, to the inventor of a yellow solder, possessing the properties and qualities of ordinary tin solder, and to be used for soldering brass or similar alloys so that the seams will not be visible.

Osseine, Gelatine, Osmazone.—M. E. Monier, in an essay in *Les Mondes*, expounds the divers nutritive and physiological properties of the three substances just named, which are often confused together. Osseine is nutritive, as proved in the case of dogs, wolves, and similar animals, who can digest bones and excrete the inorganic matter. Gelatine alone, and osmazone (largely contained along with salts in extract of meat), are not by themselves nutritive, but, especially the latter, aid the digestion as condiments.

Fruit Syrups.—It appears that a considerable trade is carried on in fruit syrups, which, on the *lucus a non lucendo* principle, contain no fruit whatever, but are artificially prepared from solutions of sugar flavoured with ether and coloured with aniline dyes. There are fortunately various tests for this disgraceful imposture—such as nitric acid, which, when mixed in equal volume with real fruit syrup, causes no change, but turns the imitation yellow. With solution of carbonate of soda, the artificial remains unchanged, and the real becomes lilac or green, so that the preventives against making our interior an ethereal dye-house are easily obtained and put in force.

NOMINAL HORSE-POWER.*

WHAT is a nominal horse-power? This is a question often asked, but one which, under existing circumstances, it is impossible to answer. Under these circumstances "nominal horse-power" has long ceased to be a term possessing any definite value, and has gradually come to be considered as little better than a nuisance; and this being the case, it is not surprising that it should have been proposed to do away with it altogether, and rate engines by their indicated power alone. We have ourselves advocated such a change on more than one occasion, and we have as yet met with no arguments which incline us to modify the opinion we have several times expressed, that the indicated power alone can be regarded as a satisfactory measure of the capability of any given engine. But while this is the case, we are by no means blind to the commercial advantages to be derived from the employment of a unit of measurement which can be applied to an engine before it is constructed, and, therefore, before it can be tested by the indicator in the usual way; and it is the desirability of possessing an unit of this kind which brings us to the immediate object of the present article.

When a competent engineer is called upon to design an engine to do any specific amount of work —such as to raise a given quantity of water, for instance—the term nominal horse-power never enters into his consideration. Having decided upon the pressure of steam which is to be employed, and the ratio of expansion and piston speed at which the engine is to be worked, it is perfectly easy to ascertain the diameter of cylinder which will be required to develop the power which it is considered necessary that the engine should indicate. Now, under such circumstances, this required power may be termed the "calculated indicated power," and it forms just such a unit of measurement as it is desirable to possess for commercial purposes. But if we reverse the operations, of which we have just been speaking, and attempt to rate any given engine by calculating approximately what indicated power it would develop, we are met at once by important practical difficulties, which are by no means to be easily surmounted. The first and most important of these arises from the fact that the indicated power of any given engine may vary within very wide limits, according to the circumstances under which it is worked. Thus, a given engine may be equally capable of being worked with steam at from 30lb. to 50lb. pressure, with a cut-off varied from one-sixth to three-fourths of the stroke, and with a piston speed of from 200ft. to 600ft. per minute, and the question would at once arise as to which set of conditions should be assumed in determining the "calculated indicated power." In instances where the conditions of working are known, the approximate indicated power of the engine could, of course, be readily calculated; but it would scarcely be fair to assume that because under certain conditions an engine would develop, say, 80 indicated horse-power, that, therefore, it should be rated at that horse-power under all conditions of working.

These considerations tend towards the conclusion that any commercial unit of measurement applied to steam-engines must not simply state the power which any given engine is capable of developing, but must also indicate the circumstances under which that power would be developed. A ready way of affording this information might very easily be planned. Thus, if, for instance, it was generally understood that an engine rated at "80 C.H.P. $\begin{smallmatrix}60''\\5\\400\end{smallmatrix}$" was calculated to develop 80 indicated horse-power when worked with 60lb. steam, fivefold expansion, and at a piston speed of 400ft. per minute, the rating would not only give a definite idea of what the engine was capable of performing under the circumstances stated, but would also enable an estimation to be made of the power which it would develop if worked under other known conditions.

An objection, which will perhaps be urged in some quarters against the adoption of any system of rating founded on the calculation of the approximate indicated horse-power, is that the use of such a system of measurement would involve calculations of a more complex character than it would be desirable should be requisite for obtaining the commercial rating of any given engine. This, however, is an objection to which we are not inclined to attach any great importance. Let it once be determined to employ a system of rating similar to that we have suggested, and it will be a comparatively easy matter to frame simple rules, applicable to different classes of engines, which would enable the "calculated indicated horse-power" to be determined with the requisite degree of accuracy.

We may take the opportunity of directing attention to one important point of difference between land and marine engines, which must be borne in mind in framing rules for the former, and this is that, whereas on shipboard the engines and boilers may be considered together, in dealing with land machinery they must be treated separately. It thus happens that one of the best rules suggested by Mr. Gray, namely, that which takes account, not merely of the proportions of the engines, but of the steam-generating power of the boilers in connection with which the engines are worked, would not be applicable in general land practice. In factories, boilers frequently have to supply steam for other purposes besides driving the engines, while it is also not uncommon to find two or more engines supplied with steam from one range of boilers; so that, as we have said, no rule involving reference to the dimensions of the boilers can be employed in rating stationary engines, and hence the necessity—to which we have already alluded—of the "rating" stating specifically the conditions under which the engine is worked.

Of the various obstacles in the way of introducing a satisfactory system of rating steam-engines there is, however, none so great as that of finding authority to enforce such a system, supposing it to be once determined upon. In the case of marine engines the Board of Trade may probably do much, and may, if they choose to take the trouble, introduce rules which would eventually be largely, if not universally, adopted by marine engine builders, in the same way as the Royal Agricultural Society's rule is generally accepted by the makers of portable engines. But the action of the Board of Trade in the matter, though it would undoubtedly do good service to a certain branch, would not affect the engine-building trade generally, and it remains for some body of recognised standing in the profession, such as the Institution of Civil Engineers, or, perhaps, more appropriately, the Institution of Mechanical Engineers, to take up the subject, and after investigating it thoroughly, to issue rules for rating engines, which might be generally accepted by all engine builders, in this country at least, to the utter abolishment of the present nuisance of "nominal horse-power."

* From *Engineering*.

The "Patent Cat Exterminator."—The American "grand pig-sticking machine" must yield the palm to the latest novelty, "the Patent Cat Exterminator." This is truly a fearful and wonderful invention. It is described as a large sheet-iron cat, "with cylindrical attachment and steel claws and teeth." It goes by clockwork, and a small bellows inside causes the tail to swell, and also "by a tremolo attachment" causes the patent cat to utter those wild cries so familiar to the sleepless. Being duly wound up, the machine is placed on the roof of the house. Its diabolical yells attract every cat within half a mile. Then the iron teeth and claws go to work, and with lightning rapidity all the assailants are torn to shreds. It is said that on some occasions as many as 50 or 100 domestic pets are slaughtered in a single night.

Prizes for Art Workmen.—To encourage technical education in the design and execution of works of art in the precious metals, the Goldsmiths' Company have resolved to give the following prizes, viz.:—An annual prize of £50 for the best design for some article in gold or silver which, when manufactured, shall exceed 80oz. in weight; an annual prize of £25 for the best model of some such article as aforesaid; and an annual prize of £25 for the best execution and workmanship of some such article as aforesaid. Also, three annual prizes of £25 each for (1) the best design, (2) the best model, (3) the best execution and workmanship of some article in gold or silver which, when manufactured, shall be less than 80oz. in weight; and annual prizes of £25 each for the best specimens of (1) chasing or *repoussé* work, (2) engraving, and (3) enamelling in the precious metals. Originality is necessary to obtain either of the prizes for design, and no copy shall be the subject of a prize. The prizes will be awarded in November. It has also been decided to found a travelling scholarship of £100 per annum, to be awarded by the wardens to a student who has shown exceptional talent, and who shall have obtained a prize for design for three successive years, in order to enable him to study art in the precious metals on the Continent.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. Passmore Edwards.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

AN ASTRONOMICAL CATASTROPHE.

[4086.]—Does "E. L. G." really suppose that his arguments from the action of water upon a soft quiescent heap of clay or sand are at all applicable to the form, past or present, of the earth's surface, or the effect of the various agencies we now see modifying the form of that surface? If we assume the conditions we can always attain any result we please. But if, without desiring to establish any particular theory, we endeavour to trace back in our imagination the various conditions of the earth and its original formation, then if one thing is more absolutely certain than another, it is that the original condition of the earth was *not* that of a mass of clay, mud, or sand, subjected to the abrasion of falling torrents of water; for if, again, anything in geology has gained the rank of a fact, it is that clay, mud, and sand are the products of the wearing away of old solid rocks, and that these destructive products pass again into solid (so-called primary) rocks under the influence of forces readily to be conceived and partially to be observed. Furthermore, if the conditions of the earth had ever been anything like those employed by "E. L. G." as the argumentative basis for his notions, the only possible result would have been the reduction of the earth to a true spheroid of rotation, covered with water over its whole surface. That is the condition of things which one set of natural agencies, the disintegrating forces of sun, rain, and rivers, are ever tending to produce; they wear away the hills and transport their materials to the depths of the sea. But the other set of forces (absent from "E. L. G's." heap of clay), very possibly due mainly to the gradual cooling and contraction of the earth, and to the uneven thickness of its external crust, produce an opposite effect; vast tracts of land are steadily rising, almost as if forced up by the pressure of the materials added to the sea bottom; in other parts an occasional upheaval occurs, of which we see abundant evidences in the "faults" in our mines, where whole series of strata are split, and one part lifted bodily through hundreds of feet; in other cases the strata are simply tilted edgeways; in others, as at Vesuvius at this day, vast masses are raised in a fluid condition. Are we to shut our eyes to all these operating causes which produce excrescences, which, sharp at first, are converted by the disintegrating forces into that rounded and undulating contour so dear to "E. L. G."? And are we to accept his pure dictum, and without one particle of evidence, assume with him that this contour is the result of cataracts, and further, to assume that these cataracts are caused by comets, as to which comets what knowledge we have may be described as testifying that they do *not* contain or consist of water, and that their mass is far too small to produce any universal deluge by contact with one, even if they were nothing but water?

Every geological fact which could be attributed to a deluge is just as readily explained as due to those local floods which are constantly happening, and which would result from any great upheaval; but that any such deluge ever covered the whole earth at one time and destroyed all its inhabitants is absolutely negatived by many facts inconsistent with such an occurrence having happened—at all events, within very many thousands of years. Notably is it inconsistent with the distribution of life, animal and vegetable; take as one fact that the native quadrupeds of New Holland, from the kangaroo to the rat (so-called) are marsupial, a class existing elsewhere only as a few rare species.

The misfortune is that this which is purely a matter of fact and of evidence is mixed up with religious opinions, and consequent passion and prejudice, and thus there is generated a supposed antagonism between religion and science which does not really exist, but which is due to the advocates of each taking up a partial and erroneous view and ignoring the link which should bind them together.

I will tender to "E. L. G." another form of "astronomical catastrophe," which may help him to demolish Lyell and all the geologists, if he can only prove 's occurrence, though such a trifle as that, perhaps, ..ed not be insisted upon. I once met with a book ..illed, I think, "The Electrical Theory of the Uni..rse;" it was written by an exceedingly clever and widely-informed foolish person, evidently suffering from intellectual dyspepsia and dreams, due to ill-digested facts. This book contained an immense amount of shrewd argument mixed up (as is usual with universe theorisers) with a good deal of downright nonsense, and no little of hasty and baseless assumption. The author showed that the earth was once where Neptune now is (and that it was before that a comet), and is gradually running into the sun, hardening and condensing in its progress, the moon being now, from its smaller size and consequent more rapid progress, such a hardened dead world as this must by-and-by become when all its liquids and gases have been condensed. He then made the very reasonable guess that when the earth was in the position of Jupiter, Saturn, and the other distant planets, it must have had, like them, some half a dozen moons, and the nearer of these approaching their primary one by one fell down, and their wreck formed the Alps, the Himalayas, and great mountain ranges. Now, for this idea there is more evidence than is necessary for "E. L. G.," because the Alps and the Andes, &c., are actually to be still seen, and must have come from somewhere, while as to "E. L. G.'s tale of a comet—where is the water gone to? Sigma.

P.S.—The more this idea is considered the more it would seem to suit those who must find a reason for a deluge. In the last moon that may have fallen, it is quite possible there was a good deal of sea left, and this showered down would account for the inland salt lakes and for the fish not having been killed as they would by fresh water; besides, the sudden shock would have sent our seas up in a shower of spray to come down again in cataracts, besides accounting for a good many geological facts. It will certainly answer better than that very shaky comet's tail, for "E. L. G." and all those who want a theory, and are not too particular about evidence.

"M.R.C.S." ON VENTILATING.

[4087.]—The joke of Charles II. on the courtierly founders of the Royal Society has surely been too recently called to our notice for "M.R.C.S." (let. 4043, p. 151) to expect success in trying it anew on me already! He asks me to "kindly to explain how it is" that all warm-blooded animals are benefited (?) by drawing back "into their lungs a large proportion of the air that has just left their lungs" (but not their body), "such being the universal arrangement for respiration," which "cannot be disputed by any one who *remembers* that a large proportion of the air expelled from the lungs" remains in "air channels to mingle with and help to warm the air drawn into the lungs;" a patent "respirator" in short, of mephitic air instead of platinum wires!

He then proceeds to adduce, apparently in support of this astounding physiological dogma (to me at least, I confess, as new as astounding), the single fact, well known, that breath exhaled by a forcibly deep expiration contains proportionally more carbonic acid than ordinary breath. I fail to see the least bearing of this on his doctrine. It merely shows that commonly much of the air exhaled has either not entered the lungs or not been mephitised. It nowise proves any mephitised air, or even any that has been in the lungs, to be afterwards retained in the body; but whatever it might prove or disprove (and I would be all attention to the evidence for any such novelty as our "M.R.C.S." has propounded); whatever may be Nature's arrangement with any air while retained *in the body*, what can this possibly have to do with "ventilating"—*i.e.*, with a builder or ventilator of buildings?

Surely my business, and "Philo's," and "An Architect's," in building or ventilating, is with air that has left not only the *lungs* of people or animals but their *bodies*. Does "M.R.C.S." mean to tell us Nature has anywhere arranged for any breath which has once left a man's nostrils to be "drawn into" them or another man's again? Knowing how wide is the Mechanic's circulation, we must suppose him to have been born and bred in too warm a climate to have noted a phenomenon familiar in all places that have any winter. Cold air, by condensing the vapour of our exhaled breath, makes it visible, like steam-cloud from a kettle; or, in the Arctic regions—so voyagers have told us—like smoke from a pistol, and visible half a mile off. All of us, away from subtropical latitudes, then, often have ocular demonstration of how Nature disposes of men's or animals' breath. We see it shot from the nostrils forward a foot or two, and then mounting up skyward, so that no negation seems plainer to us than that Nature has *not* arranged for one particle of it to be inhaled again, or, rather, *has* arranged against *any* being re-inhaled. Not so do our builders arrange (or rather buildings arrange themselves), for it were ridiculous to use of nineteenth-century English work any language implying personality above itself, it is a product of *development*, nowise of *mind*. All our architecture (or at least, all inhabited) so develops itself as (exactly contrary to the above, Nature's *visible* development) to retain *all* the exhaled breath possible, as *long as* possible, and to be rebreathed as *much* and as *often* as possible, with the particular amount of aëration or inblow then and there existing. Of course, be your form of shelter what it may, a sufficient wind through your room will carry away exhaled breath without permitting time for it to be re-inhaled more than under the open sky. But my position is, that whatever be the amount and nature of air-inlets, or of supposed outlets (which latter, I believe, I have said, as well as "M.R.C.S.," must, in any place that has a chimney, go finally *into* the chimney; but *that* is far from all, or the chief matter about them to attend to), whatever amount of intake or outlet openings there be, whether two square *inches* or two square *yards* to each cubic yard of chamber, in any case your architecture, through ignoring this (as it does nearly every other worthy object of rational building) has come to retain and return to you your exhaled breath as fully as possible (with the said amount of openings), and make you re-breathe it as much and as often as possible (under the same condition). I say that if this retention and re-breathing were the main objects aimed at, then they could not be better insured (in the face, of course, of a given amount of air openings), by any contrivance than by most of our newest dwellings and public buildings. Neither "Philo," nor "An Architect" has disputed this broad charge—will "M.R.C.S."?

What *can* I say, when he asks me (p. 153) "to prove that the air at the very top of a room" (the rooms I am complaining of) "is materially different except in temperature from" the rest? That is precisely what any denier of my charge has to prove! I complain that the top air is *not* materially different, whereas it *ought to be* so, and *is* in any really ventilated place, as a lantern. The highest pint of air at any moment, say, in a lighthouse, is not the warmest indeed, but is the *worst*, the least respirable in the building, which it is just leaving. So it ought to be in every room, but is *not*, and that is the gist of my complaint. In mere living or assembling rooms, the air next the ceiling (owing to that ceiling's malformation) is not materially worse than any below. All is, as nearly as possible, equally foul; the structure being such as to cool and send down all that attempts to escape, and mix up the whole as rapidly and thoroughly as possible. The top stratum, instead of being the worst, is merely the warmest; which it ought *not* to be, for every breath cools in rising, just as the lighthouse lamp-vapours do, and are less hot at the outlet than when leaving the flames. To make the uppermost air in a lantern the hottest, or its top hotter than it now is (without increased flame), is always very easy! You have merely to stop the right outlet, and instead thereof make wrong ones; in short, assimilate it to a dwelling-room, church, or any English building! The top air will then be at once made the hottest and cease to be "materially different except in temperature" from any other in the lantern. But no one dare thus treat a lighthouse, observe. For light costs oil or gas or electric force, and oil or gas or force costs *money*. Where you are dealing with merely such rubbish as human life and health, mere architects' work, not engineers', blind chance and development may rule all. But not so when actual *value* has to be economised by the right ventilative form of structure. None dare erect a lighthouse as bad and absurd pneumatically as a Queen's sitting-room, or even no better than Barry's last House of Commons (blundered into after a quarter-million's worth of experiments); for in the lantern, right aëration, the contriver well knows, involves more than human life, even sixpences!

The last question of "M.R.C.S.," whether upward drainage is essential, as well as that which he says he "will believe when he sees it done," lies in a nutshell. He has only to accept the challenge from which "Philo" has run away (pp. 589, 637, Vol. XIV.), and settle both points by experiment. I defy him or any one to make a place without upward drainage stand the simple fire and bird test; and I engage to satisfy it with no more area of air-passages than he names. E. L. G.

[This letter must conclude this attenuated discussion.—Ed.]

OUR SUMMER VISITORS OF THE FEATHERED TRIBES.

[4088.]—These are for the most part quite a different class of birds to our winter visitors. They consisted principally of water-fowls, and came from the northern latitudes, seeking food and shelter in our milder land, but our summer visitors come from the sunny climes of the south to sojourn here for awhile, and enliven our woods and fields with their joyous songs; and though the former species were more in number, and afforded more sport for the gunner, yet the return of our summer friends is more welcome, and the birds themselves are better known, and certainly more loved, for who does not rejoice to hear the cuckoo's note, or who does not love the twittering of the martin above his window, or of the swallow on the chimney-top?

And we cannot wonder at this: they come to us in the spring, when the earth is clad with green, and life, and joy, and hope appear on every side; neither can we wonder that the migration of birds should in every age have excited the interest of man. The unerring instinct which at fixed periods of the year induces them to leave one clime for another, and leads them not only to the same country, but to the same spot, is truly astonishing. Linnæus makes mention of a starling which built in the same tree for eight years, though it migrated every autumn; and swifts and swallows in our own country have been marked and found to return to the same spot for many years; and doubtless many other species would be found to do the same if the experiment were tried. Bird-fanciers also tell us how uneasy and restless caged birds become when their fellows are leaving for other lands, and often do not survive the trial very long. But we must hasten on to the birds themselves, leaving this interesting subject of migration to some future time, or to abler hands.

Taking our visitors in systematical order, and not as they arrive, the nightjar (*Caprimulgus Europæus*) stands first on our list. This bird has an evil name, but it is well for it that it is without any true reason; in days long gone by the poor bird was accused of sucking the teats of goats, and from this absurd accusation received the name of goat-sucker, a name which even to this day it has never lost. It arrives in this country towards the end of May, or beginning of June, and again leaves us about the middle of August, returning, it is said, to Africa to spend its winter. In habits it is semi-nocturnal, solitary, and rather a shy bird. Next on our list comes the white-bellied swift, or alpine swift (*Cypselus melba*); this bird belongs to the well-known group of *Hirundinæ*, or swallow tribe, several members of which are among our most familiar friends; this one, however, is not a common visitor to us, having but rarely been found in Britain. The common swift (*C. apus*) arrives here early in May, and leaves towards the middle of August, making a shorter stay than any other of the swallow tribe. Its black plumage and harsh piercing voice are not attractive, but its powers of flight are truly wonderful, and deservedly claim our admiration. The common swallow (*Hirundo rustica*) is always a welcome and a favourite visitor; it builds a shallow cup-like nest, open all round the top, generally under our eaves, though frequently in the chimney-top, from whence it is often called the chimney swallow. It usually arrives in the beginning of April, and leaves in September, winging its way back to Africa. The forked tail, and the absence of the white patch above the tail, easily distinguish it from the house martin. The purple swallow (*Progne purpurea*) has occasionally, though very rarely, been found in this country; North America is its true home, where it is said to be much beloved and protected. The sand martin (*Cotile riparia*), like others of the tribe, puts in its appearance in April, and leaves early in September; it is the smallest of our Hirundinidæ; its nest is made in holes scooped out of sandy banks, and often in such great numbers that the banks are literally honeycombed. The common or window martin (*Chelidon urbica*) usually arrives here a little later than the swallow, but it is so familiar a bird that we need only mention its name here.

The bee-eater (*Merops apiaster*) is a very rare visitor, its true home is Africa, though it is common in many parts of Southern Europe. The hoopoe (*Upupa epops*) is also another African bird which visits us; in the southern counties it is not uncommon, but it is very rarely seen in the northern; its beautiful plume of feathers makes it a very conspicuous object, and like other rare birds it is sure to be persecuted instead of protected. It is said never to have been known to breed in England.

We are now come to a group of birds which are rightly called warblers, for they contain amongst their numbers some of our sweetest song-birds. They are not much known in Scotland, but most of them are common with us. The white-throat, nettle-creeper, or hay-chat (*Sylvia undata*), is a lively and pleasing songster; it comes to us about the middle of April, and leaves towards the end of September; low bushes, hedges, and underwood, are its favourite haunts. The garden white-throat or greater pettychaps (*S. hortensis*) is another summer bird; it is ever on the move, though seldom coming in sight as it flits about the bushes, thick hedges, and low underwood, warbling out its sweet and mellow tones, which are fuller and richer than those of the last-mentioned bird. The chiff-chaff (*S. rufa*) is the smallest of our warblers, and the first to arrive, often making its appearance in the beginning of March, and stays with us till the middle of October; it has even been seen at Christmas, so that it seems likely that some of its members may remain with us throughout the year. The willow wren (*S. trochilus*) is another of our migratory warblers; it arrives here about the end of March, and leaves about the end of September or beginning of October. The wood warbler (*S. sibilatrix*) visits us in April, and leaves again in August; like the two last species this bird builds a domed nest—that is, one shaped like a ball, with a small hole at the side for an entrance, and it is placed on or very near to the ground. The lesser white-throat (*S. Curruca*), comes to us towards the end of April. The song of this warbler is not so pleasing as most of the others, for though low, some of the notes are rather harsh. The blackcap (*S. atricapilla*)—so named from the black patch of feathers on the top of its head—is, with the exception of the nightingale, the finest and most powerful of our British songsters; indeed, some of its notes are thought even to surpass that bird. It is generally heard about the end of April, seldom before, and though they leave in September a few birds are sometimes seen in the winter. It frequents woods, orchards, and groves, particularly those which are thick and bushy. Next on our list comes the much celebrated nightingale (*Luscinia Philomela*), or sweet philomel. Very little need be said about this well-known bird; it generally comes to us about the middle of April, and leaves again in August. In the southern and midland counties it is a common bird; but in Yorkshire and the North of England it is rarely, if ever, seen. Its song, though heard sometimes during the day, is louder and sweeter at night; indeed, it is during the twilight and evening hours that it loves to pour forth its warbling melodies. In some parts of England the grasshopper warbler (*Salicaria locustella*) is not an uncommon bird, in others it is very rare. Being of shy and retiring habits it lives in localities which are overgrown with long grass, sedges, and such like, amongst which it dives if disturbed. It is called grasshopper warbler from its peculiar kind of note, which greatly resembles that of the field cricket or grasshopper. It arrives here in April and leaves in September. The sedge warbler (*S. phragmitis*) is a most indefatigable songster, and arrives in this country about the beginning or middle of April, and leaves towards the middle of September. It frequents reeds, sedges, and osier beds, seldom appearing far above their tops, and in these quiet retreats its song may be heard throughout the livelong day, and often during the night. The last of our true warblers, the reed warbler, r reed wren (*S. arundinacea*), is nearly as great a songster as the sedge warbler. Its haunts, too, are the waterside, amongst the willows and reeds, and where the herbage is thick and deep to afford it a hiding-place. Like that bird, too, it sings during the night as well as the day. Its nest is ingeniously fastened to the reeds, and remarkable for its great depth. The bird arrives in England about the beginning of April and leaves in September.

The wheatear (*Saxicola œnanthe*), usually arrives towards the middle of March, and leaves about the end of September or beginning of October. This is a very highly-prized bird, but not on account of its song, but for the delicate flavour of its flesh, so that the bird gets sadly persecuted throughout its sojourn with us, particularly in the autumn, when they become very fat, and many thousands are caught and sold in the market. The stonechat (*Pratincola rubicola*) and the whinchat (*P. rubetra*) are two pretty birds, and not uncommon in furzy districts, or where the broom trees abound. The former bird might, perhaps, be called both a visitor and a resident, as numbers of them remain with us all the year round, but very few of the latter are found during the winter. The two birds are often confounded with each other, but the stonechat is readily distinguished by its black head and neck, which in the whinchat is speckly, with a white band over the eyes. This latter bird comes to us in April and leaves towards the end of September. The pied wagtail (*Motacilla Yarrellii*) and the gray wagtail (*M. campestris*) are only migratory birds in the North of England, remaining all the year through in the southern counties, but the yellow wagtail (*M. sulphurea*) or, as it is sometimes called, Ray's wagtail (in honour of that distinguished naturalist) leaves us entirely in September, and returns in the spring. The tree pipit (*Anthus arboreus*), or tree lark, is another of our summer birds, and arrives in the end of April, and departs in September. The mode in which this bird ascends and descends the trees is remarkable; settling on some outside twig it ascends by little flights from twig to twig, singing out its not altogether unpleasant song, till it reaches the topmost branch, where it will sing for awhile, and again descend by similar successive flights till it reaches the ground. In some districts the ring-ouzel (*Turdus torquatus*) is not an uncommon visitor; in habits it is a wild and shy bird, loving the wild moorland, hilly districts, and rocky glens, far removed from human haunts; it comes to us in April, and leaves by the end of September. The song notes of this bird are few, and though loud and wild, are not unmusical. The beautiful golden oriole (*Oriolus galbula*) is an extremely rare bird with us, but having been occasionally found in Britain it claims passing notice here. Two species of flycatchers are found in England, the spotted flycatcher (*Muscicapa grisola*) and the pied flycatcher (*M. atricapilla*), and both, as might be supposed, are summer visitors; the former is common, especially in the southern countries, but decreasing as we proceed northward; it is a late arriver, often not making its appearance till the end of May; it is found in gardens, copses, and shrubberies, particularly where flies abound; the latter bird is not uncommon in some localities, though never found in any great numbers; it arrives here in April and leaves in September. The whole of the under part of this bird is white, while in the former the front of the neck and breast are speckled.

The red-backed shrike (*Lanius collurio*) or lesser butcher bird, is not uncommon in many places; its food consists not only of insects, but also of small animals, reptiles, and unfledged birds, which it impales upon thorns, after the manner of the rest of its kind, before devouring them. The time given for its arrival is the end of April or the beginning of May. The woodchat shrike (*L. rufus*) is sometimes found here, but generally speaking is very scarce.

The pretty wryneck (*Yuux torquilla*) now claims our notice. It belongs to the order of *Scansores*, or climbers, birds which have their toes placed two in front and two behind, which arrangement enables them to climb up the trunks and branches of trees with great facility. The wryneck heralds in the cuckoo, appearing just before that bird. It is often called the cuckoo's mate or cuckoo's footman. Its food consists principally of ants and their eggs, using the tongue to pick them up with instead of the beak; and wonderfully is it adapted for this purpose, the bird being able to extend it some little distance beyond the beak; and it is horny at the tip, and covered with a glutinous substance, and so rapid and unerring does it dart in and out that the ants disappear like magic. The voice of this bird is not very musical, but when once heard is not easily again mistaken. That welcome messenger of spring, the cuckoo (*Cuculus canorus*), is a visitor more often heard than seen. It arrives in April and leaves in August. It is well known that the cuckoo never builds a nest or hatches its own eggs, but trusts this important duty to some other bird, generally to the hedge-sparrow, the pied wagtail, or the meadow pipit, though sometimes this business is forced upon the lark, chaffinch, or blackbird. But perhaps it is not so well known that the young cuckoo is not at all merciful to the young birds that are hatched in the nest with it, but throws them all out, remaining sole occupant; and not only is this instinct instilled into the cuckoo at a very early stage of its existence, but it is also peculiarly formed by Nature to accomplish these feats, the shoulders being very broad, with a slight depression down the back, in which the young birds are lodged, while the little cuckoo shuffles to the edge of the nest and tosses its burden over.

Next on our list comes the passenger pigeon (*Ectopistes migratorius*). This is, rightly speaking, an American bird, where it is met with in prodigious numbers; but with us it can scarcely be called a visitor, it having been so very few times found here. The turtle dove (*Turtur auritus*) is a very pretty bird, especially the male, and the smallest of our wild pigeons. Its entire length is a little over eleven inches, and weighs not more than six ounces. It arrives here early in May, and leaves by the beginning of September.

The quail (*Coturnix communis*) is another regular summer visitor, though never found in any great abundance; in many places on the Continent, as well as in Asia and Africa, it is found in prodigious numbers, flocks of many thousands being seen in the course of the day. In general appearance and manners it strongly resembles the common partridge; but differs from that bird in being a polygamist, and the care of bringing up the family is left to the female bird. It comes to us in May and leaves in October.

The great plover (*Œdicnemus crepitans*) comes to us in April, and leaves in September; it is not an uncommon bird in marshy places and open downs, but is nearly confined to such districts; its call strongly resembles a very shrill whistle; it seeks its food principally during the night. The dotterel (*Charadrius morinellus*), or foolish dotterel, was in former times a much commoner bird than now; on its first arrival it frequents heaths and open grounds, but these it soon leaves, and betakes itself to high hills and mountains, particularly those bordering on lakes; like the last-named bird it is a nocturnal feeder. The ruff (*Philomachus pugnax*) and the reeve are the same species of bird, the former being the male, and the latter the female; the male is so named from having a most capacious ruff of feathers round the neck; which can be raised or lowered at the will of the bird; this ruff, however, is only found during the breeding season. They were once very common visitors to our fenny districts, but are now fast decreasing, owing to the drainage and cultivation of those localities. When fat the birds are much prized for the table. They arrive in April, and leave by the end of September. The corncrake (*Ortygometra crex*) is a regular visitor to most parts of Britain, though rarely found in any numbers; it arrives about the same time as the quail, when its cry of "crake! crake! crake!" may be heard at almost all hours of the day and night, particularly during the evening, but to tell whereabouts the bird may be is a difficult, if not impossible, matter. We are now come to the last bird on our list of summer visitors, the spotted corncrake (*O. porzana*.) This bird is by no means so common as the last; but still it is known to visit some of our marshy lands, and to breed there. And now having finished these brief notes on our summer birds, I must conclude without any further remark upon them, my letter having already run to such a length.

AVON.

GRAVITATION AND REPULSION.

[4089.]—WITH reference to Mr. Proctor's accusation in letter 4053, p. 172, that I endeavoured to convey the impression of Ganot being on my side, because in letter 4008, p. 144, I commended the able reasoning in Book III., Chapter 2, of his "Elementary Treatise on Physics," I have to remark this is so far from the fact that the very first statement in Book IV., Chapter 1, is opposed to my ideas concerning the physical forces of matter—namely, "Gases are bodies whose molecules are in a constant state of repulsion." I deny the existence of a repulsive force in nature, and invite Mr. Proctor to give a single instance of its action.

T.A.

"T. A." AND GRAVITATION.

[4090.]—IT seems the corrected "proof" of letter 4053, page 172, did not reach you (as usual) in time. In it I modified the remark at the close of the letter, considering that, after all, "T. A." might be able to explain what looked to me like a *suggestio falsi*. Should this appear to be the case, "T. A." will oblige me by considering my apology as made herewith.

RICHARD A. PROCTOR.

[The corrected proof did not reach us in time.—ED.]

COAL-CUTTING MACHINERY.

[4091.]—THE introduction of such machinery as alluded to on p. 140 is not a question of economy only, or even chiefly. If such machines are to be worked, as the most promising now are, by compressed air, which, when it expands on escaping, becomes very cold, their use will introduce large quantities of fresh and cool air in the very places where the men are working, adding greatly to their comfort, and something to their safety. One I saw working reduced the temperature of the gallery about ten degrees in an hour, which would have been considerably raised by a dozen lamps and a dozen pair of lungs, had not cold air been introduced. A still more important advantage will be that the pitmen will be saved from the most dangerous and injurious part of their toil—that of holeing—*i.e.*, undermining the seams of coal. On the average, 416 pitmen are killed a year by falls of coal or roof, and a far larger number crushed and maimed—a large, but to me unknown, proportion of which accidents occur by coal unexpectedly falling upon the men when undermining it. To this danger, those who work the machines will be very much less exposed, as they need not lie beneath the coal at all, as the hewers must do when holeing. I have no clear evidence that holeing is injurious work, but cannot doubt that working in so constrained a position—with the mouth and nose full of coal dust, which has to be coughed up as black spit—must be hurtful, and I know that metal miners complain greatly of the somewhat similar work of beatin[g] the borer as very trying and exhausting, and it is ju[st] the sort of work one would wish to have done by m[a]chinery, if it can be.

P. H. HOLLAN[D]

VENOMOUS SERPENTS.

[4092.]—In the discussion on this subject printed in the last volume, I ventured to doubt (p. 368) whether any warm-blooded animal is proof against the poison of the thanatophidia save one of their own kind. It has also been frequently asserted, sometimes in well-informed quarters, that the mongoose is able to throw off the effects of the cobra-bite, by partaking of a certain herb, which it immediately seeks when bitten. I have recently come across some further information on this point which I beg to submit to your readers. It is from an assistant of Dr. Fayrer, and will be found in the Transactions of the Boston Natural History Society for March, 1871. I learn from this that the mongoose, when attacking the cobra, seizes it by the neck or throat, and usually retains its hold for a few seconds, at the same time sucking the bood from the large vessels in its neck. Sometimes the snake and mongoose roll over together several times, and there are some so ignorant of the habits and powers of these animals, as to suppose that during this time the weak jaws of the cobra are holding the mongoose, and on seeing the blood about its head and mouth think that it comes from wounds on its own body, received from the fangs of the cobra.

Another mistake is often made in supposing that the blood frequently seen on the cobra's nose comes from a wound inflicted there by the mongoose. And assuming this to be the case, the question was often asked how the mongoose bit the cobra's nose without receiving in return wounds from the cobra's fangs. On carefully observing the movements of the cobra when snakes and other animals were put into its cage, Mr. Sceva found that it would strike at them with its nose without opening its mouth, and in many instances the cobra, by striking past them, would bruise its nose on the side of the box, or against the wire-netting in front, causing it to bleed. This occurred in every case he witnessed of cobra encounters with the mongoose.

Dr. Fayrer made the mistake in one of his first experiments of thinking the mongoose bitten when it was struck by the nose of the cobra, and as the mongoose did not die, his report, published in the *Indian Medical Gazette*, stating that the animal was "bitten," was regarded by some as conclusive evidence that the poison must have entered the blood, but could produce no bad effect on it. Dr. Fayrer, however, soon discovered that when animals were put into a box with a cobra it was very difficult to tell—merely by watching the snake's movements—whether they were bitten or not; and in nearly all the experiments made afterwards he had the animal secured, and the fangs of the snake applied to any part of the body required, or the poison taken from the snake and injected under the skin with a hypodermic syringe. Several experiments were made on the mongoose by both methods, causing its death in every case.

Mr. Sceva believes that hogs attack and kill poisonous snakes in almost every part of the world. He has never seen a hog at the commencement of his attack upon a poisonous snake, but on one occasion he saw one with both fore feet on the snake's head and neck while he was tearing open the body with his teeth. He has met with many people in North and South America, and in India, who thought that the venom of snakes could not affect the hog, but this supposition has been proved by careful experiments to be incorrect. In India he had seen a hog bitten on the ear and on the inside of the fore leg; the action of the poison and the time of the hog's death were shown to be about the same as in the case of dogs.

"E. L. G." will thus see that, in the opinion of one who has experimented with the living animals, hogs are not proof against cobra-poison. Whether in the event of a bitten hog not dying, there was no poison injected, or its "fat" coat protected it, we cannot easily decide; but the venom of these terrible reptiles once in the blood, no human power seems able to prevent death.

SAUL RYMEA.

CO-OPERATIVE SOCIETIES.

[4093.]—The system of duplicate cheques I described would, of course, be imperfect unless the cheques are given in all cases; nor, indeed, unless there be a money-taker as well as a seller, and unless collusion between them be prevented. If, however, the seller be required to give a cheque in all cases for the money he receives, if the omission to do so be treated as a serious fault, or even as presumption of dishonest intention, and if all customers be requested to see the cheques written in the book, and that they correspond with the money paid, the system, though not perfect, would be an important guard against either mistakes or fraud, or the suspicion of it.

The plan described by "Loach," besides being much more troublesome than the cheque system—which is much less costly than he seems to suppose—is open to the very serious objection that it affords no protection to the buyer against short weight or inferior quality of goods, against which it is even more important to guard than against direct embezzlement.

I think the cheque system the better plan of the two, but there is no objection, except the trouble involved, to the adoption of both. The advice of "F. C. S.," that those interested should read the report of the discussion at the Co-operative Congress, is very wise. In many stores it is customary to allow to customers not members a share, though a smaller one, of the so-called profits—more properly, savings of cost in retailing. The adoption of this plan renders the cheque system less imperfect, but even without it the effect is useful, as is found by some omnibus proprietors, *e.g.*, those of Plymouth, who require their conductors to give every passenger a cheque, and who, I believe, generally do so.

PHILO.

DRILLING MACHINE.

[4094.]—In reply to "Linum" (let. 4039, p. 151), the small wheel below F (see p. 57) is a ratchet-wheel. The crank E has a spring fitting this wheel. The crank is worked backwards and forwards on the wheel like any ratchet-brace.

C. CHURCHILL.

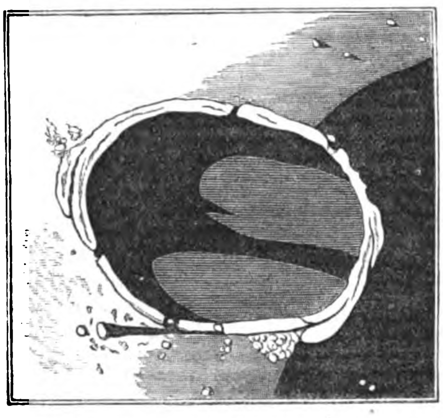
RAISING WATER BY TIDAL POWER.

[4095.]—I think the power of the tides might be used to supersede manual labour for raising water to baths. Suppose, for example, that the rise of the tide is 10ft., a reservoir might be built, or embanked from the shore, and fitted with a sluice, the water passing in and out to work a hydraulic ram. In a rising tide, when it was half tide, the sluice would be opened so as to admit the water gradually into the dam or reservoir, maintaining a fall of 5ft. for nearly three hours, and working the ram for three hours; the sluice would then be closed and the ram stopped, the dam being full; when the tide had half ebbed, the water would be allowed to flow through the sluice and actuate the ram until low water. The ram would need to be turned half round at each tide, or it might be contrived to have its waste water to fall into the sea or into the dam, as was required by the falling or rising of the tide. For example, if the dam had an area of 400ft., 2,000 cubic feet of water would pass through the ram during each tide, and a quantity of this, depending on the height of the baths, would be raised to the bath-rooms (say 250 cubic feet each tide, to a height of 20ft. or 25ft. above high water), or a float attached to a lever might be used to work a forcing-pump. If the float displaced 500lb. weight of water, and was raised a foot high by the waves six times in the minute, it would give 3,000 units of work in the minute, or rather more than a man's power at pumping. I should like the opinions of correspondents.

PHILANTHROPIST.

PLATO.

[4096.]—I inclose a drawing of Plato as I saw it with an excellent 8¼in. clear aperture on April 16 at 9.20 p.m. I noticed that the shadows on the floor had not so good definition as the exterior ones. Know-



ing that Mr. Birt and other observers are readers of the MECHANIC, I thought it would be interesting to know if they observed such a phenomenon. Also, may I ask Mr. Birt if the floor is supposed to be convex, as I noticed that the longest shadow rapidly shortened, and that the edge of the floor was not so bright as the centre?

J. W. D.

[This drawing of Plato is the *earliest* that I remember to have seen in which the shadows are depicted as having fully taken shape. As a companion to Mr. Elger's sketch (ENGLISH MECHANIC, December 15, 1871, No. 351, p. 332) it shows the shadow of the rock δ extending along the floor, with its characteristic truncated termination just within the east border. Mr. Elger's sketch exhibits the same shadow much shortened, illustrating "J. W. D.'s" remark "that the longest shadow rapidly shortened." The floor of Plato is by no means level; as seen under oblique light it dips to the east and west borders, occasioning the phenomenon witnessed by "J. W. D." of the edge of the floor not being so bright as the centre. As regards the definition of the interior shadows not being so good as that of the exterior, Mr. Neison noticed on the 17th and 19th of April the interior objects, especially the streaks, to be less distinct than objects on the exterior slopes, which were sharp and well defined. The gaps in the south, west, and north portions of the wall are well shown in "J. W. D.'s" sketch. Instrument, 8¼in. aperture.—W. R. BIRT.]

THE DELUGE.

[4097.]—May I be permitted to express my hearty thanks to "E. L. G." for his letter (4068), "One Proof of the Deluge," which I think of so great value that, for my two years' subscription to the ENGLISH MECHANIC, I consider myself well repaid by this letter alone? It will be an additional favour if, in his next communication, he will kindly mention the publisher and the date (of latest edition) of the work of which he speaks highly: Colonel Greenwood, "On Rain and Rivers."

Sandhurst, Torquay. P. H. GOSSE, F.R.S.

THE ALCOHOL QUESTION.

[4098.]—In differing from Dr. Richardson as to the cause of the accelerated action of the heart while under the influence of alcohol, Mr. Barwick has, *more suo*, (let. 4052, p. 171) taken a "leap in the dark." Mr. Barwick assumes that after the administration of alcohol the blood is too "suddenly carbonised and hydrogenised" (for there is no proof that it is so), and on this assumption he propounds the theory that "accelerated heart-beats may be from rapid oxidation," leaving your readers to suppose that he has discovered a point overlooked by Dr. Richardson. Now, I have read the article on p. 109 somewhat more carefully than is my wont—for it happens to be written in a style which I should like to see adopted by the teetotallers—and I fail to perceive whence Mr. Barwick obtained his idea of "rapid oxidation." True, if the blood had more than its proper proportion of carbon, it would require more rapid oxidation; but the heart has no sense, it could not know this, and consequently would not pump the blood to the lungs in a more rapid and larger stream unless it received a monition from some source which governs its action. This would make alcohol a stimulant of the heart's action, and this Dr. Richardson is convinced is an erroneous idea. Again, accelerated heart-beats must precede accelerated oxidation, and there is no proof that, even if the blood is "carbonised and hydrogenised," it can be accomplished "too suddenly"—whatever value Mr. Barwick may attach to that expression. There is also no proof that alcohol is split up into carbon, hydrogen, and oxygen in the system; and if there were, his crude hypothesis fails, because rapid oxidation means increase of temperature, which should be sustained while there is any excess of carbon to be burnt. This is contrary to observed facts, for, according to the article on p. 109, there is a steady decline of the bodily temperature after the slight increase exhibited on the surface has radiated, and dram-drinkers know that "drops" require to be indulged in with increasing frequency to keep the cold out.

But suppose we say the accelerated heart-beats *are* caused by rapid oxidation (which reads very like the cart before the horse), if Mr. Barwick had consulted a friend it is very likely that "two heads" would have come to the conclusion that after all Dr. Richardson might be right; for what would be the cause of accelerated heat-beats in the following case:—Given "Saul Rymea" in a narrow lane with impassable hedges, and a mad bull rushing at him, what is it that makes his heart go about three times as quick as it ought to? It can't be "too suddenly carbonised and hydrogenised" blood; is it not rather caused by the conveyance to his brain, through the optic nerve, of an alarming fact, which so acts upon the sensorium as to cause paralysis of the "organic nervous supply of the vessels which offer resistance to the heart"? Other cases will suggest themselves to Mr. B., showing that the action of the heart is regulated by the brain and not by the amount of carbon in the blood. Alcohol is really a true narcotic: it first unhinges those parts of the brain which govern the nervous supply of the vascular system, and so on, step by step, till the nervous centres which govern volition and speech are involved, the last to go off duty being the "seat of life"—the centre which actuates the heart. Now, if Mr. B. can show *how* alcohol so affects the brain, he will be doing a service to science; but he need not bring up ideas that are utterly incapable of holding water, or hypotheses that have been examined and laid on one side as unsatisfactory.

I do not pretend to reconcile the statement in the article that the effects of alcohol and chloroform are "very similar" with Mr. Barwick's dictum that "chloroform's effects are widely different," but the P.S. shows how well able he is to speak on the point. I cannot say either whether there is an accumulation of "molecules obstructive to atomic recombination" because I do not know what he means, or to what the "it" refers. Perhaps some of those better versed in physiology than Mr. B. or myself will explain.

SAUL RYMEA.

ORNAMENTAL TURNING.

[4099.]—Your illustration (p. 146) of a tool for turning short round rods is calculated to mislead any one seeking useful information. No one can cut soft wood with a tool set in a radial line, it must be set at a tangent to the circumference of the rotating wood to be of any use in cutting, and the same cutter-frame will only serve for one diameter of rod.

SMITHERREENS.

COMMUNICATING ROTARY MOTION TO BALL FIRED FROM SMOOTH-BORED GUN.

[4100.]—The object of rifling is to present inequalities in the form of the ball in different directions successively, so that they may not act as rudders to divert the ball from its course; also, as the centre of gravity of the ball does not quite coincide with the, direction of the line of propulsion, the rotation of the ball avoids also this source of deviation. A rifle ball leaving the muzzle at a velocity of (say) 1,000ft. per second makes about 150 turns a minute, but it loses its rotary force more rapidly than its projectile force, and thus at long ranges shoots indifferently. (See "The Story of the Guns," by Tennent). By my plan, the force of rotation, slow at first, would increase. Of course, it is on the principle of Barker's Mill. I had not seen a description of Boxer's rocket when I wrote it; I fear, however, the motion in my ball would be too slow. The holes might point backwards so as to ignite the composition by the fire of the gun.

PHILANTHROPIST.

CONCRETE MULTIPLICATION.

[4101.]—I BEG to thank "Sigma" and "E. L. G." for their replies to my letter (3965), but would like to ask the former wherein lies the extraordinary oversight which he says I have made. I quite agree with him that multiplying pounds by pints or yards is a proposition savouring somewhat of lunacy, but multiplying pounds by pounds or shillings is rather different, and seems to me no more absurd than multiplying feet by feet or inches, as in the example given in my last letter. I may here quote "E. L. G." to the effect that "feet multiplied by feet do not make square feet. Not at all." So say I. Neither do pounds multiplied by pounds necessarily make square pounds. In fact, the expression pounds multiplied by pounds, like that of feet multiplied by feet, is merely a "compendious way of expressing an arithmetical dodge."

Since writing the foregoing, it has occurred to me that, perhaps, "Sigma" may think that arithmetics do not give rules for the multiplication of moneys, weights, &c., in the way referred to. If so, I beg to submit to his notice the following rule, culled from a book now before me (not by Hind):—"Problem: To multiply pounds, shillings, and pence by pounds, shillings, and pence, a pound being taken as the integer." This is the rule: "Pounds multiplied by pounds produce pounds; pounds multiplied by shillings—every 20 is a pound, the rest shillings; pounds multiplied by pence—every 12 is a shilling, the rest pence; shillings multiplied by shillings—every 20 is a shilling, every 5 is three pence, and each 1 is two farthings, and four-tenths of a farthing; shillings multiplied by pence—every 5 is a farthing, and each 1 two-tenths of a farthing; pence multiplied by pence—every 60 is a farthing, and every 6 is one-tenth of a farthing." The author then proceeds to give several examples, all of which I omit for the sake of brevity, and adds the following note:—"The above question (referring to one of his examples) was given in a former edition of this work, but finding so few who could be brought to understand it, the author has entered into it more fully. To those who still stumble at this problem, he begs to refer them to the first and second books of Euclid's 'Elements.'"

My object in writing on this matter, is to draw attention to the fact that the opinions of the leading authorities in "our" journal are at variance with the rules laid down in books published for the instruction and guidance of students. Surely these rules should be omitted or altered, if they appear so absurd to those who are qualified to judge, as every step taken in a wrong direction has to be retraced by the beginner, and the ground gone over again, with more or less of labour and pain. For my own part I always use the rule of practice for such calculations, and consider it the easiest and best.

No. 170.

[4102.]—I BEG to remark that the explanation of "Sigma" (let. 4009) as to concrete multiplication is not satisfactory. It is equally absurd to talk of multiplying feet by feet as it is to speak of multiplying pounds by pounds. A foot multiplied by a foot has no meaning, nor can the process produce a superficies—a thing of perfectly different nature. The arithmetical process of multiplication has no such creative power, nor is it "because there is such a thing as a square" that "linear" feet can be multiplied together, but because we introduce the important step or hypothesis of giving a new and arbitrary meaning to the unit of which the "product" represents the multiple—*i.e.*, that instead of the linear unit, of which the abstract number in the multiplier and multiplicand are the multiples, the unit shall in the product be a superficial foot—*i.e.*, that one foot multiplied by one foot shall be taken to represent a superficial square foot, an hypothesis perfectly arbitrary, as with equal reason and correctness we might assume it to be a rhomboidal foot, the notions of squareness and obliquity being both alike foreign to the idea of multiplication. Another step will be necessary—viz., on this assumption to show that the result holds good for all numbers, or the process may be reversed.

The simplest explanation, as far as arithmetic is concerned, is to suppose the unit changed prior to, and not subsequently or in consequence of, multiplication. If 10ft. multiplied by 12ft. means anything practically, it can only have the arbitrary meaning of the number of square feet in a surface of these dimensions. The best way to ascertain this number is to take a strip along one side a foot wide, say 12ft. long. This will be 12 square feet, for taking a square foot as the unit, and multiplying by the abstract number 12, we get 12 square feet. There will evidently be 10 such strips, and again multiplying by the abstract number 10, we get 120 square feet; and there is no mystery in the matter, nor have we incurred any risk to our personal liberty for having endeavoured to multiply together concrete quantities! M. A.

FASTENING LOOSE WINDOW SASHES.

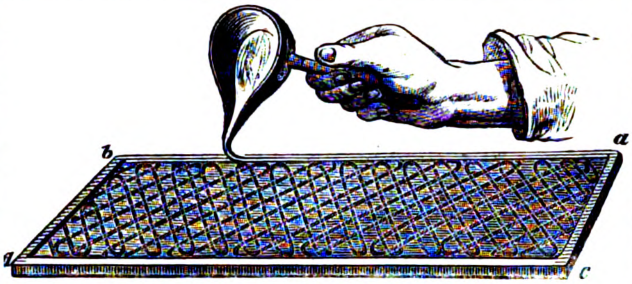
[4103.]—THE plan described at p. 152 seems a convenient one for preventing loose window sashes rattling, but it is a pity they should be pressed quite closely together, so as to prevent the entrance of air into a room at one of the places where it is best it should enter, for enter it must somewhere if an open fire be burning, and if it enter between the sashes so as to displace air previously cooled by contact with the cold glass, more air can be admitted with less loss of heat than anywhere else, except at the top of the window. It is easy to intercept dust and to check too strong a draft, without stopping the entrance of air altogether. PHILO.

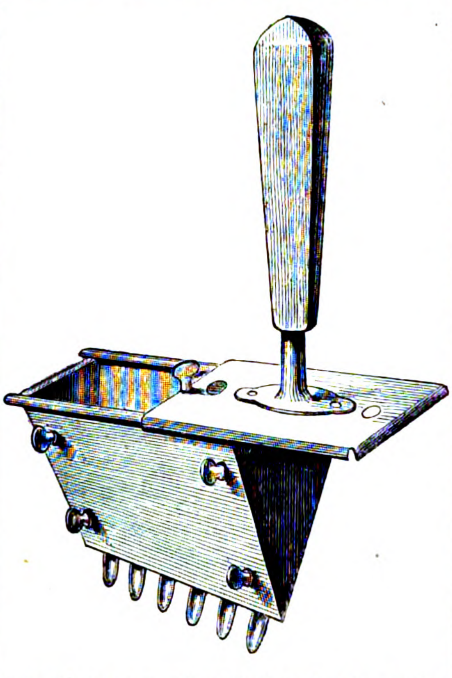
IMPROVED MEANS OF MANUFACTURING CONFECTIONERY.

[4104.]—THE manufacture of confectionery has lately received attention in your columns, so possibly the following may interest some of your readers:—

Monsieur A. E. C. Landry, cook to the Turkish Embassy, has recently patented in England and France, through our agency, an invention for improvements in the manufacture of sultanes and other similar articles of confectionery, and in the apparatus employed therefor, whereby the said articles are made in a much more rapid, perfect, and economical manner than at present.

To make the cylindrical parts of the sultane, or other similar article of confectionery, which has hitherto been attended with much difficulty and labour, Mr. Landry employs a flat mould *a*, *b*, *c*, *d*, similar to that shown in illustration; this mould is made of a suitable metal or alloy of metal, and is cast, or otherwise formed, with a raised lozenge pattern or design, the sides of the raised lozenge-shaped parts being slightly inclined; or the mould may be formed with any other desired design or pattern.





To make a sultane the prepared sugar in a liquid state is poured into the sunken parts of the mould until a sufficient thickness is obtained, but so as not to run over or cover the raised parts of the mould. When sufficiently cool, but while yet in a plastic state, the sugar is rolled over a tin or copper cylinder, and the two ends joined by any of the means well known to confectioners. By this means M. Landry obtains, in a short time, and with but little labour, a hollow cylinder of sugar formed with openings, of the size and shape of the raised parts of the mould. The voluted or other ornamental parts of the sultane, such as the borders, &c., may also be formed by moulds.

The second illustration shows a view of M. Landry's apparatus for forming hair sugar. It consists of a box or receiver made of copper or tin, and provided with a sliding lid, to which is fixed the handle of the apparatus; the ends of the box are fixed to the sides by screws as shown, so that the box may be easily taken to pieces for cleaning; in front of the strips or projections at the bottom of the box are slits for the passage of the sugar. To use this apparatus, the box is filled with sugar in a semi-liquid state, and the apparatus being held in the position shown, the sugar will pass through the slits in the bottom of the box, and along projecting pieces in thin streams or hair sugar, which may be guided according to the effect desired.

L. DE FONTAINEMOREAU & CO.

ELECTRICAL SPARKS.

[4105.]—MY statement that I had been told by a young lady who was well known to me that she had frequently, in America, lighted the gas by electric spark from her finger, the electricity being apparently excited by friction of the soles of her slippers upon the carpet, but that she could not do this in England, because, as she supposed, of the air being less dry, was treated as an impossibility by one correspondent at p. 62, while another (Mr. Tonkes) seemed to consider that in no part of America was the air likely to be very dry, because in other parts ague is often prevalent. I have lately received confirmatory evidence from another lady (whose truthfulness, also, is above suspicion) that in certain seasons the phenomenon is quite common in the neighbourhood of New York, as the correspondent quoted by "G. J. H.," at p. 148, states that it is at Boston. I learn from my informant that some persons only seem able to perform the experiment, but why I have not learned; that it needs for success hard frost out of doors and dry heat within—*i.e.*, a great difference between the dew point and the temperature—and that the feet often have to be repeatedly rubbed upon the carpet to excite the electricity. My informant believes that ordinary slippers were worn, not those with guttapercha soles.

If the theory of those who would pass as authorities on electrical science does not correspond with well-authenticated facts, if not the theory, at least the theorists may possibly be mistaken. It would become them in future to be less positive and more polite.

PHILO.

[When a correspondent makes an extraordinary statement, as "Philo" did, which was discredited, he should, when offering confirmatory evidence, as "Philo" professes to do, authenticate his facts. It is not enough for an anonymous correspondent to repeat observations communicated by an "informant" in America, and it is unreasonable to expect that men accustomed to look at facts scientifically will be influenced by such a mode of teaching. In such matters correspondents will be credited and respected in proportion as they are precise as to persons, places, and dates.—ED.]

A GUN-COTTON ENGINE.

[4106.]—THE invention of a controllable gun-cotton has possibly provided such a material as I have considered necessary for the fuel of an engine, which should be at once comparatively light, somewhat powerful, and, above all, consume a substance in which great mechanical force is resident, without occupying considerable space. A machine of such a character is obviously of the greatest importance. It would probably have considerable influence on the study of aëronautics, while it would certainly be invaluable on tramways in the event of proving safe and uniform in its action.

The conditions above mentioned seem to me to point in the direction of explosives, but as they are so violent in their action, formidable obstacles to their employment in this direction are presented. But by the invention of the controllable gun-cotton, which is said to be moderated in its explosive properties by the application of saccharine matter to the filaments, it does seem to me that, if no considerable loss of force is sustained by the addition of the moderating elements to the extent requisite, some approach to its employment as a source of mechanical force is at hand. May I, therefore, ask some of your practical readers whether an engine with a cylinder into which a cord of such prepared gun-cotton is driven, and portions exploded by being cut off at the orifice, permitted to fall between the poles of a battery inclosed therein, and so to propel the piston by the agency of the evolved gases, presents any obviously insurmountable defects? It would be necessary to realise the condition that but a small quantity of cotton would be consumed at each charge, and not to confound the violence of the concussion resulting from the firing of a piece of artillery, which has to do immense work at a considerable distance from the seat of the development of force, with the working of an engine subject to a somewhat uniform pressure upon its motion, and for which some means might be devised of approximating the production of force to the amount of resistance to be overcome; in which case I apprehend the concussion would be reduced to an inconsequential minimum, and the evenness with which the quality of gun-cotton may be prepared would go far to fulfil the conditions.

E. J. N.

THE FAIRLIE LOCOMOTIVE.

[4107.]—WILL you kindly find room for the following few lines in reply to Mr. Amos Appleyard (let. 3966), also to Mr. G. A. Boyd (let. 4041)?

It is clear from the style of reasoning in Mr. Appleyard's letter that he does not understand the principle of the Fairlie engine. It would appear that weight of rails, their maintenance, weight on wheels, wear of tires, equal loaded wheels, absence of oscillation, perfect articulation, absence of friction, have no meaning for him, hence his proposal to build ordinary engines (if he could) as powerful as the Fairlie tried not long ago in Yorkshire.

Mr. Boyd could have easily supplied himself with the information he seeks, as it has been frequently published, and, I believe also, in your very excellent journal. However, to save Mr. Boyd the labour of searching, I now give him shortly the information he seeks. Why Mr. Allan did not do so I am unable to say; but as the letter was addressed to me, I gave it for the benefit of your readers, just as it is. "Welsh Pony" and "Giant": cylinders, 8in. diameter; stroke, 12in.;

wheels, 24in. diameter; representing at the periphery of the wheels, with 1lb. pressure, 32, or 64 for the two engines. "Little Wonder": cylinder, 8 3-16in. diameter; stroke, 18in.; wheels, 28in. diameter; representing at the periphery of the wheels, with 1lb. pressure, 62, or only 96·8 per cent. of the "Giant" and "Pony." The "Wonder" weighs 19¼ tons on 8 wheels, load equally distributed over each. The "Pony" and "Giant" weigh 10 tons each—that is, 20 tons on the same number of wheels. The "Pony" and "Giant" are four-wheeled coupled tank engines. It is quite true that some one out of a lot of identical engines may turn out more economical or more extravagant in fuel than others, but I never yet heard of a difference of 25 per cent.—Mr. Spooner asserts the saving to be over this—on the work done.

I think Mr. Boyd is in error in saying Fairlie bogies were ever used before the first engine on this principle was built.

It should be understood that the Fairlie engine is proposed for economy pure and simple, the nature and extent of the traffic having nothing to do with the question. It only happens that Fairlie engines have been ordered for duties which could not possibly be performed by the ordinary engine—necessity has here driven the purchasers to this type of engine; but because necessity compels this it does not follow that a great economy would not result by employing the engine on the ordinary duty. I assert most confidently this would be the case, and I am in hopes of seeing the engines employed for every duty which can possibly be required for a locomotive.

If Mr. Boyd would only think for a moment he would find the great economy of a Fairlie engine arises out of its running without oscillation with only half the weight on the wheels, and yet giving out as much force as the ordinary engine. You can remove a bogie from a Fairlie engine and substitute another without dropping the steam in the boiler. If Mr. Boyd will take the trouble to obtain my specification of my radial carriage and waggon couplings he will be better able to say whether it is the same as described in the "Encyclopædia" to which he refers. Not knowing what is in the latter, I cannot enlighten him; perhaps some one of your numerous readers would do so.

I have built and am building engines on 2ft. 6in. gauge to work gradients of 4 per cent: and curves of 150ft. radius. R. F. FAIRLIE.

WEIGHT OF THE EARTH AT CREATION AND NOW.

[4108.]—I HAVE to thank "E. L. G." for his letter (4068, p. 175) in your last number, in which at last he gives us something tangible to go upon. As he appears to rest his case entirely upon physical appearances, I will not trouble you with any palæontological evidence to the contrary; but will content myself with pointing out one or two causes at present in action which seem capable of producing the sweep vales and undulations which he attributes to the action of a flood; one of these causes is the solubility of lime in rain-water, this acts precisely in those parts of the country where there are few streams—that is to say, where the ground is so porous that the water percolates through instead of forming surface rivers; each drop of rain carries off a particle of limestone, and so in time rounds off the edges. This action is well marked in the chalk downs; in fact, in all countries where soft limestone forms the superficial stratum; but in those places, such as Wales, where the hard palæozoic rocks predominate, we get the ravine formations, so graphically described by "E. L. G.," because all the rain collects in surface streams, not being able to permeate the strata. The other cause to which I have alluded acts universally in this and higher latitudes, and rounds off the edges, more or less, of both hard and soft rocks. I mean the action of alternate freezing and thawing. It seems to me that these two actions are capable, either separately or combined, of explaining the phenomena in question, without calling in the aid of comets, or any other extraneous agencies whatever.

P. SANTALINUS.

THE ATOMICITIES, VALENCIES, &c., OF MODERN CHEMISTRY.

[4109.]—IT is amusing, were it not to some extent pitiful, to observe the page upon page of conflict and disquisition on the varied aspects of useless hypothesis; but it is encouraging that Mr. Bottone "is beginning to doubt the existence of valency;" and G. E. Davis and "many other chemists have for some time past denied it *in toto*."

Quite on a par with this is the intensely hypothetic character of molecules, as apart from atoms. If I understand rightly, Wurtz and some others regard the triatomic N or P as forming a molecule PCl_3, which combines with another molecule, Cl_2. "But," says G. E. Davis, "this harmonious reasoning is destroyed when we unite PCl_3 with one-half molecule of O, or replace the 2 Cl with one atom of O, or one-half molecule of oxygen. Surely there is no molecular force where there is no (whole) molecule. . . . I do not believe in molecular combination." But, in reply to "Eclecticus," he is obliged to resort to this hypothetic bewilderment, and the voltaic circuit consists of an interchange, not of atoms, but of molecules. "'Eclecticus' is quite right about the relative weights of platinum, &c., deposited, with reference to one H in the circuit, or atomically; but for every diatomic Pt there are two H liberated molecularly." Be it so; but, like all shifts and dodges, this is incomplete. Truth is simple, and cannot easily be circumvented; and the greatest point with "Eclecticus" was that one atom of Pt, Cu, or K replaced one H in the type ammonia, &c.

I have long wondered at the idea of molecules, and half considered them as useless or unmeaning; I shall henceforth, or until I see some evidence of their existence, consider them as mischievous and confusing.

Why is not an equivalent of cyanogen, of ethyl, or of ammonium, as essentially atomic as any metallic or other element? They all evince chemical functions perfectly identical, and replace each other, atom for atom. "But," says an objector, "one is an element, the other is a compound." Granted; but what is an element beyond the expression of human ignorance? Berzelius thought his vanadium was an element; we now know it is a compound. All unnecessary assumption is weakness, and the great fact to lay hold of is, that elements (or radicals) combine with or replace elements, and the atomicities, the valencies, &c.—or, as I should put it, the ratio or type of combination—is mainly dependent on their difference of electro-characters.

By the same law, and in the same relative way, compounds unite with or replace compounds, whence result double oxides, double chlorides, and double sulphides. G. E. Davis says, "The chlorides of the heavy metals unite with the chlorides of the light metals." There have been many riddles propounded in the name of atomic weights, but none of these things will stand a fair and close investigation, not even the beautiful and very useful law of vapour densities. It would be easy to show that weight stands for nothing, where relative chemical force means everything. The alleged diatomic oxygen unites with alkaline metals in the ratio of 1 to 1, with some others 2 to 1, ascending to bismuth and gold 3 to 1, while with its upper or nearer congeners, acids are formed with 5 and 7 to 1. Where, then, are the definite valencies or atomicities, *per se*? and a closer examination will show tendencies to all the intermediate ratios of 1¼, 2½, 3½, &c.

These plain facts of old chemistry, with the ½ vol. O, are strictly paralleled with the 1 vol. monad chlorine, and the same law equally applies to the iodides, bromides, sulphides, &c. G. E. Davis takes up the challenge of "Eclecticus," and essays to prove that Pt replaces 2 H, and gold 3 atoms. We remark, first, that the proof aims at too much, because it is the diatomic Pt which ought to replace 2 H, as it undoubtedly does, being 2 atoms; whereas, if Mr. Davis be correct, this Pt must replace 4 atoms of H. This, therefore, leads to my second remark—viz., the attempted proof is utterly irrelevant and invalid, for by it we can prove either 2 or 4.

Modern chemistry is becoming exceedingly rich in facts of substitutional displacement, but all cases prove that these metals, whether diatomic or triatomic, only replace 1 H, as in the varied chloride of ammonium, H_3HNCl; chloride of auro-ammonium, H_3AuNCl; chloride of plat-ammonium, H_3PtNCl. How, then, does G. E. Davis prove the contrary? He says, referring to the old notation:—

$$\text{Trebly condensed molecule of water } \left\{\begin{matrix} H \\ H \\ H \end{matrix}\right\} O_3.$$

$$\text{Auric oxide } \{ Au''' \} O_3.$$

$$\text{Doubly condensed molecule of H chloride } \left\{\begin{matrix} H \\ H \end{matrix}\right\} Cl_2.$$

$$\text{Platinum bichloride } \{ Pt'' \} Cl_2.$$

Hoffman similarly notates 14 condensed molecules of water, &c.; but, in the name of common sense, what are these molecules but fictions of the imagination? And with such license, what may we not prove? We thus prove that platinum replaces 4 atoms of H; the modern Pt is notated thus, $PtCl_4$. Therefore—

$$\text{Quadruply condensed molecule of H chloride} \left\{\begin{matrix} H \\ H \\ H \\ H \end{matrix}\right\} Cl_4.$$

$$\text{Platinum tetrachloride } \{ Pt'' \} Cl_4.$$

Further remark is quite unnecessary.

ECLECTICUS.

A STUDENTS' COMPLAINT.

[4110.]—MAY I be permitted to pour out my complaints to your readers? perhaps some are similarly situated, and if so, united action may remedy the evil? Then, sir, I sent in my name for examination to the Local Committee of Science in the town wherein I reside. In due course I presented myself for examination, other students also being there. The time appointed for giving out papers came and went, and so on for half an hour. About twenty minutes to eight (instead of at seven) I commenced my paper. It was well within my grasp. I exulted, and scribbled away as hard as I could. One or two catch questions caused some trouble; time went by, and write as fast as I could, by ten o'clock I had answered six questions. I thought that I should get my three hours, but no, the gentlemen conducting the examination asked for my papers. We did not commence till late, I said. Time is not up. "I can't help that," was the answer, and I had to deliver up my paper. According to Government instructions, the gentlemen who attended during the first part of the examination, and who were not punctual, had been relieved by others who were punctual, and probably had other engagements requiring punctuality. Now, sir, I have to suffer for this. I had no time to look over my answers again, or to finish the required number. The examiner, of course, has nothing to do with this, and I fail, not because I can't answer the questions, but because inexorable fate compels me to scrawl on without regard for "method" or anything, and to do three hours' work in something like two and a half hours.

A DESPERATE CHARACTER.

DR. CARPENTER AND PERSPECTIVE.

[4111.]—IT is extremely disheartening to discuss any matter with "E. L. G." (let. 4044, p. 152); he is so very Laputan. I am only astonished that a man of his mathematical attainments should believe in what is called parallel perspective. I am quite sure there is, in strict truth, no such parallelism possible. Pictures are nothing to go by, because we all know they are conventionally arranged. Let me remind "E. L. G." that when we look at any object bigger than a mere spot, we must, to see it all, move the eyes, which is equivalent to altering the direction of the camera. Let us, instead of the exceeding high tower, take a long wall perfectly equal in height. Now we know that the very first axiom in perspective is that all objects diminish as the distance increases. We also know that a straight line can touch a circle but in one place. Let "E. L. G." station himself in front of this wall and he will see at once that the height diminishes even within the 45°, which he may, perhaps, include in his view. If the wall were infinitely prolonged, would it be the same height as far as visible? "Oh! but," "E. L. G." would say, "you must not move your eye or your camera." Then you will see, not a wall, but a small portion of a stone or brick. Therefore, the top of a high tower being farther from the eye than its base must, although really of the same breadth, appear to an uncorrecting eye narrower. Which was to be demonstrated. M. PARIS.

[4112.]—THE difficulty raised by "Bobo" (let. 4067) p. 175), and which has more than once, I believe, been raised even in your pages before, is more real and practical than "Bobo" probably imagines; for though artists have never to represent a tower ten miles high, or any earthly straight object with one part forty times as distant as another part, this is really required in representing some phenomena of scientific interest, as auroral beams. I know not whether these beams are usually perpendicular to the earth's surface, or so directed that all their feet prolonged downwards would meet in her centre; but this certainly *was* the case in the only two displays I have been lucky enough to witness of decided "merry lancers," or separate beams, or "streamers." Though the forms of the curves, or lower curtain edges, whence they seemed to ascend, were very different (after making all allowance for perspective), yet all the lances, it seemed obvious to me, would meet in the zenith, to which some, indeed, nearly extended, and must thus have been all vertical, while much longer than "Bobo's" ideal tower, their feet being certainly some scores of miles, and tops some hundreds from the ground. And this parallelism contradicted all paintings and diagrams I had seen, which (being assumed, as we habitually assume all pictures to be, on vertical planes) yet never represent the beams by paralleled lines, but either diverging upward or (much less commonly) converging upward. The latter would be right if we suppose the painter, for the sake of embracing more sky, to have assumed an overhanging plane of projection, in delineating the auroras I saw.

This has occasionally been done, even in representing (or at least photographing) some remarkable scenes, mountainous or even architectural. The most singular and instructive case is a stereogram, that I recommended to the notice of M. Paris in one of his perspective puzzles, that was published some years ago, of Salisbury spire, viewed from the ground, within, I think, less than 100ft. (or a quarter of its height) from its base. To view that stereogram intelligibly, you have to place it in a 6in. stereoscope, stand with your back to a window, and look up toward a point in the ceiling two yards inside the window, when the effect will be marvellous; the architecture towering up all solid, square, and plumb, though in the views regarded apart it is a confused, tumbling mass of distorted turrets and pinnacles, as if thrown in a heap, like toys out of a box; and not even, like the toys, each piece rectangularly or intelligibly formed in itself!

E. L. G.

[4113.]—IN perspective, I believe, the rule for limiting the amount of view represented in a picture is that the rays of light coming from the extreme objects on either side to the eye should form there an angle of 60°. This applies vertically as well as horizontally. By this rule, in order to sketch a tower of the supposed height, one must be at the distance of about seventeen or eighteen miles. According to "Bobo's" own showing, one must, at a distance of a quarter of a mile, look in two separate directions in order to see the whole of the tower, which, of course, makes it necessary to have at least two separate pictures to represent it. It is rather hard to expect to see shown in one drawing that which cannot be seen in one view. CERVUS.

FAITH, SIGHT, AND MYTHOLOGY.

[4114.]—WHEN I remarked (p. 146, let. 4011) that our valued "F.R.A.S.," instead of supporting his scoff at the "quasi-mythical Noachian Deluge" (p. 61) by any single bit of either his own science, or geology, or even what goes for geology in England nowadays—even a bit of Lyell or Scrope—had "only given us" a most notorious or sensational line or two from a writer so extremely ungeological and professedly unlearned in physical science as Bishop Colenso, "exactly copied with all its blunders," I did not think any one would suppose this to imply *verbal* copying. Of course any one who referred to the bishop's preface would see that "F.R.A.S." had not copied its words; and, as he tells us he has this week made his first acquaintance therewith, of course he had not *directly* learnt the matter therefrom. But nevertheless it had reached him from that source, and he had *unwittingly* reproduced nothing else than the bishop's hypothetical argument, point for point, and blunder for blunder, with all the Chinese exactness I have said! The explanation of course is, that though he had never seen the book, this particular bit of blundering (either its words or its matter) he could scarce avoid having seen, with all educated England; because there was no newspaper or periodical in England seven years ago that could let Colenso alone, and probably not a single notice of his book, long or short, which did not either quote or paraphrase this very sentence! The reproduction by "F.R.A.S.," therefore, is very natural, though he may as little know whence he got it as he knows what farm grew the corn of his this morning's breakfast roll.

But the astounding marvel of this matter, which will some day yet excite great attention, is this: that not merely your correspondent, not merely many another "F.R.A.S.," not merely all these newspaper critics, and the bishop's hundred answerers, for these ten years; but the bishop *himself*, in edition after edition, was, and remained, and remains, so very far from *once* caring to ascertain whether there were any such facts as the hypothetical ones that he meant to argue from,—so very far from this, as never even to have taken the small care to understand his own argument! never even once to have made it go on all fours, by so much as setting down on his paper the hypothetic facts necessary to have made it any argument at all! Just turn to the sentence, as quoted by "F.R.A.S." (p. 171, let. 4048, line 11), which is as the bishop, observe, has republished it about twelve times—and suppose every word verifiable (as probably it is), and *verified*—"Volcanic hills of vast extent, which must have been formed" (of what? say "adamantine" lava, as our correspondent, "Manus," forms those in India) ages before the Noachian deluge" (say, with "F.R.A.S.," 60,000 years ago), "and which are covered with light and loose substances, that must have been swept away by a flood, but do not exhibit the slightest sign of having ever been so disturbed." Marvellous! Probably some are "covered," too, with grass or bushes "that must have been swept away by a flood, but do not exhibit the slightest" disturbance!

You see, the episcopal wanderer into geology, and equally our astronomical one after him (who reproduced this precious feature with Chinese exactness (let. 3960, p. 117, par. 2), each of them is in too furious a hurry even once to see (the bishop once in ten years!) that to make any argument at all, he should have told us that the very *same* things which were older than Noah were undisturbed! or that the very stuff he says is undisturbed, the *same* stuff is older than Noah! This identity neither of them *once* implies! Says Colenso, "Hills which must *have been* formed ages before" Noah, and "*are* covered" (not *were* covered, observe) "with light and loose materials," &c. Says our "F.R.A.S." (p. 117), "Mr. Scrope and every one who has examined . . . *the volcanoes* . . . are agreed in referring them to a period . . . &c. . . . Pliocene." And then, "on the steep sides of these cones *lie* undisturbed, scoriæ," &c! The *hills* antediluvian, and the *coverings* on them undisturbed, ergo there has been no flood! Well, by the same rule, how could there be a bishop ten years ago in Natal, when the coat Dr. Colenso wears was not made?

"Oh, of course, he *meant* to write that the *covering* was completed those ages ago, as well as the hill; or else that a flood would have swept away hill as well as covering." Of course, we know he *meant* to write some such thing, every one means to write something and not nothing. But here is the point: though he *meant*, he *never wrote* it! Your authority for turning history and oracles upside down, putting out your eyes and "walking by faith," is a man so far from ascertaining whether facts or figments are his foundation, as not even to care (in ten whole years) once to write *what he means!*

Well, our "F.R.A.S." finding he has got himself into a job here, and not being able *this* week to furnish us with the pumice-stone evidences, that you may not be kept waiting quite in the dark, proceeds to favour us with a professed quotation of (or rather through) his new episcopal instructor, from Professor Owen, who is doubtless all that he says. But this italicised passage (p. 171) really strikes me as rather stale news either to a Christian or Unchristian "Young Men's Association." Why, supposing any one so *very* Christian as to have seen no book but the Bible, it would hardly have been news that a "*notion of the divergence of all existing air-breathing or drownable animal species from one Asiatic centre*" (and the present geography) was untenable; supposing so anile a "notion" to exist. Let us see (Gen. ix., 10, "And I, behold, I establish my covenant with you, and with your seed after you; and with every living creature that is with you, of the fowl, of the cattle, and of every beast of the earth with you, *from* all that go out of the ark, *to* every beast of the earth." That is not much like any such "notion." What *could* the "knowledge" be that the Christian young men needed a professor to tell them was "incompatible" with it? Were they ignorant whether Australia joined Asia? whether there were any ornithorhynchus or kangaroo? whether pumas and jaguars could get to South America through the northern ice?

Where did I complain that the Geological Society ignored anybody? or that any of them refused information civilly asked for? Only one was ever asked by me for any, and was very courteous, and gave information I shall produce in due time. Meanwhile, as it is "F.R.A.S." and not I, who gave your readers the pumice-stone statements, I cannot see what business any of us have writing for information except from or through *him*. Does he mean to retract them as mistakenly supposed to be known, or to show us *how* they are known? As for our "bettors," and the paper in which I offered not a *bet* but a subscription toward the expense of settling this matter of fact, it was not *Bell's Life*, as he conjectures, but the High-Church *Guardian*, wherein Colenso (then in England) and sundry opponents (all clerical, and all assuming his science absolutely faultless, only *unknowables* wrong!) and defenders (as the late Professor Daubeny, and Professor Ansted, F.G.S.) were writing all at once, and of what they wrote I can assure him the end is not yet.

E. L. G.

TERRESTRIAL GRAVITATION.

[4115.]—I THANK Mr. Proctor for his reply to my letter, but I am still of opinion that the proof given by Thomson and Tait, of the attraction of a sphere on an external point is independent of the integral calculus, even with his extended meaning of the calculus, and I think Mr. Proctor will at once admit it, as he states that he would consider "a simple proof of the problem, such a proof as is given of the corresponding problem, for the attraction exerted by a spherical shell on a particle within it." The proof I refer to is just such a one. Shortly, it is as follows:—A line being drawn from centre of attracting sphere (C) to attracted particle (P), a point (V) is taken in that line, so that C P : r : : r : C V; r being radius of sphere, it is shown that if any double cone of very small vertical angle be drawn, having vertex in V, the elementary spherical areas H H', included within the conical surface on opposite sides of sphere, exert an equal attractive force on P; the resultant consequently bisects the angle H P H', but the line P C also bisects this angle.

The expression for the attractive force of these two opposite elementary areas, H H', is found to be $2\rho\omega\frac{r^2}{CP^2}$, ω being the solid vertical angle of the cone. Consequently the total force of the whole spherical shell must be equal to $\frac{4\pi\rho r^2}{CP^2}$; 4π being the sum of all the solid angles that can be described about a given point. The numerator of this expression represents the whole mass of the spherical shell, and the denominator the square of the distance of the attracted point from the centre of the sphere.—*Q. E. D.*

Now, in order to understand the complete demonstration of the above, no further knowledge is wanted than elementary geometry and the rudiments of trigonometry. I should be happy to send a more detailed demonstration if any of your readers not acquainted with the calculus should like it.

F. N.

NEW DOUBLE STAR IN VIRGO.

[4116.]—THE following fine double star was found last night:—

VIRGINIS = P XII., 104, 12h. 23m. 23s., S. 12° 40′: 6½, 12 : 356¼° : 3″.—This interesting double is *p*, and nearly equidistant from two 6m. stars about 1° apart, lying *n* of δ Corvi. These bright stars (not shown on Proctor's maps) are 45 B and 48 B Corvi of Argelander. The position angle given above is the mean of two or three micrometrical measures, but as the telescope was moved only with the tangent screw, the result is perhaps but little better than a careful estimate. No attempt was made to measure the distance. The companion, however, was seen perfectly with the strongest possible illumination. Having seen this pair but once, I cannot speak very positively of its difficulty with a 6in. aperture, but judging from this occasion, though the companion is a delicate object, it could hardly be called a severe test. I may be mistaken, as the night was a very good one. This star is B. A.C. 4213. Among other pairs picked up and since found catalogued was OΣ256, the distance of which is given by Otto Struve as 0·5″.

I would call the attention of Mr. Knott and Mr. Bird particularly to this new pair, and also to the new double *np* γ Crateris mentioned in a letter forwarded a day or two ago (4024, p. 148). The pair also there given in Sextans, the place of which had not been carefully determined is Weisse X 242, 10h. 15m. 15s., S. 9° 7′.

Is there not some mistake in the magnitude of the companion to γ Crateris, given in Loomis's "Practical Astronomy" as 14? It would seem to be nearer 10 or 10½ now, and is a very easy object.

Chicago, April 12. S. W. BURNHAM.

NEW DOUBLE STAR IN HYDRA.

[4117.]—THE following double star, found last night, is not in any of the catalogues of double stars that I have:—

HYDRÆ = L. 17586, 8h. 47m. 55s., S. 8° 16′: 7½, 9½: 170°: 1·5″—about three-fourths of a degree *s.* of 17 Hydræ (Σ1347), and easily found. The magnitude of the primary is given from Lalande. As I have seen this pair but once, and then with a bright moon, the estimates of position and distance, and particularly the magnitude of the companion, may need revision.

Chicago, April 20. S. W. BURNHAM.

VIEWING THE SUN.

[4118.]—MR. BERTHON has found his ingenious plan very successful, but does not the single concave lens introduce a little colour—also a little spherical aberration for high power? Has Mr. Berthon tried this plan against the Hodgson (or Herschel) plane? With a concave lens silvered there must be a half focus somewhere not far from the plane; would not a convex of long focus be better still?

T. H. BUFFHAM.

ANTS, &c.

[4119.]—IN the *Illustrated London News* for November 30th, 1861, there is a notice to the effect that, according to the statement of a gentleman in Texas, "An ant there forms a hole in the ground, and raises the earth around it; outside it lays the earth smooth, and destroying all the weeds around, but a species of grass, the seeds of which, when ripe, it gathers and hoards." How much truth there is in this tale I cannot say; but I have seen a statement to the effect that an ant (*Atta providens*) at Poonah, has been observed by Colonel Sykes to make store of the seeds of a kind of millet. But I believe that all the British ants are animal feeders, excepting their love for sweet things, in search for which they may attack fruit. The use made of their carnivorous propensities by the anatomist is well known. I was very much amused some time since in watching several ants conveying a caterpillar, the size of which must have required great comparative strength on the part of its diminutive captors. Some years ago (I have no dates) a small red ant made its appearance; it chiefly infested a warm room used for drying purposes, though it was also found in other warm places on the premises; it was evidently a foreigner, for it could not stand the cold, and there was every probability of its introduction with some bags of sugar. Before this the blackbeetle and black cockroach had been far too plentiful about the place, but these remarkably decreased in numbers; whether this was really the result of the introduction of the ants I will not pretend to say; but I actually caught them in the act of feeding on a blackbeetle, it was lying on its back not quite dead, and covered with the little red ant; a little brown cockroach, about 1in. long, also a foreigner, was in high favour with it; and empty skins were to be seen in plenty. It was interesting to see these little insects following each other in regular paths, in different directions, apparently with some definite object in view, but which I could never discover. They were very fond of yelk of egg. We caught great numbers by placing a basin of water in their way; they would crawl over the edge of the basin, and when once they got into the water they had no power to get out again. It has been said that ants will not pass over chalk; I took the opportunity of testing this by drawing a circle of chalk around them, but their escape was evidently no difficulty to them. From when these ants first made their appearance their numbers appeared to increase until we were swarmed with them. Though I have kept no dates I can say with safety that they were plentiful in the warm room for three years at least, almost certainly more. I never observed any with wings; if the sexes are invariably winged in the ants, as I have understood, how were the numbers kept up for such a length of time? I think I must have noticed them if any winged ones had made their appearance. The conditions of existence were evidently unfavourable, and their extinction progressed as stated by Darwin; the species first becomes scarcer and scarcer until it is ultimately lost; not one has been seen for some time now, and the small brown cockroach has disappeared with it. The *Blatta orientalis* is found in the basin of water in which we used formerly to catch the ant, along with a fresh arrival, a large brown cockroach about 2in. long.

J. C.

BRIDGE CONNECTING ENGLAND AND FRANCE.

[4120.]—I HAVE read with interest "S. D.'s" letter (3879, p. 62), on the proposed bridge connecting England and France. Although I cannot pronounce a decided opinion before further experiments are made on the many valuable suggestions proposed by him, I may state at once that I was so much interested with the novelty and importance of the plan given for building the bottom towers that I immediately set about testing the veracity of the principle.

The shroud employed by me was simply a straight tube 9ft. long, 1ft. 2in. in diameter, closed at the top end and open at the bottom. The open end was sunk down 4ft. 7in. through sand and gravel by means of weights applied at the top, when the pump and vacuum gauge were attached, the depth of water being 1ft. 3in. When the pump was applied it was a few minutes before any indication of a vacuum could be observed, but the moment the gauge indicated the fact of a vacuum being formed, each stroke of the pump speedily increased it up to 7lb. per sq. in., when a further sinking of the tube took place, the vacuum at the same time decreasing 1lb. per in., but by continuing the pump it soon rose to 9lb. and, after standing for upwards of six hours, it still indicated 8½lb.

If Mr. Douglas, or any reader of the ENGLISH MECHANIC, can explain why the pump required to be kept in motion for at least three minutes before any indication of a vacuum could be perceived, it would oblige me, as otherwise I am inclined to think that his plan of building the bottom towers, &c., will be found practical.

A FRIEND OF PROGRESS.

WATERCRESS.

[4121.]—I SEND you the following paragraph, taken from a local paper. I think it may not be uninteresting to some of your readers:—"*Caution to Eaters of Watercress.*—A correspondent of a Bristol contemporary writes:—'On Saturday last a man passed my house crying fine fresh watercresses. One of my boys ran after him and bought a pennyworth. Fortunately, before being placed on the table, my attention was called to them, and I found that three-fourths of the lot were composed of water cowbane (*Cicuta virosa*), one of the most virulent of English vegetable poisons.'"

V.

IMPROVED SCALE FOR THE LENGTHS OF PIANO STRINGS.

[4122.]—SOME years ago a pianoforte-maker of my acquaintance, who had then not been established many years, whose business was then less extensive than it has since grown, and who, although accustomed to copy, almost slavishly, the productions of Messrs. Collard, was nevertheless much too intelligent not to perceive the imperfections of all the scales then in use, said he would willingly give me a £5 note if I would design for him a really good scale which, while being safe, inasmuch as that it should cause but little or no danger of broken strings, should considerably improve the power and quality of his trebles. Probably, although things are somewhat better now, the tenor and bass have also been so greatly improved in power since then that modern trebles are yet relatively as weak as the trebles of ten years ago were to their contemporary basses, consequently the need of improvements in the trebles is little, if any, less now than then, so, without any intention of competing for the above prize I—now my experiences having become considerably more varied and extended since that time—proceed to assist in supplying what I have good cause to believe yet to be a practical want.

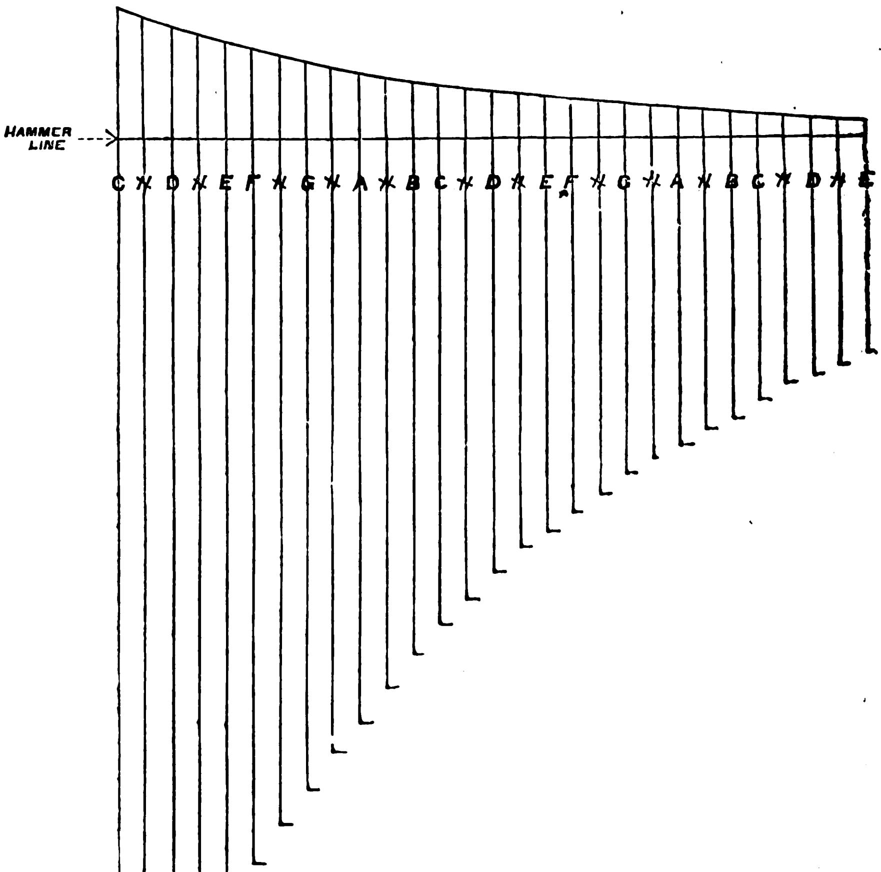
The subjoined diagram represents the full lengths of the strings for two octaves and four semitones only. For saving room the centres of each of the notes are drawn less than half the distance from the note next above or below it that they ordinarily occupy, it being usual, when all the notes are equally spaced at the hammer line, which is far preferable when practicable, to make the distances from the centres of each of the notes equal to that from the centres of the keys to each other.

Probably most practical pianoforte makers will consider this scale objectionably long, and until I had experience of the enormous tenacity of the steel music wire, made by Messrs. Smith and Houghton (notwithstanding all that rashness which is the too common characteristic of amateur designs), I really should have "funked" the consequences of subjecting strings to so severe a strain as these lengths necessitate; but after the experiments of Mr. Chew, I consider this scale quite a safe one, provided proper care be taken of the instrument, and its strings never suffered to become rusty, which evil thing is rather apt to make the writer ditto.

Mr. Chew, who has unlimited faith in his extraordinarily long middle C, once said to me "the power of a piano is simply a question of the amount of tension to which its strings are subjected." Now, without admitting this assertion to its full extent, for, practically, the power of that instrument is also greatly dependent on the rigidity of its soundboard, the force with which its strings are struck, and the character of the material with which its hammers are covered;—probably, next to the judicious construction of its soundboard, the suitable covering of its hammers, the form of their striking surfaces, the distance from the bridge of their places of impact, their weight, and the velocity with which they are impelled;—there is nothing which so greatly influences the power and timbre of its sounds as the lengths and thicknesses of the strings employed to cause it to produce sounds of any given pitch.

As a rule, the longer and thicker, within reasonable limits, the strings of a piano are, the more powerful and the clearer the sounds it produces—at least, in the treble, and, probably, the proportions of no portion of the instrument have undergone greater variation than its strings. In the earliest example of a square piano I ever saw, made in England about 1768 or 1770, by Zumpé, the middle C strings were only 18in. long, of No. 7 iron wire. Instead of half a yard, Mr. Chew, who has probably carried out the improvement of increasing the length of piano strings further than any of his predecessors, makes his middle C just double that length; in other words, a yard long, and he assured me that after more than two years the No. 21 wire, with which that note was strung, had become but little stretched, and its pitch not much lowered, which is not surprising, when we consider that a wire, after being stretched pretty nearly as much as it can bear without breaking, can hardly be expected to become stretched much further; and I think when the pitch of the F strings—ordinarily 3ft. long—is raised to C, the fifth above F, this operation, although somewhat within the limit of the breaking strain, and, therefore, quite a possible truth, may fairly be termed "a stretcher."

From 18in. of No. 7 to 36in. of No. 21 wire for the same note, or, perhaps, for a sound fully a semitone, if not a whole tone higher (for our concert pitch has risen considerably), is a long stretch, and I opine it will be some time before we generally agree to stretch it further. Increase of thickness has, however, already been carried out to a much larger extent. On middle C I have tried strings whose sizes varied from No. 16 to No. 32, but found little benefit. When the size of the wire was increased beyond No. 26, so long as their vibrations were caused by the blows of hammers, and not by the action of a fiddle-bow, in which case it seemed hardly possible to use strings too thick. I also tried No. 24 on C, 3¼in. long, and the tone was simply abominable. No. 20, the same length of wire, produced a tolerable sound, and No. 18 one of yet better quality. I preferred No. 17, which is as thick as it seems desirable to use for that note, but I found both the quality and power improved when it was made ½in. longer. Middle C 34in. long, with No. 23 wire, I found to be of very disagreeable quality, both short and harsh, perhaps because the instrument was not suitably bellied, also because the hammer stuck too near the bridge—viz., at one-sixth of the string's length.



Experience has convinced me that all so-called equal tension scales are very objectionable. If we make the treble strings of a piano long enough to produce sounds of great power and fine quality, those of the middle and bass parts of its compass must be too lengthy, and are necessarily too tight to vibrate long. The tone becomes "short," especially if their thickness be increased in anything like the proportions needful to induce breadth or fulness of quality. On the contrary, if we copy J. J. Hawkins or Robert Wornum, by employing wire of the same thickness throughout the compass, we are compelled to sacrifice both power and quality in the tenor and bass for the sake of the high treble which Mr. Wornum carried up to C, and strung with No. 15. This afforded a very good treble, but a very poor tenor and bass. Messrs. Broadwood, in their pamphlet, published for private circulation, A.D. 1861, describe a so-called equal tension scale, and I believe Mr. Chew prefers the same. No doubt equal tension scales are the very easiest of all to construct, because the lengths of the strings for each note may be obtained mechanically, without the trouble of calculation, by means of the diagram engraved in Messrs. Broadwood's pamphlet on grand pianofortes above referred to.

In the accompanying design and the specification of the lengths and thicknesses of the strings below C above the lines, I have endeavoured to make the best compensation between the theoretically best lengths and practical requirements which I felt able to do. I am far from expecting pianoforte-makers will for some time to come—unless the tenacity of steel music wire be generally increased until it equals Messrs. Smith and Houghton's hard-drawn wire—be willing to adopt my lengths for their notes. All pianoforte-makers have a wholesome terror of very long scales, because a broken string, which costs but little to replace in the factory, costs them, after the instrument is sold and delivered, not only the pecuniary sacrifice entailed by sending the tuner to the purchaser's residence, but also a loss of reputation, for most purchasers of pianos assume a broken string to be a proof of either bad workmanship or inferior design. Pianoforte-makers, like all other manufacturers who obtain their livelihood by supplying the requirements of the unenlightened public—"Those who live to please must please to live"—cannot afford to make what they believe to be the very best, because, as a rule, the very best don't sell best. Just as Solon, when asked "Are these the best laws you can make?" replied, "No! They are the best you unenlightened Athenians can bear," so pianoforte-makers make the best instruments John Bull, his wife and daughters, can bear, or are willing to purchase.

Should my very practical friends the pianoforte-makers fear to suffer from broken strings they can insure, at the cost of some power and quality, by taking the length of my D string for their top C. My C's will then all become B flats, and my A flats become F sharps. This change, however, being only one of lengths, and not a change of species, neither they nor their customers need fear being "bitten" by those domestic pests which are the namesakes of those notes. If this be done the C's will be reduced to 2in., 3¾in., 7¼in., 13¾in., 23⅞in., and 45½in., which lengths, with the excellent and tenacious wire in ordinary use, need not frighten the most timorous of pianoforte-makers, because the pitches of treble strings of those lengths might be raised about four semitones without breaking them, which seems an ample margin for ordinary contingencies. The scale thus obtained—if inferior to that shown in the diagram—would be a very great improvement on those in ordinary use, in which pitch C is about 12in., and the C's above it about 6in. and 3in. long. Besides affording more powerful sounds of clearer quality, and standing in tune much better than shorter strings do, I may remark this scale is but little longer than that of a modern drawing-room grand piano which I lately saw, constructed (I believe within two years) by Messrs. Collard. Now that firm, of all others, is noted for safe scales, so we may assume that any pianoforte-maker who adopts my suggestion to make his C strings the same lengths of those of the D's in the diagram and specification, will be in no danger of being "bitten" either by the blacksmith or by the musical, not insective, F sharps and B flats he may himself construct.

I did not carry the subjoined specification of the lengths of the strings below C above the lines of the treble staff below tenor C, because very few uncovered strings longer than about 4ft. are required for the tallest cottage pianos, or even the popular 6ft. grands. Sooth to say, the latter, when the action is below the strings, cannot well be made to admit strings unless they be oblique, exceeding 4ft. 8in. long, provided the bridge on the soundboard be not objectionably near its end. A 6ft. grand piano, with its hammers above its strings, but posited beneath its keys, may have strings about 7in. or 8in. longer, but a really satisfactory down-striking action it has not yet been my good fortune to become acquainted with; probably the very best of that evil family is the German action, introduced, I believe, by Mr. F. Greiner, and used in those excellent, if not very powerful, instruments the "compact" square pianos, manufactured by Messrs. Stodart some twenty years ago. The chief defect of these instruments was that the hammer (which was lifted by the key) did not rise quickly enough for rapid repetition; but it is obvious this might easily have been remedied, either by using lighter hammers, the key balance remaining unaltered, or, at least, but slightly altered (this would have enabled the same preponderance of the key to have lifted the lighter hammers more quickly without increasing the weight of the touch); or, if doing so could be allowed, by increasing the load of lead inserted in the keys, which would have caused them to lift the original (heavier) hammers quicker. Should any of my fellow-readers be tempted to construct a tall cabinet or long grand piano, they will find tolerably good lengths for uncovered strings below tenor C in the scale of the grand upright cottage piano figured in No. 285 of ENGLISH MECHANIC, but after all no very great accuracy in setting out the lengths of strings for notes below tenor C is necessary; a few inches makes no sensible difference in the power or timbre of their sounds. Along with the subjoined specification I have also stated the lengths of the C strings of Broadwood's long scale grand, and of Mr. Chew's, assuming he, like them, employs what is termed an equal tension scale. The remarkable differences of length are matters worth cogitation. I need hardly add the lengths of nearly all my strings are quite arbitrary, and simply a matter for judgment based on experience; at least, I know rule when equal tension is departed from.

Specification of the lengths of the strings in the improved scale, below C above the lines; also lengths of the C's of same, of Mr. Chew's, and of Broadwood's longest scale, copied from their pamphlet on grand pianos:—

All the notes of new scale from C above the lines to tenor C inclusive.				The C's only of new scale.	Ditto Chew's scale assuming equal tension.	Ditto Broadwood's long grand scale.
B	$8\frac{3}{4}$	$15\frac{7}{8}$	$27\frac{3}{4}$	... $2\frac{2}{10}$	... $2\frac{1}{4}$	... $1\frac{3}{32}$
A♯......	$9\frac{1}{4}$	$16\frac{5}{8}$	$29\frac{3}{8}$	... $4\frac{2}{10}$	... $4\frac{1}{2}$	... $3\frac{3}{16}$
A	$9\frac{3}{4}$	$17\frac{3}{8}$	$31\frac{1}{4}$	... $8\frac{8}{10}$	... 9	... $6\frac{5}{16}$
G♯......	$10\frac{1}{4}$	$18\frac{3}{16}$	$33\frac{1}{8}$	... 15	... 18	... $12\frac{5}{8}$
G	$10\frac{3}{4}$	19	$35\frac{1}{4}$	... 26	... 36	... $25\frac{1}{8}$
F♯......	$11\frac{5}{16}$	$19\frac{7}{8}$	$37\frac{1}{4}$	... 50	... 72	... $50\frac{3}{8}$
F	$11\frac{7}{8}$	$20\frac{3}{4}$	$39\frac{1}{4}$			
E	$12\frac{1}{2}$	$21\frac{5}{8}$	$41\frac{1}{4}$			
D♯......	$13\frac{1}{8}$	$22\frac{5}{8}$	$43\frac{3}{8}$			
D	$13\frac{3}{4}$	$23\frac{5}{8}$	$45\frac{1}{4}$			
C♯......	$14\frac{5}{16}$	$24\frac{3}{4}$	$47\frac{3}{4}$			
C	15	26	50			

N.B.—The wide differences in the lengths of the same notes in these scales seems worth consideration.

THE HARMONIOUS BLACKSMITH.

MICROSCOPICAL.

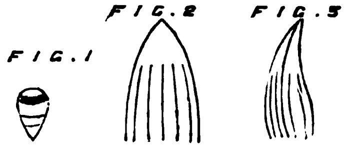
[4123.]—"H. P. H.," in his microscopical notes of last week, wishes for a cement which will keep in essential oils. I cannot help him in that, but I can make a suggestion which I am surprised has not occurred to him before; it is simply to withdraw the superfluous oil with blotting-paper, and substitute Canada balsam dissolved in benzole, when he will have a preparation that does not require cement. This plan was recommended by Prof. Ludwig Stieda in "Max Schultz's Archiv.," but he prefers creosote. For the benefit of those who use glycerine I will quote from the same author a recipe for a cement which I rather think is to be procured in England. It is as follows: Rub up some oxide of zinc with turpentine to a paste, then add to each drachm (gr. 60) one ounce of a solution of gum dammar in turpentine of the consistence of syrup. P. SANTALINUS.

CLIMAXODUS AND A NEW REPTILE TOOTH.

[4124.]—I HAVE recently had a considerable accession to my collection of Northumberland coal-measure fossils, and among those added are two of very great interest to palæontologists—viz., a minute tooth of *Climaxodus*, and a fine and peculiar tooth of a large new labyrinthodont or reptile. The smallest teeth of *Climaxodus*, previously described—and they have not the true *Climaxodi* form, but are somewhat *Petalodontoid* in appearance—are three-eighths of an inch in length, while that now before me is one-eighth of an inch long, and one-tenth of an inch broad; it is crossed by two well-defined ridges, has the distinct characteristics of a fully-developed tooth of *Climaxodus*, and is without doubt the smallest specimen of *Climaxodus* that has yet been described as belonging to our northern coal strata, and is probably the smallest *Climaxodus* tooth that has yet been discovered in any locality. The annexed sketch, Fig. 1, represents the tooth of twice the natural size, and its resemblance to the larger *Climaxodi*, will at once be apparent to those who are acquainted with this peculiar form of dental armature. Figs. 2 and 3 represent a front and side view of a reptile tooth, which is new to the Northumberland coal-measures, and which is, I believe, new to science. The length of the tooth is five-eighths of an inch, its width at the base is three-eighths of an inch, and its thickness at the base is one-fourth of an inch. Fig. 2 illustrates a front view of the tooth, which is curved forward, as represented by the side view, Fig. 3. The tooth near the apex is tolerably smooth, but from the base up two-thirds of the body of the tooth there are a number of widely separated delicate grooves, and between the grooves there are broad but not bold convex ridges. The tooth, as seen in its side aspect, is represented by Fig. 3; it is considerably curved, and from the apex to about two-thirds along the body of the tooth it is characterised by a peculiar form of cutting edge, the lanceolate character and form of which differ from the form and lanceolation of any other teeth of Northumberland coal-measure labyrinthodonts or reptiles, the teeth of which are known. *Anthracosaurus*, *Loxomma*, *Strepto-*

FIG. 2 FIG. 3

FIG. 1

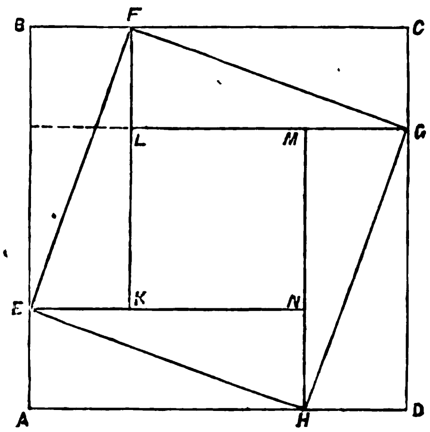


dontosaurus, and *Orthosaurus*, have lanceolate teeth, but none of them resemble that just described. *Pteroplax*, the teeth assigned to which are pre-eminently doubtful, are lanceolate, but unlike that figured; *Amphisaurus*, *Leptognathosaurus*, *Batrachiderpeton*, and *Labyrinthodontosaurus*, the teeth of which are circular; and *Macrosaurus*, *Mesosaurus*, *Megalocephalus*, and *Amphicalosaurus*, the teeth of which are unknown, are the only large labyrinthodonts and reptiles yet found in our Northumberland coal-measures. None of the labyrinthodonts or reptiles named have teeth which at all resemble that which has for the first time been described and figured in this communication.

T. P. BARKAS, F.G.S.

A NEW PROOF OF PYTHAGORAS' THEOREM.

[4125.]—THIS theorem (Euclid I., 47) is justly considered as the most important theorem in geometry. The following figure renders its truth so palpable that it may be worthy of a place in the ENGLISH MECHANIC:—



A B C D is a square, and equal lengths, A E, B F, C G, D H, being cut off from its sides, the figure is completed. Now, it is easily seen that E F G H and K L M N are squares; and that the eight triangles, A E H, E N H, B F E, F K E, C G F, G F L, D H G, H G M, are equal. Moreover, the figure A H M L F B A is made up of the two squares, A M and L B, and also of the square K M, and the four triangles forming the two rectangles, A N and K B. Again, the square E G is made up of the square K M, and the four triangles, K F E, L G F, M H G, N E H; therefore the squares A M and L B are, together, equal to the square E G; or, in the right-angled triangle A H E, the squares on A H and A E are, together, equal to the square on E H.—*Q. E. D.*

The proofs of several other less important propositions, some of which form part of Euclid II., could be easily deduced from the same figure.

C. J. RECORDON.

THE ECONOMY OF SMALL BIRDS.

[4126.]—WITH a slight hope to induce those individuals callous to everything but their own selfish amusements or paltry gains to forbear acting the part of a human blight upon the natural produce of the earth by destroying in the breeding season the eggs and capturing the young of those beautiful and most useful creatures wisely appointed to keep in check destructive vermin, I wish to say a few common-sense words of expostulation. Those birds which are more especially insectivorous would at first sight seem to have a more particular claim to human kindness and protection, though it will be found that some of those which live on a mixed diet, such as the finch tribes, consuming as they do large quantities of the seeds of noxious weeds, likewise contribute in their special province to the farmer's benefit, and also deserve justice and fair play, as such feed their young chiefly on grubs and caterpillars. Even the common sparrow, although generally pretty omnivorous, has been reckoned to destroy daily while feeding its young such a multitude of grubs as to constitute a heavy balance in its favour, being a circumstance which those who seek its destruction would do well to consider. The well-known devourers of the seeds of noxious weeds, birds of the goldfinch and linnet class, likewise eat greedily those blights of vegetation, the aphides or plant lice, which they search for with great assiduity. Our hedges are depopulated of these beautiful and useful little creatures, either to supply the shops or for the heartless amusement of children. Those that are of the unquestionably beneficial classes, being chiefly insectivorous, do not escape the snare or the gun directed by the thoughtless or the utterly heedless. Now, among those tribes of birds may be mentioned in particular for their utility, the swallow and the starling, and often both are wantonly and foolishly shot down from sheer ignorance or thoughtlessness. The latter may be said to be in particular a most valuable assistant to the agriculturist, owing to its peculiar habits. I fully concur in the forcibly expressed opinion of "Joe" that it should be protected from injury. This bird has an especial predilection for fly maggots and other larvæ. They may be seen in flocks during the hot months busily engaged among sheep and cattle, who—doubtless better appreciating their good offices than the ruthless bird murderer—suffer them to run over their backs and sides whilst laying down or grazing, whilst their little friends kindly relieve their bodies from the stinging gadfly, and the sheep from ticks and the horrible fly maggots, which, but for such assistance, would burrow deep festering holes in their skin. I have myself seen such holes eaten out of the wretched creature's hides as large as a walnut, full of maggots, which the farmer well knows to his cost are a source of trouble, detriment, and expense. Now, it is the especial province of all birds of the starling genus (and there are many varieties of them in other countries, all with the same habits) to frequent flocks and herds in order to devour their parasitical and other stinging pests. It follows plainly, therefore, that every one of them that is shot down is a pecuniary loss to the farmer, who must then needs find a substitute for this natural and wise intention of things by the free application to the animal's hide of tick and maggot ointments, many of which, if powerful and corrosive enough to destroy the vermin, would very likely, by absorption, do some mischief to the creature's health. Who that has seen the worried cattle on a hot summer's day racing frantically over the fields trying to escape the bloodsucking gadfly, and who has also, as I have, witnessed on other occasions the friendly offices of their little feathered attendants, but would feel indignant at their wanton and wicked, and foolish destruction? How the proboscis of the cattle fly with its obtuse spongy suctorial end obtains an entrance into the skin I cannot explain, but it certainly is gradually insinuated deep down into the skin, and the fly then fills itself slowly with blood like the mosquito, this operation occupying some two or three minutes or more, till gorged—a curious fact which some entomological contributor will perhaps kindly explain. It would be well if common sense and kindly feeling were sufficient guarantee against bird murder, but, as unhappily such is not the case, a supplementary "Land" to the "Sea-birds Protection Bill" is a thing very much to be desired by all who wish to see the equal balance and wise providential arrangement of things neither disturbed nor disorganised. ANIMALS' FRIEND.

DR. LIEBREICH AND TURNER.

[4127.]—HAS not Dr. Liebreich jumped to a conclusion rather too hastily, as regards Turner at least? Mr. W. Matthieu Williams has published a letter in a contemporary bearing upon this question of streakiness in Turner's pictures, and as I have noticed similar effects from watery eyes myself, I have made an extract for the purpose of obtaining opinions from some of "our" contributors. Let them try to look at a landscape under the conditions mentioned, and I am much mistaken or they will see it as Turner painted it. Mr. Williams says:—

"On p. 67 of 'Through Norway with a Knapsack,' published in 1859, speaking of some of the peculiar midnight sunset effects of the North, I said that 'Turner, like an eagle, has dared to face the sun in his full glare, and to place him in the middle of his pictures, showing us how we see a landscape with sun-dazzled eyes, when everything is melted into a luminous chaos, and all the details blotted out with misty brightness.'

In all these peculiar pictures that I have seen the sun is thus placed in the middle of the picture, and just sufficiently above the horizon (from about 10° to 20°, or at most 25°) to pour his rays about perpendicularly to the curvature of the eyeball, when the face is in position to contemplate a landscape. I have frequently repeated the experiment of contemplating a landscape under such circumstances, and on every occasion of submitting to such torture have seen all the effects of even the most extravagant of Turner's later pictures, which are so well described by Dr. Liebreich. I have seen the 'vertical streakiness, which is caused by every illuminated point having been changed into a vertical line,' with an 'elongation, generally speaking, in exact proportion to the brightness of the light,' and that 'there proceeds from the sun, in the centre of the picture, a vertical yellow streak.' These appearances may arise from an affection of the crystalline lens of my eye similar to that attributed by Dr. Liebreich to Turner, or it may be due to something else much simpler, and which is more or less common to all human eyes. If the simpler explanation based upon normal conditions covers the facts, it certainly must be the more acceptable.

My explanation of the vertical streaks is this: When we thus look full-faced at the sun, the dazzle produces slight inflammation or irritation, and a flow of tears. The liquid accumulates, and rests upon the lower eyelid, forming a little pool, the surface of which has a considerable vertical curvature—*i.e.*, the lower part of the retained tear curves upwards from the surface of its base at the root of the lower eyelashes to its summit contact with the conjunctiva. Thus in a vertical direction it must act as a lens of very short focus, it must refract and converge the rays of light in a vertical plane, and thus produce a vertical magnifying effect, the definition of which will, of course, be very confused and obscure, on account of the irregular curvature, and the fact that the eye is focussed to the distant objects. This want of directive focussing will limit the distortion to the bright objects whose vertically magnified images will be forced upon the attention.

To test this explanation, let any one select a bright afternoon, and at about 6 p.m. or a little later, at this season, gaze sunward upon any landscape free from London smoke or other medium of solar obscuration. At first, if his eyes are not very sensitive, he will see a circular sun, but presently, as the tears accumulate, the vertical elongation of the sun and general 'vertical streakiness' will appear. When I tried the experiment last week the sun appeared like a comet with a brilliant vertical conical tail, the point of which rested on the horizon. But I was then slightly troubled with what is called 'a cold in the head,' and my eyes watered very vigorously, and thus the conditions for producing fine Turneresque effects were highly favourable. On carefully drying my eyes these effects were, for a moment, considerably diminished.

I have adopted another method of testing this explanation. Having caused the eyes to become somewhat suffused, I bring the upper and lower eyelids so near together that the liquid shall occupy a sensible depth—*i.e.*, from the conjunctiva to the base of both upper and lower eyelashes, and by compression be bulged or curved outwards, in the vertical direction. On looking through this tear-filled chink at a gaslight the vertical elongation is remarkably displayed, and it extends upwards or downwards or both, according to the position of the liquid. When looking at the sun and landscape with the eyes fully opened (which is very painful), the elongation is chiefly downwards, and obviously connected with the tear on the lower eyelid; but if the eyelids be nearly closed to diminish the intensity of the light, an upward elongation is also commonly visible."

The other peculiarities of Turner are necessarily contingent on this "wateriness" of eye, and are, no doubt, faithful reproductions of what appeared to him. If this is the true explanation, however, it will spoil a good anecdote I remember reading of the painter, to the effect that Turner having sent in a quiet-toned piece to the Academy was very much annoyed at finding it hung in close proximity to pictures containing masses of brilliant colour, and actually put in it a large spot of vermilion, which he afterwards turned into the morning sun just above the horizon, and altered the whole character of the piece. P. B. M.

SILVERING THE SURFACES OF FIELD LENSES.

[4128.]—I AM receiving applications from some of your correspondents to silver them the convex surfaces of the field lenses of their Huyghenian eyepieces. Will you kindly allow me through your columns to explain to them that these lenses cannot be silvered while in the brass cells, and that, generally speaking, the cells will have to be sacrificed in any attempt to take them out, as there would not be brass enough left to bevel them in again? A cell requires to be made for the purpose when the lens has to be silvered, and must contain a counter cell, so that the lens can be removed and replaced at pleasure. It is rather a nice matter to silver a surface lens with a film of a particular thickness, and this thickness should vary according to the aperture and focal length of the telescope it is required for. This is just one of those experimental jobs that should be done by the observer himself, as if a fair charge were made for the time consumed in doing such a matter by an optician it would certainly cause dissatisfaction.

Those of your correspondents who are fond of experimenting will find the following simple contrivance answer their purpose tolerably. Take a film of thin microscopic glass, or fine mica, and silver it on both sides thinly (this is easier than silvering it on one, and it answers better), leave it unpolished, and mount it at an angle of 45° in the eye-tube in front of the field lens, or second-glass. Make a hole of 1in. diameter at the side of the tube for the reflected heat to pass out through. This contrivance could be made for one shilling. JOHN BROWNING.

PIANOFORTE CONSTRUCTION.

[4129.]—"THE HARMONIOUS BLACKSMITH" (letter 3934, p. 95) is trying to show the possibility of imparting to the hammer in the treble of a piano a greater power than that which we usually can get. Now, he must either fail to show it, or he has actually discovered perpetual motion. But I differ from him. I take half a dozen wheels or levers and arrange them so that when the first wheel or lever moves five-sixteenths of an inch, the last wheel or lever must move two inches. Now that lever or wheel which moves five-sixteenths of an inch is the key, and that which moves two inches at the same time is the hammer in a piano. Supposing we take two such machines, one for the treble and one for the bass of a piano, where then is the possibility to gain more power in one than in the other machine? Certainly we can arrange one machine so that the last lever or wheel moves quicker in the beginning of its path, then it requires more power; and the other slower, which requires less power in the beginning of its path, or *vice versâ*—more power we cannot get. And besides this we cannot make this difference, for it would be a touch on one side of the piano, and a "poke" on the other. This will be quite clear to any one: if we suppose the lever for the bass end moves quicker in the beginning, then it requires more power; and the lever for the treble moves slower in the beginning, then it requires less power; but then the touch in the bass must be light at the end, while that in the treble must be heavy—in fact, we should have to poke the key right down before the lever or hammer would reach the strings, because it would move but little in the beginning. "The Harmonious Blacksmith" has put the damper below the centre of the hammer, some four or five inches below the striking-point on the strings; that will certainly not do; we want the dampers just where the hammer strikes the strings, or as near as possible; if we put them much lower they will create a sound something like *mean*, and if the hammer rebounds once more, which it certainly will before it comes to rest, it will sound *mee-an-an*. Then the "Harmonious Blacksmith" will, to avoid this, require a damper-rail, lifters, socket, and all the rest of it, like other mortal pianoforte makers.

J. H. SCHUCHT.

COMPRESSIBILITY OF THE ATMOSPHERE.

[4130.]—WITHOUT laying claim to the title of a learned correspondent, I don't think that it is established as a fact that if a truly bored gun be aimed and fired horizontally that the ball will rise, as the difference in the density at upper and under side would be too minute to influence it. The theory of the top spinning is decidedly wrong, as a top spins because, when motion is communicated to any body, such body will endeavour to travel in a straight line through the angle of least resistance, but being restrained from doing so by the circular form it is constantly endeavouring to fly off at a tangent; and as long as the velocity is maintained sufficiently the body has an equal tendency to fly away in all directions, and the effect of gravitation is nullified. A top would undoubtedly simply spin much longer in vacuo. Has J. M. Taylor witnessed the following experiment? Let A represent a piece of cord with one end attached to ceiling, on the other a loop; B, a heavy wheel and axle caused to spin quickly, and then one axis placed in loop, the wheel will continue in same position as in drawing, and the cord remain plumb until the velocity falls.

Liverpool. A.

[4131.]—WITH reference to the top part of letter 4040, page 151, it has been found that a top will spin much longer in a vacuum, the friction of the air not retarding its rotation. The top is supported by the rectilinear tendency of its particles being sufficient to overcome the force of gravity. Each particle endeavours to move in a straight line in one plane; the attraction of cohesion converts the motion into a circular one. The plane of rotation remains as in the gyroscope parallel to itself until other forces preponderate. The steadiness of the earth's axis is insured in the same manner. M. PARIS.

[4132.]—THE fact of the lower strata of air being more dense than the higher would not account for a bullet fired apparently horizontally being deflected upwards, as it is if it be reflected from a surface of water, for the difference of density of the air just above and just below the bullet is almost infinitely small, not as that of water is to that of air—about 800 to 1. It is impossible that a bullet really fired horizontally should rise, but the fact is so frequently asserted that I presume it must often appear to do, and that this cannot be accounted for by slight irregularities of the gun, as those would cause deviations in various directions with different guns, not more frequently upwards than otherwise. I suspect the reason of the apparent deflection being, as is commonly stated, most frequently upwards, is that the gun is unconsciously raised slightly, at the instant after the trigger is pulled, by the shooter's left hand, which has to hold the gun against the pull on the trigger by his right, for it is scarcely possible to hold anything steady when the balance of resistance to force is suddenly changed. If the gun were fixed in a frame, it would be thrown upwards at the same instant when the pull on the trigger ceased, unless, indeed, the frame were perfectly rigid and inelastic, as it may, practically speaking, be made.

Mr. Taylor is mistaken in supposing that a top would not spin in a vacuum; it would spin longer if its motion were unresisted by air, and it would very soon cease spinning in water. The difference in the density of the air at the surface of the earth and very near it is quite inappreciable, and can produce no such effect as he suggests. PHILO.

RADIUS OF SURFACE OF OBJECT-GLASS.

[4133.]—MR. CASH (letter 4069, page 176) will see, from what I have before said on the subject, that if the qualities of his glass are what he has stated he cannot expect with his radii to get a perfect object-glass. He will also easily understand that it is very difficult to make out wherein he may have failed in workmanship simply from a description of the appearances he may observe in his telescope. The sign of want of spherical correction is a sort of fog or atmosphere when looking at the circle as described by Mr. Cash, and the want of correction for colour causes it to show up on pushing in or drawing out the eye-tube, but if the object-glass is placed square on the tube those appearances would surround the image and not spurt out from it. A want of homogeneity in the glass causes wings, but not, I should say, such as described by Mr. Cash, and I should think it probable that in some way or other he has pinched one or other of the lenses in the cell, which he ought to be very careful not to do; in fact, with a large object-glass, it is almost necessary to give the lenses a spring bearing to allow of the requisite amount of tightness in all temperatures without any pinching. I should strongly advise Mr. Cash not to complicate the thing by adjusting screws, but to place the lenses in a carefully turned cell, and screw them down by means of a ring in the ordinary way, with just sufficient tightness to prevent their falling away from their bearing on the fore part of the cell and no more, and possibly three pieces of millboard placed inside the brass work of the cell might prevent any shifting across and keep all tight in that direction. Before finally screwing the lenses down he should turn them round on each other until he gets the best effect, as generally it makes considerable difference which portion of their edges are in contact.

As to Mr. Cash's definition, I think the less he says about it the better, and he really needn't trouble himself, for if he succeeds in making a decent telescope it will not very much matter whether he knows exactly what a lens is or not. HENRY T. VIVIAN.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

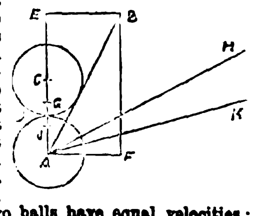
HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[8615.]—**Whitworth Lathe.**—To J. K. ENGLAND.—I have drawn out a table of factors for you, which you can have with the letter I wrote to accompany it to the Editor of the ENGLISH MECHANIC; but it is too long to expect him to print it, so you had better write to me at Pitcairn's Library, King's College-road, N.W., and I will forward it to you.—J. K. P.

[10640.]—**A Reason Wanted.**—Mr. Jerard Smith (p. 152) will find, I think, that it is rather inflation of the lungs than expiration to which the advantage is due in lifting heavy weights. This, at any rate, is Sir David Brewster's view of the matter. Mr. Smith is not alone in giving a reason for this fact, which he has often verified, and at the same time heading his information with "A Reason Wanted." Sir David Brewster gives the same reason—viz., the bracing of the cords, &c., about the joints or fulcrums round which they act, and then calls the experiment "inexplicable." Thus, important as his explanation is, he was not fully satisfied with it. He looked for something more, but missed it in this way. The four men lifting and the fifth man lifted, could not, he says, be lighter for the air they have inhaled, but the heavier. Very true, but there is an increase of the bulk of each body in greater proportion than that of the weight. There is a displacement of the fluid atmosphere by each expanded body without proportionate increase of gravitation; for the air inhaled is heated and expanded. The atmosphere, therefore, becomes to this extent a lifting power, as in the case of the fire balloon. The simplest illustration of this lifting force is afforded by the swimmer. In floating he rises by inflating his lungs with air, and is more deeply immersed when he has expelled it again. He is, of course, the heavier for the air he inhales, and according to the quasi-philosopher's reasoning should rather sink than rise. He does not, because the air he inhales is lighter than its equivalent bulk of water which it has displaced; and so the air which the lifter inhales is, by expansion by heat, lighter than the equal bulk of atmospheric fluid which it has displaced. That stout men float so much more easily than others is due, no doubt, in part to the greater heat developed within. This is not put forward as the principal, but as an additional, reason for the fact so often verified.—J. M. TAYLOR, Seer Green Vicarage.

[10664.]—**Angle of Reflection and Incidence.**—I feel greatly obliged to "F. N." (p. 152) for the trouble he has taken to supply me with the details of the interesting experiments of M. Athanase Dupré. I am sorry to confess I know less of mechanics than I do of billiards, but have frequently endeavoured to account for the effects of side and strength. The following is the effect of strength and my view of the "rationale;" and if I err, and I fear I do, I shall feel greatly indebted to "F. N." if he will point out my error and set me right :—Place the red ball on the spot, and place the white in a position 3ft. 5in. from the top cushion, and 16in. from the side cushion, measuring from the face of the cushions; play at the red a half ball with gentle strength, so that the red returns from the top cushion to the pyramid spot, the white ball will run into the top corner pocket. Place the red again on the spot and place the white ball in a position 4ft. 5in. from the top cushion and 19¼in. from the side cushion, measuring, as before, from the face of the cushions; again play a half ball but with a quick stroke with great strength, and the white will again run into the pocket. The difference in the angles formed by the path of the white ball in these two strokes is about 18°, which I account for as follows :—Let A, travelling in the direction A B, strike C at rest; at the point D decompose the velocity A B into its components A E and A F, draw the parallelogram A E B F, the velocity A F is not affected by contact, but the velocity A E is first reduced to one half, and the ball C receives a velocity equal to E C, at this moment the two balls have equal velocities; the elasticity of the balls now comes into play, and with the lighter blow the velocity A C is further reduced to A G, and the ball C receives a corresponding increase of velocity, and the ball A takes the direction A H, being the resultant of the forces G A and A F. Now with the harder blow the velocity A C is reduced to A J, and the ball "A" takes the direction A K, being the resultant of the forces A J and A F.—BILLIARDIST.



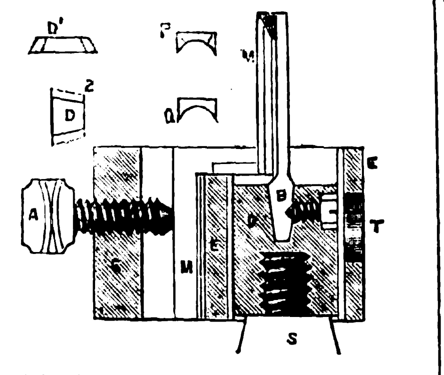
[10702.]—**Terrestrial Gravitation.**—"T. A." asks for proof that the attraction of a sphere is equal to what it would be if all its particles were at its centre, but you could hardly spare space for what occupies four pages of Maclaurin's account of Sir Isaac Newton's discoveries (3rd edition, 1775, pp. 297 to 300) which, besides being too long for quotation, is not needed to show that the attraction of a spheroid to a body on its surface must be greatest at the points nearest to its centre, as those points must evidently be at a less mean distance than any others from all the other points of the spheroid, and therefore that bodies there situated must be more strongly drawn by the joint attraction of all the particles contained in the spheroid. I think Mr. Proctor would consider Maclaurin's so-called geometric demonstration to be one of integration disguised.—PHILO.

[10781.]—**Fastening Escape-Wheel in Lever Watch.**—The remarks by "A Yorkshire Pivot" (p. 152) fail to convince me that a soldering iron should form any portion of a watchmaker's tools, or that there was any necessity for the use of soft solder in the case of "S. H. L.'s" escape-wheel. If "Y. P." thinks it would be easier for an inexperienced workman to turn a collet on the escape-wheel arbor than on a plain arbor suitable for the purpose, why could it not be done without solder in the one case as it would be in the other? I fear his "simple method" would prove more embarrassing to the inquirer, and more injurious to the watch, than the right and proper method of going to work. It is a remarkable fact that watches suffer more at the hands of incompetent workmen than from wear and tear, though even for a hundred years. Again, our northern friend, in his first communication on the subject, says he uses a copper bit for soldering the job, yet in his second communication he informs us he would have done the job without solder. He also alleges three instances of the use of soft solder in the original manufacture of watches, verges, balance-staffs, and fusee caps. It is entirely incorrect that English verges are soft soldered in the collet, neither are balance staffs treated in that way. And with regard to fusee caps, they are certainly soft soldered in verge watches and in some lever watches, but in Geneva watches (entirely omitted by our correspondent) there is none whatever; therefore there is yet a large proportion of watches in which there is not a particle of soft solder in the original composition. "Y. P.," in concluding his remarks, half admits his weakness for solder, yet congratulates himself that after twenty years' experience he can give watch querists a "few practical wrinkles." Oh, these "few practical wrinkles"! How frequently are they brandished before the eyes of "our" readers, yet how seldom do their possessors make them available for the general good!—WEST CORNWALL.

[10954.]—**Circulation of the Blood.**—I may be wrong, and shall be very happy to be corrected if I have made an erroneous statement, but as the presence of carbonic acid is always attended, to a certain extent, by the absence of (uncombined) oxygen, may not we infer that death from respiration results from oxygen starvation alone? If M. Paris means the effect of carbonic acid, exclusive of the absence of oxygen, he may quote any number of gases, and death through respiration, would, therefore, be the result of so many causes.—C. W. H.

[11057.]—**Watchmaking.**—If the pallets, stones, and acting parts of wheel are polished, oil does more harm than good, but in the absence of good workmanship, oil is the best friend you can find. If I had been asked about oiling staff holes of a good English lever or pocket chronometer. I should have said no. I have long since done away with the practice, having experienced this in trials I have made with the class of watches mentioned. What I told "J. O." I practise myself, and also what I have stated here. I have been engaged on new work nearly twenty years, and I may say what I send to "our" MECHANIC in answer to queries is what I have experienced and know, and no more.—INDEPENDENT CHRONOMETER.

[11101.]—**Mortices in Hard Woods.**—I forward a section of the former, hoping "Leander" will be able to understand the whole arrangement. The affair for cutting the angular hole is not to revolve, but is to be bolted upon the headstock by its foot; this sketch is a section through the centre of chuck mortice E E E, chuck drill or bit C A being the set-screw for morticing-tool, and M M the morticing-tool, it being in section at D double dovetailed (see D 1 and D 2), that it may be

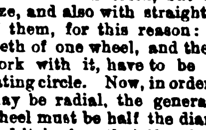


inserted in the chuck more readily, and held firmly. P is a section of the tool, or rather more front or end of the tool M, and Q a section of it through the line below M; the dotted line along M is the boring bit, which runs in close proximity to M, but still clearer of it. G is the lathe spindle, and the chuck for holding the bits screwed upon it; there is a hole at T for the purpose of tightening the set-screw to hold the bits. The tool M is nothing more nor less than a double buzz which the wheelwrights use, with this difference, the semicircular section in the step, and the mouth having two cutting angles instead of one, the said two being at right angles.—JACK OF ALL TRADES.

[11120.]—**A Question of Sight.**—The solar rays are almost parallel, and by ascribing too much divergency to them, I admit I may have looked at the sun too much as a point. Shadow, however, is the space surrounded by direct rays, but itself unreached by any one direct ray, whilst the direct rays reach the shadow's boundary all around, imparting to it its modified shape of the intercepting object. Intercepted rays, by repeated reflection, soften a shadow somewhat, as angularity distorts shape—hence "penumbra," a partial shadow. "E. L. G." seems "well up" in his subject, but when we speak of shadows extending three diameters farther in July than in January, we should state not only the hour of the day, but whether we mean shadows parallel to objects or else at what angle; for I certainly thought he meant the shadow of upright objects as cast on the earth's surface, which he may attribute to my stupidity. "E. L. G." is quite right as to the ratio between speed of sound and speed of light. My 170 × should be 170 × 5280 ×, to convert miles into feet, so that speed of sound through air is to speed of light through interstellar ether as 1 is to about 881,000, being 1,130ft. per second for sound, and 180,000 miles per second for light. As for Regnault's experiments at Paris, "E. L. G." says: "At different degrees of heat, though with the very same number of atoms in the same pipe, the speed differs." Why, it is impossible for equal number of uncompressed aërial atoms to occupy equal space at different temperatures. Fill a bladder with air, and increasing heat extends the amplitude of the atomic vibrations till the bladder bursts; but these atomic vibrations are not more those of nitrogen or oxygen than those of the ether uncaptured by chemistry, and which we may call "ultramicroscopic." But "E. L. G." says that with air varying in density as 5 to 1, and the distance of atoms as about 19 to 11, the velocity of sound was just the same at a given temperature. Now, air varies in density only by degree of temperature or mechanical compression; under compression atoms would be closer and temperature higher simultaneously. He says "heat or cold alters the rate, though the atoms be at one unaltered distance; but distance of atoms alters it not at a given temperature." I say, except under special mechanical pressure, varying temperature alters the distance between atoms as exhibited by expansion and condensation; so that the experiments may but show that effects of external temperature are counteracted by applying mechanical force, which alone can maintain equal atomic distance under different degrees of heat. I never said air was "a number of things kicking one another;" but I know if the pulsations of solar combustion were communicated by a needle from the sun to "E. L. G.'s" eye, the pulsations would reach him instantly, instead of occupying a second to pass over 180,000 miles. I continue to believe that rate of speed of sound shows, or is a key to, the vacuity or distance between atoms of air, and that the rate of speed of light and heat is a key to the distance between the atoms of the ultramicroscopic ether of interstellar and all space. In reply to "Saul Rymea," I say I quoted from Gutch's "Register" for 1859, that 11,090ft. was sound's speed through cast iron; it gives steel 17,000, water 4,900, and wood as varying from 4,636 to 17,000. If heat increases atomic velocity as it increases amplitude of swing in vibration, it may suffice to account for adding about 5 per cent. to a rise in temperature of 80° C. My object has not been to show rates of speed, but that rates of speed are a key to the distances between atoms, or rather the total vacuum length in the line of transit.—J. BARWICK.

[11123.]—**Lantern Pinions.**—Since I wrote my rejoinder on this subject to "Tubal-Kain," on p. 125, I have obtained a copy of "Camus on the Teeth of Wheels," published by J. Taylor, 59, High Holborn, 1806. The editor states that Camus in the original French does not give "the generation of the epicycloid curve, nor its application, so as to render it familiar to practical mechanics." (See p. vii., preface.) Afterwards (p. 5) in the body of the work, he says that "in pinions which have few leaves or spindles, as 5, 6, 7, 8, and even 9, the true radius ought always to be greater than the primitive radius. Now, I must confess, that on first reading this sentence I was a bit staggered; but when I came to examine it, I found that the signification of it is this—viz., that pinions of greater numbers than the above may have their true radius (which is what he calls the outside measure over all) reduced by filing away the tops of the teeth down to the end of the primitive radius, which is what we call the radius of the pitch circle; but that these small pinions must not be treated so on account of the very large angle each successive tooth passes over during the revolution of the pinion, which makes the teeth go out of contact too soon, unless they are left with long points. This filing away of the points of the teeth of a wheel or pinion only when driven, but not when it is the driver, is mentioned by Denison in his 1860 (fourth) edition of "Rudimentary Treatise on Clocks and Watches" (p. 267), and I adopted it in the dial work of my regulator clock with advantage. Now, looking a little further into "Camus," let us read "Advertisement," as it is somewhat oddly translated, on p. 70, second paragraph :—"As they cannot hope to form the teeth" quite true, in order to prevent shocks, "machinists may prevent this inconvenience by making the primitive diameter of the wheel a little larger than it ought to be in regard to that of the lantern or pinion." In the third paragraph (p. 71) he explains that though the motion obtained this way is somewhat smoother than that of badly-shaped teeth which are not so fiddled or cooked, yet the relative velocities of the wheel and pinion are rendered very uneven as every tooth passes, or in other words the uniformity of the velocity is destroyed. In the fourth paragraph he says that similarly when the pinion is to drive the wheel (and never to be driven), the primitive circle of the pinion may be enlarged to prevent shocks, but he at the same time shows that a lantern pinion is unsuitable for driving a wheel at all, and that in that case a leaved pinion must be used instead, so we may put the enlargement of the lantern pinion recommended by "Tubal-Kain" on one side as unpractical. I do not think "Camus" a suitable work for students to read, as his teaching is now behind the march of improvements in machinery, for he does not give a single illustration of a tooth with a hypocycloidal flank, which should be adopted in all cases where wheels of more than two different diameters have to gear with each other. Any single pair of wheels can be made to run together with radial flanks to their teeth, but no third wheel of another size, and also with straight flanks, will work with both of them, for this reason: the tops or points of the teeth of one wheel, and the flanks of that which is to work with it, have to be struck with the same generating circle. Now, in order that the flanks of the teeth may be radial, the generating circle used for either wheel must be half the diameter of the opposite one, and it is clear that if a third wheel of another size is introduced, those generating circles must be either greater or less than half of its diameter, and therefore unsuitable for making its flanks radial, and if much greater would make the teeth impossible. The whole affair is to be found properly explained in Willis's "Principles of Mechanism," of which, I am glad to say, there is a new edition out, and in Binns's "Second Course" of Orthographic Projection, which proposes a modification of Willis's scheme, though without departing from his principle of construction, and resulting in a superior proportion of tooth. I need hardly say that Willis's "Odontograph," or tooth drawer (not extractor), renders the setting out of wheel teeth a matter of the greatest simplicity, and any one can construct one for himself out of a piece of cardboard, from the directions given in Willis's work. There is, however, a mistake in the last column, fourth line of table of places of centres, opposite "No. of Teeth, 16," where 191 is printed for either 131, or more probably for 119, in the old edition, and a similar mistake in the same place in the new edition, but I think the figures are not the same in that. In conclusion, I will only say that when I made my regulator clock I did not use a depthing tool, but calculated all the diameters of the wheels, and set out the pivot holes with dividers from a scale of hundredths of an inch, and that the clock goes, which I am absolutely certain it would not if I had used enlarged pinions.—J. K. P.

[11168.]—**Wood Rods.**—Reduce the strip of hard wood nearly to the required size with an ordinary smoothing plane. And having a lathe with a hollow mandril screw on a chuck holding a crown saw of required diameter, the reduced strip on being passed through will come out as round as if turned. In the absence of a hollow mandril the strip may be placed in an ordinary lathe, and the crown saw (made in the form of a common screw nut, with projecting saw, to be made according to Fig., which represents a section, the saw to be filed out of the edge S S), held in hand and pushed along the revolving strip.—SUFFOLK AMATEUR.



[11196.]—**Drowning.**—Speaking from my own experience I would say that there is no truth in the supposition that drowning persons invariably rise to the surface three times, neither more nor less, before death. In one case I saw a drowning person rise four times before he finally disappeared, and on another only twice. An exhausted swimmer will sink and rise many times before nature finally gives out. The number of times a drowning person rises to the surface depends upon his muscular energy, and the tenacity with which he clings to life.—J. Hopkins.

[11223.]—**Stereotyping.**—If "Saul Rymea" or any other obliging correspondent will kindly give details, it will, I think, be welcomed by many. To avoid giving further trouble in this matter may I here ask a few questions? 1. May not the metal be poured over the cast instead of immersion? 2. Does the process of making the cast injure the type by filling it up or in any other manner? 3. What is the cheapest and best metal to use?—A Country Printer.

[11272.]—**Diastase (U.Q.).**—May be purified by repeated solution in alcohol and precipitation in water; but it cannot be obtained perfectly pure.—W. L. G.

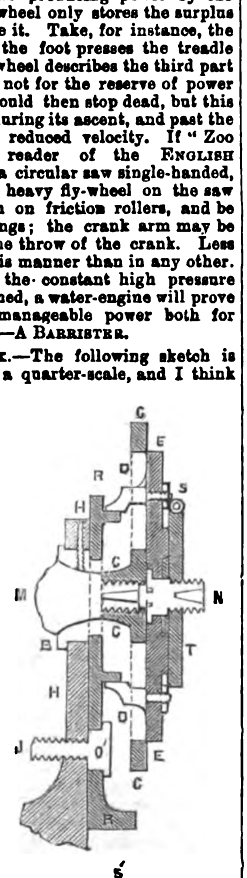
[11275.]—**Darkening Walnut (U.Q.).**—Egyptian asphalte dissolved in benzole and turpentine makes a fine transparent stain for darkening walnut, and makes a good imitation of that wood if applied to poplar, or wood of similar grain.—A Barrister.

[11282.]—**Preserving Plates (U.Q.).**—Years ago I made many experiments in this subject. I succeeded in getting honey and sugar plates to act as quickly as wet collodion, but found they could not be depended upon for more than half an hour or so. I abandoned the process in favour of the collodio-albumen, which gave me far better results.—A Barrister.

[11283.]—**Photo. Lens (U.Q.).**—I should recommend "Aremac" to obtain what is called a half-plate portrait lens of a good maker. This will be suitable for portraits, cartes de visite, and small landscapes or groups. I commenced with a quarter-plate, and progressed until I have a whole-plate portrait and a large landscape lens, but found them so cumbersome that if I had to begin now, I should choose the above. I prefer landscapes taken with a portrait lens to those taken with a single lens.—A Barrister.

[11333 and 11457.]—**Motive Power for Amateurs.**—Are we never to be free from the perpetual motion incubus? I thought this subject was tabooed in the pages of the English Mechanic, but it seems to be perpetually cropping up in one disguise or another. "Zoo Andra" fancies he can multiply his power by means of a huge pendulum, the only effect of which would be to waste a portion of it, from whatever source derived. "Novi" proposes to use coiled springs as a motive power, forgetting that only a fraction of the force employed in coiling the springs is utilised, and he makes no provision for the latter operation: how is this to be done? Even the practical Samuel Smither speaks of producing power by the use of a fly-wheel; a fly-wheel only stores the surplus power, it does not produce it. Take, for instance, the fly-wheel of a foot-lathe; the foot presses the treadle only during the time the wheel describes the third part of a revolution, if it were not for the reserve of power in the wheel the lathe would then stop dead, but this reserve carries the crank during its ascent, and past the dead point, with slightly reduced velocity. If "Zoo Andra," or any other reader of the English Mechanic wishes to use a circular saw single-handed, the best plan is to fit a heavy fly-wheel on the saw spindle, which should run on friction rollers, and be cranked outside the bearings; the crank arm may be adjustable so as to alter the throw of the crank. Less power will be wasted in this manner than in any other. I believe that wherever the constant high pressure water supply can be obtained, a water-engine will prove the cheapest and most manageable power both for amateurs and mechanics.—A Barrister.

[11372.]—**Oval Chuck.**—The following sketch is as near as can be, about a quarter-scale, and I think will convey all "L. S." requires. It is—well, I may say, the long section, as it is through the length of slide. M is the mandril of lathe or mandril nose; B is the steel bush; H the head stock; R R the eccentric thing which gives the oval motion the same as the original used, but dispensing with those long arms, screws, and branches upon the headstocks, which are in the way and unsightly. This you can clear away at a moment's notice, and it can be applied to any lathe of ordinary type, and the ordinary face-plate used for the foundation of chuck. J is a jamb-bolt which holds it fast against the headstock, and K in the old sketch shows the projection and screw for adjusting the same which passes through the head of nut, which is made of a T shape, serving for



a nut for the adjusting screw as well as jamb-bolt; D D are rubbing pieces that act upon the ring, and give motion to the long slide E E, to which they are bolted with a tail bolt or tag, the holes into which they are inserted being made long to compensate for wear and tear as well as adjustment; C C being the ordinary face-plate with four slots in at right angles, which is the foundation plate upon which the other is built or mounted; G is the micrometer screw which works in the edge of wheel; the head is left long for a few rings to be put upon it and divided, and instead of having a square end on for a key to fit on is made with a square hole drifted in, that you may never be at a loss to find a key to turn it. The numbers I have found useful for minute work I have given. T is the dividing plate which is fixed in its place by the round-headed screw which serves for a screw nose for chucks, &c.; a spare one or two are very useful, one being furnished with a taper screw for wood-work. They are screwed in from behind with a fork screwdriver, and serve for a swivel for the dividing plate to turn upon. S 1 is the screw in the old sketch; the screw is represented as a left-handed one, which is a mistake.—Jack of All Trades.

[11393.]—**Metallic Harmonicon.**—If "Tuba" (page 154) will read well "Zoo Andra's" excellent description of the musical glasses in his possession (page 103, No. 11393), and look at Fig. 1 in accompanying diagram, I think he will see at once what "Zoo Andra" means by "similar to an inverted aquarium." Should "Tuba" fail to see the meaning, let him get a tumbler with a stalk and break off the round flat stand at the bottom, so that the tumbler has a tang, and he will then have a model of a moderate-sized musical glass. But if he tries to produce a musical sound out of it in the manner described by "Zoo Andra," he will be disappointed. "Zoo Andra" (page 103, No. 11393) asks if pressed glasses would do as well as blown ones. I beg to inform him, no. In the English Mechanic for April 19th, I advertised a set of musical glasses in the "Exchange Column." I was, in consequence, inundated with letters, upwards of twenty asking for information as to structure, &c. I answered every one, giving as much information as I could spare time for. One gentleman at Sleaford said he was in communication with a glass manufacturer on the subject; perhaps he or some of the others who stated their intention of endeavouring to construct a set, and asked my advice, will, for the benefit of "Tuba" or any other brother reader who may have a like intention, state through "our" journal their success.—Samuel Kempling.

[11398.]—**Stings of Bees, Hornets, and Wasps.**—"H. B. E." is very much mistaken with regard to the stings of these insects. The fact is that the sting of a wasp is more sharply and more numerously barbed than that of either the bee or the hornet.—R. H. H.

[11423.]—**Surgery.**—To "Jack of All Trades" (p. 154).—Some years ago, when it was my business to peruse the official reports of our naval surgeons, whom it appears to be the fashion now to run down, but in my humble opinion very unjustly, considering their top-hamper, I read an account of a successful search for a broken needle by a cunning sea-leech. A tar had broken a needle in the palm of his hand, and the place having healed was undiscoverable by sight. Whether the bit of needle took to walking in its sleep or wanted to get out I do not know, but Jack finding that he could not use his hand, told his sad tale to the doctor. The doctor magnetised a sewing-needle, and, suspending it "de more," with this divining-rod found the exact spot, and cutting down, duly unfleshed the offensive steel. I may add that in case of an abscess forming the needle might be drawn out by means of a magnet, as recommended by, I think, a continental surgeon.—M. Paris.

[11443.]—**Warming Greenhouses.**—I could not answer "Anxious" sooner, as I only take the monthly parts, but if he only wants to keep his plants and not to have a hothouse, I think he will find my plan by no means a bad one. My greenhouse is not a small place, but along the front I put some hooks, and have an old sail, which in cold weather I hang up over the whole front. Supposing the weather is frosty but fine, I leave the sail down till between two and three o'clock; and during part of the time I open the windows. Damp is the great enemy, and during frosty weather, and especially the month of December, the plants should have, I might say, no water, or next to none. Well, as I said I shut all up a little before three, and in the course of an hour or two more, according to the cold, or I light the lamp and all is safe for the night. Of course "Anxious" knows that the size of the lamps differ, but one with an inch wick gives a great deal of heat. It requires no pipe, and does no harm. All that is wanted in a mere greenhouse is little water to the plants, as much fresh air as possible when it don't freeze, and it is quite sufficient if the frost is just kept out. The lamp should have one of the globular glasses: it is best.—E. T. Scott.

[11448.]—**Chronometer Balance Spring.**—The watch you speak of, I think, must be a lever with a common compensation balance. My opinion is, these balances are only put to watches to improve the appearance. I have many times removed them, and put gold ones in their place. You ought to have a good English lever for £6 5s., but the seller, no doubt, got a good profit. If you have a gold balance put to the watch, and the spring properly adjusted, it ought to keep good time.—Independent Chronometer.

[11524.]—**Pitch of Roof.**—Supposing the span or distance between the walls the same way you want the principal, say, 18ft., that would be 6 yards, and I always reckon 10in. to the yard, that is 5ft. high at the ridge. Some reckon 9in. to the yard. My father before me would not make them more than 9in. to the yard, and the reason was that the slates held enough to the slate laths, while there is more stress on them with the 10in. yard, but the roof is better. For an ealing roof reckon double or 20in. to the yard.—Birstall.

[11525.]—**Fresh-Water Aquarium.**—I use a bell-glass aquarium 33in. diameter at the top; height of water, 8¼in.; plant, Anacharis. The great mistakes of aquarium keepers are these:—1. Too much light. The remedy for this is: Hang a green-coloured cloth over the aquarium, and let the light in on one side only. 2. Overstocking. I think for this size, three minnows, one small newt, three or four water-snails (the largest, as they are the most useful), one eel (very small!), and one small roach. Have a tin cover made to fit the aquarium; the upper part must be of perforated zinc, this will keep the dust out, except the very little that enters the holes. I cannot make out what "Auon." (page 156) means by a cassavery.—V.

[11531.]—**Water-Wheel.**—In reply to "P.W.H.J." (p. 156), I have some reason to believe that he is not really practically acquainted with motive-power engines, for he says no really practical man will now advocate a rotary engine. "Would it surprise him to learn" that I have in my possession a rotary (water) engine that will beat any reciprocating engine, in spite of all he may say to the contrary? It is fitted up with every appliance required to test its power, and after overcoming its own friction it is found that 95 per cent. of what is due to the power of the water expended is obtained. I know that this statement will be considered an exaggeration, but when it is understood that my engine of 10 horse-power is got up expressly to test a principle in the motion and pressure of liquids it can be imagined that I have no interest in over-stating its merits.—D. S.

[11551.]—**Cement.**—Seeing the conclusion "Jack of All Trades" comes to in reference to cementing meerschaum, I recommend the inquirer to try the following, as kindly given by "M.R.C.V.S." under the name of "A Really Good Cement," Vol. XIV., p. 612. From practical experience I find it first-class.—W. K. Donaldson.

[11552.] — **Meerschaum.** — "A., Liverpool," says that he has never known a composition pipe to float lightly in water. I can sell him pipes by the gross which are daily sold as meerschaum pipes and are only composition. They will float in water, but he must remember that they are mere sham pipes, not meerschaum.—C., Glasgow.

[11566.]—**Equisetum.**—I am very much obliged to "M. D." for his kind offer, but I asked the question on account of observing the pollen gathered by myself, being desirous of calling the attention of our microscopists to a particularly curious object. I do not dabble much in microscopic work, being obliged to save my eyes all unnecessary fatigue. I should, however, be glad to learn from "M. D." what other pollens show such motion, as I have tried a great many without effect.—M. Paris.

[11569.]—**Telegraph Posts.**—The reason, I believe, the lower 3ft. is left unpainted or untarred, is not from economical motives, but to prevent the rotting from taking place so soon as it would do if painted or tarred. Wooden posts should never be coated with any waterproof material, such as paint, tar, or varnish, for at least 6in. above the ground, in order that the moisture from the ground may have free vent. If confined fermentation will always be set up, and what is called dry rot is produced, dry rot being nothing more than slow combustion of the tissues.—Brake.

[11571.]—**Virginia, Its Climate and Soil.**—"E. R. E. A." would get all information at the *Free West* office, Alexander A. Wise, 9B, New Broad-street, London. Ask for the "Virginia Settler."—Carpenter.

[11601.]—**Cracked Oven.**—Make a cement of steel filings and common yeast, and fill the crevice tightly while the oven is cool.—T. A. Bradley.

[11610.]—**Defective Battery.**—As "G. F. L." now says that the vibrating contact breaker itself does not act, it seems pretty clear that the defect must lie in the primary circuit; but it is one of those things which it is impossible to pronounce upon without first seeing and testing the apparatus, because failure may be due either to fault in the apparatus or to some oversight of the operator. As a rough test it may be well to screw the contact breaker down, connect one pole of battery to coil, and the other to a coarse file, and with a wire from the other connection of the coil (primary) scratch the file. If the circuit is right there will be a shower of sparks.—Sigma.

[11618.]—**Deadening Sound.**—The following simple method answered well in my office some years ago. Cover the joints of the boarded partition on both sides with unbleached calico (thicker the better), cover the whole of the partition with coarse brown paper, and then with room paper to suit taste.—Thos. A. Bradley.

[11619.]—**Electrical.**—If the glass of the jar is sound and good, and fitted as described, it ought to work well. Perhaps it has been standing on some insulating material while being charged, such as a dry woollen table-cover. It is possible, however, that the surface of the jar was damp. If there is a moist, heated atmosphere in the room, it will keep the glass damp, and conduct away the electricity as fast as it is generated. A number of people in the room will cause this state of things, and even a few may do harm by standing about the table, their breath falling on the apparatus. I have been, on several occasions, making electrical experiments in crowded school-rooms, and found it almost impossible to charge the jars; but as soon as the doors were opened and the crowd dispersed, so that the damp, heated air was driven out, the indicator on the jars would at once rise to its usual height. The room should be kept as well ventilated as possible.—OCCASIONAL PHOTO.

[11624.]—**Photography.**—I, likewise, live in the country, and have used nothing but rain water for photography for a good many years, and find it all I could desire. If the district is clear of smoky works, and the rain carefully caught without splashing on the ground or anything else that would pollute it, there is very little of either organic or mineral matter in it. As a precaution, however, it is well, after filtering, to add a few drops of silver solution. Shake well, and stand the bottle in the sunshine for a day; this will throw down all the impurities in it, which can then be filtered out, and the water is much purer than a great deal of the distilled water used by photographers. Instead of placing it in the sun try a weak solution of permanganate of potass, added carefully till a slight pink tint remains, then filter.—OCCASIONAL PHOTO.

[11626.]—**Electric Bells.**—If Thomas Whalley will refer to p. 564, Vol. XIV., he will find a description of an electric bell by Mr Tonkes, but instead of a rigid bracket marked D, I would recommend a spring bracket reaching up to the magnet, with a back nut to the screw.—W. BOLTON.

[11632.]—**Debility.**—I have often wondered what class of people they are who patronise Solidway's pills and other marvellous panaceas. But that wonder is somewhat satisfied by the reply under this head on p. 182. There is no necessity to defend either allopaths or homœopaths against the charges of "Amateur," which carry their own refutation broadly written in those very words he uses to stigmatise the medical profession. I am curious to know, however, by what occult erudition the author of the altera-tonic system has convinced your correspondent that the "one sole cause of all disease" is nervous debility. Only fancy, cholera, which sometimes strikes and kills in twelve hours, is produced by nervous debility! Typhoid, eczema, rheumatism, heart-disease, and other ailments exhibiting the most opposite characters, are all occasioned by nervous debility! Even our children, those we regard as strong and healthy, are suffering from nervous debility, for do they not take measles, whooping-cough, scarlatina, and smallpox much more readily than the "lean and slippered" shadow of a man with scarce a sound nerve in his body, whose every sense is tottering to ruin? Really, it is surprising how readily even readers of the ENGLISH MECHANIC swallow the theories of the quacks, and hesitate not to fling hard words at scientific men. Whence, for instance, did "Amateur" obtain his peculiar idea of the system of the allopaths?—SAUL RYMEA.

[11663.]—**Steam Power.**—"T. W. J. M." has not stated whether the firebox communicates by several small tubes or a single flue. This would make a considerable difference in the heating power. This boiler might make steam for half horse-power; but it seems improbable, because small boilers seldom approach to their theoretical efficiency. He has not mentioned either the pressure of steam or the resistance that the engine would encounter. The engine might run all right when empty, and yet stop when the work is thrown on. The area of the bottom end of firebox is 19·635 sq. in., of which probably 19 sq. in. will be effective area. This makes out the evaporative power of the boiler to be about one-seventh horse-power when working in everyday work; it may reach to one-sixth if the fuel employed is charcoal. If the boiler works the engine at all with an adequate amount of resistance proportioned to its size, either the speed must be reduced, or it will work at a very low pressure. I will work out the pressure that the boiler would sustain. Let P be the pressure, then, $1 \times \frac{11}{14} \times \frac{400 \times 2}{1728} \times \frac{P}{1} \times 2 = \frac{1}{6}$ by supposition; $\therefore P = \frac{1}{4}$lb. This is, of course ridiculously low for a high-pressure engine, and it can only be remedied (without a larger boiler) by lowering the speed. Next, for the weight of fly-wheel. The rules given in the books are of no use for so small an engine; in fact, they were never intended for such. I have seen engines working of about that size with 18in. diameter fly-wheel. The size that I should recommend would be 18in. diameter to centre of rim, thickness of rim 2in., breadth 1in. The wheel to have five spokes ½in. thick. The rim will weigh about 20lb., and the boss and arms about 15lb. to 20lb. more, total 35lb. This may seem rather heavy, but I have found it advantageous to err in excess with small engines.—P. W. H. J.

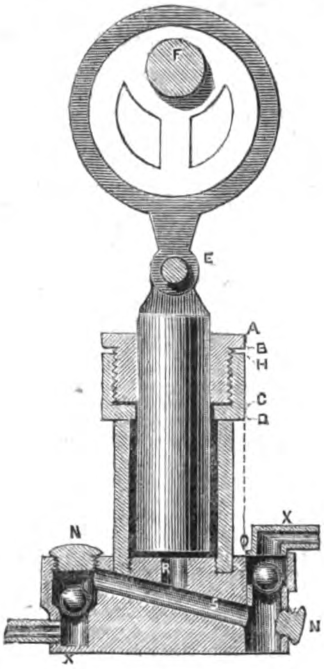
[11664.]—**Polishing Bullock's Horns.**—Well scrape with glass or steel scraper, afterwards with finest glass cloth, then with powdered bath-brick and oil, and finally with rotten stone and flannel, or old cloth or felt hat.—JACK OF ALL TRADES.

[11664.]—**Polishing Bullock's Horns.**—First scrape with glass to take off any roughness, then grind some pumice-stone to powder, and with a piece of cloth wetted and dipped in the powder, rub them till you get a *smooth* face. Next polish with rotten stone and *linseed oil*, and finish with dry flour and a piece of clean *linen rag*. The more rubbing with the stone and oil the better the polish.—A. E. F. F., Clapham.

[11666.]—**Qualitative Analysis.**—The chief impurities of water are carbonates and sulphates of calcium and magnesium. (1) Carbonate of calcium may be detected by boiling, being deposited as "fur" (it is always precipitated when a solution of an alkaline carbonate is added to a solution of that base). (2) Chloride of calcium is detected by adding a solution of silver nitrate, a white precipitate of silver chloride falls, insoluble in nitric acid, but soluble in ammonia. (3) Calcium sulphate: 1°. Test for calcium. Add a solution of ammonium oxalate, which forms with a lime-salt a white precipitate insoluble in acetic acid: 2°. Test for sulphuric acid. A solution of barium nitrate gives with sulphuric acid a precipitate of barium sulphate insoluble in all acids. A drop of pure water evaporated on a slip of glass leaves no mark.—W. L. G.

[11667.]—**Carbon Points.**—The best carbon points you can procure can be got from the gas-works. I purchased a piece of carbon for 3d., broke it into pieces with a hammer, filed up the bits into points with a rough file, and became possessed of as many as I shall ever require. This carbon is sublimed upon the roofs of gas retorts, and is exceedingly hard.—J. HOPKINS.

[11669.] — **Trunk Engine.**—This engine would drive a boat of 4ft. or 5ft. long, but 3ft. is too small. The practice of the leading model-makers is to put a single cylinder trunk engine of 1in. stroke to a 3ft. boat. I inclose directions and drawing for making force-pump. Take a piece of rod brass, turned down to ⅜in. diameter, bore a hole ⅜in. diameter through it for seven-sixteenths of an inch long, and the remainder drill with a hole a shade larger than five-sixteenths of an inch in diameter. At ½in. from the end with the larger hole, turn down to ½in., to the length of ¾in., you will then have something like the section A S in the drawing. This pipe is then to be fastened into the brass block, having a section like X X. This may be an oblong piece having a ring



turned in its centre to fit the end of the tube. It may be soldered on with common soft solder over a spirit lamp, and then finished off in the lathe. The holes R S have to be drilled before it is soldered, and then the holes N N plugged up. They may come in useful afterwards when the valves want cleaning. The plunger is easiest made out of a piece of brass tubing, plugged up with melted lead at one end. The plunger to be five-sixteenths of an inch in diameter, and 1⅛in. long. The stuffing-box gland to be turned out of a piece of solid brass, like A in the drawing, and tapped to fit H D. The eccentric band will be difficult to make without a casting, though with a deal of trouble it may be cut out of a piece of ⅛in. brass plate. Another plan, which is easier, but does not look so well, would be to turn a brass ring out of ⅛in. brass plate, and tap three brass rods into it, meeting in a small brass ring, for E to work in. The distance from F to E he must find out by trial. The metal employed must never be less than one-sixteenth of an inch. Any further information, if I am able, I will gladly afford.—P. W. H. J.

[11673.]—**Hydraulic Rams.**—There is only one kind of hydraulic ram, and with this you can theoretically lift to any height, but when it has a high lift there is a great amount of waste water, and but a small quantity is supplied at the exit pipe. It seems sometimes to require a small river to supply a house that is situated on the top of a hill; besides that, the valves do not last long. I should only think it suitable for moderate lifts.—P. W. H. J.

[11675.]—**Solder for Britannia Metal.**—Use tinman's fine solder, two parts tin, one part lead; use chloride of zinc, otherwise spirits of salts killed by adding as much zinc as it will dissolve.—W. BOLTON.

[11675.]—**Solder for Britannia Metal.**—See indices. Where several have been given.—JACK OF ALL TRADES.

[11676.]—**Lemonade Syrup.**—Take 3lb. of good loaf sugar and one pint of water; boil, skim, and cool, till about lukewarm; then add 600 grains of citric acid dissolved in a pint of water, one ounce of tincture of orange peel, and 30 drops of essence of lemon; stir well together and allow it to settle for twenty-four hours, then pour off from the sediment, if any.—J. L.

[11677.]—**Rendering Wood Incombustible.**—A very excellent way to render wood incombustible is to soak it in a strong solution of alum and the sulphate of copper. About one pound of alum and one of sulphate of copper should be sufficient for 100 gallons of water. These substances are dissolved in a small quantity of hot water, then mixed with the water in the vessel in which the wood is to be steeped. The timber to be rendered fireproof can be kept under the liquor by stones or any other mode of sinking it. All that is required is a watertight vessel of sufficient dimensions to hold enough of the liquor to cover the timber, which should be allowed to steep for about four or five days. After this it is taken out and suffered to dry thoroughly before being used. A plan of rendering the wood partially fireproof would be to whitewash it two or three times. You will probably require a glue to hold against fire, here is the recipe:—Mix a handful of quicklime in four ounces of linseed oil, boil them to a good thickness; then spread it on tin plates in the shade and it will become exceedingly hard, but may be easily dissolved over the fire, and used as ordinary glue.—P. W. H. J.

[11680.]—**Mildew in Boat Sails.**—You will not find anything better than dilute carbolic acid for this purpose. Sprinkle them well over with a solution of one part of commercial acid in fifty parts of water.—ETHYL.

[11680.]—**Mildew in Boat Sails.**—"Kirkway's" safest plan is to dry the sails thoroughly, in the open air if practicable, and to sweep them well on both sides with a strong hair-brush, having sprinkled it beforehand with water, in which a little ammonia has been dissolved. Do not roll the sails up while wet, as it is damp which has produced the mildew. If "Kirkway" wants to disinfect the sails, or prevent infection, carbolic acid is a good thing for the purpose. It might also prevent the depredations of moths and small insects; but I cannot say what effect the acid might have on the sails.—RAT-TAT.

[11681.]—**Water Glass.**—This substance, being soluble in water, would not answer for the purpose mentioned by your correspondent.—J. L.

[11685.]—**Canary's Song.**—Has "Exon" ever tried hard-boiled eggs and maw seed? I have found it an infallible cure whenever I have tried it, and would strongly recommend "Exon" to try it also. Many birds do not sing about this time. I have three that do not; the only way I can account for this is that it is the breeding season. Sparrows very often destroy the song of the canary by their chirping. I should advise "Exon" to keep the bird in a room where he will not hear them. Sometimes birds lose their voice altogether for some considerable time after moulting, especially if they do not moult freely, but when warm weather comes in they get it back again. When birds are moulting, there is nothing better for bringing them through than a rusty nail in their water, which may be kept in all through the winter, as it strengthens them very much.—BED OF STONE.

[11687.]—**Speeding Machinery.**—Multiply the diameter of the driving-pulley on the shaft into the number of revolutions of the driving-pulley, and divide the product by the required number of revolutions of the machine-pulley—thus: Driving-shaft running 50 revolutions per minute, diameter of driving-wheel 3ft., speed required on machine 135 revolutions per minute. Then $\frac{3 \times 50}{135}$ is required diameter of machine-pulley $= \frac{150}{135} =$ 1ft. 1⅓in. Similarly for number of teeth. Multiply the number of teeth on the driving-wheel by the number of revolutions per minute of the driving-wheel, and divide the product by the required number of revolutions of the machine. Thus, if the number of teeth on driving-wheel be 54 $\frac{54 \times 50}{135}$ is the number of teeth on machine-wheel $= \frac{2700}{135} = 20$.—W. L. G.

[11687.]—**Speeding Machinery.**—Divide 135 by $50 = 2\frac{7}{10}$ to 1, that is pulleys 27in. and 10in. Now for wheels multiply by 3·1416, or 3, and adding 1 to every 20 or 21, and either divide by the number of teeth you require, will give you the pitch, or by the pitch will give you the number of teeth, and the above will be the pitch line or any other in proportion got by multiplying both by the same number.—JACK OF ALL TRADES.

[11687.]—**Speeding Machinery.**—The diameters of the wheels are to be in inverse proportion to the speed. For instance, let D be the diameter of one pulley, and D′ the diameter of the other; and let S be the speed that the first pulley is working at, and S′ the speed of the other. $\therefore D : D' :: S' : S$ (always let the letters with the dashes represent the greatest number); $\therefore D \times S' = D' \times S$; and substituting the numbers you have given, $\therefore D \times 135 = 50 \times D'$ $\therefore$ the diameter of the driver is 135in., and the diameter of the other is 50in. The teeth of wheels can be managed in just the same manner, wheels having teeth of the proportion of 50 : 135, or any multiple of the By the formula that I have given, the number of can be got for any speed. I will give an example:—Suppose a shaft revolves at 300 revolutions, and another at 400 per minute, to find the number of teeth for each cogwheel. Substituting in the formula $D \times S' = D' \times S$; $\therefore D \times 400 = D' \times 300$; $\therefore$ number of teeth in driver = 300, and number in follower = 400. Numbers can be cancelled or multiplied on each side of the equation, to make the wheels convenient for manufacture.—P. W. H. J.

[11687.]—**Speeding Machinery.**—Suppose your driving-shaft runs 20 revolutions per minute, to be increased to a 100 revolutions in the same time. Let a wheel be keyed on the shaft 5 times as large as the secondary wheel, as 100 is 5 times 20. In the case given the shaft is supposed to run 50 revolutions, and he wants to drive a machine 135 revolutions for every 50, putting a wheel 135in. in circumference on the driving shaft, and connecting it by bands or otherwise with a secondary wheel of 50in., would obtain the desired end, or if "A Reader" wishes to use smaller wheels, dividing the numbers of revolutions by 5, which gives 10 and 27; then a wheel 27in. in periphery would drive a secondary wheel of 10in. 135 revolutions for every 50, 27 for every 10, or nearly three times as fast. The diameter to the circumference is as 3 : 1 or ⅓ nearly, or for greater accuracy multiply by 3·1416 for the diameter from the circumference; the number of teeth in each wheel depends on the size chosen.—RAT-TAT.

[11688.]—**Cleaning White Sheepskins.**—Let "Housekeeper" hold the skin over the steam of boiling water, wool side up. Throw back the fleece, and as the skin becomes softened by the steam, brush it briskly with a hair-brush, using powdered chalk, whiting, or pipe-clay. Rinse it in cold water, using soap if necessary, and apply the brush in bringing back the fleece to its former position. Dry in the open air.—RAT-TAT.

[11694.]—**Green Fly.**—Try syringing them with a solution of the concentrated tobacco-juice, which is now sold at a cheap rate for this purpose, duty free. A florist informs me that this is the best remedy he has tried.—ETHYL.

[11695.]—**Succession Duty.**—It depends upon whether the leaseholds are held for a long or a short term. If the value of the lease is evidently greater than the value of "C. P.'s" life, interest duty will be payable as upon an annuity equal to the net annual value of the property during his life. But if "C. P." is a young man, and the lease has only a few years to run, duty may be paid on the saleable value as on a capital sum. In the former case the duty is payable in eight half-yearly instalments, and in the latter in one sum. "C. P." may prepare and pass the accounts himself, but I would not advise him to do so.—SHYLOCK.

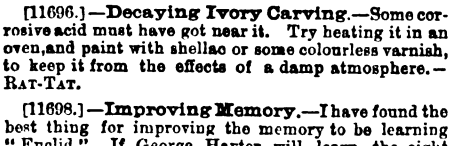
[11696.]—**Decaying Ivory Carving.**—The following extract from Layard's "Nineveh" may encourage your correspondent to seek for further information: "In many cases the ivory ornaments were so completely decomposed that they could not be removed. Those preserved, and now in the British Museum, were restored in England by an ingenious process, which replacing the gelatinous matter, and thus reuniting the decaying particles into one solid body, gave them the appearance and consistency of recent ivory."—X. X.

[11696.]—**Decaying Ivory Carving.**—Some corrosive acid must have got near it. Try heating it in an oven, and paint with shellac or some colourless varnish, to keep it from the effects of a damp atmosphere.—RAT-TAT.

[11698.]—**Improving Memory.**—I have found the best thing for improving the memory to be learning "Euclid." If George Hayter will learn the eight books of "Euclid," I will guarantee that he will have a tolerable memory, and be possessed of an argumentative power, which is of immense use in learning anything—nay, everything else. When at school I had the worst memory in my class, but by perseverance in learning these books, I acquired a surprising facility for learning other things that I could never otherwise have hoped for. This method I consider better than the plan of learning poetry, because it engages the mind more fully, and when the memory is at fault the mind assists it.—P. W. H. J.

[11701.]—**To Mr. Knott.**—My friend Mr. Knott will, I know, pardon my replying to a question addressed to him by C. Gaudibert. In May, 1868, I observed this star (ζ Cancri) with great care, and under peculiarly favourable circumstances, on two successive nights, the 7th and 8th, with my 18in. equatorial reflector, when A and B were much closer than they are at present. Not having a micrometer at that time, I had no means of ascertaining the distance; but an idea may be formed from the following diagrams of the discs as seen with

1 2 3 4 5 6



different apertures. No. 1 being with 8in., No. 6 with 18in., and the others with 10in., 12in., 14in., and 16in. respectively. With 8in. the disc was very nearly round, with 18in. the two stars were just separated, and no more. They may now be divided with 8in. On April 30 and May 2, at 8 p.m., I was fortunate enough to secure a satisfactory set of distance measures, the mean of which is 0·583″; I think I may safely say the distance is not greater than this. The mean of the measures of position is 162·9°; powers used, 500 and 752. The small star has thus retrograded 80° in eight years; Mr. Dawes' last measures, in 1865, being—position = 243°, distance = 0·6″; the stars having been closing up for 22 years previous to that date.—H. C. KEY.

[11703.]—**Ink.**—Take ½oz. of sugar candy and 2oz. gum arabic, and just cover with sufficient water to dissolve them; take acetate of iron, and fill about the same height as the gum, and well shake; now brush it over a plate of glass, or pour it into a dish and evaporate, and when dry powder it and put up in a bottle for use, or a tin canister will do. Now take the best galls, very finely powdered, and if you place ½oz. of this in hot water and pour off, using from ½oz. to ¾oz. of the above, you will find you will have a pint of good ink. If not strong enough you can add more; it will keep for years, and stand any climate. You must keep these powders separate, or one will destroy the other, and both will become useless; they are best prepared in the way I mention. Either hot or cold water will do, but if you want a clear free ink decant the clear. Acetate of iron is made by digesting some iron filings in vinegar, having subjected them first to a red heat.—JACK OF ALL TRADES.

[11704.]—**Rats.**—A single drop of oil of linseed on the tongue of a common steel trap will be a first-class bait. Oil of rhodium is equally as good; but the cheapest and most convenient bait is as follows:—Of good oatmeal take two parts and roast meat dripping one part, mix them together, and roast them just before going to bed; bait the traps with this mixture hot, and before morning you may be sure of having, at least, half your traps occupied. I have known a trap five times occupied in one afternoon in broad daylight.—BED OF STONE.

[11704.]—**Rats.**—"M. A. B." desires to be informed of a method to destroy rats; for his satisfaction and the public good generally, please to accept of the following:—Take nux vomica beaten into fine powder by the apothecary, one ounce, or less, as you have occasion, mix with butter or hog's lard into a paste, and put pieces of about the size of a hazel nut into pieces of thin writing paper, and put them into the holes; it will kill them without the danger of poisoning anything else; should a cat or dog meet with one of these doses, it will make them very sick, but a spoonful of oil will cure them.—RALPH LOWDON.

[11706.]—**Optician's Lacquer.**—The following recipes I have heard spoken highly of:—8oz. of shellac, 2oz. of sandarac, 2oz. of anatto, ½oz. of dragon's blood resin, 1 gallon of spirits of wine; or 8oz. shellac and 1 gallon of spirits of wine. The article, if it is not a casting, should be heated slightly, and the lacquer should be applied by means of a soft camel's-hair brush. If the article is a casting, it will require a little more trouble to turn out a creditable article. It is to be dipped in nitric acid, but before that it is to be well cleaned from sand and dirt. It is then washed and placed in clean water until ready to be lacquered. It is then to be taken out and placed in the hot oven for a few minutes, and then taken out when quite hot, and either of the lacquers applied to the parts required.—P. W. H. J.

[11706.]—**Optician's Lacquer.**—One drachm of gum benzoin dissolved in one ounce of spirits of wine at proof strength. The article should be thoroughly cleaned, and warmed as hot as the hand will bear, and the lacquer applied with a soft brush, and immediately placed under cover to avoid atmospheric dust whilst drying.—J. L.

[11708.]—**Gas Burners.**—Perhaps the following table will be of use to "Loach." It is the result of the experiments of Dr. Fyfe:—

Burner.	Consumption per hour.	Light given, comparative.	Illuminating power per foot of gas burnt.
	c. f.		
Jet, 5in. high.........	1·0	1·0	1·0
Small fishtail........	1·98	2·80	1·45
Large fishtail........	2·60	4·0	1·53
Small bat'swing.....	3·0	4·40	1·46
Large bat'swing.....	4·60	8·40	1·87
Argand of 40 holes	4·50	7·84	1·74

—P. W. H. J.

[11711.]—**Time at our Antipodes.**—This will depend on whether the Antipodes are inhabited by persons arriving there from the east or from the west. By the time that two travellers round the world, who have left a given meridian at the same time by directly opposite courses, meet again on another meridian, one will have gained an hour for every fifteen degrees of longitude he has passed, and the other will have lost in the same proportion. Consequently, one will be twenty-four hours in advance of the other, one considering the day of the week (say) Tuesday, while the other considers it Monday. The same effect would be observed by a traveller arriving after a tour of the globe at the same meridian from which he started. If his return occurred on a Monday he would, if his course had been easterly, have gained a day, and would consider it Tuesday. If, on the other hand, he had gone round the world from east to west, he would have lost a day, and would consider the day of his return Sunday (Herschel's "Outlines," section 257). Practically, as regards Australia and New Zealand, I imagine (speaking under correction) that, since the course of vessels sailing thither lies, as a rule, round the Cape of Good Hope, to say nothing of the overland traffic vid Galle, time is reckoned in the same direction—that is to say, the Australasians are in advance of us. Moreover, the longitude of New Zealand is within 180° east of Greenwich, and it is, therefore, more natural that time should be reckoned by the shorter distance, and that our time should be considered ten or eleven hours slower than Australasian time instead of fourteen or thirteen hours faster.—V. B.

[11713.]—**Composition for Moulding.**—The following is used by gilders:—Mix 14lb. of glue, 7lb. rosin, ½lb. pitch, 2½ pints linseed oil, 5 pints of water (more or less according to the quantity required). Boil the whole together, well stirring until dissolved, adding as much whiting as will render it of a hard consistency, then press it into mould, which has been previously oiled with sweet oil. No more should be mixed than can be used before it becomes sensibly hard, as it will require steaming before it can be used again. Another recipe is this:—Make a very clear glue with three parts of Flanders glue and one part of isinglass, by dissolving the two kinds separately in a large quantity of water, and mix them together, after they have been strained through a piece of fine linen to separate the filth and heterogeneous parts which could not be dissolved. The quantity of water cannot be fixed because all kinds of glue are not homogeneous, so that some require more than others. The proper strength may be found by suffering the glue to become perfectly cold, it must then barely form a jelly. The glue is then to be gently heated, then mixed with sawdust sifted through a fine sieve. The moulds are then to be oiled with nut oil, and the glue pressed into the mould, covered with weighted board, and then set to dry near a stove. When the casting is dry it is to be trimmed.—P. W. H. J.

[11715.]—**Testing Acetic Acid.**—Evaporate about an ounce to dryness, it should leave little or no residue. If any remains, dissolve in water and add a few drops of solution of barium chloride and hydrochloric acid, if a precipitate forms it shows the presence either of a sulphate or of free sulphuric acid. To distinguish the latter from the former add a few grains of pure cane sugar to an ounce of the acid, and evaporate to dryness at a heat of about 120° C. The residue will be blackened when free sulphuric acid in any quantity is present. It may also contain hydrochloric acid, which could be easily known by diluting the acid with water, and adding silver nitrate. If a white curdy precipitate falls it is due to the presence of chlorine. Dilute another portion of the acid with water, and pass a current of sulphydric acid through it. A blackening denotes the presence of lead or copper. These are the usual impurities in vinegar. Sometimes capsicum or red pepper is used to make it pungent, and to make it appear stronger than it really is.—ETHYL.

[11715.]—**Testing Acetic Acid.**—Sulphuric acid is added in small quantity to vinegar to check the decomposition or mothering when the acidification is complete. Sulphuric acid is best detected by barium chloride, or barium nitrate dissolved in water: upon addition of sulphuric acid in any soluble state of combination a white precipitate is formed insoluble in nitric acid. Nitric acid, when boiled with a solution of indigo in sulphuric acid, bleaches the indigo solution. Hydrochloric acid may be detected easily by solution of nitrate of silver; upon adding the former or any soluble chloride to the latter, a white curdy precipitate of chloride of silver falls, insoluble in nitric acid, but freely soluble in ammonia of cyanide of potassium.—W. L. G.

[11722.]—**Eyebrows Falling Off.**—Has not "Subscriber from the First" some other symptoms denoting ill-health, of which this is only a minor manifestation? Plumbum (lead) in poisonous doses will occasion the hair on the eyebrows to fall off, and we homœopaths say it will consequently stop it. Is subscriber in any way engaged in a trade where he inhales the fumes of lead? If so, that is the cause, and confirms the homœopathic proving of lead. If the falling off is not caused by lead he might try it. From some homœopathic chemist procure a sixpenny bottle of plumbum, No. 3 trituration, and take a grain (as much as will lie on a threepenny piece, not piled up) morning and evening, in a little water on an empty stomach.—WATTS.

[11722.]—**Eyebrows Falling Off.**—Rub with a little olive oil and rose-water.—RAT-TAT.

[11723.]—**Defective Contact Breaker.**—I have been in the same bother, but got over it. I have now had an electric bell at work, with one pint Daniell's, for nearly five months; but being in a warm place I have had to add some acid solution to porous cell. I made it, also a coil (I used bottling wire for the coil, which, I think, is superior, being bright, soft, charcoal wire), made a machine, covered my own wire, &c., from instructions given in "ours" to others by Mr. Tonkes and other kind correspondents. I found the fault of my contact breaker was owing to the screw being fixed to a rigid arm, the vibrations gradually unscrewing the screw. I have now mounted the screw on a spring arm similar to the spring the armature is mounted on, and added a nut to the screw to tighten it when in its proper position. The springs must be of a proper strength, which a few trials will determine.—W. BOLTON.

[11724.]—**Discharge of Water Over Weirs.**—I extract the following from Templeton's rule for the number of cubic feet discharged in any number of seconds. Multiply together the number of seconds, the width of the weir in feet, and the co-efficient taken from the table, the product will be the numb of cubic feet discharged in the time. (There is a tr given that gives the value of k for different depths.) The value of k in the case mentioned is ·29171. ∴ 86,400 × 4 × ·29171 = 100,597·876 of cubic feet, and if any other of the elements of this question was wanting, it could be found, with the help of the others, by substitution.—P. W. H. J.

[11728.]—**Adjusting Balances and Main-springs.**—The information respecting balances will be found on pp. 102 and 279, Vol. XIV. of the ENGLISH MECHANIC. The balls on an adjusting rod are used to slide up or down until they nearly balance the power of the mainspring for the first revolution after the chain is wound up, and by which the force of all the other revolutions is compared.—WEST CORNWALL.

[11729.]—**Teeth of Spur Wheels.**—If a "Pattern Maker" gets an odontograph, an instrument (price 5s.) invented by Professor Willis, of Cambridge, he will find in it correct information for setting out forms of teeth, so that any two wheels of a set may work truly together. The use of the instrument is very easily learned.—GO-AHEAD.

[11730.]—**Artificial Gum.**—Dextrine, also called British gum, would probably suit "Wrinkle." It would be much cheaper to buy than make, as it is prepared in enormous quantities. I give the recipe on a small scale:—Malt (crushed small), 1lb.; warm water, 2 gallons; mix, heat the whole to 145° Fahr., add of potato starch 5lb., raise the heat, to 160° Fahr. and mash for about twenty-five minutes, or until the liquid becomes thin and clear; it must then be instantly run off, and raised to the boiling point to prevent the formation of sugar; after boiling for three or four minutes the whole must be filtered and evaporated to dryness by a steam heat.—A BARRISTER.

[11731.]—**Hair Wash.**—If "Excelsior" consults "ours," p. 140, he will find an excellent recipe for the hair and many other purposes. I have used ammonia for years. My head is entirely free from scurf, the hair smooth and glossy, and I seldom require pomatum. Pour a few drops of ammonia into a basin of tepid water, and wash the head thoroughly, at the same time using a little soap. Well rinse in warm water.—M. POPE.

[11732.]—**Temperature of Ice and Water.**—Let x be the temperature of the water after the melting of the ice. 3 kilogrammes of water on passing from 79° C. to $x°$ will lose 3 (79 − x) units of heat; whilst 1 kilogramme of ice will absorb on passing from 0° to $x°$ a quantity of heat represented by 79 + x. Consequently we have the equation $3\ (79 - x) = 79 + x$, from which we conclude x = 39·5° C.—F. T.

[11736.]—**Extracting Iodine from Seaweed Ashes.**—"J. R." will easily extract iodine from seaweed ashes by mixing them with dioxide of manganese and sulphuric acid, heating moderately, when iodine will evolve in fine violet vapours, which will condense if received in a cool recipient.—F. T.

[11736.]—**Extracting Iodine from Seaweed Ashes.**—Kelp (the half vitrefied ashes of seaweed) is exhausted with water and the solution filtered; the liquid is then concentrated by evaporation until reduced to a very small volume, the chloride of sodium, carbonate of soda, chloride of potassium, and other salts, being removed as they successively assume the crystalline form. Oil of vitriol is now added in excess to the residual dark brown "mother" liquor (iodine lye), and the evolved gases are either kindled or allowed to escape by a flue; the liquid, after standing some time, is filtered, heated to about 140° Fahrenheit, and mixed with as much binoxide of manganese as there was oil of vitriol employed; the whole is then introduced into a cylindrical leaden still, furnished with a very short head, and connected with two or three large globular glass receivers, and heat is applied, when fumes of iodine are evolved and condense in the receivers. During the distillation very great care is taken to watch the process, and prevent the neck of the still becoming choked with condensed iodine. For this purpose the head of the still is usually furnished with a movable stopper, by which the process may be watched, and additions of manganese or sulphuric acid made, if required. To render the product pure, it should be passed between blotting paper, and then resublimed in glass or stoneware.—A BARRISTER.

[11738.]—**Cyanide of Potassium.**—It is really astonishing that "Dentiste" has not met with a serious accident for using, with so little precaution, cyanide of potassium. This substance is one of the most deadly poisons known, and second only in that respect to prussic acid or nicotine. Compared with it, arsenic is quite harmless. Its best antidote is a mixture of the following substances:—Sodium carbonate, ferrous sulphate, ferric sulphate.—F. T.

[11738.]—**Cyanide of Potassium.**—This is one of the most powerful and dangerous poisons known; it is, in fact, solid prussic acid. The only available treatment is instantly to place the head and face of any one poisoned with this drug (or with prussic acid) under a powerful stream of water from a tap or pump, but a delay of a very few minutes would be certainly fatal. It is impossible to say what the precipitate in "Dentiste's" bath is unless we know what it is composed of; he speaks of a saucepan, in that case probably all the gold has been precipitated. Cyanide baths give off fumes which are very unhealthy.—A BARRISTER.

[11747.]—**Canoe Voyage.**—Having been used to the sea for some years past, and having a skiff of my own in which I take long trips, I shall be glad to give "Afloat" any information I can on the subject. 1. I think "Afloat" would find it the safest and wisest plan to keep to the English coast, as going far from land in a small boat is too great a risk. In going along the coast, in case of being caught in a breeze, "Afloat" might find a suitable place to run his canoe on shore, and haul up whereas if in the middle of the Irish Channel he may stand a good chance of going to Davy Jones's locker. I should think the best trip "Afloat" could take would be to the south of Wales and up the Severn; he would, no doubt, be able to reach some place of interest each day, and find accommodation for sleeping. 2. As regards the fitting of canoe, &c., preparing is preventing, and "Afloat" before starting should be well fitted out, and at one end of canoe have a water-tight cupboard or locker, where he might keep the following articles, which would prove useful:—A small compass and binnacle, which he would require in case of fog, or not reaching the intended place till after dark; also some hand charts of the coast he intends to go. I have always found them most useful things in going along a strange coast, they give you nearly every information you require, are not very large, and each one takes in about sixty miles of the coast, they cost about 1s. 6d. each. A *Nautical Almanac* would also be a very useful thing to have. "Afloat" would have the time of high water at different ports, all the lights, buoys, courses from place to place, &c., or for a few shillings may get a book in connection with the charts; all these above could be obtained at any marine shop. 3. I should recommend "Afloat" to have a lug sail fitted to his canoe, that he may use when he has a fair wind, I have one to my boat which answers well, and saves a great many miles pulling. All the gear is made very light, and the sail, made of unbleached calico, is hoisted by a halliard which is attached to a traveller which runs on the mast, and the gaft hooked to the traveller. The sail is a large one that I might take advantage of light winds, but will reef down to half its size when wanted; it is very compact, can be hoisted or taken down without having to move, and when down does not take up much room. I shall be most happy to give "Afloat" any information I can through your valuable paper.—JACK TAR.

[11748.]—**Artificial Manures.**—If "Guano" is sufficiently acquainted with the French language I should advise him to read the following book, "Recherches Chimiques sur la Végétation," par M. George Will, Professeur au Museum d'Histoire Naturelle de Paris, as it is the best book, in my opinion, published about such matters.—F. T.

[11748.]—**Artificial Manures.**—The information requested would doubtless be exceedingly interesting. Several years' experience as a consulting farmer (not, however, pecuniarily interested) has taught me that a good soil should originally contain silex, alumina, lime, and magnesia; the two latter, however, can be supplied if absent for little more than the cost of carriage, when the former earths are absent, as on chalk and peat soils, the farmer must make a surface soil by carting marl on it, if he can get it; but silex alone—viz., pure sand is not worth even carting. Now for manure: if the soil does not contain sulphur, chlorine, and soda, these can be given cheaply to it in gypsum and refuse salt; then all we want more are potash, phosphorus, and the valuable stimulant nitrogen; how to obtain these cheaply is the farmer's problem. Coprolites and bones will give us the phosphorous with the less valuable lime and magnesia. Superphosphate gives us the same ingredients with sulphur; the bones give a little nitrogen. Peruvian guano gives us much more, but both these valuable manures are deficient of potash, hence their failure on a non-potassiferous soil to raise good crops of potatoes, which are great potash requisitionists; so we must supply this alkali in seaweed or kainit. Saltpetre would be a glorious fertiliser, but it is too dear. Nitrogen I have called a stimulant, for its presence greatly excites growth, and if used alone will rapidly exhaust the soil. Hence the landlords' prohibition of the use of soot and gas liquor, and the old farmers' prejudice against guano, which is about as sensible as a merchant having a prejudice against his cheque-book because its use diminished his balance at the banker's. It would be an interesting experiment to crop successively a patch of land manured with nitrate of ammonia alone, and note the results both on land and the produce. What salts plants and crops of various kinds really require, and how far they possess power of substitution of one ingredient for another, *e.g.*, soda for potash, lime for magnesia, can only be decided by a series of careful experiments, far out of the power of an individual farmer to make; they should be made by a Government department, and the results published for the benefit of the community at large.—HAMMER.

[11756.]—**Power of Water-Wheel.**—In your issue of this day (May 3), I see a query from "Water-Wheel" requiring the power of a water-wheel under three distinct times of supply—viz., 4h., 6h., and 8h. All who are in any way acquainted with hydraulics must be aware that unless the head or fall of water is known or given, no power can be arrived at. I shall and am always ready to answer such queries; but unless the most essential part is given, I must decline even attempting a reply. In this case there are several of the most important data missing. Let your correspondent give the following, and no more is required:—The fall or head in feet or decimal parts, the principle of wheels to be adopted, the size of pipe to be used and distance, the mean contents of each bucket, or, if he cannot arrive at such, give a sketch of the shape, giving principal dimensions, to enable the mean contents to be deduced, also whether buckets are iron or wood, and, if possible, approximate weight of wheel, so that the velocity may be arrived at from the revolutions given.—J. GILLAIRD.

[11761.]—**Magnetism.**—The second experiment has nothing to do with "increased transparency of iron;" the particles are simply arranged in polar order with their longest axis in the line of the tube; this, of course, diminishes the obstruction offered to the passage of light when the particles are floating about in all directions. If the beam of light were sent across the tube, probably the light would be diminished, owing to the concentration of the particles in that direction.—SIGMA.

[11770.]—**Magnetic.**—I am of opinion that "H. G. W.'s" needle was all right if he had let it alone. He has probably neutralised it by using the wrong end of his horse-shoe magnet in his manipulations, or he has rubbed in the wrong direction. If he will examine his horse-shoe magnet he will find the north pole marked. Let him use this pole alone, and stroke the needle from north to south, as marked upon the needle, repeating the process until it again becomes magnetic.—J. HOPKINS.

[11770.]—**Magnetic.**—In answer to "H. G. W.," I beg to say I think he must have rubbed the needle with the magnet in an improper manner. The proper way would be as follows:—Apply the magnet directly in the centre of the needle, in such a manner that its north pole would be near the south pole of the needle, and its south pole would be near the north pole of the needle. Then draw the magnet from end to end of the needle with a little friction (keeping both poles of magnet upon it). After a few such rubs, return the magnet to the centre of the needle, and withdraw it, when I have no doubt he will find the needle magnetised. If "H. G. W." applied the magnet to the needle with their respective poles in the same direction, the magnetic state of the needle would be destroyed, owing to the repulsive tendency of like polarities. I should mention, that if a needle is magnetised at all, it must point in the proper direction, provided no magnetic substance is present to interfere with its directive power.—DU FER.

[11774.]—**Caulking Boats.**—An excellent material now very much used for this purpose is cotton yarn. It is spun for the purpose and made up into balls like lamp wicks. It may generally be purchased at a cheap rate at any sea-side town.—A BARRISTER.

[11785.]—**London Blackbeetles.**—Introduce a hedgehog to your cellars or kitchen and it will soon demolish all such pests. Proved.—M. POPE.

[11786.]—**To "J. K. P."**—This query should have been headed "Screw Cutting," as it refers to a query (No. 11426), under that title, on p. 51, to which I gave an answer on p. 104. I have in consequence had to search the back numbers, at some trouble, having forgotten in the meanwhile all about the name of "Digby" and his requirements. "Digby" has only to remember that the wheels are not all in a line, as the joint of the wheel-plate gives great choice of position, and he will then see that if the change wheels are not too coarse in their teeth, he will have room to put on any reasonable variety of trains.—J. K. P.

[11788.]—**Bunions.**—If the case "Der Mend" refers to is a hardening of the skin or corn on the joint of the great toe, it may be relieved by frequent bathing, and using a felt corn plaister; if the great toe is turned away from the straight line of the inner side of the foot, wearing boots large and wide at the toes, and fastened firm round the instep to prevent the boot slipping, will be a great assistance, and will allow the toe to grow back to its old line; but if it is an enlargement of the bony joint (exostosis), I am afraid there is no help for it, as the many cases daily seen prove. Iodine ointments and strong liniments are sometimes recommended, but they have no more effect than to destroy the cuticle of the skin.—R. T.

[11790.]—**Photography.**—Try another sample of collodion; it is impossible to say what is the matter with it without knowing the composition and state of the old collodion. When necessary it should be diluted with sulphuric ether, and not with alcohol, as it is the former which has evaporated, and most collodions have as much spirit added to them as they will bear before they reach the consumer. It does not signify how much salt is added to the precipitating tube, so long as the quantity is in excess of the silver, which is precipitated in the form of gray mud, being, in fact, in a metallic form finally divided. A positive fixing bath, if sufficiently large, may be used for months; if only a small quantity be employed it quickly deteriorates. I should think, from many experiments I have made, that the exposure required in a glass-house would be four or five times as much as in the open air.—A BARRISTER.

A Remarkable Locust.—In a lecture on spontaneous generation recently delivered by Dr. J. C. Dalton, the well-known Professor of Physiology at New York, he remarks that there is no point connected with the habits of animals surrounded by so many obstacles to a complete elucidation as that of their reproduction. The deposit of eggs in one season, which are not hatched until the parents are dead, or have disappeared, for example, Professor Dalton illustrates by the case of an American locust (*Cicada septendecem*). A period of seventeen years elapses between the hatching of the larva and the appearance of the perfect insect, the larva all this time remaining buried in the ground, while the life of the insect in its perfect state does not last over six weeks. A brood of these locusts appeared in the city of New York in 1843, and again in 1860; they return, the Professor remarks, with their accustomed regularity, their next appearance being in 1877.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "W. L. G." has answered 11272; "A Barrister," 11275, 11282, 11283.

11352 Fox Skin, p. 49
11355 Model Steamboat, 49
11356 Candied Peel, 49
11366 Blankets, 49
11368 Precious Stones, 49
11375 Brickmaking in Canada, p. 50
11379 Wardian Case, 50
11383 Sulphur Soap, 50
11385 Salt, 50
11389 On Fortifications, 50
11395 Foreign Wood, 50
11396 Ivory Handles for Whips, 50
11397 Sting-proof Gloves, 50
11404 Analysis of Albite, 50
11412 Painting, 50
11416 Crossbow, 50
11420 Sewing Machine Extras, 50
11424 Botany, p. 51
11425 Fitting New Roller and Lever to Watch, 51
11430 Lapidaries' Tools, 51
11433 Porous Charcoal, 51

QUERIES.

[11791.]—**Col. Stuart Wortley's Emulsion Process.**—Will any photographic reader kindly give the details of this process—the composition of the preservative and the developer, the time of exposure, &c.—R. M. H.

[11792.]—**Compound Engine.**—Could any of "our" readers tell me what proportion the high pressure cylinder should bear to the low pressure cylinder? Also the size of steam receiver for a given size of engine?—FALSTAFF.

[11793.]—**Area of Chimney.**—Can any of "our" readers tell me of a rule to determine the area of a chimney, from a given area of firegrate surface? I have a small heating furnace to make; the area of firegrate is 800 square inches. I should like to know what size of chimney it will require.—FALSTAFF.

[11794.]—**Clutch for Driving-Wheel of Veloce.**—I should be glad if any readers would kindly describe and sketch me a clutch for the driving wheels of a veloce. Essentials: 1. An instant, certain, and firm hold of the driving-wheel, at the commencement of the stroke. 2. Self-acting release at the end of the stroke. 3. Noiselessness during the interval between the strokes. 4. Simplicity.—J. W. TAYLOR.

[11795.]—**Rough Pitch, &c.**—To HENRY W. FIELD.—I return thanks for information in the ENGLISH MECHANIC, of December 22, 1871. Would you again favour me with some information on rough pitch, and how to ascertain the breadth of tool for cutting screws?—THOMAS BRADSHAW.

[11796.]—**Coloured Printing Inks.**—An "Amateur Printer" would be greatly indebted to any person who may be kind enough to inform him the method of mixing the different coloured printing inks, such as yellow, violet, &c.—H. W.

[11797.]—**Preserving Moths and Butterflies.**—Can any of "our" readers oblige by telling me the easiest way of preserving small moths' and butterflies' bodies from decay? I have tried camphor, and that does not have the desired effect.—CHERRYEATER.

[11798.]—**Uncoiling New Wire Rope.**—I shall be obliged if any readers will inform me the proper way to uncoil a new wire rope. Not having had much practice, I am sometimes troubled by the rope twisting very much, when uncoiling by hand, thereby making it difficult to handle, and damaging the rope, besides loss of time.—BOILER-MINDER.

[11799.]—**Botany in Cornwall.**—Would any reader kindly inform me whether there exists a list of the flowers, &c., found in the north of Cornwall, round Bude, stating places where they may be found—also the best book, with plates, for naming the specimens?—T. A. D.

[11800.]—**Electrical.**—I should be glad to know the way by which (1) the electromotive forces of two different kinds of battery are compared; (2) the means of estimating the resistance, both internal and external, of a battery, in terms of a given length of wire, using the T galvanometer, both for 1 and 2. I know that this is possible, but don't see my way quite clearly. Perhaps "Sigma," or some other of "our" electrical friends would help me.—T. A. D.

[11801.]—**Question in Trigonometry.**—Perhaps some kind reader would give some information as to how the following question in trigonometry could be solved. The sides of a triangle, A B C, are given as follows:—A B = 1127; A C = 1044; B C = 953·9. If P be a point within the triangle, at which the sides subtend each an angle of 120°, find the values of A P, B P, C P.—NUMA.

[11802.]—**Date of Patent.**—Can any one please inform me of the date of the patent described in the ENGLISH MECHANIC, No. 324, June 9, 1871, called "An Improved Bakers' Oven"? I have been at work upon such an idea, for a smelting furnace, for some 3 or 4 years, and would if possible, be glad to learn the date of this American patent.—A SUBSCRIBER FROM THE FIRST.

[11803.]—**Euplectella spinosa.**—Can any of your correspondents kindly give me a description of Euplectella spinosa?—A CONSTANT SUBSCRIBER.

[11804.]—**Estate Agencies.**—I should be much obliged if your correspondent, a "Thirteen Years' Agent," who so kindly answered my query on the above [illegible] 11251, p. 153), would now give me further information on the following particulars:—(1) Which are the countries in which a beginner is most likely to succeed? (2) Would that beginner experience any difficulty in finding a gentleman who would be willing to take him as a pupil? (3) What are the usual terms for such education? (4) At what age ought it to commence? (5) How long is it generally continued? (6) What is the usually accepted social position of an individual following this profession?—L.

[11805.]—**Extracting Gelatine from Bones.**—Would the person who informed me that to extract gelatine from bones would require 4lb. pressure give further information? I have tried 4lb. and up to 12lb. without success, and have steamed them till quite soft. The French and Germans obtain it from this method with great success, so please inform me the reason of my failure and what bones you used, and the length of time they require to steam. Do the bones require to be subjected to any chemical preparation before steaming?—R. NEWHAM.

[11806.]—**Power Loom Weaving.**—I should be much obliged to any one who could inform me of any work on power loom weaving, as I want to get some information about the various improvements lately made in weaving plain calico, and the best sort of healds, reeds, and picking and tappit motions?—LANCASHIRE LAD.

[11807.]—**Preserving Heat and Boiler.**—Will any of our readers kindly give advice as to the following:—We have a vertical boiler, half of which and a quantity of steam-pipe is exposed. What is the best covering to keep in the heat and prevent the plates scaling away with rust? Also a few hints how to arrange a sieve to work by power would be deemed a great favour by—SIMPLEX.

[11808.]—**Photographing the Sun.**—Will some one of "our" many astronomical correspondents give me information in reference to photographing the sun? I have tried a flash exposure (slit ¼in. wide) on 3in. achromatic, but all the negatives are solarised, or burned up; also tried with aperture capped down to 1½in. Any suggestions would be acceptable to—PASSYUNK.

[11809.]—**Cool Air in Hot Climates.**—I am living in Malta, with the prospect of remaining here some years, and am told that the summer heat is great and trying, the nights being nearly as hot as the days. Now, if ice can be manufactured cheaply, I see no reason why large houses should not be supplied with a steady flow of cool pure air at a very moderate expense, but this is a matter for landlords to take action in. My object in writing is to see whether, by the kind assistance of some of your practical and ingenious subscribers, an unfortunate tenant, liable to sudden changes of quarters, may not be able to adopt some plan for securing cool and fresh air whilst asleep or quite quiet. I believe a patent has been taken out for making ice by the alternate compression and expansion of air, and, if this answers, it is evident that about 1,000 cubic feet of air could be reduced 15° in temperature, instead of converting 1lb. of water into ice. According to a late number of "ours," cars have been actually propelled by means of cases of compressed air, then, why should not a box bed or miniature sitting room be constructed of some non-conducting material, and be furnished with one of these cases, so arranged that the air in escaping from it should draw in a current of external air, cooling it to 60°, exactly as it cools the water in the ice-making machine, and at the same time driving out the hot respired air? What a boon some such arrangement would prove in India. I shall be much obliged for information as to nature and cost of machinery for compressing air, and of cases to contain the air, and to whom I might apply to try and get this idea carried out. Also for any suggestions of some more feasible plan.—C. H. B.

[11810.]—**Colds in the Head, &c.**—Will some one kindly acquaint me with a remedy for continual colds in the head, accompanied by a constant stuffing of the nostrils, and consequently producing a most annoying and disfiguring enlargement of the nose?—X. Y.

[11811.]—**Lime-juice and Glycerine.**—Will "Mayland" (reply 11593) kindly say the quantities each of glycerine, carbonate of potash, and lime-water?—COUNTRY BARBER.

[11812.]—**Aerated Waters.**—Will a brother reader kindly inform me whether I can make the above in small quantities, and if so, give particulars of same, to be used for lemon and other syrups?—COUNTRY BARBER.

[11813.]—**Oatcake Making and Baking Machine.**—Could any kind reader inform me if he knows whether such a machine is made for making or baking oatcakes? I know in some parts of Lancashire oatcakes are sold wholesale very much, and I have been told there are machines in existence for this purpose. Are there?—T. E.

[11814.]—**Lathe Queries.**—Would "J. K. P." inform me if there is any other way of fitting a double coned mandril than the (to all appearance) complicated one of Whitworth's, I mean, for a single gear lathe? In what way are the lighter lathes of the ornamental makers fitted? Are theirs different, or is Whitworth's considered the best method?—ANGLO-CELTIC.

[11815.]—**Fishing Rods.**—Can "Jack of All Trades" tell me if the first-class English rod makers use any particular kind of plane for rounding or finishing their rods? as I was informed by an Irish maker that the superiority of English rods resulted from some secret of the kind. Also could he give me the secret of the brown stain used for the ashen butts?—ANGLO-CELTIC.

[11816.]—**Fixing Balance-Wheel on Verge.**—I should be obliged to "Yorkshire Pivot" or "West Cornwall" if they would tell me the best method to fix the balance-wheel on the verge. I have had to put a new verge in; the brass was too high to hammer down, and pivots too long, which was very difficult, not having the proper tools. I am obliged to both of them for their recent information. I hope they will not quarrel about which gives the best information. I did use solder to fasten the escape-wheel in lever watch.—S. H. L.

[11817.]—**Portland Cement.**—Could any of your numerous correspondents give the best plan of kiln for burning Portland cement, and how long it requires to burn the same, and what proportion of fuel to cement burnt? Also what kind of machine used for crushing before entering the mill, to be ground fine? Any practical advice on the above will oblige—RELWOT (Hungary).

[11818.]—**House Heating.**—Fuel being extremely dear on the Continent, could any of your numerous correspondents give a practical plan of heating four rooms with one fire, they all being on one floor, and forming a square? Say from the cooking stove, it being placed in one of the four rooms.—RELWOT (Hungary).

[11819.]—**Roof of International Exhibition Building.**—On what principle is the glazing of the above roof done?—H. B. E.

[11820.]—**Gas Bags.**—I shall feel very grateful if some kind reader will oblige me by answering the following questions, to enable me to construct a gas bag and pressure boards for oxygen gas:—1. What kind of twill is employed for the bags, and where obtainable? 2. How are the seams made in the twill, and how is the tubing connected? 3. Is there any difference in construction of the bags used for oxygen and hydrogen? 4. How are the pressure boards made?—J. HUGHES.

[11821.]—**Holly.**—Can some one tell me how holly ought to be treated in order to preserve the extreme whiteness of the wood? That which I have cut down and seasoned in a dry room, though good and sound, is not white.—X. X.

[11822.]—**Slide Rest.**—Would "J. K. P.," or some other reader, kindly give me the sizes for a 3½in. slide rest, as I should like to fit one up for my lathe? I am going to make my own patterns; as I have no planing machine, I shall have to fit them by hand. A few hints as to the best way of doing the same would greatly oblige—AMATEUR ENGINEER.

[11823.]—**Holtz's Electrical Machine.**—Will some one of my fellow subscribers help me in a difficulty? I am endeavouring to make a Holtz's electrical machine, like the one figured on p. 90. I cannot succeed in cutting the windows and central hole. If any one will tell me the proper method, I shall be very much obliged.—J. STARLING.

[11824.]—**Punching Machines.**—Can any reader tell me the best kind of steel to make punches to punch through ½in. bars, and the best way to temper the same?—A CONSTANT SUBSCRIBER.

[11825.]—**Testing Bleaching Powder.**—Would some of our readers give me the means of testing chloride of lime or bleaching powder? Can none of our able chemists give this test, as it would be of great service to me and perhaps a few more of our readers, as I have seen the question asked before, and it has not been answered.—BLEACHING POWDER.

[11826.]—**Tinning and Soldering.**—Seldom a week passes but questions on this subject are asked and answered in the ENGLISH MECHANIC, but I do not recollect any reason given why the articles are tinned. During the articles on the "Amateur Workshop," which appeared in an early volume, it was stated that rosin was employed, and sometimes tallow, to prevent oxidation of the surfaces to be tinned, and I think if this was the only condition necessary, then rosin would only be required for tinning iron, &c.; but as we require chloride of zinc or salammoniac, &c., to tin iron, &c., I suppose there must be some other reason for these substances being used, besides the preventing oxidation on the surface of the metal, particularly as these things seem more likely to favour than retard such oxidation. Can any of our talented correspondents give us any information on this subject? I have set up a theory of my own to account for it, but as I am not able to carry out the requisite chemical manipulations to prove its correctness or otherwise, I shall be thankful for the information from those who may know better than myself. My reason for asking this question is, that as the solder and the surface of the metal seem to be so well amalgamated, then if the conditions requisite for this amalgamation were thoroughly understood and could be applied to the whole of the particles of the metal when in a molten state, it may be a step in the direction of alloys of metals not at present used, say an alloy of iron with lead or tin, which, while possessing the rigidity of iron, would yield more easily to the file or turning tool.—A. B.

[11827.]—**Sight.**—I want the opinions of some of our oculist readers on the following:—I cannot see distant objects at all distinctly, things appearing double or treble if very far off. Printing the size of that in the MECHANIC appears most distinct at the distance of 4in. from my eyes, and when writing I often find my cheek touching the (6in.) penholder. I cannot read the name over the shop window across the street, and the letters composing it are 6in. high. At experimental lectures I lose half the pleasure and benefit from not being able (from the middle of the lecture-room) to see what is done by the lecturer at the table. When out for a walk with others, a distant object, say a house or church, is pointed out, but I cannot see it, when it is plainly visible to others. But how is it that I can, by looking through a pinhole, held close to my eye, read the name opposite, count the windows in a distant house, and read letters 6ft. off, which, otherwise, appear only a lot of misty strokes? Is mine a case of myopia, or is it weak sight? I do not fancy it is the latter, as I can see well enough when objects are brought sufficiently near. Should I wear spectacles (and, if so, how may I know the degree of concavity?), or what other remedy can I adopt? What are the "invisible" spectacles?—W. P.

[11828.]—**Duration of Boiler.**—A common saddle boiler has been in constant use for heating my plant houses rather more than eleven years. Is there any reason to conclude, merely from its age, that it is becoming unsafe? By what tokens may approaching insecurity in a boiler, from wearing out, be suspected? If mine be replaced, which is considered the best form of boiler? Is the double L a very good one in all respects?—P. H. G.

[11829.]—**Tackle Poles.**—Will some correspondent kindly tell me the best way to fasten two poles at the top for a block tackle, with loops for hanging on the block and fixing guys?—A. B.

[11830.]—**Indicating Tablets for Electric Bells.**—I should be much obliged if some of "our" electrical friends would explain the construction of the indicating tablets for electric bells. A sketch would assist.—W. BOLTON.

[11831.]—**Thermometer.**—Can any of "our" correspondents inform me of the reason of the mercury [illegible] thermometer dividing, so that it registers [illegible] degrees higher than the actual heat? Also [illegible] would oblige.—A. G.

[11832.]—**Paper-hanging, Sizing, &c.**—I have lately built a house, and would like to know which is the best means to be used before putting on the paper-hangings. Should the walls have a coat of size? or should they be coloured with brown umber or some such colour? or is the paper best put on the bare walls just as the plasterers left them? and what time should elapse after plastering before the paper may be put on? The stone jambs of fireplaces I want to paint—should they be sized, and how many coats of paint should they have?—J. F. R.

[11833.]—**Smoky Chimney.**—I have a fireplace in a back kitchen, the flue of which runs up the eaves at the back of the house. The chimney-pots' tops are 7ft. above the eaves, while the ridge is 9ft. The consequence is, when the wind blows over the ridge, the chimney smokes. As it would be expensive to raise the chimney on account of the difficulty of scaffolding, could any form of chimney-pot be used that would prevent the smoke?—J. F. R.

[11834.]—**Springs.**—Will "Jack of All Trades" kindly give the process adopted to temper gun-lock springs, as those are made in Birmingham. I can make them after a fashion, but not satisfactorily. I harden by immersion in water when at a red heat, and then fry them in tallow until the tallow is burnt up, allowing them to cool in the pan. If a lead and tin bath is used, will he kindly give the proportions of the metals?—AN OLD GUNNER.

[11835.]—**Arsenic in Wall Papers.**—Can any of "our" readers inform me of a simple and easy mode of ascertaining whether any preparation of arsenic has been used in colouring wall papers? I believe the very bright and vivid shade of green called "Scheele's green" is a chemical compound of arsenic and copper, and the application of a drop of liquid ammonia to the paper will indicate the presence of the latter metal, by turning the green to a bright blue; but I have heard that some of the less brilliant shades of green paper really contain arsenic, and in these its presence is not so readily detected.—G. C. C.

[11836.]—**Voicing Organ Pipes.**—I am now far advanced in the construction of a small organ, having everything ready for the metal pipes. Now, I am but a poor man, and could not see my way to purchase metal pipes, so I made a row of zinc ones, but try as I will, I cannot get anything but a cracked note out of them, and I am persuaded that this is owing to the voicing. Why should I fail? I am not acquainted with any organ-building friend, and know nothing of the subject but what I have learnt in the MECHANIC, but nowhere can I find a clear explanation of the voicing. Would some kind friend assist me out of the difficulty? I have a row of S. Diapason, one of flute with the bevil of the mouth inside, and a row of zinc pipes; they all want voicing; how must I proceed? I have still room for another row of metal pipes. Would it be breaking the rules the editor has laid down to ask where I should get them cheapest, and what would be the cost?—ALEPH.

[11837.]—**Organ Bellows.**—Will "J. D." or any other correspondent kindly tell me the dimensions of bellows required to supply efficiently an organ containing the following stops, and if these described by "J. D." will be large enough for the purpose?—

GREAT ORGAN CC TO G, 56 NOTES.

		Pipes.
1	Open Diapason, large scale	56
2	Open Diapason or Gamba, small scale, ten C	44
3	Stop Diapason	56

PEDAL CCC TO E, 29 NOTES.

11	Bourdon	29

—Y. Z.

[11838.]—**Clock Pallet.**—Would "Yorkshire Pivot" or "West Cornwall" give the best method of making an anchor-shaped pallet for an eight-day cased clock, or any other shape?—LANCASHIRE AMATEUR.

[11839.]—**Plates Chemically Clean.**—I hear that Dr. Anthony says, in a paper read to the Photographic Society, that he finds cleaning his plates in a bath of cyanide of potassium to be the best means of making them chemically clean. It seems to me that the sensitising bath would be spoiled by introducing plates cleaned with cyanide, and if the plates be washed under the tap after using cyanide I fancy that they might become greasy or otherwise unclean. I should feel greatly indebted to any fellow reader for a few suggestions regarding this or any other expeditious mode of making plates chemically clean.—ADOLESCENS.

[11840.]—**Whooping Cough, &c.**—Will a subscriber kindly inform me how to make balsam of horehound and aniseed? also an effectual remedy for whooping cough?—T. C. H.

[11841.]—**Human Relics.**—Will any correspondent oblige me with a little good information regarding the oldest human relic in the world? I believe it is to be seen in the Etruscan Vase Room at the British Museum. If I mistake not, it is the skeleton of Pharoah Mykerinus.—RALPH LOWDON.

[11842.]—**Indiarubber Gig Apron.**—Will any reader of the MECHANIC kindly inform me how to prevent the above sticking together when sat upon?—Z.

[11843.]—**Iron Castings.**—Will some fellow reader give me some information respecting the method of obtaining a solid casting when a wrought-iron bar is put in? I have tried by putting the bar in red-hot, but this does not answer.—PERRY.

[11844.]—**Rabbit Skins.**—The "Hampshire Farmer" has not responded to my inquiry about the red weed. I fancy it is the *persicaria*, which has a pink or reddish hue over the whole plant, and is a great weed wherever it gets a chance of seeding and growing. My rabbits are now increasing so fast that I shall soon be putting them to account, but as we mean to eat, not sell them, I want a hint as to preserving the skins. Can any of our friends say how they should be dressed in a simple ready way?—SENECIO.

[11845.]—**New and Excellent Sun Screen.**—Will Mr. Berthon (let. 4037) have the goodness to explain how the film of silver is deposited? He says the process is "extremely easy, and may be done by any one in a few minutes." I suppose an ordinary concave lens answers the purpose—it need not be a Barlow?—ALBIREO.

[11846.]—**Gold Beating.**—Can any reader explain the process of beating gold-leaf?—AN AMATEUR GILDER.

[11847.]—**Curry.**—Will some contributor kindly give a recipe for making curry? Captain White's is generally considered best. Is the recipe of this known?—PETTY CURY.

[11848.]—**Conic Sections.**—How must a cone be cut to produce the different conic sections—viz., the ellipse, the parabola, and the hyperbola, especially the two latter?—RUSTICUS.

[11849.]—**Printing in Canada.**—Would some subscriber having correct information kindly say what would be the prospects of a printer in Canada with a small capital (say £150)? and would it be advisable to take the cash or material?—A COUNTRY PRINTER.

[11850.]—**Pitches of Screws.**—I shall feel obliged to any of your readers, practical shipbuilders, who will give me the following information. A known vessel of fine lines, whose displacement is 3,500 tons, is propelled by an 18ft. screw, of 28ft. pitch, at the rate of 14 knots per hour, the screw making 55 revolutions per minute. Its disc area is 254 sq. ft. Is it probable that another vessel of like displacement, but drawing only 10ft. of water, could be propelled by three or four screws of about 16ft. pitch and 9ft. diameter, making 100 revolutions per minute at the same rate, assuming the position of the screws, lines of vessel, midship section, skin resistance, &c., to be equally favourable for speed in both cases? or would power so applied be wasted, and result only in churning the water? I should be glad to know, also, whether pitches of from 15ft. to 20ft. have been found admissible in practice for screws of about 10ft. diameter. I am under the impression that Rennie, about the year 1856, made some experiments, giving favourable results, with small screws driven at high velocities, and read a paper on the subject at a meeting of the British Association.—T. C. H.

[11851.]—**Supercargo.**—Will some obliging reader inform me what are the duties of a supercargo on board a merchant ship, what qualifications should a person have to fill such a situation, and what salary would he receive for going to Australia? Are such jobs easy to get?—O. N. C.

[11852.]—**Pallet Springs.**—Will "Jack of All Trades" tell me of what size and number the wire most suitable for making the above should be?—MUSICAL.

[11853.]—**Pedal Harmonium.**—Will any brother reader give me the dimensions for a set of 29 pipes for a pedal harmonium, the reeds to be 16ft. tone, and how to put the reeds on to them? Also a plan for a foot-blower for the bellows, which is a single feeder, 10in. fall.—G. J. C.

[11854.]—**Raising Salt Water.**—How is salt water usually raised to bath-houses? Is there any other way except by manual labour? How many feet above high-water is usually necessary for the water to be raised to enter the bath or bath cistern?—PHILANTHROPIST.

[11855.]—**Hygrometer Motive-Power.**—What is the substance that turns the index of the hygrometer that is generally on the top of the wheel barometer or weather-glass? I have tried catgut, but without success.—THOMAS DUNLOP.

[11856.]—**Military Examination.**—Would some one advise me on this subject? The requirements for this examination include mathematics, modern languages, and history ancient and modern, with geography. Does this include all the different branches of mathematics? If not, how many? How many modern languages are required? I would be thankful for a few hints on this examination relating to the age of the candidate. Perhaps "Sword and Pencil" or "Artillery Captain" would answer this.—ARIEL.

USEFUL AND SCIENTIFIC NOTES.

Caution about Potatoes.—The use of potatoes is a preventative against scurvy, if not an actual cure for it. Potatoes that have been exposed to the air, and have become green, are unwholesome; and new potatoes—*i. e.*, unripe ones—have much to do with the prevalence of cholera, and such like diseases, during the summer months.—*Food Journal.*

Fruit and Grape Wine.—The main point of interest in distinguishing between the wines is, says Dr. F. Vorwerk, that the phosphoric acid present in genuine grape wine is combined with magnesia, while in fruit wines it is present in combination with lime. The simple addition, therefore, of ammonia (1 part to 9 parts of wine) will produce in genuine wine, after twelve hours' standing, the well-known precipitate of ammonia-phosphate of magnesia.

Flexible Marble.—There has been exhibited in America a flexible marble slab, which is procured from the Portland quarries, Vermont. Professor Hay, of the Western University, of Pennsylvania, describes its constitution as—carbonate of lime, 97·50; magnesia, a trace; silica, 2·05; water, 45 = 100. The above composition and its crystalline character together proclaim it to be a true marble, and, at the same time, a pretty pure specimen of that mineral. The indubitable flexibility of the slab is its most remarkable feature. Dana states that "some of the West Stockbridge marble is flexible in thin pieces when first taken out." The slab in the possession of Mr. Holliday is about 2in. thick, and is nearly as flexible as an equal thickness of vulcanised indiarubber.

New works will soon be erected on a large scale at Cambuslang, Scotland, for the manufacture of steel rails by the Siemens-Martin process.

At Reay, Caithnesshire, a very large deposit of hematite ore of a superior quality has been found, and satisfactory reports are made by the surveyors.

Communications which can only appear as advertisements to hand from Delves, Adver, Workman, F. G. W., J. H. Savage, A Joiner, W. Bull, Calculator.

AMATEUR GILDER, E. J. R., W. L. Clarke, and S. W., are respectfully requested to consult indices of three last vols. of ENGLISH MECHANIC.

J. A. G.—Your query involves the whole history of the American Continent. How considerate! There are a few people who appear to think that the ENGLISH MECHANIC was made exclusively for their especial benefit, and you are one of them.

MUSCOVADO thanks "Cocoa-Nut" for the kind and courteous manner in which he favoured him with information on Jamaica.

A SUBSCRIBER (Lewisham) and 3RD CITY are referred to indices to back vols.

R. M. HATCH.—You appear to require all the minute details of Col. Stuart Wortley's dry-plate process. As we do not recollect them we have inserted your query. The developer is an alkaline one—if we recollect rightly carbonate of ammonia, and the preservative is a gum and tannin formula.

ONE AFFICTED.—Consult a medical man.

D. Y. Z., and GO-AHEAD.—Write Lockwood and Co., Stationers' Hall-court, for a catalogue.

W. F. R.—We know of nothing but hair powder.

AMBOLE.—You cannot expect us to give space for the unimportant details you want. Write Millikin and Lawley for their pamphlet, "Model Steam Engines and How to Make Them."

RALPH LOWDON.—We scarcely think your conjectures concerning the Roman name of the Trent deserve the space they would occupy.

P. W. H. J.—Drawing to accompany reply 11656 (Boiler for Small Steamboat) is mislaid, or was not sent. Will you send another?

RUDEZ.—Inexpensive; advantage nominal; must be done personally.

A. H. C.—The illness of your birds is doubtless due to the cause mentioned, and no remedy will be thoroughly effectual short of substituting tinned wire for the corroded copper wires at present in the cage.

PADDINGTON.—We believe it has been decided that a person may not alter his ancient lights without endangering his right to them, that is, if the alteration be an enlargement or increase. In such case the owner of the adjacent property may entirely obstruct them until they are reduced to the original form and number, but no longer. Ancient lights cannot, however, be obstructed merely because the owner has opened new ones, but only where in obstructing new lights, he unavoidably obstructs the ancient ones also. See "Every Man His Own Lawyer," p. 72. We believe a book on the subject has been published by Mr. Homersham Cox, but forget the name of the publisher.

H. BIRCH.—What do you want to know? The idea of the caliper compass referred to is, of course, founded on the fact that the circumference of a circle is 3·1[illegible] times that of its diameter.

TELEGRAPHIST.—Culley's "Handbook of Practical Telegraphy," 14s., Longmans and Co.

P. E. T.—Zinc tubing would be better and much cheaper.

L. E. L.—Write to the Commissioners for the Reduction of the National Debt, Old Jewry, or procure prospectuses from half a dozen of the best insurance companies. Your distilling apparatus is identical in principle and form with several that have appeared in our columns.

M. O.—We will illustrate the contrivance if you will send a fuller description. A sketch showing the action of the machinery in the central pedestal would be desirable.

C. J. SMITH.—Glass-making was fully described in the ENGLISH MECHANIC about two years and a half since.

T. N. B., BOILER FEEDER, and M. A. send queries which can only appear in the advertisement columns.

E. G. CLARKE.—Please send drawing.

J. H. HOLMES, of Cambridge, says, in answer to our note a week or two since, he has invented a successful hair-cutting machine.

B.—You don't attempt to answer "E.L.G.," but criticise his involved sentences in still more involved sentences. If "E. L. G." is diffuse, he says something worth listening to; you are diffuse and say nothing.

J. RAE.—You are not the first who has complained that our print is too small for most of our readers. We may possibly make a slight modification at the commencement of a new volume.

J. RICHARDSON.—Consult last few numbers.

A. HILDEBRANDT, Hon. Sec. of the Manchester English Mechanics' Society, has sent us a report of the last year's proceedings of the society, including a list of the papers read, and also a list of the subjects discussed, including "Heating Surfaces and Firegrate Area of Steam Boilers," "The Lever," "The Pendulum," "Balancing of Locomotives," "Railway Wheels and Axles," "Feedwater Heaters," "Feeding Apparatus," "Incrustation of Steam Boilers," &c. But what practical good can be realised by our readers by merely recording the names of the subjects discussed? Our readers would, no doubt, be glad to know the salient points of the discussion, which might lead to a still deeper and wider discussion in our columns. The formation of English Mechanic Societies in Edinburgh, Manchester, Bristol, and elsewhere, may be of advantage to local members, but what they have gained in some instances our readers have lost, as the prominent members, or some of them, who used to give the scores of thousands of ENGLISH MECHANIC readers the benefit of their experience now confine their teachings to local limited societies. So a movement which was at one time hailed with satisfaction has not proved an unmixed blessing. We are in favour of the largest amount of knowledge to the largest number of persons. Though we cannot find room for a dry record of names and subjects of papers read, we should be glad at all times to give the essence of such papers and discussions.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING APRIL 30, 1872.

1208 L. T. Grousain, Paris, for improvements in infants' cradles or cribs.

1209 E. Peyton, Birmingham, for improvements in spring mattresses and other elastic surfaces for sitting and reclining upon.

1210 A. M. Clark, Chancery-lane, for an improved motive-power engine, applicable also as a pump. A communication.

1211 W. H. Davey, Islington, for improvements in washing machines.

1212 N. Thomas, Glasgow, for improvements in heating feed water supplied to steam boilers.

1213 W. A. Lyttle, The Grove, Hammersmith, for improvements in poles for telegraphic and other purposes.

1214 J. Kite, Vauxhall, for a new or improved apparatus for basting food in cooking.

1215 J. W. Gray, Billiter-street, City, for a new or improved lithoidal composition to be used as a paint and for other purposes. A communication.

1216 A. Cochrane, Gracechurch-street, City, for an improved mode of and apparatus for facilitating the teaching of languages, arithmetic, and other sciences (such as chemistry and anatomy) in which diagrams or pictorial illustrations are required.

1217 J. E. Outridge, Lewisham, Kent, for improvements in equilibrium slide valves.

1218 A. M. Clark, Chancery-lane, for an improved process of hardening tiles and other moulded articles. A communication.

1219 A. Paget, Leicester, for improvements in apparatus for raising, propelling, and distributing water and other liquids.

1220 W. Scott, Bilston, Staffordshire, for improvements in the bottom plates and bearers for puddling and balling furnaces.

1221 W. Broughton, Derby, for communicating between railway passengers and the guard and driver of railway trains.

1222 R. Maynard, Whittlesford, Cambridge, for improvements in portable mahinery for husking and dressing clover and trefoil, and other similar kinds of seeds.

1223 W. A. Gilbee, South-street, Finsbury, for improvements in the manufacture of shells and shot and in the machinery or apparatus employed therefor. A communication.

1224 E. Simcox and W. Banks, Birmingham, for improvements in box irons.

1225 A. E. Webb, Jamaica-street, Stepney, for a method of destroying the labels on bottles, jars, and other similar vessels on the cork or stopper being drawn therefrom.

1226 G. Westinghouse, jun., Southampton-buildings, for improvements in apparatus for working brakes on railway trains by compressed air, parts of which improvements are also applicable to brakes worked by other means.

1227 T. Midelton, Stratford, for an improved method of securing greater adhesion in railway locomotive engines.

1228 R. Maynard, Whittlesford, Cambridge, for an improvement in horse-shoes and drills.

1229 C. G. Kleberg, Martin's-lane, City, for improvements in the manufacture of sugar and in the apparatus employed therein. A communication.

1230 W. Richardson and J. Fidler, Oldham, for improvements in cotton gins.

1231 W. Cunningham, Dundee, for improvements in snipping, combing, and beating jute, flax, and other fibrous substances, and in the machinery or apparatus employed therefor.

1232 L. Pochet and L. Lemoine, Paris, for an improved system and machinery for removing smoke, vapour, and gas proceeding from locomotive engines in tunnels of railways.

1233 H. H. Doty, Bury-street, St. James's, and E. T. Gardner, Strand, for improvements in roof lamps for railway carriages.

1234 L. W. Pritchard, Kensal-green, for improvements in valves.

1235 W. C. Holmes, Gracechurch-street, City, and W. Hollinshead, Peckham, for improvements in the process of manufacturing gas, and in the apparatus employed therein.

1236 J. K. Collett, Cardiff, Glamorganshire, for improvements in packing and preserving butter.

1237 M. Cendle, Glasgow, for improvements in sewing machines.

1238 F. Durham and H. E. Hupton, Lowestoft, Suffolk, for an improved indicating or checking apparatus.

1239 B. Naylor and T. Gelderd, Leeds, for improvements in machinery or apparatus for tilting barrels, casks, or other receptacles.

1240 H. Gahn, Sweden, for improvements in cosmetics called "amykos."

1241 J. Bain, Liverpool, for improvements in screw-drivers. A communication.

1242 C. W. Vick and J. Cooke, Stroud, Gloucestershire, for improved machinery for feeding, preparing, and carding engines.

1243 S. W. Rich, Chenies-street, Tottenham-court-road, for improvements in the manufacture of sulphates.

1244 W. R. Lake, Southampton-buildings, for improvements in steam engines and parts connected therewith, chiefly designed for the propulsion of street vehicles. A communication.

1245 A. M. Clark, Chancery-lane, for improvements in drying and bleaching fabrics and fibrous materials, and in apparatus for the same. A communication.

1246 A. M. Clark, Chancery-lane, for improvements in locomotive engines and carriages and permanent way for the same. A communication.

1247 J. Lewis, Preston, for improved studs for sharpening horse-shoes for frosty or slippery roads, likewise applicable to boots and shoes.

1248 J. Witty, Manchester, for improvements in the manufacture of packing material.

1249 E. Gardner, West Strand, for improvements in lamps to enable them to burn hydrocarbon oils.

1250 C. F. Whateley, Birmingham, for improvements in railway, ship, and other lamps.

1251 M. Mayer and A. V. Deshayes, Paris, for improvements in embroidering machines.

1252 G. Cazes, Paris, for improved machinery for screwing boot and shoe soles and other articles.

1253 J. Oppenheimer, Manchester, for improvements in recording votes and in apparatus connected therewith.

1254 J. H. Johnson, Lincoln's Inn-fields, for improvements in magneto-electric machines. A communication.

1255 W. E. Gedge, Wellington-street, Strand, for an improved draught apparatus for steam-engines. A communication.

1256 C. Powis, Gracechurch-street, City, for improvements in umbrella and parasol slides or runners.

1257 W. R. Lake, Southampton-buildings, for improved processes of treating phosphatic rock and other phosphatic substances for the extraction of the phosphoric acid or soluble phosphates therefrom. A communication.

1258 M. Benson, Southampton-buildings, for improvements in elastic hose stockings for horses. A communication.

1259 P. Prince, Derby, for a self-acting regulator for the variations in the length of metallic wires employed in working signals on railways, &c., when caused by atmospheric temperature.

1260 B. Clark, Bilston, Staffordshire, for improvements in connecting crochet needles or crochet hooks to their handles.

1261 S. Chandler, sen., S. Chandler, jun., and J. Chandler, Southwark, for improvements in apparatus for cleansing water-closets.

1262 J. Chadderton, J. Allmark, and B. Haigh, Dukinfield, Cheshire, for improvements in cocks and water gauges.

1263 T. D. Eagles, Fenchurch-street, City, for an improved method of warming or heating rooms, railway and other carriages, and which is also applicable to general domestic use. A communication.

1264 W. A. Lyttle, The Grove, Hammersmith, for improvements in the preparation and utilisation of bituminous asphalte.

1265 E. A. Cowper, Great George-street, Westminster, for improvements in the process of converting wood and other fibrous materials into pulp, and in apparatus therefore.

1266 J. H. Johnson, Lincoln's Inn-fields, for improvements in apparatus for facilitating the examination and repairs of the submerged parts of ships or vessels. A communication.

1267 H. J. Smith, Glasgow, for improvements in extracting metallic oxides and in precipitating oxides from metallic solutions.

1268 J. Young, Kelly, Renfrewshire, for improvements in the manufacture of carbonic acid.

1269 R. Clews, Dundee, for improvements in weaving the end borders of rugs and mats.

1270 W. M. Brown, Southampton-buildings, for improvements in steam generators. A communication.

1271 J. S. Richard, Southampton-buildings, for improvements applicable to warping or beaming machines, and to other machines in which excessive slackness, breaking, or exhaustion of a thread, other than a weft thread, necessitates the stopping of such machines, and also cases where an expanding comb is required.

1272 J. Ducomet, Paris, for an improved construction of packing cases. A communication.

1273 R. Atkin, Crawford-street, Portman-square, for improvements in the construction of ships and other floating vessels.

1274 E. Russell, Millwall, for improvements in screw caps or covers for the axle-boxes of carriages and other vehicles for common roads.

1275 J. G. Tongue, Southampton-buildings, for improvements in the manufacture of cut pile, Brussels, or Wilton and tapestry carpets, and other pile fabrics. A communication.

1276 J. B. Fenby, Birmingham, for improvements in apparatus for regulating the flow and pressure of fluids.

1277 S. G. Soame, Marsham, Norfolk, for improvements in elevators for raising and stacking hay, corn, straw, and other similar substances.

1278 R. McVey, Jarrow-on-Tyne, for improvements in steam engines.

1279 H. Highton, Putney, for improvements in submarine or other cables for the conveyance of electricity.

1280 E. S. Lenox, New York, U.S., for improved means of concentrating light and in appliances connected therewith.

1281 G. Ayres, New Cross, Kent, for improved means of signalling on board vessels and in appliances connected therewith.

1282 A. Prince, Trafalgar-square, Charing-cross, for improvements applicable to tobacco pipes and cigar tubes. A communication.

1283 C. Woolley and G. H. Woolley, Mark-lane, City, for improvements in the construction of bottles, decanters, and other similar vessels, and means for closing the same.

1284 C. Woolley, Mark-lane, for improvements in the construction of bottles, decanters, and other similar vessels, and in means for closing the same.

1285 E. Pace and J. H. Howard, Bow-common, for improvements in machinery or apparatus for cutting splints.

PATENTS SEALED.

2575 E. P. Baville, for improvements in tool holders.

2583 T. W. Lockyer, for improvements in the manufacture of silk, linen, cotton, and other fabrics, so as to resemble horse-hair cloth.

2906 C. F. Claus, for improvements in the manufacture from blast-furnace slag of blocks suitable for building purposes.

2907 J. Roberts, for improvements in the construction of floating swimming baths and of the approaches to be used in connection therewith.

2908 J. H. Johnson, for improvements in paving and asphalting roads, streets, and footways, and in the composition employed therefor.

2921 S. J. Machen, for improvements in boilers used for the circulation of hot water for heating hot-houses and other similar structures.

2926 A. P. Vassard, for improvements in treating liquid sewage and other ammoniacal liquors.

2930 J. G. Cameron, for improvements in apparatus for steering ships by steam power, partly applicable to the slide valves and valve boxes of steam-engines generally.

2971 T. Briggs, for improvements in waterproof and other fabrics.

2980 J. C. R. Okes, for improvements in working steam-engines and pumps in mines for draining purposes.

3051 R. Wolstenholme, H. Buckley, and R. W. Buckley, for improvements in the mode of manufacturing velvets and velveteens.

3189 C. D. Abel, for improvements in rotary or centrifugal pumps.

3339 A. Tylor, for improvements in apparatus for regulating the working and ventilating of mines, buildings, sewers, and underground workings, and for increasing the certainty, safety, healthiness, economy, and facility of conducting such operations, and for the distributing, regulating, measuring, and purifying of liquids and fluids, such as air, vapour of water, smoke, and water, and in setting out and proportioning liquid and fluid passages and channels for irrigation and other purposes, and in the arrangements connected therewith.

3350 G. Ireland, for improvements in the manufacture of knives and forks.

3493 F. Clinch, for improvements applicable to the feet of horses and other animals.

195 W. Hulse, for improvements in metallic bedsteads, cots, couches, and chairs, and in machinery or apparatus to be employed in the manufacture of the said articles, parts of which improvements are also applicable to the manufacture of metallic railing for other purposes.

363 R. Brough, for improvements in steam-engine governors and speed regulators for machinery.

482 E. T. Truman, for improvements in covering wire or other suitable conductors with insulating materials, and in machinery employed in the covering process.

633 W. Lancaster and J. Bullough, for improvements in machinery for sizing and dressing yarns.

710 G. T. Bousfield, for improvements in sewing machines.

717 W. R. Lake, for improvements in machines for cleaning cotton.

722 W. R. Lake, for improvements in governors for steam-engines.

732 A. Johnson, for improvements in machines for rolling metal.

733 S. H. Hodges, for improvements in machinery for trimming or burnishing the soles or both soles and heels of boots or shoes.

2950 E. V. Neale, for improved methods of governing and arresting the motions of sliding and of hinged or swinging windows, doors, and objects, and of rotating shafts, rods, and objects.

2953 J. Robinson and J. Smith, for improvements in cutting wood into shavings or shreads for the manufacture of paper, and in machinery connected therewith.

2963 J. Shanks, for improvements in and connected with water-closets.

2972 C. Townsend and A. Rollason, for improvements in the treatment of materials and fabrics, rendering such materials and fabrics waterproof and transparent, and also for adapting them to general and surgical purposes.

2994 S. Osborn, for improvements in apparatus for grinding and polishing reaper and mower knives.

3003 E. W. Barnsley and T. Barnsley, for improvements in gutters and down pipes for conducting water from the roofs of buildings and for other like purposes.

3031 J. S. Crabber and W. Mellor, for improvements in machinery or apparatus for rigging or doubling, finishing, and cuttling textile fabrics.

3063 A. MacMillan, for improvements in buttons, and in fastenings for securing buttons, clasps, and such like to garments and other articles, and in tools to be employed for applying the same.

3071 J. Mitchell and J. H. Mitchell, for a new or improved apparatus for utilising the waste heat from steam boiler and other furnaces, thereby economising fuel.

3104 J. Birt, jun., and A. W. Birt, for improvements in life-preserving mattresses for saving life at sea.

3153 J. H. Johnson, for improvements in combined apparatus for the filtration and distribution of water.

3226 J. Crossley, for improvements in kilns for annealing plate glass.

3365 A. Ball, for improvements in invalid beds and couches, and in fittings therefor.

3328 C. Touaillon, for a new or improved process for preventing incrustation in steam boilers.

3378 A. Barrett, for improvements in croquet stands, applicable also to receptacles for implements used in other games.

3509 J. H. Johnson, for improvements in the jaws of machinery or apparatus for breaking stones and other hard substances.

223 A. Ford, for improvements in the mode of treating linseed and other seed and vegetable oils, so as the better to fit them for employment in the arts and manufactures.

269 D. T. Bostel, for improvements in what are known as "dry earth closets" and "urinals."

404 J. H. Johnson, for improvements in the production of alcoholic and other fermented liquors.

439 C. Notara, for a new and improved method and apparatus for separating various kinds and qualities of grain and seed, and for regulating the feed or supply of grain or seed in connection therewith.

465 D. Carter, for improvements in what are known as "dry earth" closets.

520 J. Rice, for improvements in the construction of firegrates, stoves, and furnaces.

592 O. G. Bolitho, for improvements in apparatus for applying railway brakes, also for effecting communication between guards, passengers, and engine-drivers.

669 T. Broughton, for improvements in the construction of foundations of buildings and in apparatus employed therein.

741 F. Cooper, for improvements in finishing velvets and velveteens.

760 W. R. Lake, for improvements in the manufacture of boots and shoes and in apparatus therefor.

The English Mechanic
AND
WORLD OF SCIENCE AND ART.

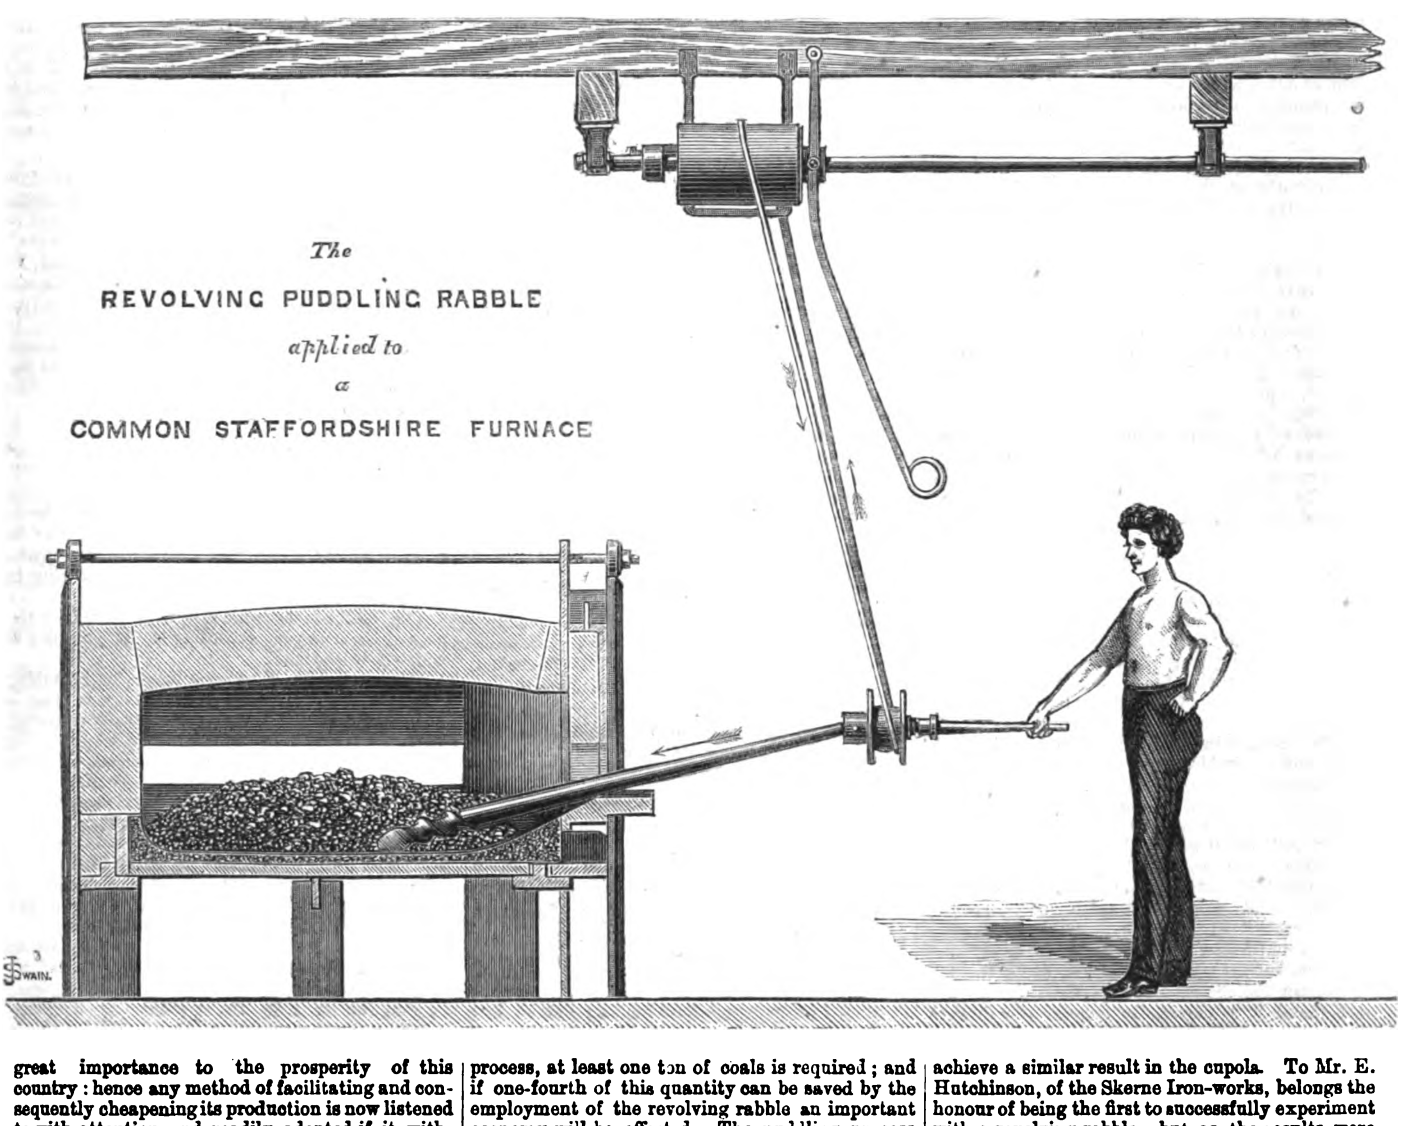
ARTICLES.

DORMOY'S REVOLVING RABBLE FOR PUDDLING.

ANYTHING which in the smallest degree affects the production or the manipulation of commercial iron must necessarily be of interest to large numbers of our countrymen, and especially to English Mechanics. The cheap and rapid extraction of that invaluable metal from its ore, if not of the first, is at least of very great importance to the prosperity of this country: hence any method of facilitating and consequently cheapening its production is now listened to with attention, and readily adopted if it withstands the test of practice. As evidence of this we can point to the way in which the Iron and Steel Institute investigated the merit of Danks's mechanical puddler, which we described on p. 579 of our last volume, and to the efforts of other inventors to accomplish equally economical results without rendering it necessary to make so radical a change as the use of Mr. Danks's ingenious apparatus implies. We have already illustrated the result of one of these efforts, which, following in the track of Mr. Danks, seeks to utilise a portion of the ordinary furnace, while adopting the rotary principle of the mechanical puddler (see p. 83 *ante*), and we are now about to describe an appliance which can be used with the ordinary furnace, and which, it is said, whilst increasing the yield of puddled bar and reducing the expenditure of fuel, relieves the workman almost entirely of the heavier portion of his arduous and exhausting labour. This appliance is Dormoy's revolving rabble, a brief account of which, by Mr. F. A. Paget, C.E., will be found in the ENGLISH MECHANIC, p. 35, No. 366. It will be seen from the accompanying illustration that the principle of M. Dormoy's invention consists in the application of steam-power for operating the rabble while the puddler simply guides it amongst the molten metal. The assistance which this simple contrivance affords to the puddler, and its value from an economical point of view to the ironmaster, formed the subject of a paper read before the Society of Arts last week by Mr. Paget. From this we learn that there are more than 7,700 puddling furnaces in Great Britain, representing an invested capital of more than £1,000,000. If we take 6,500 of these as actually in work, each making about 700 tons in the course of the year, the value of the iron produced would amount in round numbers to about £34,000,000. These furnaces require no fewer than 26,000 men, the majority of whom die before reaching 50, whilst the remainder are incapable of the requisite severe labour on attaining that age. For each ton of puddled bar produced by what may yet be termed the present process, at least one ton of coals is required; and if one-fourth of this quantity can be saved by the employment of the revolving rabble an important economy will be effected. The puddling process consists of four stages—viz., melting, boiling, "coming to nature," and balling. In the first, the pig iron, together with a sufficient quantity of oxide of iron, is placed on the previously fettled furnace bed, and as it softens is broken up by the puddler and mixed with the cinder. After about forty minutes the metal reaches the boiling stage, when it has to be violently agitated by the rabble of the puddler, which requires a great exertion of strength, and is, of course, carried on in a "warm" atmosphere, and with the intense glare of the furnace burning the face and eyes. The iron now thickens and becomes of a stiff pasty consistence, "comes to nature." It is worked in this state from side to side of the furnace, and is separated into pieces, after which it is collected into balls and removed to the hammer or the squeezer—one heat, as it is called, being thus completed. The whole operation lasts for about an hour and a half. It will be observed that nearly one-half of the time thus occupied is taken up by the first stage, the ordinary reverberatory furnace not being a very rapid or economical melting apparatus; and the question will doubtless be asked why the metal is not run into the puddling bed direct from the blast furnace. Methods of doing this have been patented and tried more than once; but hitherto they have resulted in failure, owing to the inability of unaided muscular power to puddle out the largely increased quantity of carbon. But as a matter of fact the melting of the pig in the reverberatory furnace, though costly as regards fuel, is a boon to the puddler, for during the thirty or more minutes occupied by this part of the process his work is comparatively of a light nature, and an opportunity is afforded for recovery from the exhausting exertion required during the latter stages of the previous "heat." But with M. Dormoy's rabble, a saving of fuel could doubtless be effected by melting the cast iron in a cupola, for according to a calculation made by Mr. Paget a charge capable of yielding 400lb. of puddled bar requires about 177lb. of coal merely to melt it in the reverberatory furnace, while 50lb. of coke would achieve a similar result in the cupola. To Mr. E. Hutchinson, of the Skerne Iron-works, belongs the honour of being the first to successfully experiment with a revolving rabble; but as the results were never published, and the use of his apparatus was discontinued within a few months, the idea of a revolving rabble and its successful adaptation to the ordinary furnace may fairly be considered as originated by M. Dormoy. It is a sine-quâ-non that any machinery for the purpose of puddling must be not only simple but free from any tendency to get out of order when subjected to the roughest and most careless treatment. The annexed figure will show how far the inventor has succeeded in meeting these requirements. The rabble is a bar $2\frac{1}{2}$in. in diameter and weighing about 80lb.; one end is loosely jointed to a sheave turning on a pin held in the hand of the puddler. This pin is generally covered with gasketting secured in a leather or rubber sheath to prevent any jarring action to the hand of the workman. An ordinary belt, driven by a broad pulley on shafting about six feet above the furnace, rotates the rabble at any desired speed, and while



supporting part of the weight acts as a universal joint and a friction brake. The belt, of course, readily adapts itself to the variety of positions taken by the rabble in different parts of the furnace and to the progressive changes in the metal, diminution of speed being obtained by permitting "slip" through lifting the weight of the rabble off the strap, while any unusual resistance is overcome by keeping the belt tight and so utilising all the power it gives. The tool is run at the high speed of from 300 to 800 revolutions per minute for white pig, and from 800 to 1,000 for gray, which is found to yield the requisite mechanical energy, the end of one form of rabble, which is 4½in. in diameter, having a surface speed of 600ft. a minute when revolving at the rate of 500 revolutions. The tool when too hot is removed by means of a light chain and hook and laid on low trestles, the substitution of a fresh rabble occupying altogether but thirty seconds. The power required has been indicated at from a quarter to a half-horse per hour for each furnace, the draught being greatest towards the end of the heat. This revolving rabble has been used in France, Hungary, and Styria, and the experience of its durability thus gained has shown that the apparatus is not liable to get out of order, the only part at all likely to give way being the belt; which, however, if properly cared for, lasts about four months, while, in the event of its breaking, the puddler can, of course, continue his operations in the ordinary manner. This difficulty is generally met in practice by providing an extra belt, which can be adjusted in a very short time. Independently of the relief this revolving rabble affords the puddler, there are other advantages attached to its use worthy of notice. Thus from the greater command over the melting metal there is less liability of burning, while by means of the power of steam the iron can be worked after it has come to nature, the rabble working like a drill through the tough pasty mass, and facilitating the after operation of kneading under the hammer. The saving in time, and consequently of fuel, is put at 25 per cent., for charges of 800lb. to 1,000lb. of gray iron are worked by the rabble in twenty to thirty minutes, while white pig requires only from ten to fifteen. No pig, however much carburetted, has, it is said, being able to withstand its action, and soft, fibrous iron, fine-grained iron, or steel, can be produced at the will of the puddler.

It is well known that we have vast quantities of pig iron which remains in that state from the want of puddlers to work it; in fact, the production of malleable iron could be increased by more than one-fourth if the requisite number of hands were forthcoming to do the work. It is claimed that by using this rabble the amount of iron now produced in a year would occupy but nine months, while the remaining three could be utilised as a relief for the men, or in producing more iron, as might be found advisable. But it is also claimed that independently of these advantages the employment of the revolving rabble would give a better quality of iron and a less number of ruinous "cobbles" or "wasters," while it would also facilitate the working up of very gray and inferior kinds of pig without any "fined metal," and would diminish the loss by "mill scale" at the rolls. All these advantages would follow its application to the ordinary furnace, but the proper method of using the tool to obtain the greatest results would be to melt the metal in a cupola, to enlarge the furnace, increase the charge, and to have two doors; but this would, of course, cause alteration, which it is the principal purpose of this invention to avoid. The adoption of the revolving rabble involves no alteration whatever in the present furnaces, and it can be fixed in a couple of hours. During the discussion which followed the reading of Mr. Paget's paper, the chairman, Mr. Jones, of Middlesbrough, spoke very favourably of the invention, and pointed out its utility to those ironmasters whose trade did not require the metal in masses so large as those turned out by the Danks furnace. Mr. Jeavons, of the Millwall Ironworks, said that he had practically tested the invention, and would be pleased to show it to any person interested. It is in constant use at his works, and has given great satisfaction. As an instance of the facility with which the puddling process can be carried out by means of M. Dormoy's rabble, we may mention that at a recent trial at Mr. Jeavons's works an elderly gentleman in overcoat and spectacles brought a heavy charge to "nature" in about a quarter of an hour, working the rabble for most of the time with one hand. It may be hoped, therefore, with the filip thus given to invention of late years in this direction, that while our iron manufacture is improved the puddlers will find some relief from their arduous and killing labour.

LESSONS ON CHEMISTRY.*

By SELIMO R. BOTTONE.

(*Late of the Istituto Bellino, Novara, Italy.*)

(*Continued from p. 112.*)

SECTION 7B.—COMPOUNDS OF SULPHUR WITH OXYGEN.

SULPHUR unites with oxygen in eight different proportions: of the resulting compounds only *two* have as yet been obtained in the free, or uncombined, state; the remainder being known only in the state of combination with the elements of water.

A. SULPHUR MONOXIDE.[1] *Symbol*: $S''O''$ (?). *Molecular weight*: 48 (?).

157.—This body has not been isolated. It may be considered as the anhydride of the following compound:—

A2. MONOTHIONOUS ACID.[2] *Symbol*: $H_2'S''O_2''$. *Molecular weight*: 66.

158.—PROPERTIES.—This acid exists as a lemon-yellow fluid, having a peculiar smell, somewhat resembling that of slightly-tainted beef. Its bleaching properties are very marked, and it might be used to great advantage for the whitening of wool, which is so tenacious of its colouring matter. Unlike most of the members of the "thionic" group of sulphur acids, it does not appear to dissolve the so-called insoluble silver compounds, but is instantly decomposed, with the formation of silver sulphide. It is extremely prone to decomposition at temperatures above 32° Fahr., sulphuric acid being formed, and the liquid becoming turbid owing to the deposition of sulphur in a state of extreme division. The results of a few experiments conducted by the author tend to show that besides sulphuric acid and sulphur, water, sulphuretted hydrogen, and oxygen are also evolved during its decomposition. The annexed equation will give an idea of the probable mode in which these changes take place:—

$$\text{Monothionous acid, 6 mol.}\left\{\begin{matrix} H_2 & S & O_2 \\ H_2 & S & O_2 \\ H_2 & S & O_2 \\ H_2 & S & O_2 \\ H_2 & S & O_2 \\ H_2 & S & O_2 \end{matrix}\right\} = \left\{\begin{matrix} \text{2 mol. sulphuric acid} & H_4 & S_2 & O_8 \\ \text{1 mol. sulphur} & & S_2 & \\ \text{2 mol. water} & H_4 & & O_2 \\ \text{1 mol. oxygen} & & & O_2 \\ \text{2 mol. hy. sulphide} & H_4 & S_2 & \end{matrix}\right\}$$

$$H_{12}\,S_6\,O_{12} \qquad\qquad H_{12}\,S_6\,O_{12}$$

The above represents the results of the decomposition *when air is excluded*, but if air be admitted no hydrogen monosulphide appears to be formed. In all probability oxygen is absorbed from the atmosphere, and sulphuric acid formed instead. Sulphur, however, is invariably deposited.

159.—PREPARATION.—By the action of granulated zinc on a concentrated solution of sulphur dioxide, as the following equation illustrates:—

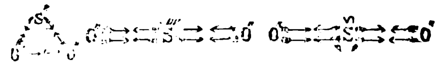
$$Zn + H_2O + 2SO_2 = ZnSO_3 + H_2SO_2$$

B. SULPHUR DIOXIDE. *Synonym*: *Sulphurous anhydride*.[3] *Symbol*: $S''O_2''$. *Molecular weight*: 64.

160.—PROPERTIES.—Pure sulphur dioxide is a transparent colourless gas, possessed of a most pungent and suffocating smell, well known as that of burning sulphur. Its specific gravity is 2·2464 (air 1·000); or, in other words, it is 32 times heavier than an equal volume of hydrogen. It is incombustible, and instantly extinguishes a lighted taper immersed in it. Sulphur dioxide is one of the most easily condensible gases; a temperature of about + 14° Fahr. being sufficient to reduce it to the form of a colourless liquid, at ordinary pressure; the same result may be obtained by subjecting the gas to a pressure of about two atmospheres.[4] The specific gravity of the liquid is 1·45. When this liquid is exposed to a temperature of − 105° Fahr. it freezes to an ice-like mass. If the liquid be allowed to evaporate it does so with such rapidity as to reduce the temperature of bodies in vicinity, to − 76° Fahr. (See paragraph 151.) When perfectly free from water, sulphur dioxide neither bleaches nor reddens blue litmus paper; but the presence of water immediately determines the production of both these effects. For this reason sulphur dioxide is largely used in the arts as a bleaching agent for straw, silk, wool, and other bodies which would be injured by chlorine. It is worthy of remark, however, that the colours bleached by sulphurous anhydride are not *destroyed*, but only *masked*; and may, in most cases, be caused to reappear, by immersing the bleached substance either in boiling water or in a dilute solution of potash or soda. Litmus paper, which has been bleached by sulphurous anhydride, is reddened by immersion in dilute sulphuric acid. Sulphurous anhydride possesses very marked antiseptic properties, and may be used for the preservation of meat, &c. It has been proved, by several well-conducted experiments, that beef, &c., which has been exposed for a few days to the action of this gas may be kept for several months without deterioration or loss of flavour. Sulphur dioxide is also much used as a powerful disinfectant.

Sulphur dioxide is very soluble in water: the amount absorbed varies with the temperature.[5] Thus at 32° Fahr. 1 vol. of water absorbs 68·861 vols. of this gas; at 50° the amount absorbed is only 51·38 vols.; while at 68° only 36·22 vols. are retained. If the water be boiling the gas is not absorbed at all.

161.—Besides its practical importance, sulphur dioxide possesses many points of theoretic interest, for it may be regarded as the basis of most of the oxy-sulphur compounds. It is usual, when speaking of it in this theoretic aspect, to designate it by the name of *sulphuryl*. We will return to this view when treating of the constitution of the oxy-acids of sulphur. According to whether we consider sulphur divalent, quadrivalent, or hexavalent, so may we represent the molecular constitution of this body as being either:—



Divalent Quadrivalent or Hexavalent.

162.—PREPARATION.—Sulphur dioxide may be formed by the direct union of its constituents, aided by heat: hence, when we burn sulphur in air or oxygen, this body is produced.[6]

The methods by which it is prepared for the uses of the arts vary according to the purposes to which it is destined.

When sulphur dioxide is used for bleaching purposes it is generally obtained by melting a quantity of sulphur in an earthenware recipient. The sulphur is then ignited, and the containing vessel placed in a large wooden chest, in which the straw, &c., to be bleached, is suspended. The chest is covered with sacking to prevent the escape of the sulphur dioxide gas produced.

For the preparation of sulphuric acid, sulphur dioxide is often produced by burning iron pyrites in a current of air. The sulphur contained in the iron pyrites combines with the oxygen of the air, producing thereby the body in question.

Sulphur dioxide may also be prepared by acting on carbon with strong sulphuric acid, aided by heat. Sawdust may be substituted for carbon; but in either case the product is contaminated by the presence of carbon dioxide, which is also formed. The following equation serves to illustrate the mode in which the changes take place:—

$$C'''' + 2H_2'S''O_4'' = 2H_2'O'' + C''''O_2'' + 2S''O_2''$$[7]

Should the sulphur dioxide thus produced be required for purposes in which the presence of carbon dioxide would be injurious, this body may be removed by passing the mixed gases through ice-cold water, which dissolves sulphur dioxide freely, while it absorbs very little of the carbon dioxide. By placing the solution thus produced in a retort, and applying heat, the gas is again evolved, and may be collected over *warm* water in the usual mode.

1 Monothionous anhydride. As sulphur forms so many oxygen compounds, it is found convenient to designate some by the Greek name of sulphur—viz., θεῖον, theion.

2 Hydrosulphurous acid.

3 Sulphurous acid. Sulphuryl.

4 The pressure of one atmosphere is roughly estimated at 15lb. to the square inch, hence two atmospheres equal 30lb. to the inch.

5 This is the case with most gases.

6 It would appear from the researches of Williamson, that when the temperature at which combustion takes place is high, sulphur trioxide is formed. It is the opinion of the author that sulphur dioxide is produced in the first instance, and that this body at the high temperature absorbs another atom of oxygen to form the trioxide.

7 As sawdust acts by virtue of the carbon it contains, no note is taken of the other constituents.

Where perfect purity is a desideratum it is found better to decompose the sulphuric acid by means of copper or mercury. The reaction may be expressed by the following equation:—

$$Cu'' + 2H_2'S''O_4'' = Cu''S''O_4'' + 2H_2'O'' + S''O_2''.$$

The gas evolved, after being passed through some desiccating body to free it from moisture, may be collected in the usual mode, *over mercury*; as *water* dissolves it too freely to admit of its use.

B2. SULPHUROUS ACID. *Synonym: Hydrogen sulphite.*[8] *Symbol:* $H_2'S''O_3''$. *Combining weight:* 82.

163.—It is presumed that this body is formed when sulphur dioxide is absorbed by water; for although it has not been found possible to eliminate the excess of water, yet the resulting solution is found to possess all the essential properties of a true acid. The concentrated solution of sulphur dioxide may be, therefore, considered as a solution of sulphurous acid in water; and the mode in which sulphur dioxide acts on water to produce sulphurous acid may be represented as follows:—

$$H_2O + SO_2 = H_2SO_3.$$

Sulphurous acid possesses most of the properties of sulphur dioxide, with the addition of the power of combining with several metals with the elimination of its hydrogen, thus:—

$$H_2SO_3 + M_2 = M_2SO_3 + H_2.$$

It is an active bleaching agent, and absorbs oxygen greedily. Hence it easily reduces (or deoxidises) many metallic oxides, in the following mode:—

$$M_2O + H_2SO_3 = M_2 + H_2SO_4.$$

Here the oxide is reduced to the metallic state, while the sulphurous acid absorbs oxygen, and is converted into sulphuric acid. The same absorption of oxygen takes place when the aqueous solution is exposed to the action of the atmosphere, thus:—

$$O_2 + 2H_2SO_3 = 2H_2SO_4.$$

Exposed to a temperature of about + 40° Fahr., the solution of sulphurous acid yields transparent crystals of a hydrate[9] containing a definite quantity of water. The composition of these crystals is:—

$$H_2SO_3 + 14\,H_2O.$$

As sulphurous acid contains two atoms of replaceable hydrogen it is divalent—that is to say, that to saturate it it requires either two monovalent atoms or one divalent atom.

For this reason the compounds which it is capable of forming with metals may be ranged under three heads—viz.: (1) Those in which both atoms of the hydrogen are replaced by two atoms of a monovalent metal, as illustrated by the annexed formula:—

$$M_2'S''O_3''.$$

(2) Those in which both atoms of hydrogen are replaced by one atom of a bivalent metal:—

$$M''S''O_3''.$$

(3) Those in which only one of the two replaceable atoms of hydrogen are replaced by one atom of a monovalent metal, thus:—

$$\left.\begin{matrix}H'\\M'\end{matrix}\right\}S''O_3''.$$

Compounds belonging to the two first classes are designated *sulphites*; those belonging to the last division are called *hydrogen sulphites*. When acted on by stronger acids all three groups give up their sulphurous acid. In solution the sulphites absorb oxygen readily, being thereby converted into *sulphates*.

C. SULPHUR TRIOXIDE. *Synonym: Sulphuric anhydride.*[10] *Symbol:* $S''O_3''$. *Molecular weight:* 80.

164.—PROPERTIES.—Sulphur trioxide is a white solid, crystallising in fine filamentous prismatic crystals of a silky lustre, much resembling *asbestos* in appearance. The specific gravity of the crystals is 1·9546. These filamentous crystals are very tough and difficult to cut. At a temperature of about 66° Fahr. they melt, and on increasing the heat, boil, when the temperature reaches 114° Fahr., giving off colourless transparent vapours if no moisture be present. In the presence of damp air dense white suffocating fumes arise. An allotropic modification of sulphur trioxide exists, which differs principally from the one just described, insomuch as the crystals are acicular, and the melting point considerably higher—viz., 122° Fahr. Sulphur trioxide does not redden litmus paper, and (unless moisture be present) may be handled with impunity. In the presence of water it acts as a most powerful corrosive agent. Thrown into water sulphuric anhydride combines with it with such violence as to produce great heat, and sometimes light, accompanied by a hissing sound, similar to that produced on quenching red-hot iron. Exposed to the atmosphere, sulphuric anhydride rapidly absorbs moisture, and becomes liquid, or *deliquesces*. The product of the combination of sulphuric anhydride with water is sulphuric acid.

Sulphur trioxide is decomposed when its vapour is passed through a red-hot porcelain or platinum tube, being resolved into two volumes of sulphur dioxide, and one volume of oxygen. Hence sulphur trioxide may be conveniently viewed as an oxide of sulphuryl (see 161), and we can express this decomposition in the following mode:

$$2S''O_2''O'' = 2S''O_2'', + O_2''.$$

165.—PREPARATION.—According to Williamson, sulphur trioxide may be formed by the direct union of its elements, aided by a high temperature. It would appear that by burning sulphur in oxygen at very high temperatures the sulphur dioxide first formed combines with a third atom of oxygen, thus:—

$$SO_2 + O = SO_3.$$

But this method is not the one usually followed. Sulphuric anhydride may be easily prepared by distilling, at a gentle heat, Nordhausen sulphuric acid—a brown liquid which consists essentially of sulphuric anhydride mixed with sulphuric acid; when the sulphuric anhydride passes over, and may be collected in a dry, well-cooled receiver; while the sulphuric acid remains in the retort, as the adjoined equation illustrates:—

$$H_2'S''O_4'', S''O_3'' = H_2'S''O_4'' + S''O_3''.$$

Or common sulphuric acid may be distilled along with phosphoric anhydride when this latter body seizes upon the elements of water contained in the sulphuric acid, liberating the sulphur trioxide, which may be collected as before. The reaction is as follows:—

$$P_2O_5 + H_2SO_4 = 2HPO_3 + SO_3.$$

Another mode of preparing this body is by heating a body called hydrogen sodium sulphate in a glass retort. The composition of this hydrogen sodium sulphate is:—

$$\left.\begin{matrix}Na'\\H'\end{matrix}\right\}\overline{SO_4}''.$$

On being heated, it loses hydrogen and oxygen in the proportions to form water; and a body, resembling in composition Nordhausen sulphuric acid (in which the hydrogen is replaced by sodium), remains behind, as may be gathered from the following equation:—

$$2\left(\left.\begin{matrix}Na'\\H'\end{matrix}\right\}\overline{SO_4}''\right) = Na_2'S''O_4''\,.\,S''O_3'' + H_2O.$$

If this body be further heated, it breaks up into sodium sulphate and sulphur trioxide, thus:—

$$Na_2'\,S''O_4''S''O_3'' = Na_2'S''O_4'' + S''O_3''.$$

[8] Hydric sulphite.

[9] A hydrate is a body containing water. A body is said to be anhydrous when free from water.

[10] Sulphuric acid.

A NEW PHOTOMETER.

FOR making visible to a large audience small variations in temperature, a thermometer containing a saturated solution of iodine in bisulphide of carbon is well suited, on account of the high co-efficient of expansion of that liquid. Comparing the co-efficient of this solution with that of bisulphide of carbon, M. Provenzali found that under the action of light the former exceeded the latter by 0·20, and sometimes even 0·25; whereas, in darkness, the two co-efficients were almost equal; and a thermometer, having a solution of iodine in bisulphide of carbon, rose or fell on passing from darkness to light, or *vice versa*, while a mercury thermometer was stationary.

This phenomenon, he says, is not so extraordinary as it would seem at first sight. The saturated solution referred to is a body with very feeble reflective power, perfectly opaque, and undergoing no chemical change from the action of light. Thus the luminous rays, which are reflected by the mercury, are absorbed by the solution, and transformed into heat, which increases the temperature and volume. Hence thermometers with a solution of iodine in bisulphide of carbon, may be utilised for photometry. The following is the mode adopted: "Two thermometers, one mercury, and the other containing the solution, are placed near each other on a table. The graduation of the mercury thermometer is as usual, except that the scale is divided into fifths of a degree. The graduation of the thermometer with iodine solution is such that the two thermometers agree in their indications in the dark. Under the influence of light, on the other hand, the thermometer with iodine solution rises above the other, in proportion to the intensity of the light.

After the beautiful experiments in which Tyndall separated obscure heat from light by means of opaque solutions of iodine in bisulphide of carbon, there is no reason to think that the obscure rays will have a marked influence on the relative indications of the two thermometers forming the photometer. Nevertheless, in order to know better the diathermancy of the opaque iodine solution, I inclosed two good mercury thermometers in two equal glass tubes; the bulb of one remained uncovered while that of the other was plunged in a saturated solution of iodine in bisulphide of carbon. So long as both were in darkness, and exposed to radiation from obscure sources, they gave the same indications; but when brought into a somewhat strong light, the thermometer with its bulb in the solution rose a little higher than the other, and the difference increased to a degree when the sunlight was admitted into the room. We may, then, believe that the diathermancy of the solution referred to extends to all the obscure rays, and therefore that the obscure rays cannot materially alter the indications of my photometer.

It is necessary here to remark that the two thermometers should be made of the same kind of glass; for I found that a difference in the quality of this altered the relative indications of the thermometer.

Having exposed to the same source of obscure heat three thermometers of the iodine solution, and having bulbs of the same diameter, but made from three different kinds of glass, the apparent variation in the liquid volumes was as the numbers, 1, 1·3, 1·5. These differences are probably due to differences of diathermancy in the glass. Melloni observed that different kinds of glass, though equally transparent, did not absorb and transmit obscure heat in the same degrees. More recently Tyndall, having made a plate of platinum incandescent by strongly concentrating obscure rays with a lens, observed that a piece of window glass placed between the source of heat and the platinum sensibly enfeebled the incandescence, while with glass of a different quality, it was very little enfeebled, and glass that was quite opaque had less enfeebling effect than the window glass. It seems to me that even in meteorological observations, made with the aid of mercury thermometers, the effect of diathermancy in the glass is not to be neglected.

I will now give the results of experiments made with this photometer on solar light, diffuse and direct, in the month of May. In the morning, before sunrise, the two thermometers showed nearly the same degree of temperature; they also did so about half an hour after sunset. At 8 o'clock in the morning, and in a room of the laboratory with open windows, the mean difference of the two thermometers was 0·2°; the greatest difference having been 0·4°, when the sky was perfectly serene, and the smallest 0·1°, when it was entirely covered with clouds. At 11 o'clock the mean difference was 0·3°, the greatest having been 0·5° when the sky was slightly nebulous, and the smallest 0·1°, when it rained heavily. In open air, as was to be expected, I found the differences greater and more variable; thus at 8 o'clock they had varied from 0·3° to 0·7°; and at 11 o'clock from 0·5° to 1°. At the time of the greatest difference the sky showed a number of cumuli strongly illuminated, and at the time of the smallest it was very much darkened by a thick cloud. The mean at 8 o'clock in the open air was 0·5; and at 11 o'clock 0·7°. On carrying the photometer into the open air I observed several times a somewhat curious phenomenon. The two liquids moved in opposite directions, the mercury falling, and the iodine solution rising. The reason of this was, that in the open air the temperature was somewhat lower, while the intensity of the light was greater than within doors.

As regards direct radiation from the sun in open air, the mean difference of the thermometers, when exposed to the sun on serene days, was 5·1° at 8 o'clock and 7·7° at 11 o'clock. This gives us the proportion of 1 to 1·5; and we get nearly the same proportion on comparing the differences 0·5 and 0·7, obtained at the same hours from diffused light in the open air, and the othe differences, 0·2 and 0·3, obtained from diffused light in the laboratory. Thus the intensity of light indicated by the photometer increased from 8 o'clock to 11 o'clock in the proportion of 1 to 1·5, equally within doors and in the open air (the light being diffuse); and in the direct sunlight I have also experimented with phosphorescent light and that of electric discharges, which were only visible in the dark, and on lunar radiation; the photometer shows itself sensitive to all of these.

For lunar rays I experimented in a room which had been made for optical purposes. I placed a bi-convex lens, 247 millimetres in diameter, behind the glass of the window (which faced south), and, at the focus of the lens, the bulb of a thermometer of the iodine solution, with a scale on which it was easy to distinguish the one-hundredth of a degree. It was the 16th day of the lunar month, and between 10 and 12 o'clock in the evening, and many clouds covered the sky, some of them very dense. On the passing of a cloud before the moon the liquid in the thermometer fell, and it rose again when the cloud had passed. The variation of the liquid column under these circumstances reached one-third of a millimetre, corresponding in this thermometer to one-seventy-eighth of a degree C."

BORING AND MORTISING MACHINE.

THE past decade has witnessed the introduction of numerous machines for the rapid working of wood used in the arts of construction and in the various articles of our domestic furniture. What

being adjusted to any required length of mortice. At opposite sides of the machine a table is situated, upon which a leg or other part of a chair or other piece of furniture is placed, and secured thereto by a cramp; the part wherein it is desired to make the mortice being brought in front of the bits, and being pressed against them by means of a screw, an accurately placed mortice is speedily formed, corresponding in width to the diameter of the boring bit and in length to the distance through which it moves. The part of the machine by which the dowel holes are bored consists of revolving bits, carried in brackets situated upon compound slides arranged upon the upper part of the framework, by means of which the bits can be brought into any position to suit the dimensions and nature of the piece of work or to the width of holes required to be bored, the bits being forced or drawn against the wood to be operated upon by hand levers, actuated by the attendant. The patentees prefer to make the machine duplex, so that two similar pieces of work may be operated upon simultaneously. In order to finish the joints of the work after it has been mortised and the dowel holes cut, the back legs and rail are put together by the tenons of the latter being entered into the mortices of the former, and cramped together in a machine for cutting the back joint; this consists of two saws situated upon a transverse hollow shaft, through which a right and left hand screw passes, whereby the saws can be adjusted to any distance apart corresponding to the length of the back rail of the chair, sofa, or other similar piece of work. The back is brought against the saws by a guide plate

in dotted lines the front and back leg of a chair about to be operated upon by the mortising bits B, are carried by brackets bolted to the framing of the machine, and are adjusted to the required height by means of screws and hand wheels, shown in Fig. 1, the screws being kept in position when adjusted by pinching screws. The tables I are situated upon horizontal slides, and by means of the screws and nuts placed under the tables are caused to travel to or from the mortising bits B by the operator turning handles affixed to the rods L (omitted here for want of room), in a right or left hand direction, similar to the manner of operating the slide-rest of a self-acting lathe. The legs or other parts of a chair or other piece of furniture, when placed upon the tables I, are secured thereto by the cramp K, which consists of a horizontal shaft furnished with a feather fitting into a corresponding groove in the eye at the head of the bracket O to allow of the position of the shaft being altered. At the end of each shaft a vertical screw is carried, furnished with a hand wheel, and upon tightening this the piece of furniture placed upon the table under it is firmly held in position, so that the parts wherein it is desired to cut the mortices being brought in front of the bits B, and being pressed against them by means of the screws worked by the handles on the rods L, accurately-situated mortices are speedily formed, corresponding in width to the diameter of the mortising bits B, and in length to the distance through which the bits travel in the race C. The portion of the machine by which the dowel holes are bored consists of revolving bits driven at a high velocity by

FIG. 1

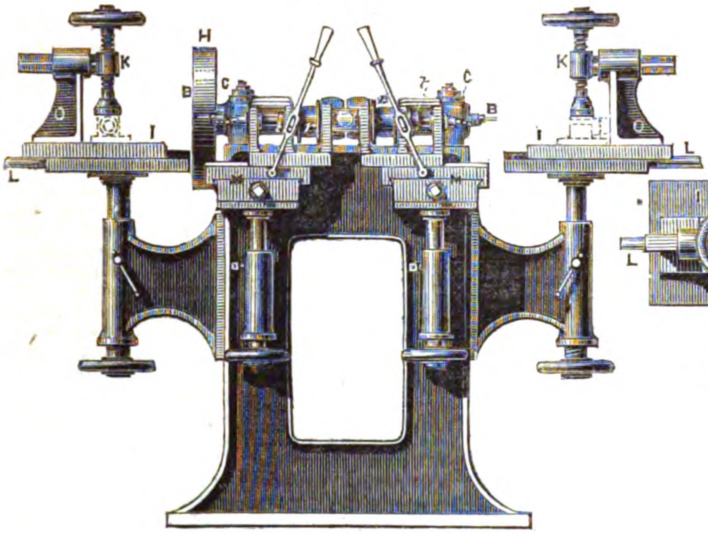


FIG. 2

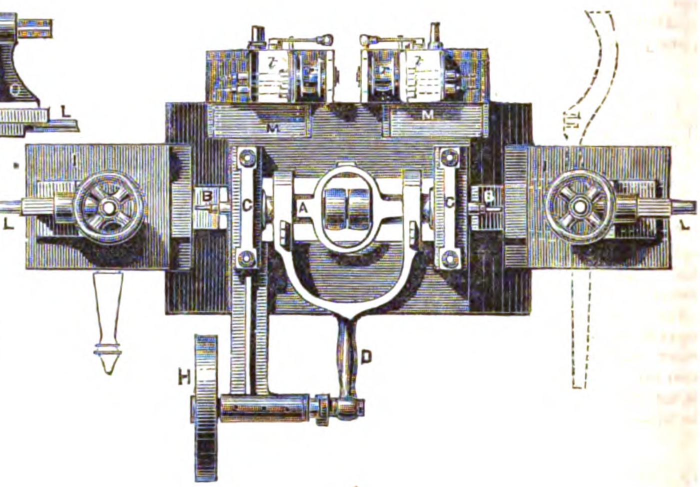


was formerly manufactured with a great expenditure of labour is now cheaply produced in large numbers by the employment of machines, and although the apparatus has not yet been designed capable of turning out a finished chair or table from the rough log, the various parts are now shaped by machinery, leaving only the fitting together and finishing to the skill of the workman. We this week illustrate one of the most recent of these introductions—a machine for cutting mortices and boring holes in the different parts of chairs, tables, sofas, &c., which is supplemented and accompanied by another of similar construction for shaping the tenons and pins for the counterparts produced by the mortising and dowelling machine. These contrivances form the subject of a patent recently granted to Matthew and John Pollock, of Beith, Ayrshire, and will, we think, be readily understood from the following description, with its accompanying illustrations. By way of introduction, however, the principle of the machine may be described as follows:—The part by which the mortice is cut consists of a revolving shaft fitted with bits, the diameter of which is equal to the width of the mortices desired. This shaft is carried in bearing blocks situated in a race, in which it is caused to reciprocate through a distance equivalent to the length of mortice required by means of a connecting-rod attached to a crank upon a revolving shaft near one end of the machine. This crank is preferably arranged with an adjustable throw, so that the range of the reciprocating spindle, and consequently that of the mortising bits, is capable of

or slide set at right angles to the plane of action of the saws. This latter machine is also applicable to cutting and boring the dowel holes in back stays for chairs, having a compound boring apparatus attached thereto, the action of which is similar to that used for boring the dowel holes in the legs of furniture, the bits being placed at the same distance apart, so that the dowel holes in both legs and back stay correspond; the same saws which cut the joints for the back also cut the ends of the back stay to bring them to the required length.

In the engraving, Fig. 1 represents a front elevation of the mortising and dowel-hole boring machine, and Fig. 2 is a plan. As shown in Fig. 2 the part of the machine used for mortice-cutting is constructed with a revolving shaft A, the extremities of which are fitted with bits B, whose diameter is equal to the width of the mortice desired. This revolving shaft A is rotated at a high velocity by means of pulleys, and it is carried in bearing blocks situated in a race C. The shaft A and bits B are caused to reciprocate in the race C through the required distance by means of a connecting-rod D, attached to a crank on a revolving shaft carried in bearings supported by a bracket bolted to the framing of the machine. The crank is preferably constructed with an adjustable throw, so that the range of the reciprocating shaft A, and the mortising bits B, is capable of being set to any required length of mortice. The revolving shaft to which the crank is attached is driven by a belt passing over the pulley H. The tables I, upon which are shown

means of the pulleys R, the bits being geared
together in pairs or other num rs by means of
spur pinions T, carried in brack upon the hori-
zontal compound slides M, whicl carried and
adjusted, as regards their height by means
of vertical screws passing throug B bolted
to the framing of the machine, a on posi-
tion by pinching screws. The attaides
M are acted upon in one directio this irs
the square heads of which are as a cu
direction at right angles thereto by other po
so that the boring bits can be b German g
position to suit the dimensions ar ones, then
piece of work about to be bore
pressed or drawn against the wood
actuating the hand levers.

The sawing machine which forms the complement to the one illustrated is constructed on the same principle, and with as little difference in the arrangement of details as the nature of its work will permit. It will be observed that all the parts, whether those for carrying the work or those bearing the tools, are adjustable one to the other to suit the difference in size of the various articles to be operated upon.

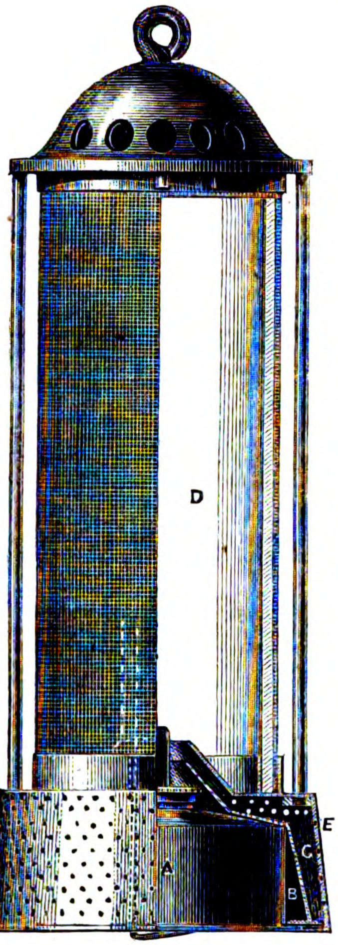
ELECTRO-DEPOSITION OF NICKEL.

THE value of nickel as a preservative coating for metals liable to corrosion or oxidisation is now well known, but, so far as we are aware, little use has hitherto been made of it for the purposes of ornamentation. This arises principally, we believe, from the fact that the colour of electro-deposited nickel does not harmonise with that of gold,—a defect which Mr. Thomas Fearn, of Aston, claims to have removed by employing a deposit formed of iron and nickel, by which the colour is greatly improved, and some useful effects obtained. The process invented and patented by Mr. Fearn consists in the employment of a solution of nickel and iron, by means of which an alloy of these metals is deposited on articles suitably prepared in the usual manner. For this purpose he dissolves twenty-four parts by weight of muriate of ammonia (chloride of ammonium), in 160 parts by weight of water, and saturates the solution with protoxide of nickel, at a temperature of about 120° Fahr. From this solution a good deposit of nickel may be obtained, if desired, with a moderately intense battery power. When the first solution is saturated with nickel the same quantity of a like solution of muriate of ammonia is added; but in order to deposit from this solution the alloy of nickel and iron it is necessary to charge it with iron in addition to the nickel which it contains. This the patentee prefers to do by electricity. He employs an anode of iron, by which an electrical current from a voltaic battery, or other source of electricity, is passed through the solution until the required alloy of nickel and iron is deposited at the cathode. This is ascertained by observing the colour of the deposit. As soon as the required deposit is obtained the solution is ready for use. A film of peroxide of iron forms upon the surface of the solution, but this, it appears, does not interfere with the working of the process. In using the said solution for obtaining a deposit of nickel and iron two anodes are necessary, one of nickel, and the other of iron; so that if the deposited alloy gives any indication of either metal being in excess the anode of that metal is raised either wholly or partially from the solution, and work continued with the other anode until the required deposit is produced. The battery which the inventor prefers is that known as Wollaston's—that is, plates of amalgamated zinc and copper, two or more pairs being employed, but other batteries or sources of electricity may be used. For obtaining quickly thin deposits of the alloy an intense electrical current may be employed, even causing copious evolution of gas from the deposited surface without detriment to the appearance of the deposit, but for giving a strong coating a weaker current is necessary. In depositing an alloy of nickel and iron upon articles of iron or steel it is, of course, necessary to previously coat them with copper or by preference with brass. The coating of alloy upon "parcel" gilt work—that is, articles coated only in parts—is said to be an excellent substitute for the tarnished effect produced in silver-plated articles, commonly called oxydising. For stopping off "parcel" gilt work any suitable varnish mixed with a colouring powder may be used; rouge or Prussian blue answers very well for the purpose, the colour enabling the workman to see better how to apply the varnish. The varnish may be removed from the work after it has been coated with the alloy by means of a hot solution of potash or by oil of turpentine.

Although the above method of preparing the solution of nickel and iron works satisfactorily, and is the best with which the patentee is acquainted, its preparation may be modified in various ways. For example, the solution may be charged with nickel by the use of an anode of nickel instead of dissolving oxide of nickel therein. Or the solution of nickel and iron may be made separately, and afterwards mixed in the required proportions. By thus combining iron with the deposit of nickel a clearer and more agreeable tone of colour in the deposit is obtained, and the nickel contrasts agreeably with gold in ornamental work.

SAFETY-LAMP FOR MINERS.

THE principal feature of the safety-lamp patented by Mr. Plimsoll consists in permitting the ingress of a sufficient quantity of the dangerous gas to cause an explosion which at once puts out the light and warns the miner of his danger, thus preventing all risk of the main body of gas in the mine being fired. The accompanying figure will give an idea of the arrangement of the lamp, and the following is a description of the principles on which it is constructed:—The body of the lamp is made with an internal chamber or passage through which air is supplied to support the flame. This air-chamber communicates with the external atmosphere through wire gauze or a perforated metal plate, such as is usually employed in safety-lamps, and the air chamber surrounds the wick, so that the incoming current of air converges on the flame. Thus, whenever the atmosphere becomes explosive, the air current will be ignited by the flame and will explode within the air-chamber or passage, causing the instant extinction of the light. The explosion is prevented by the wire gauze or perforated metal from communicating flame to the external atmosphere. In the figure, A is the oil receptacle, which is wholly or partly received in a cavity B in the lower part of the casing of the safety-lamp; C is the air-chamber surrounding the lamp. The walls of this chamber are made of plates of sheet brass fitted together concentrically in the manner shown, so as to leave an annular space of about one-ninth of an inch between them in a lamp of the size drawn, and less for a lamp of larger diameter (as the capacity of the chamber or passage must not be increased beyond certain limits), the said plates being soldered at bottom to a flange or ring on the inner plate. The outer plate E is made with a



number of minute perforations through which the entire supply of air required for the combustion of the flame passes. The thickness of this plate depends somewhat upon the size of the perforations, but it must be of such thickness as to prevent the passage of flame through the perforations when the ignition of explosive gases takes place in the chamber C. Perforations one-fortieth of an inch in diameter in a plate one-fifteenth of an inch in thickness will answer the purpose, the object being to prevent the passage of flame without obstructing the admission of air to the lamp. The perforations should be disposed at equal distances apart, and not too close together, so as to leave sufficient metal to cool and destroy the flame resulting from the ignition of explosive gases in chamber C, nor should the perforations be more numerous than is required to admit an adequate supply of air to feed the flame of the lamp. The top of the chamber C is bent into a conical form at the centre around an opening through which the wick tube rises, the opening being of sufficient size to permit the air to pass freely to the flame, and allow for its free escape or expansion when the ignition of explosive gases takes place in chamber C. The top of the inner wall is also similarly bent or made into a conical form at the centre, and has a central aperture for the passage of the wick tube. The upper plate is provided with a gallery to carry the glass chimney D and wire gauze covering, as usually employed in some kinds of safety-lamps, and to this plate the ordinary rods of the framework are also attached, as shown. The glass chimney D is carried up to the top of the lamp, which is provided with the usual protecting top of wire gauze and perforated sheet metal for the exit of the products of combustion. The chimney D is cemented air-tight in its gallery, so that the whole of the air supply must pass through the chamber C to the flame, thereby preventing any accumulation of explosive gases in the upper part of the lamp.

SENSITIVE FLAMES.

SOME experiments on sensitive flames are detailed by Dr. Isaac Norris in the *Journal of the Franklin Institute* for April. The arrangement of Barry for rendering a flame sensitive is well known, and offers the great advantage of using the gas at the ordinary pressure, so that the experiment is arranged in a moment. The size of the pin-hole aperture determines the height of the flame burned above the wire gauze. I have found after many experiments that it is rendered much more sensitive by using a chimney: an ordinary glass one, such as employed with the argand burner, answering perfectly and rendering the flame at the same time much more steady. It may rest on the gauze, which must be placed at the proper height above the burner. The gas should be burned on until it begins to flare, and then lowered a little until it becomes steady. The nearer it is to this point the more delicate the result. Tyndall's caution with regard to obstructions from stop-cocks, &c., is also very important. Wishing to measure the height, I attached a small scale to the chimney, and found, as recorded, that the flame is much more sensitive to some sounds than others. Any sound in which the letter *s* enters seems to affect it particularly. Attaching a telescope to the apparatus, something like the arrangement in a cathetometer, I found that even when the flame appears to the eye perfectly steady, it was continually varying in height—sounds that were quite inaudible to any one near it, evidently producing a marked result. A tall flame, 6in. or 8in. in height, is not as sensitive as one of only 2in. or 3in., and placing the gas in a bag at the same pressure as it issues from the pipe did not alter the result. The whole subject is a very curious one, and I am inclined to think this flame is *the most delicate* yet produced, despite the accounts of the wonderful steatite burner of which Tyndall speaks. A description of Barry's sensitive flame will be found on p. 244, Vol. XIV., and it is to be hoped the present little article may lead to other experiments in the same direction.

PHOTO.-ENGRAVING ON METALS.

WILLIAM A. McGILL and Robert G. Pine, of Memphis, Tenn., have invented a new process for photographing engraving on metals and other substances, which they describe as follows:—We take, as a base of operation, a pure silver surface or an alloy; and, after finely polishing or frosting it, it is subjected to the action of iodine, and a film of the iodide of silver is formed on the plate. We then expose the plate to the action of light in the camera obscura, or under a photographic negative, until a faint image of the object is formed. The plate is then submitted to the action of an electrotype battery (copper solution), when a well-defined image of the object in copper is formed, the cupreous deposit attaching itself only to those parts of the plate which were rendered conductors of electricity by the action of light, while the unexposed parts will remain non-conductors of electricity. The plate is now dried and etching solution poured on it, composed of sulphuric acid saturated with nitrate of potash, or their equivalents. This solution immediately attacks the shadows or exposed portions of silver surface, while the cupreous deposit from the electrotype bath is not affected. After etching the required depth the copper deposit on the plate may be readily removed by *aqua regia*, which will not act on the silver plate, leaving a finely-etched image in the silver plate.

To engrave or etch on steel, gold, copper, and other substances, the surfaces are first coated with pure silver. We then proceed substantially as above explained, with the exception that different acids or combinations of acids are used on the various metals or other substances after the silver plating or surface is etched through, according to the nature of the base to be operated upon; for instance, in etching on gold, after the silver ... etched through with the saturated solution ... sulphuric acid and nitrate of potash, we use ... *regia*, or nitro-muriatic acid, which acts on the ... but leaves the silver intact. The ... specially applicable to the ornamentation ... plate and jewellery.

MICROSCOPICAL CABINETS.

THE principles to be kept in view in constructing and arranging cabinets for microscopical objects are thus stated by Dr. Murie, in a paper read to the Royal Microscopical Society, which is replete with information of value to local societies as to the arrangement of their collections, and will be found suggestive by the advanced histologist. We can only extract a portion:—

As to a choice of the cabinet, so much depends on the intention and tastes of the individual, and the nature of the collection itself, that no rule or recommendation on my part can be given which would meet the conceptions and wishes of every amateur microscopist or professed histologist. I shall discuss the subject, nevertheless, in its broader aspect; that is to say, on such grounds as may be of general interest, or lead others to make suggestions on what at present there is no very definite standard or agreement upon. The dimensions of a cabinet is a matter concerning economy, convenience of space, and the conception the collector intends to fulfil. If the numbers of slides are likely to be or already are very extensive, then large-sized cabinets are in some respects most advantageous. At the same time they are not free from serious drawbacks. Smaller-sized cabinets, while deficient in solidity, roominess, &c., have several points of recommendation, not the least of which is that if made to a uniform size and of a cubical form, they can be piled up one above the other, and so built together as to command all the advantages and none of the drawbacks of an immense single cabinet. I cannot offer a better instance, forcing conviction of the last-mentioned proposition, than by reference to the Botanical Department and Insect Room of the British Museum. There (besides old wall cabinets) they have a set of cubes identical in measurements, each devoted to a group or subsidiary division, numbered and labelled accordingly, and so arranged that to all intents and purposes they represent but one vast cabinet. For study and reference they are uncommonly handy, as they can be brought down to the table, and, in fact, shifted about at pleasure without the slightest injury to contents.

Such is my beau ideal of a microscopic cabinet, compound, yet harmoniously single; adapted to meet the wants of a limited, a moderate, or a numerous series; expansion being in the ratio of increment of slides. But furthermore, as I shall presently mention, the same principle is applicable to very modest microscopical collections; such, indeed, as even the amateur or those of limited means may aspire to. As a closing sentence to this clause, I may even make bold to say that, like other fashions and hobbies, that of cabinets is an infectious one: a handsome piece of furniture is attractive. Would that the zest for a thorough mastery of the contents were as powerful a stimulant.

I do not propose giving a lengthened dissertation and criticism upon every sort of cabinet, but, by allusion to a few, indicate in passing the more desirable features pertaining to economy, easy access, and desirability for classific purposes.

1. As regards space and cheapness, the common boxes with racks, sold by all microscopic object makers, are undoubtedly very handy. They are subject, however, to three great faults. 1. Many specimens, particularly those in fluid, are liable to spoil in them. 2. Reference to individual slides is awkward, from their being tilted in position. 3. Numbers and names cannot easily be read, unless by picking up one and then another, in guess-like fashion. As an example of a considerable collection kept in the ordinary rack-boxes, I may mention Dr. Greville's specimens of Diatomaceæ in the British Museum, of which there are 3,637 in all. His method of numbering and cataloguing, to which Mr. Carruthers kindly called my attention, I shall again make reference to.

2. Dr. Muller, assistant to Professor Hoffmeister, of Heidelberg, a few years ago kindly favoured me with a sight of their Histologico-Educational Collection. They were then adding a series of sections illustrative of medicinal woods. In lieu of an expensive cabinet, they had adopted the following economical arrangement, whereby the slides lay flat and were easily got at. A piece of stout millboard 7¼in. × 9¼in., and covered with coloured paper, had forty-two holes punched out. The holes, drilled at equal distances, ran in parallel lines 1in. apart. Through these an elastic cord was passed, down one hole and up the next; continuing along one line of holes and returning the next. Having reached the farther one from the point of starting, the cord is reversed and brought back hole by hole to the latter, where a knot joins the extremities of the cord. Slides are then introduced beneath the cords, which retain them in place. Each corner of the millboard, above and below, has a wedge-shaped piece glued on to it, and there is a narrow strip introduced in the middle. The trays filled above and below with slides are then piled one over the other on a shelf, or in boxes, open in front, with labels attached to each consecutive group. I mention the inexpensive mode of forming a cabinet rather on curiosity than to recommend it. There is one [illegible] also to be borne in mind—viz., the rangelas[illegible] are shorter than the English quent[illegible]

3. Dr. Carpenter warmly commends a form of book-box as excellently adapted in lieu of an ordinary microscopical cabinet. As he says, a large histological collection can be stowed away in the library shelves, among the other books, and consulted with the greatest ease. My friend, Mr. David Forbes, has a few of such boxes slightly altered from Dr. Carpenter's plan, so as to suit the different shape of slide used by himself. The construction otherwise is similar, so that one description may suffice for both. Each case is about 10¼in. high, 8¼in. long, and 4in. thick in outside measurements. It opens only from behind, and has a fixed shelf across its middle. Trays of light cardboard, to the number of eighteen above and as many below, are piled on the top of each other. A small tack serves as a handle to each tray or *quasi*-drawer. Mr. Forbes uses slides each 1½in. square, so that eight of these occupy a drawer; the number or name, according to circumstances, being towards the knob end of the drawer. Dr. Carpenter's slides are generally those in common use, 3in. × 1in., and these to the same number, eight, lie athwart. Doubtless these book-boxes are neat, and in many instances a very excellent substitute for a large cabinet. The different sets of objects are most readily classified, and the title placed on the back, apportioned to the contents. The great fault, however, lies in the one tray being so placed above the other that to consult those which happen to be below, all the trays above must be taken out. The depth of each tray, besides, does not well admit of labelling, so that, like the rack-boxes, it is a case of trouble in searching for an object. It would be an improvement if each tray slid in on fillets, so that one might be taken out without disturbing the others, and by deepening the face labels could be placed outside. To do this would, however, spoil the compactness, and in part materially cripple their intended utility.

4. Piper's original Portable Horizontal Slide Cabinet, as described by himself,* is composed of any number of flat cardboard trays, divided into six or more compartments, each holding a single slide in a horizontal position. The trays are inclosed in a strong millboard box, the front of which is made to fall down, so as to permit the trays to be readily withdrawn. When closed, an elastic band renders the whole firm and secure. "It may be made of any desired capacity. Specimens are placed on the table capable of receiving from six to 250 slides. The smallest is well adapted to contain a 'half-dozen series' of anatomical or other subjects; and its great strength, combined with lightness, makes it peculiarly available for transmission through the post. Among the advantages which may be derived from the cabinets, I will mention the convenience of displaying, at one view, the entire collection of slides, and the facility thus afforded for the selection of any required specimen, without the troublesome search and difficulty of removal frequently experienced with the old form of box, in which the slides are dropped (out of sight) into perpendicular grooves. It also prevents the possibility of the covers becoming detached by shaking about in transit, which is important when it is to convey a rare or valuable collection. The trays, being all of uniform size, may be transferred from one cabinet to another of larger or smaller dimensions, without necessitating the disturbance of the slides. In addition to its portability, it possesses the merit of cheapness, durability, and neatness of appearance." The advantage of Piper's horizontal cases is marred by the trays resting on each other, and hence is only applicable to a very limited series of objects. The Eulenstein† collection of the British Museum, containing 100 types of diatoms, is contained in a case after Piper's pattern, but larger, and for this purpose it answers very well.

5. Mr. Henry George brought before the notice of this society a few years ago an inexpensive, compact form of store-box, wherein considerable ingenuity was displayed. The merit of his plan of store-box, or, indeed, small portable cabinet, lies in its being composed entirely of tin (japanned or otherwise), therefore of small compass, light, and not liable to warp; in the sides lying flat; and in a simple arrangement whereby the slides are kept in place without chance of overriding each other. Each box is made to hold three or six dozen slides, or by increase of capacity to hold proportionally more. In that which contains seventy-two the outer casing is of oblong figure, 6¼in. long, 3¼in. wide, and about 2¼in. deep. The lid is unhinged, and of ordinary form. The four sides of the box are each incised by a wide, deep semilune, so that the trays can be readily extracted. Each tray is a simple sheet of tin, out of which a large, long, oval piece has been cut, to insure facility in taking up each side. At the two farther extremities the tin is turned on edge, and forms a rest to the tray which lies above it. The opposite sides of the tray have their edges curvilinearly bent in, so that the slides slipping beneath are held firmly in place, alongside of each other. The slides thus lie secure, transversely to the long diameter of the box or tray, six in a row; and when one or more is wanted, by a tilting motion of the finger below the glass through the open space, extraction is easily effected. The defects in this otherwise capital little case apply equally to those of Mr. Piper and the book-boxes—viz., if a specimen is wanted from the bottom row, all above have first to be removed. Again, while the labelling of each slide is readily seen on being raised, yet unless the entire contents are known, every tray has to be gone over before the thing wanted is to be found.

6. I may refer en passant to Mr. Furze's zinc cases, the chief recommendation of which is their being of metal. Thus there is no liability to warp, as is also the case in the material used by Mr. George. These certainly have advantages over wood, which, unless mahogany, and that well seasoned, is so liable to warp, and render drawers stiff and troublesome to open.

7. As a modification of the rack principle, Mr. Sorby (according to my friend Mr. David Forbes) uses a small form of box wherein the slides are ranged in rack, but instead of their lying tilted, each is placed horizontally. A further extension of the same principle, and what are really most excellent capacious store-boxes (or to those who are satisfied with a moderate thing, a compact cabinet), cheap, portable, and each specimen of easy access, will be found in Mr. Norman's adaptation. In a mahogany box, 7in. high, and 4¼in. broad, 150 slides lay in racks horizontally, and by a marginal number are easily got at and referred to. There is a diaphragm across the middle of the box, and another running up the centre longways. This gives four compartments, so many in each. A folding door at each end provides easy access, and, with a handle on the top, the box can be carried about anywhere.

8. Mr. James Smith has described and figured what he terms a microscopical cabinet, wherein the slides are arranged after the mode of some entomological collections. Shaped like a back-hinged book-box, on its being opened back the contained slides are all seen at a glance, being each retained in place by a double elastic band. If I am correctly informed, Professor Hughes Bennett, of Edinburgh, uses a form of box or serial cabinet similar to the above. Other objections might be offered, but that the slides all rest vertically is against its frequent adoption.

9. Lastly, as everything depends upon individual requirements, some wishing a small, others a larger case, it is hard to recommend one form of cabinet that will do for all. Piper's, George's, and Norman's, are each good in their way for small series, but a larger-sized cabinet of square form, with trays coming out separately, is the most preferable article. Mr. Beck sells a cheap plain kind, made of polished deal wood, wherein the trays are cardboard. In this, as in more expensive sorts, every specimen is of easy access. The latter lie flat, the numbers and name facing the observer; and labelling is provided for outside the drawer. A number of such boxes can be piled above one another, and by degrees an extensive cabinet ultimately attained.

It is now universally admitted that objects preserved in a moist medium are retained in a sound state longer and better when laid down flat. This is easily understood, for the finest and firmest cement is not always a safe protection when the slide is tilted edge upwards. In the case of a cabinet with drawers, these are better not too deep; although some drawers of sufficient depth to admit easily the large-sized deep-celled slides are an essential desideratum. Unless in collections devoted to special subjects, deep drawers for the reception of larger objects need not be distributed throughout the cabinet; it is sufficient if they are confined to the lowermost tiers. In this way heavy specimens can be kept together, especially if exceeding in thickness the ordinary drawer's depth. The appropriate position of such objects in the general series can be replaced by a dummy, or blank slide, numbered *seriatim*, and with a reference where its real counterpart is to be found. The latter, meanwhile, also bears its consecutive number in the series. Entire sets of deep drawers having an additional shelf let in from the top I consider objectionable. These may, indeed, come in handy where a cabinet with a set of deep drawers, originally intended for another purpose, is converted into a microscopic receptacle. The microscopic cabinet of our Royal Microscopical Society has been altered in this fashion, and the available area of the double tiers consequently can contain twice the number of specimens they originally did in the deep drawers. It behoves, however, that a sufficient proportion of deep ones be retained.

The compartments of the drawers should admit of the slides lying with the narrow ends, or long diameter, fore and aft. In this way there is no chance of the slides overriding and, when the drawer is suddenly drawn out, injuring each other. In the event of a specimen, not too deep for the drawer, occupying a greater surface than the usual 3in. by 1in., provided it is not over 3in. square, it may readily be placed transversely to the tray or drawer's direction. If it should be above 3in. in diameter, the transverse bar or partition can be cut in such a manner that the slide shall occupy a double interspace. The end of the divided bar will prevent

† "Diatomacearum Species Typicæ, Studiis," Th. Eulenstein. Cent I. Stuttgartiæ, 1867.

it moving sidewards. This simple plan, and such like trifling mechanical contrivances, are very useful in preserving unanimity in a series. They keep specimens in their proper classified position, instead of being scattered to a distance.

AGRICULTURAL MANURES.

FROM an interesting paper on the important subject of manures for agricultural purposes, read by Mr. C. D. Hunter, of Blennerhasset, before the Wigton Farmers' Club, we extract the following particulars obtained from practical trials. In commencing his remarks Mr. Hunter drew especial attention to the necessity of a knowledge of agricultural chemistry to the farmer who desires to learn his business thoroughly, and then went on to give an account of his experiments, beginning with the effect of different manures on hay.

On seeds, nitrate of soda applied alone in 1868-71, gave, as the average of four years, 54 stones of hay for every cwt. of manure applied; when used along with superphosphate and muriate of potash it gave 58 stones of hay per cwt. Sulphate of ammonia used alone gave 50 stones of hay per cwt., and in conjunction with mineral manure 48½ stones. Peruvian guano, again, used alone for three years, gave about 8 stones less than sulphate of ammonia for the same period, or equal to 42 stones; and in mixture it gave equal to 80 stones. Nitrate of soda, it will be seen, proved the best nitrogenous manure for hay, and also went farthest when used with a mineral manure. On a clay soil Mr. Hunter had only one experiment. The land was in very poor condition; the unmanured crop weighing only about 10 cwt. per acre. On this poor clay, sulphate of ammonia proved superior, giving, when applied alone, a return of 65 stones per cwt. of manure, and with superphosphate and muriate of potash 95 stones.

Nitrate of soda gave, alone, 89 stones of hay, and in mixture 66 per cwt. The experiments on oats **are more trustworthy, but having been tried on but one soil and under the unusual conditions of three years on the same land, they must not be regarded as entirely applicable to ordinary farming.** From a **want** of reliable no-manure and mineral-manure **plots** for comparison, the figures given may be, as a **whole**, a little too high or too low; but the comparisons between the three manures are quite exact. **Applied** alone, sulphate of ammonia proved superior **for oats**; and, taking its return per cwt. of manure **at 12** stones of corn, Peruvian guano gave 11, and **nitrate** of soda nearly 7 stones. Applied in conjunction **with** mineral manure, nitrate of soda proved **superior; and, taking its return per cwt. as 20 stones, sulphate of ammonia gave 18,** and Peruvian guano **17 stones.** It is rather curious to find nitrate of **soda last** when used alone, and first when in **mixture**; further experiments may but confirm this **fact, but** without further trial, said Mr. Hunter, I **could** not undertake to say which was the best **manure** for oats. One point seems, however, pretty **well** established, viz., that sulphate of ammonia and Peruvian guano proved of nearly equal value in **both** cases. The guano used was the Chincha **Island** of best quality, the supplies of which are now exhausted; but any good guano containing over 6 **or** 8 per cent. of ammonia will prove a good corn **manure.** Barley was also experimented with for **three** years upon the same soil; the same remark **applies** to this as to oats, viz., that the weight, as a **whole**, may be a little too high or otherwise, but **that** the comparisons are just enough. Nitrate of **soda** here takes a decided lead all through, and, **taking** its return per cwt. of manure at 20 stones of **corn**, Peruvian guano gives only 9 stones. Sulphate **of** ammonia was not tried alone, but in mixture **proved** superior to Peruvian guano; thus, nitrate of **soda**, used with mineral manure, gave about 14 stones of corn, sulphate of ammonia 11¼, and Peruvian guano about 7 stones per cwt. of nitrogenous manure. This shows nitrate of soda twice **as** valuable for barley as Peruvian guano, and **slightly** superior to sulphate of ammonia. On potatoes I have experimented very largely, and have, **from** over four hundred trials, a number of very **valuable** facts bearing upon the seed cultivation **and** manuring for this crop. **An average** of six very **reliable** plots gives 161 stones of potatoes as the produce per cwt. of sulphate of ammonia, used in conjunction with superphosphate or nitrate of potash; Peruvian guano, in the three years' trial **against** this gave equal to 99 stones, and nitrate of soda 39 stones. Some other experiments place **nitrate** of soda still lower, and two trials with **Peruvian** guano, used alone, give 84 stones per cwt. **of** manure, but these are not strictly comparable **with** the others, being on different soil each year. **From** the foregoing experiments on nitrogenous **manures**, it is evident that the value of a manure is **affected** by the source of its nitrogen as well as by **its amount**, and that a statement of the raw **materials** used in making the manure is essential **to a** correct estimate of its value. An analysis protects the farmer from adulteration, and a composition may protect him from misapplication; thus, **if** these results hold good on the generality of light **soils in** Cumberland, it is evident that a potato **manure containing** nitrate of soda is much inferior to one containing sulphate of ammonia, though both may analyse the same percentage of nitrogen; 4 per cent. of this being supplied by either 16 per cent. of sulphate of ammonia, or by 26 of nitrate of soda.

Phosphates: Potash.

The phosphates next demand our attention, as being, after nitrogen, the most important of our manurial substances. Bones, guano, and the mineral phosphates are the principal sources of supply. In the raw state the former are, of course, almost valueless; but in the dissolved state, as bone or mineral superphosphate, their value in the field is the same —and soluble phosphates from bone are of no more value than those from coprolites. Superphosphate of any kind applied alone, is, as a rule, wastefully used. Three experiments give it a value of 6½ stones of hay per cwt. of manure so applied, and as the superphosphate costs about 5s. 6d., and the hay is only valued at 3s. 3d., it is evident that this will not pay. Used in conjunction with muriate of potash and nitrogenous manures it did much better, three experiments giving a value of 17 stones per cwt. of superphosphate. It is noteworthy that in the same series of experiments it was applied to 2 plots along with nitrogenous manure, but without muriate of potash, and its value here at once fell to 10 stones of hay. This shows how one manure helps another, and that on soils deficient in potash a good manure wanting in this element is used at a great disadvantage. Plants require many elements for complete growth, and the superabundance of nine can never make up for the absence of a tenth. For all crops, but more especially the root crops, phosphates are invaluable. Potash, from the prominent figure it makes in the ash analyses of all plants, has always held a high place in agricultural science; but till quite recently its price forbade its use in agricultural practice. The discovery of potash deposits in Germany was the first circumstance that brought potash manures into general use. In 1867, when I first experimented with potash, I could purchase at £7 10s. per ton the same article for which I must now pay £12 or £13. Muriate of potash, sulphate of potash, kainit, and crude potash salts are the chief sources of this manure. In 1868-70, I tried the first two on potatoes and clover seeds. Potash salts should not be used alone. Three years' trial of muriate of potash at the rate of 4 cwt. per acre gave it a value of nearly 6 stones of hay per cwt. of manure; two of these years gave it, however, a value of about 8½ stones. Sulphate of potash gave 15 stones; probably its superiority to the muriate is due to the fact that sulphuric acid is more essential to plant life than the muriate. On potatoes its superiority is more doubtful, and probably when used with superphosphate, sulphate of ammonia, and other manures containing much sulphuric acid, its superiority would be less evident; further experiments are, however, required to decide this point—the greater abundance and less cost of the muriate also make it more desirable as a manure. Used along with nitrogenous manures and superphosphate, muriate of potash showed much better results, giving per cwt. of manure 14 stones of hay; this, though not immediately profitable, is so nearly so that in all probability the after effects more than repaid the outlay—and I would recommend that for light land a good grass manure should contain from 10 to 20 per cent. of muriate of potash, equal to from 5 to 10 per cent. of potash. I prefer muriate of potash to kainit or inferior potash salts, because, as a rule, it contains four times more potash. In 1870, I tested kainit against muriate of potash for potatoes, and from the results on four plots of each, the muriate proved itself about five times more valuable. For potatoes potash has shown itself indispensable. In two experiments where it was mixed with lime and salt and applied both alone and with farm-yard manure, it gave the first year per cwt. of muriate, 49 stones of potatoes; the second year, 64; and the third year, 104 stones. With farm-yard manure 1½ cwt. was used, mixed with an equal quantity of salt and 1½ cwt. of lime; alone, nearly double these quantities were used. Applied in conjunction with superphosphate and sulphate of ammonia it gave over two years an average return in four experiments of over 250 stones of potatoes per cwt. of muriate; this was, however, the second and third years on the same soil, and is thus unusually high. It was tried with superphosphate against superphosphate and salt—4 cwt. of each—for three years in three different fields, and gave 55 stones of potatoes per cwt. of muriate; when added alone to superphosphate it gave only 12 stones, and in one experiment, used alone, it gave 43 stones. From these experiments it is evident that neither for hay nor potatoes should potash be used alone. Plant life is in some respects not unlike animal life, and you might as well expect good health in an animal fed on water alone, or on straw alone, as in a plant fed on but one manure. A good potato manure should always contain from 15 to 25 per cent. of muriate of potash, equal to 7 to 12 per cent. of potash. On carrots, after the failure of 1868, I did not again find time to experiment till last season, when the addition of 2 cwt. of muriate of potash to a mixed manure of superphosphate and sulphate of ammonia, raised the produce nearly 8 tons per acre. On turnips, I have but few reliable experiments, but these go to show that a good turnip manure should contain some potash, though less is required than for potatoes. For grain crops I cannot recommend potash; in special cases it may be useful, but for general purposes its presence is unnecessary.

Magnesia.

Magnesia is usually present in the ash of plants to a considerable extent, and has often been recommended for hay and potatoes. In repeated trials I have not found its application attended with much benefit. Eight experiments on potatoes give it the low value of 5lb. of potatoes from 1 cwt. of sulphate of magnesia, that is 6s. worth of manure to produce 2d. worth of potatoes. In these experiments it was used in conjunction with superphosphate, potash, and salt, without any nitrogenous manure; further experiments with nitrogenous manures did not show any better result. On clover seeds, the balance of six experiments with 2 cwt. per acre of sulphate of magnesia, give it a value, per cwt. of 1 stone of hay; it gave the best result—12 stones—when used in conjunction with muriate of potash, common salt, and a little sulphate of ammonia, neither of the first two containing any sulphuric acid; and the poorest result was when added to sulphate of soda and sulphate of ammonia, a mixture containing an abundant supply of sulphuric acid. These facts point to the sulphuric acid of the sulphate of magnesia as the active portion of this manure in these experiments, but neither upon seeds nor potatoes did it pay one-fourth of its cost.

The Application of Salt to the Soil.

Salt is the last manure I shall touch upon. It has been strongly recommended by interested parties, and has doubtless its uses, but as a rule it is more serviceable as a destroyer than as a plant food. Against grub, wireworm, &c., and as a prolonger of vegetation in dry seasons, it is of value, but as a direct manure it more frequently does harm than good. On hay, 4 cwt. per acre applied alone reduced the crop in two experiments, and increased it in two, the balance showing 8lb. of hay per cwt. of salt. This seems a common result throughout all England, as thirteen experiments reported by Dr. Voelcker show only 47lb. of hay for 4 cwt. of salt per acre. The addition of about 2 cwt. of salt to a mixed manure for seeds reduced the produce in seven experiments by more than 2½ cwt. of hay per acre. The balance of testimony is thus against its use as a direct manure for hay. On potatoes, used alone, it seems to have been of service, giving nearly 17 stones of potatoes per cwt. of salt, but when added to a really profitable manure like superphosphate, it almost invariably reduced the crop. It is rather an interesting fact that, though often found in the ash of plants as soda, it is sometimes absent, and for some plants its presence is not necessary to a healthy growth. These are the most salient features of our four years of field experimenting on manures at Blennerhasset. The details of many of the experiments are very interesting, and to put them in a practical form, I will give the composition of several manures, as suggested by the foregoing results:—

Crop.	Nitrate of soda.	Sulphate of Ammonia.	Superphosphate.	Muriate of Potash.	Total per acre.
	Cwt.	Cwt.	Cwt.	Cwt.	Cwt.
Hay	1½	—	3½	1	6
Oats	1½	1½	3	—	6
Barley	1½	—	3	—	4½
Potatoes	—	2½	6½	3	12
Turnips	—	1	3	1	5

In the discussion which followed, Mr. Hunter was asked whether, in his opinion, the value of salt in agriculture did not much depend on the proximity of the land to the sea. Probably the salt would be of greater value away from the coast than near to it.

Mr. Hunter said he had heard it said that salt was not quite so useful near the sea coast as inland; but from the thirteen experiments made by Dr. Voelcker, it was shown that he got only 47lb. of hay for 4 cwt. of salt. So that these experiments, in thirteen different parts of England, showed no better results than his experiments with salt at Blennerhasset; which went to prove that it was not of much value. Many plants, indeed, could grow without any soda at all. He had himself never experimented with salt on mangolds, but it was a common saying that mangold "paid well" with salt.

Mr. Hornsby asked if Mr. Hunter had ever tried superphosphates alone, or in addition to farm-yard manure? He had tried nitrate of soda to some extent, with the best results on grass land, his being rather strong land, with a cold bottom.

Mr. Hunter said he had never tried superphosphates along with farm-yard manure. He had tried it alone on grass land and with potatoes. It always gave a heavier crop, but he never found it pay when used alone; he had tried bones and bone dust on grass land, but bone dust did not pay. For three years he tried both, and, curious to say, looking at the results of the whole period, he found that bone dust and guano, and dissolved bones and guano, produced exactly the same result, viz., each something like 15¾ tons of potatoes per acre in three years, or about 5¼ tons each year. He could not recommend bones alone. Dissolved bones, indeed, were a lasting manure, but there was no difference between soluble phosphates of bone and coprolites. It was the insoluble phosphates which were much superior He had tried kainit on potatoes, and also muriate of potash—four plots of each. What they bought for dissolved bones were not dissolved bones, because the makers would not make them, as their reputation would suffer if they sent out the nasty, dirty-looking thing which dissolved bones were. Instead, they sent out a nice preparation, consisting of, perhaps, one-third of bone and two-thirds of coprolites. If they wanted dissolved bones they must make them themselves. Last year he tried dissolved bones—that is, commercial dissolved bones—against superphosphates on turnips, and he got 13 cwt. more from the dissolved coprolites than from the dissolved bones. He did not mean to say that every experiment would be found against them, but this experiment was decidedly against dissolved bones. They were mixed with sulphate of ammonia, muriate of potash, salt, and gypsum, and everything that could give them strength, so that it was a fair trial with the dissolved coprolites.

REMOVING PHOSPHORUS FROM IRON ORES.

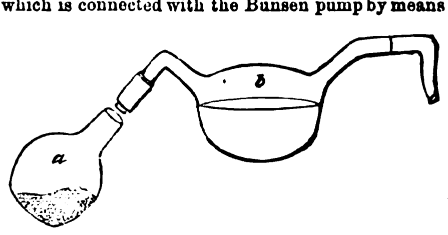
ACCORDING to one of the foreign scientific publications, Mr. Julius Jacobi, director of the smelting works at Kladno, Bohemia, has invented a process of effecting the removal (and subsequent utilisation) of the troublesome phosphorus compounds from iron ores; its efficiency in practice remains still to be tested. The process consists in changing the insoluble basic phosphates, as they exist in the ores, into soluble acid phosphates, and the subsequent removal of the latter by leaching. The ores to be operated on are placed in an appropriate vessel, after being reduced to convenient lumps of moderate size, and a stream of water charged with sulphurous acid is allowed to run upon them, or a stream of the gaseous acid is forced through the mass, and cold water is at the same time turned upon it. After the greater part of the phosphates have passed into the solution, the liquid is drawn off, and fresh water is passed through the mass to wash it thoroughly—this operation being continued as long as phosphoric acid can be detected in the wash water. If much phosphorus exists in the ores, the operation with sulphurous acid must be repeated, until a sufficient degree of purity is reached. The liquid containing the acid phosphates is heated to drive off the sulphurous acid, and the phosphates are again separated, partially by concentration, or by precipitation with lime. This being a valuable fertiliser, is relied upon to cover a large portion of the expense of the operation.

THE DURABILITY OF TEXTILE FABRICS.

WOOL and silk are the most enduring of textile fabrics. The first-named fabric gives evidence of its superiority as an article of clothing, from the fact that it is almost indestructible, and when from long service it is apparently worn out, its durability is once more seen in a new form, as it comes from the mills under the name of shoddy. Nor is this name of reproach entirely just; for are not carpets, druggets, mats, cloths, blankets, and many other articles of domestic use made from it, and does not its continued use attest the fact that for many purposes it can be employed to answer well the place of more expensive goods? The best wools for service are very strong, elastic, and soft to the touch. A variety of low grade wools similar to the Scotch cheviot, when of the right quality, will wear constantly and look well for many months, and in some cases have been known to look almost as well as new at the end of the second year. One peculiarity of this wool is that it takes the dye freely, and retains something of its original lustre until it is worn out. Cotton and flax are liable to a more speedy destruction than other textile products, and may ultimately be reduced to a mere wood fibre. Both of these materials, when made into fabrics, are frequently greatly injured by the process of bleaching, and will stand a very little use, even if their destruction is not greatly accelerated by the further abuse of the washerwomen. Unbleached cotton goods of all descriptions will outwear the bleached, and after a few times washing will look quite as well. Silk fabrics are very enduring, particularly velvet and plush, which often are in use for years, and retain their excellence and beauty until almost worn thread-bare. The manufacturers of France and Germany have beaten their English rivals in the production of cheap and showy silk goods for some years, but it is well known that English silk goods are far more durable than foreign. A textile product is obtained from several ruminating animals in the mountain ranges, known as the Llama, the Paco, the Guanaco, and the Vicugna. The fleeces are very fine, lustrous, and long, and are remarkably free from the attack of moths. The fibre is peculiar, closely resembling the down of the Cashmere goat, and appears to hold an immediate position between wool and hair. In texture it is nearly as fine as silk, besides being very durable.

APPARATUS FOR DETERMINING SPECIFIC GRAVITY.

DR. G. E. MOORE suggests, in the *Journal für Praktische Chemie*, a very ingenious device for determining specific gravity, which, as it may be serviceable to others in similar cases to the one which rendered it necessary, is here produced. The substance operated upon was the black precipitated sulphide of mercury, and as it possesses the unpleasant peculiarity of retaining with great tenacity a coating of air, a complete mixture with water was found to be impossible. The use of the air-pump was also attended with difficulty from the foaming which ensued. To meet the difficulty, the device shown in the accompanying figure was contrived. This consists of the ordinary specific gravity flask *a*, which is connected with the Bunsen pump by means



of the bulbed tube *b*, whose middle part had been widened out into a bulb of equal capacity with the flask, the communications between the bulb tube, which is filled to about three-fourths with water, and the flask being made air-tight by a moist rubber collar. As soon as the manometer of the air-pump indicates the maximum of rarefaction, the apparatus is inclined, whereby the water runs gently from the bulb into the flask, penetrating every pore of the mass without forming a particle of scum.

ON EARTHQUAKES AND VOLCANOES.*

BY AUGUSTUS LE PLONGEON, M.D.

(*Continued from p.* 194.)

3. Whence the Heat Experienced on the Surface and in the Interior of the Globe?

I WILL answer. I told you that I consider the earth as animated, a living being, living out its own life among its brothers and sisters of the immensity, just as any one of us among our fellow-beings. That, as we have our soul, which gives life, activity, and warmth to our bodies, so has the earth its soul, that gives it life, activity, and warmth, that animates all things existing in it or on its surface. I told you that this soul is electro-magnetism.

I do not suppose that any scientific man will dispute me, that electro-magnetism is the agent of the attraction that celestial bodies exert upon each other; and this is the cause of their motions through space. Nor will any one deny that motion causes friction; that in its turn engenders heat and light; that electro-magnetism causes the cohesion of all the molecules whose aggregate composes the universe is a well admitted fact. It is, therefore, the life-sustainer, the soul of the whole creation, of which our reduced planet is but one of the smallest atoms.

I have said that electro-magnetism was the agent that produced the heat of the earth. Let us see if my assertion is sustained by facts; for only through the observation of facts, and a clear unprejudiced mind, can we compare them together and arrive at the knowledge of their causes, and to the causes of these causes that form the catenation of the natural laws, whose understanding and interpretation is science.

1. The earth swims in a medium—a universal fluid that fills all space. Call it by whatever name you please—ether, cosmic fluid, imponderable fluid. This something is obviously matter under a certain form. It has been asserted to be composed of 64 elements that Graham has classified into six series or classes. This something, being matter, offers resistance, and opposes the forward motions of the bodies that pass through it. Of course it opposes the forward motion of the earth in its movement round the sun, and through the immensity where it follows this body in its rotary motion around an unknown centre. This resistance not only causes the diurnal rotation of our planet; its conical movement, which it accomplishes in 25,868 years; its vibratory motion that produces the phenomenon known as tides; but also as the earth forces its way through the universal fluid at the stupendous rate of 30,550 metres per second, besides the 464 metres per second of her diurnal rotary motion, a large amount of continuous friction is produced throughout its whole surface, but particularly at the equator, where the globe is larger. Friction, anywhere and everywhere, creates heat. It is, therefore, impossible to doubt that this is one of the causes that produces heat at the surface of the earth. That heat so generated during countless ages has progressively and steadily permeated its superficial strata, and is preserved in the inferior ones, not exposed to the external causes of refrigeration, like those above, is obvious, and men find it there when they penetrate into them.

I might illustrate my proposition by the example of the cannon ball, that when discharged from the cannon's mouth, is cold, but after having traversed the air at the rate of 500 or 600 metres a minute, is very hot at the time it reaches its destination; but the process of refrigeration begins from the surface toward the centre; and if we split it we find that the interior is yet hot while the external parts are quite cool. What is our reduced planet but a very small cannon ball, that has become heated traversing the cosmic matter, since centuries, at the frightful rate I have just mentioned?

2. The rays of the sun are another cause of the heat of the earth. These rays are not hot, certainly not; the snows that eternally cap the highest mountains prove it. How then can they impart heat if they are cold? Oh! electro-magnetism again is at work there. It is true that the rays of the sun do not convey heat, but they carry light. Light puts in motion the molecules that compose the atmosphere. They rub one against the other: there is friction; friction engenders heat—the atmosphere in its lower strata being more dense, the friction is greater, consequently more heat is evolved and communicated directly to the surface of the earth. It penetrates its lower strata, and there is preserved, as already stated, increasing the intensity of that produced by the first cause.

It is not relevant to prove how the rays of the sun carry light through electro-magnetic agency. The electric lamp of Servin is a good illustration of how electro-magnetism engenders light. The sun, immense reservoir of electro-magnetism, we may consider as the positive coal of Servin's lamp—the earth, another reservoir, but smaller, the negative coal; the light produced is in proportion to the distance of the two poles.

"All bodies," says Mr. Jacobi, of S. Petersburg, "are magnetic in a larger or smaller degree. The earth is a vast magnet, and so are, without a doubt, the other planets, their satellites, and the sun itself."

Then the rays of the sun, acting through, or rather produced by, electro-magnetism, are another cause of terrestrial heat.

3. The internal heat of the earth is also due to the immense chemical operations constantly going on under the agency of electro-magnetism, at no great depths, insignificant even if compared to the supposed crust of the planet.

This, as far as we know, is a vast conglomeration of metallic and mineral matters, which, in order to combine, only need the action of the agent. This agent is electro-magnetism. For, as says the translator of Lyell's Geology: "It would be a great error to believe that the action of electricity is powerful only when noisy and sudden. Its tacit and quiet action throughout nature is far more important. It extends its influence in nearly all combinations. The chemical affinity itself does not seem to be but a variety of electrical attraction. And since the constant reunion and the *quasi*-identity of the electrical and magnetic fluids has been demonstrated; since the phenomena of the magnetic needle, those of the thunder, of the electric fluid in the air, and its dispersion, find an explanation in the action of electro-magnetism, well may we presume that electro-magnetic currents circulate in the interior of the globe; and, indeed, experiments performed on the electro-magnetic properties of metalliferous veins have led to the discovery of marks and vestiges of these currents in the interior of the earth."

We all know that chemical combinations, decompositions, and recombinations take place incessantly in the vast laboratories of the earth. These operations are nothing else but the result of the action of electro-magnetism on the molecules of matter. These are in continual motion. During their travel they evolve heat, in consequence of the perpetual friction they are subjected to. Hence the chemical operations going on in the interior of the planet are another and third cause of its heat; and the life-sustainer, electro-magnetism, the agent.

4. The oxidation of metals is another cause of the heat of the earth.

It is a truth known and demonstrated that currents of electro-magnetism traversing metallic bodies produce oxidation.

The earth, or at any rate that portion explored by man, is a conglomeration of mineral and metallic bodies. These are constantly traversed by electro-magnetic currents. Oxidation then takes place incessantly and produces an augmentation of temperature. Slow, it is true, but constant.

Leaving aside all imaginings, which should never be invocated in the elucidation of scientific questions, as it has unhappily too often been the case in the very one under consideration, I will try to coordinate the truths enunciated, and direct their

* From *Van Nostrand's Magazine.*

light into the darkness that surrounds the mystery of the earth's convulsions, and try to discover the part they play in

4. The Productions of Earthquakes and Volcanoes.

What are volcanoes? Are they the safety-valves which prevent our poor little planet from bursting like a bomb and sending us flying towards the skies, as some pretend?

This question I will answer by another. Who would ever imagine to inquire if the boils, that sometimes, under the influence of certain pathological conditions, appear on the human body, are the safety valves, intended by nature to prevent the explosion of that body?

If there are no central fires: if it is mathematically, scientifically, nay, materially impossible there should be any, what is the use of vents or valves? If the planet is a solid mass, what danger does it run of exploding?

But let us suppose, for an instance, with Buffon, Zimmermann, Humboldt, Cuvier, La Place, Beudant, and many other illustrious defenders of the existence of an internal ocean of fire, whose burning waves sweep, ebb, and flow against the walls of the thin shell on which we live in imminent danger, and examine if the volcanoes can be the vents of that immense furnace.

Our first step will be to ascertain the number of volcanoes and the size of their craters.

Geographers tell us that there are 163, the positions of which are perfectly known: 67 are on continents, 96 on islands; adding this most singular fact, that none of these situated on continents are at a distance exceeding from the sea more than 75 miles in an air line—a peculiarity that I commend to your attention.

Humboldt asserts that they number in all 223—all active; Keith Johnston declares that there are 270—190 on islands, 80 on continents.

Never mind what these authors say about the number of volcanoes; I will grant that there are many more they knew nothing about. Let us be generous and double the number, so as not to be accused of trying to crawl though a small hole. We shall say there are 550 vents or safety-valves, if, by-and-by, volcanoes prove to be such.

Our next step will be to ascertain the size of the chimney or crater of these vents.

Geographers, again, tell us that the crater of Vesuvius, one of the largest known, is 2,000 metres in circumference. Let us continue to be generous, and say that the average opening of all the craters is 3,000 metres in circumference. One thousand in diameter, the 20,000th part of the supposed thickness of the terrestrial crust. That is, admitting that the chimney is of the same size all the way down.

What is a hole of 1,000ft. in diameter compared to the whole surface of the globe? It is not even as much as a hole made on one of the terrestrial spheres in use in our common school with a fine cambric needle.

Now, by way of illustration, and in order to keep all due proportion, let us suppose one of these globes to be one metre in diameter, hollow, made of the most refractory metal—say platinum—the thickness of which, in order to correspond to the thickness assigned to the supposed crust of the earth, would be three millimetres. We shall proceed to bore on the surface 550 small holes with a fine needle. These will represent the volcanoes or safety-valves. After these we shall introduce into it—through an opening left for the purpose, to be afterwards closed and the covering solidly consolidated, so as to present the same amount of resistance as the balance of the surface—two parts of filings, one and a half part of pulverised sulphur, and a sufficient quantity of salted water to make a soft paste. When the chemical decomposition will take place, and the heat so intense as to melt the whole mass into sulphuret of peroxide of iron, the water will have been converted into steam, this again into gases: do you imagine that the 550 little holes or safety-valves will permit a sufficient quantity of steam or gases to escape, and prevent the apparatus from bursting? Will even any steam or gas escape through these little openings?

Any unprejudiced mind will say, no. Then how can the 550 volcanoes that we have supposed to exist on the surface of the earth be considered any longer as the safety-valves of the great liquid heart said by some geologists to occupy the centre of the planet?

Their assertion cannot stand the touchstone of science. And the truth of our denial is the more obvious, if we take into consideration that not one-tenth of the known volcanoes are in activity; and that those which are active do not continually throw out lava; which they would if connected with the central furnace.

From all that I have just said I think I may safely deduce that the volcanoes are not the safety-valves of the earth, but mere local accidents on its surface, just as boils are on the human body.

There is another remarkable fact connected with the existence of volcanoes. It is this. That all volcanoes, without an exception, have for a base, and are situated on, primary formations; showing that the combination of porphyric or granite rocks with the metallic veins found in them is the only one capable of giving birth to volcanoes, through the agency of the electro-magnetic currents that traverse them. It is out of the limits of this article to enter into a nomenclature of all the substances found in the superficial strata of the planet, whose nucleus seems to be formed of granite, syenite, protogine, diorite, pegmatite, and porphyry, crossed in every direction by metallic veins.

It is well known that whenever two or more of these mineralogic and metallic substances are put in contact, and thoroughly wetted with salt water, a chemical decomposition takes place evolving heat, the more extensive the decomposition the greater the amount of heat.

It may even reach incandescence under certain circumstances; such, for instance, as the influence of the sun or other celestial bodies, that, acting one on the other as powerful magnets, engender immense voltaic arches, scattering throughout the boundless fields of creation light and heat.

Then, wherever a large quantity of these substances has accumulated, there will be a large amount of heat developed, which under proper conditions will give birth to a volcano. This is also one of the causes of the multitudinous variations that are observed in the temperature of the divers parts of the earth, even at the same depth.

It is a fact very evident, that if that heat had its source in a central fire that would emit an inconceivable quantity of caloric, the thin crust would be equally heated, even to the top of the highest mountains; seeing that the Guarisconkar, in the Himalaya, said to be with the Illimani and Sorata in Bolivia, the highest peaks of the globe, is only 9,000 metres in height, that is to say, the 1400th part of the earth's diameter.

5.—Are There any Means of Detecting the Places where such Accumulations Exist?

Seems to be the next very natural query that presents itself to the mind.

If you read carefully the history of all the volcanic eruptions; of all the great earthquakes that have laid to the ground the habitations of man, and buried the inhabitants under their ruins, you will find that premonitions have passed unheeded, because there were no inquiring, no scrutinising minds to take note of them, and draw from them the proper inferences. In many instances sulphurous vapours have been seen arising from the ground; strange and mysterious underground noises are heard, inspiring awe and terror alike in men and beasts; mineral waters are seen to be altered; soft waters are seen to become turbid in wells; the level of these waters is changed. Sometimes even the wells become perfectly dry, without any apparent reason. In caves, cellars, excavations, carbonic acid gas is noticed to emanate from the soil; magnets lose their power according to the force of the impending convulsion.

Experience has taught men to recognise in these phenomena the symptoms of a mighty underground work—the signs of some terrible cataclysm near at hand, and the same are observed in the artificial volcano of Emery. Pliny the Junior, in a letter to Tacitus describing the death of his uncle, ascribed it to suffocation, caused by the sulphurous vapours emanating from the ground, and calls them the forerunners of the catastrophe. It is well known that the sulphur mines are invariably found in close proximity to volcanoes—nay, in their very crater.

I have said that on the continents none of the volcanoes are at a distance from the sea exceeding 75 miles in an air line. By some means or other the waters of the sea penetrate into the interior of the earth, since the vapours arising from the lava and the smoke coming out of the craters are the same as would result from the decomposition of salt water, and deposes large quantities of chloride of sodium. It is then that the salt water, coming in contact with the primary materials, causes the chemical decompositions and the generation of sulphurated hydrogen gas.

The sulphurets of potassium or sodium possess the property of decomposing the water at the mean temperature.

I will try to explain.

(*To be Continued.*)

CHIPS.

The United States have about 5,000 telegraph stations, 75,000 miles of line, and over 7,000 employés, and transmit over 11,500,000 messages annually.

It may be laid down as a general principle that a larger proportion of white flowers are fragrant than those of any other colour; yellow come next, then red, and lastly blue; after which, and in the same order, may be reckoned violet, green, orange, brown, and black.

A Berlin lithographer has, it is said, after years of study, succeeded in inventing inimitable paper money. The colour of the paper is the only secret on which the invention rests. The inventor says the colours cannot be chemically analysed; on applying the magnifying glass they can be distinguished from all other colours, and in their quality as colours they cannot be imitated by photography nor any other way.

SCIENTIFIC SOCIETIES.

ROYAL SOCIETY.

The Connection Between Colliery Explosions and the Weather.

AT a recent meeting of the Royal Society a paper was read, the joint production of Mr. R. H. Scott, F.R.S., and Mr. W. Galloway, from which it appears the authors conclude that they have established a connection between meteorological changes and explosions in mines. After briefly detailing the various instances of late years which directed their attention to a study of the subject, from which we gather that out of 525 explosions recorded in 1868, 1869, and 1870, 49 per cent. may be reasonably connected with disturbance of the barometer, 22 per cent. with abnormally high temperature, while 29 per cent. are not traceable to atmospherical agency, the authors go on to say:—It may not be out of place to discuss briefly the manner in which an increased supply of gas or a diminished supply of air, brought about by any of the causes alluded to, leads to a fouling of the ventilating current in its passage through the workings; and also how the comparative purity or foulness of the ventilating current affects the condition of the air in places adjoining its course. The gas flows from the fissures of the coal and stone either into a ventilating current by which it is carried out of the mine, as when it escapes at the face of a long-wall working or bratticed bond, or from the sides of an air-course; or, secondly, it flows into a quiet atmosphere, such as that in goaves and cavities in the roof whence stone has fallen in unbratticed bonds, or in recesses between pack-walls in long-wall workings. In any of these latter cases it diffuses itself into the surrounding air, and an accumulation of a more or less explosive character is generated. As long as the average quantity of air is circulating in the mine, and the quantity of gas which escapes into the workings is not suddenly increased, we may take it for granted that little danger exists, for the districts of the mine in which explosive mixtures are to be met with are clearly defined and well known, so that precautions can be taken to prevent ignition. As soon as these conditions are in any way changed (*i.e.*, if the supply of air be diminished in quantity or deteriorated in quality by an increased escape of gas) explosive mixtures may make their appearance in places where no danger had previously existed.

It may be assumed that a ventilating current consists of pure air when it starts from the end of the in-take air-course on its passage through the workings, and that for every equal space it travels between the in-take and return air-course it receives an equal quantity of gas. Thus, when it arrives at the return air-course it consists of a mixture of air and fire-damp, whose constitution depends on the quantity of air passing through the workings, on the rate at which the gas escapes into it, and on the distance between the in-take and return air-course. It is, therefore, evident that if either the supply of air be diminished or the supply of gas increased, the resulting mixture will be rendered more explosive, not only in the return air-course, but also at every point of the passage between the in-take and return air-course. If, then, from any causes the mixture shall have reached the firing-point when it enters the return air-course, any aggravation of these causes would make the firing point to travel backwards through the workings towards the in-take air-course. In this manner the ventilating current may itself become explosive in some parts of its course. Again, although the ventilating current itself may never become explosive, its gradual fouling may cause explosive mixtures to be generated in certain places, such as unbratticed bonds, recesses between pack-walls, and cavities in the roof in the following manner. All other cases may be more or less directly referred to these.

Figs. 1 and 2 represent sections of the workings. R is the roof F the floor, C is a point where the ventilating current passes in a direction normal to the plane of the paper. In Fig. 1, *a b c* is a cavity in the roof which is filled down to the level *d c* with a mixture of air and gas. Gas may flow into such a cavity from a fissure in the sides, or from any lower part of the seam along the roof and under the edge at *a*. In Fig. 2 *d c b* is an unbratticed bond, receiving gas from the face *b c*, filled with a similar mixture down to *d c*. The space occupied by the foul air is shaded in each case; and *e f* is a plane in that space which is chosen arbitrarily. The plane *d c*, which bounds the lowest part of the accumulation, is level, and here the mixture contains the least proportion of fire-damp; the impurity of the air increases with the height, and the foulest atmosphere is found at *b*, the highest point of the cavity. If any gas flows into the cavity a corresponding volume of the contents of the cavity is displaced and escapes into the ventilating current. Diffusion is also constantly going on; and as the result of this process is to produce below the plane *c d* a mixture lighter than the ventilating current, this mixture rises along the roof and is carried away at C (Fig. 1) *d* (Fig. 2). Gas is therefore constantly being removed from the cavity, partly by displacement, partly by diffusion, and its quantity is exactly equal to that entering the cavity. If now the ventilating current becomes fouled in any of the ways we have described, the space below the plane *c d* will be filled with the same mixture as that in the ventilating current itself. If we suppose that the mixture in the cavity up to a certain level *e f* be less foul, and therefore heavier than that which now forms the ventilating current, the volume of air, &c., in the space *d e f c* will be displaced, and no further escape of gas can take place from either accumulation until the whole of the contents above the line *c d* are more foul than the mixture below *c d*. As soon as this condition is fulfilled, diffusion and displacement will go on. In order, however, that the rate of diffusion may be the same as before, the specific gravity of the whole mass must be reduced, for the square roots of the specific gravities of the mixtures above and below the plane *c d* must bear the same ratio to each other that they did before the current became fouled. This reduction of the specific gravity is, in other words, increased foulness of the air. If, then, the mixture in the space *c b f* was previously near the firing point, it is obvious that any impurity in the ventilating current will cause it to approach nearer to that point, and so eventually an explosive mixture may be generated in a cavity while the ventilating current itself is non-explosive.

It will be seen that by the above process a quantity of fire-damp may be stored up in such a cavity, which can only escape very gradually, after the ventilating current has become purer. It follows, then, that if an explosive mixture has been formed in places and under conditions similar to those described, some time, possibly several days, must elapse after the causes which have led to its formation have disappeared before the contents of such a cavity shall have been rendered innocuous again.

A few words on the subject of the dependence of ventilation on temperature above ground may not be undesirable. When the temperature of the air at the surface is less than that in the mine the phenomenon called natural ventilation ensues. The colder air which descends the downcast shaft is heated nearly to the temperature of the workings on its passage through the air courses and along the working faces, and when it reaches the upcast shaft it has a temperature which is nearly constant if the workings are extensive. The temperature of the workings increases with their depth from the surface; thus, speaking generally, it is 50 deg. at 50 fathoms, 60 deg. at 100, 65 deg. at 150, 70 deg. at 200, and so on. Now, natural ventilation ceases when the temperature at the surface is the same as that in the workings, and, moreover, as the temperature at the surface rises above that point there is an increasing resistance to artificial ventilation. The amount of the force which produces natural ventilation is still further modified by the changes in the hygrometric state of the atmosphere. For instance, if the tension of aqueous vapour in the air is less than that due to the temperature, water will be evaporated in a wet downcast shaft, and the air will not be able to rise in temperature as it descends, and may be actually much colder at the bottom than at the top of the shaft. These considerations will show why shallow mines are much less easily ventilated, and also much more affected by surface temperature, than deep ones. Whatever be the artificial means adopted for producing ventilation at any mine, the quantity of air passing through the workings must vary with every variation of the natural force, unless the artificial power be changed at the same time. It follows, therefore, that if there be no means for ascertaining what is the actual quantity of air supplied to the workings at every instant, a slight decrease, sufficient to bring the colliery into a dangerous state, may take place without being noticed. The first intimation in such a case is the fouling of the currents; the artificial power may then be increased and the crisis passed without accident, but if an explosion takes place there is no trace of its cause discoverable.

Under ordinary circumstances, in the lower parts of small accumulations of explosive mixtures there is a stratum of air containing less gas than is requisite to make it explosive; and when the miner slowly raises his candle into this stratum, shading all the flame excepting the very top with his hand, he is warned by the increasing size of the "cap," the blue flame of the gas seen on the top of the candle flame, that there is an explosive mixture above. When the air in the mine becomes very pure this stratum disappears in many cases; there is no longer a space between the pure air, in which fire-damp cannot be distinguished, and the explosive mixture above, and the gas is then called "sharp," because it ignites without warning when a candle is raised into it.

The authors take exception to Mr. Dobson's argument, in which he concluded that the march of the explosion curve coincides with the march of temperature, with a relative maximum occurring in the autumn, which he attributes to the frequency of serious storms at that time of the year. In order to test this question of periodicity, the authors have collected from the reports of the inspectors of mines all the recorded explosions for the last twenty years. The explosions are only the fatal ones, and include a few accidents due to suffocation by "choke-damp," or carbonic acid gas. They consider that they may fairly count such accidents as due to causes closely related to those which produce explosions of "fire-damp." They plotted the whole of these explosions in two decennial periods for the seventy-three intervals of five days each, and found that the curves hardly showed any agreement with each other, so that no confirmation was obtained for Mr. Dobson's alleged periodicity. The curve for the entire period of twenty years, including 1369 accidents, was also constructed, and all that is worth notice about it is that the number of accidents is somewhat greater in October than in other months. The absolute maximum falls at the end of January, and the absolute minimum in the middle of September.

The gas commonly called "fire-damp," to the mixture of which with atmospheric air the formation of the explosive mixture in coal mines is due, exudes from the coal at a certain pressure, so that the rate of its escape must, to some extent, depend on the pressure of the atmosphere, especially in the shallower mines, where the tension of the gas is not great and the fissures are open. On the other hand, the effect of a given quantity of gas in rendering the air of a mine explosive must depend on the supply of pure air to the workings. It has long been observed that when the barometer, after having stood at a high level for a time, begins to fall more or less rapidly, the accumulations of foul air and gas in the goaves and fissures of a mine emit part of their contents into the ventilating currents which flow past them. It is also well known that as the very existence of these currents depends, in almost every case, on the difference of temperature between two columns of air, those in the downcast and upcast

FIG. 1

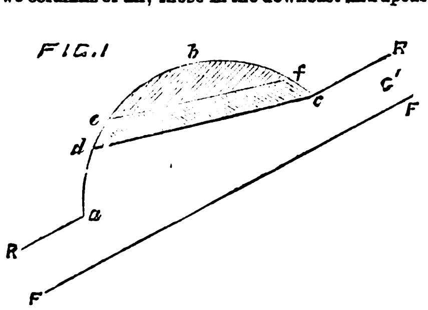


FIG. 2

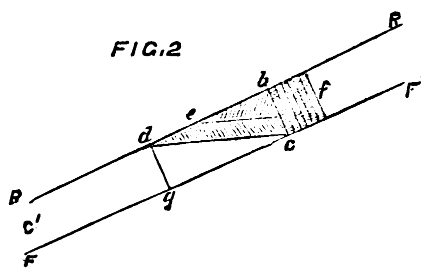

shaft respectively, any increase in the temperature of the external air, from which the downcast shaft receives its supply, must necessarily render the circulation underground more sluggish. It is, therefore, obvious that the tendency to explosion will be increased when the ordinary causes which lead to the fouling of the air in a mine, such as falls of roofs and leakages in the air-courses, are assisted from without by the meteorological phenomena just mentioned; and several investigators have compiled lists of explosions, in order to compare them with the meteorological observations which have been recorded prior to and at the time of the accidents. One serious disturbing cause, however, interferes with the value of the curves of pressure and temperature plotted from the records of the observatories, arising from the weekly suspension of work in the collieries, and in many instances of ventilation, too, on Sundays. There can be no doubt of the coincidence of certain serious explosions with severe storms; a notable instance of this will be found on the 8th of October, 1870, but the explosions do not happen only at the commencement of a barometrical depression, but occur also two or three days after the barometer has reached its lowest point, and is again rising. The cause of this prolongation of the dangerous period is that when fire-damp issues in greater quantity than usual from cavities and fissures into the workings, and more especially into places where the air is stagnant and already more or less foul by admixture of gas, the volume of the explosive portion of this mixture will increase in consequence of the increased rapidity of diffusion, or, in other words, the explosive boundary will extend itself. This extension of the explosive boundary is gradual, and in some cases a considerable time may elapse before the boundary has reached its extreme limits and begins again to recede. During all this period the mine will be in an abnormally dangerous state. Meanwhile, although the pressure of the atmosphere rises, and a current sets in backwards into the cavities, whence the pure gas has just issued, yet if the entrance to such a cavity be at a lower level than the highest portion of the space occupied by such escaped gas, which rises, owing to its less low density, it is evident that what is driven back into the cavity will be a mixture of gas and air, and that no portion of the gas which lies above the level of the aperture to the cavity can be driven back into it. Accordingly a certain volume of this pure gas remains, diffusing itself freely and fouling the surrounding air.

It is evident from these considerations that in the case of continued unsteadiness of pressure, and repeated violent oscillations of the barometer, we need not expect that each of these reductions of pressure will cause the efflux of a quantity of gas proportionate to the extent of such reduction. If the successive falls of the mercury are of less magnitude than the first, or than any previous one in the series, the quantity of gas given off cannot possibly be as great on each occasion as if that fall had been preceded by a period of high pressure. If, however, any of the latter oscillations be more serious than their predecessors, a certain fresh supply of pure gas will be given off. Hence we see that, as a general rule, we do not find a succession of explosions at a time when the barometer is in a state of continued violent oscillation.

Recurring to what has already been said about temperature, it seems that in cold weather the ventilation of the pits is exceedingly active, many collieries being ventilated easily by natural means without any extraneous agency whatever. In the height of summer, however, it is different; for then the temperature of the air in the downcast shaft is higher, and the ventilation can only be kept up by the help of the furnace. In some cases, then, a sudden rise of temperature may catch the miner unprepared, and where an active current would have remained safe, a sluggish one may become foul, and possibly an explosion may occur. Whether, therefore, the barometer falls or the temperature rises, it is absolutely necessary to keep a most careful watch over the amount of air passing through the workings, in order to prevent the formation of dangerous accumulations of explosive mixtures of air and fire-damp in all mines in which the margin between danger and safety is very small. The one cry, whether we look to security against explosion, or to affording to miners an atmosphere which is respirable without injury to health—is more air.

USEFUL AND SCIENTIFIC NOTES.

Granulated Gold.—Since 1862 Signor Castellani has made experiments in order to recover the lost art of forming patterns in granulated work in gold—that is, patterns composed of globules of gold almost miscroscopic in minuteness, each soldered separately to the surface, and arranged in lines, mottoes, &c. Hitherto this art had baffled all modern skill. Surfaces could be covered with the delicate granulated or powdered work, but patterns such as Greeks and Etruscans could execute were still a desideratum. Now the difficulty has been surmounted, and it is to illustrate this recovery of the ancient process that Signor Castellani exhibits some beautiful specimens of his workmanship at this year's International Exhibition.

The Gyro Pigeon.—A novel application of the principle of the aërial top has lately been effected by Mr. Bussay, of the Museum of Firearms at Peckham. This is the gyro pigeon, which is a plate of thin steel cut into the shape of a pair of elongated oval discs, connected in the centre, and bent at an angle like the blades of a screw propeller. This is spun from a spindle which is rapidly rotated by the action of a coiled spring inclosed in a metallic box, and released by a cord. The gyro pigeon is sprung into the air and is then fired at. It is good practice for the sportsman, as its flight is rather quicker and sometimes more erratic than that of the real bird. We are afraid, however, that it is too much to hope that the "gyro" will take the place of the birds so unmercifully slaughtered at Hurlingham and elsewhere.

American Paper Car Wheels.—In these wheels, which have lately come into use in the United States, the tire is of steel, and when turned up ready for the filling it is made taper inside, so that the inside diameter on the flange is ⅛in. smaller than on the other. The body of the wheel is a paper block made of straw-board cut into circles 30in. in diameter, pasted together with ordinary paste, and consolidated under a hydraulic pressure of about 300 tons. This block, after being slowly dried for nearly two weeks in a dry-house, is turned and fitted in a common pattern lathe. The turning tool is like that used for iron, but the speed is about the same as is used for brass. This block thus turned to fit the tire is, of course, somewhat larger, in order to insure a perfect fit. A hydraulic pressure of about 400 tons is then used to force the block into its place. The tire is heated nearly to the boiling point of water, thus insuring a perfect bearing when cool.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

*** *In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

AFTER "E. L. G."—THE DELUGE!

[4184.]—BEFORE addressing myself to the main object of this letter I must remove an erroneous impression which my own defective mode of expression would appear to have produced in the mind of "E. L. G.," and inform him that I *did* see the book (or the early part of the book) of the Bishop of Natal, when it first appeared; but that I had, as he surmises, utterly forgotten that it contained the expression which I quoted verbatim in my last communication (let. 4040), on page 171.

I think, however, that if "E. L. G." will read Mr. Scrope's book, and the various papers scattered through the *Journal of the Geological Society* on this subject, he will find that there are various indications which go to prove that certain of the volcanoes of Central France have, at all events, not been active since a date in comparison with which, that of his—imaginary—universal deluge is but as yesterday. "Grass or bushes" may have sprung up last year; but ashes, tuff, scoriæ, and lava are the product of a mountain itself; and if we can fix, even approximately, the epoch at which that mountain became quiescent, we most distinctly are entitled to consider all undisturbed volcanic ejections superposed on—or forming—it as coeval with that quiescence.

I fail to follow "E. L. G." in his objection to the validity of Professor Owen's argument, as negativing the possibility of a *universal* Deluge. If "*all* the high hills that were under the whole heaven were covered" it is merely irrelevant to talk about "the present geography," or "Australia joining Asia." And, besides, *what has become of the water?* Doubtless, there have been deluges at divers times and in sundry places, and one of these probably gave rise to the myth among the semi-barbarous Hebrews, of the whole world being drowned. Read all this as a grand old legend, and you may gain much instruction from it. Enunciate it as a scientific description of an actual occurrence, and, I say it advisedly, you play deliberately into the hands of the infidel and the scoffer. I shall not continue this discussion, as it is absolutely painful to me to find a man of the great intellectual ability, wide culture, and extensive information of "E. L. G.," arguing in a way which he would scout, were not (what he imagines to be) theological interests involved in the matter in dispute. I need go no further than his letter 4068 (p. 175) for proof that this is not an unwarranted accusation; and ask any impartial truth-seeker to read Lyell's own most circumstantial and detailed account of his visits to Niagara (both alone and in company with Mr. Hall, the State Geologist of New York); his careful measurements and calculations; and his perfectly candid summing up of the data on which his conclusions are founded; and then say what he thinks of "E. L. G.'s" sentence. "Not Lyell's '30,000 years,' which plenty of *his own* observed facts contradict, but, as any real inquirer will find, only *five* thousand ago." Was "E. L. G." ever at Niagara in his life; and if so, will he favour us with his reasons, *formed on the spot,* for differing with our great English geologist? If not, what is his definition of a "real inquirer"?

Letter 4068 is simply one mass of *assertion* from the beginning to the end. If Mr. Gosse (letter 4097, p. 198) really does value it as highly as he intimates, I can only say that, like the Scotchman, he is "thankfu' for sma' maircies." Does he regard it as a supplement to that valuable addition to our Naval defences, his own "Omphalos," long since in the hands of the butterman?

A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

TRANSIT OF THE ZODIACAL CONSTELLATIONS.—THE BARLOW LENS.

[4185.]—IF the object of your correspondent "C. A. S." (query 11765, p. 184) be to obtain a reply which shall facilitate his "star gazing," he could hardly have put a more useless question than that which he has asked; and for this reason: that the "signs of the Zodiac" (owing to the precession of the equinoxes) do not now, in any way, correspond with the *constellations* whence they originally derived their names. For example, the so-called "first point of Aries" is now in the Constellation Pisces; the first point of Taurus in that of Aries, and so on. Assuming, however, "C. A. S." to be familiar with this, and to require the information he seeks for some other purpose, I may tell him that the first point of *the sign* Leo was on the meridian, within a minute or two of midnight, on January 21st; the first point of Virgo at the same time on February 21st; the first point of Libra on March 22nd; the first point of Scorpio on April 22nd; the first point of Sagittarius will be due south about that hour on May 22nd; the first point of Capricornus on June 21st; the first point of Aquarius on July 21st; the first point of Pisces on August 21st; the first point of Aries on September 20th; the first point of Taurus on October 21st; the first point of Gemini on November 20th; and the first point of Cancer on December 20th. Lest, though, after all, "C. A. S." should have put the question which he did to obtain information which might enable him to more readily identify the Zodiacal *constellations*, I further append the days in 1872 upon which the lucida or brightest star of each of those constellations was, or will be, on the meridian at the time which he specifies:—α Geminorum (Castor), then, was on the meridian about midnight on January 12th; α Cancri on February 2nd; α Leonis on February 20th; α Virginis on April 10th; and α Libræ on May 2nd; while α Scorpii will transit at that hour on May 26th; α Sagittarii on July 10th; α Capricorni on July 24th; α Aquarii on August 20th; α Piscium on October 19th; α Arietis on October 20th; and, finally, α Tauri (Aldebaran) on November 27th.

I really must apologise to Mr. S. W. Burnham (query 11712, p. 159) for having overlooked his question last week, until it was too late to reply to it. I may now tell him that a simple concave lens would destroy the achromatism of his telescope, and that the Barlow lens, which he will be compelled to employ, consists of a concave crown and a convex flint lens of focal lengths proportionate to their dispersive powers, the combination obviously acting as a concave. By a very simple formula, which it is unnecessary to repeat here, it may be shown that to *double* the magnifying power of any telescope with a given eyepiece, if the distance of the lens from (*i.e.*, within) the focus of the object-glass be called *d*, then its focal length must be 2 *d*. Mr. Burnham will thus see that he will attain his desired result by placing a negative achromatic lens of 8in. focal length, 4in. within the focus of his object-glass (or 86in from it), his eyepieces fitting into the other or distal end of the adapting-tube.

A GUN-COTTON ENGINE.

[4186.]—IF "E. J. N." (4106, p. 199), is inclined to try and work out the idea he has, he may be quite sure that there is nothing impracticable about it. It would be quite easy to make such an engine; whether it is worth doing is quite another question, the answer to which depends upon at present unknown facts. I have often said that the construction of a flying machine is dependent, not upon occult problems as to the flight of birds, &c., but simply upon the possession of a powerful engine of light weight (to which aluminium bronze would greatly contribute), and a source of concentrated power or fuel, also of light weight. In fact, we know that if we can press an inclined plane against the air with a certain velocity it will rise and sustain itself, and its progress forwards would then depend upon the angle of inclination. All that is needed is the engine capable of maintaining this pressure practically.

Engines have been devised to be driven by gunpowder, and gun cotton, having greater energy and being more controllable, would probably be better. The quantity might be adjusted to the work readily enough; just as in some instances the governor adjusts the steam valves and quantity of steam admitted for each stroke.

SIGMA.

STRANGE AND RARE MUSICAL INSTRUMENTS, ALIAS QUEER FIDDLES AND PIPES.

[4187.]—I SHOULD be greatly obliged by any assistance in an intended paper on the above subject, which my fellow readers can afford by contributing descriptions—or references to such—of the subjoined wind and stringed instruments of music, stating the means by which their sounds are produced, the quality or timbre and relative power of those sounds, and the compass of each instrument.

CORNO DE BASSETO: (Italian, I believe) A species of clarionette.

MELO DI COW: Said to have been invented by Riffel, probably a kind of harmonicon with metal bars.

OCTO BASS: Possibly a kind of bombardon, or perhaps a very big fiddle.

HARMONICHORDE: Said to have been invented by Kauffmann, probably a species of mechanical keyed fiddle.

CROWLE: Probably a kind of bassoon or bass clarionette.

ADIA PHONON: Invented by Schuster, of Vienna, about 1820; I believe a kind of pianoforte.

SYMPHONION: Said to have been invented by Kauffmann.

CLAVACIN DE AMOUR: Probably a variety of the harpsichord—its peculiarities and why so called.

ANIMO CHORDA: Probably a variety of the Eolian harp.

OBBVALET: Probably a reed instrument of the oboe class.

ALTO BASSO: Possibly a bow instrument of the viol class.

THE HARMONIOUS BLACKSMITH.

CONCRETE MULTIPLICATION.

[4188.]—IT is never worth while to dispute about words, and therefore, in reply to "No. 170," and "M. A." (p. 199), I will readily concede that the form in which "M. A." (and before him "E. L. G.") expresses the idea is better than mine. The idea itself, however, is precisely the same; we may multiply feet by feet (or any other measures of length) and we do thus obtain a result which has an actual existence—*i.e.*, a measure of area expressed in a square unit, whether we say that this is "because there is such a thing as a square foot" with me, or with "E. L. G.," that it is an arithmetical dodge, and with "M. A." that we give a new and arbitrary meaning to the unit, of which the product represents the multiple. So, having thus multiplied feet by feet, and obtained a measure of area in square feet, we again can multiply by feet and obtain a result which has an actual existence—viz., cube feet, a measure of contents. Here we stop, we cannot for a third time multiply by feet, because there is no really existing fact or thing which the product would represent.

What we have, therefore, to consider is not words, but things and facts. We multiply 10ft. by 5ft., and we have a true result, an area equal to 50 square areas of 1ft.; we multiply this by 2ft., and we express in our result an actual fact—viz., our area of 50 square feet with a depth of 2ft.—*i.e.*, 100 cubes of 1ft. Now, this is not concrete multiplication, it is not a true multiplication of feet by feet; it only shows the meaning of the rules in the arithmetics.

If all the arithmetics published, and, furthermore, all the mathematicians living, were to assert that we could multiply 10 pounds by 5 pounds, either weight or money, their assertion would be simply a monstrous fallacy; for what existing fact, or what conceivable idea, is represented by the figures: 10 pounds multiplied by the number 5 means 10 pounds taken 5 times, and all added together producing 50 pounds? But how are you going to take 10 pounds—5 pounds times, and add them?

A schoolboy buys (we will say) 10 marbles for a penny, and having 5 pence, he expends his capital in marbles, and multiplies his stock to 50; but let him have 10 marbles in one pocket, and five in the other, and what possible multiplication can he effect, other than the ordinary process of winning those of his schoolfellows? He may, if he pleases, go to any of the arithmetics which profess to tell him how to do it, and study the first and second books of Euclid for a month, with the advantage of "No. 170's" assistance, and if at the end of the month he succeeds in doing anything with his marbles except shifting both into one pocket, and bringing out a total or product of 15, then, and not till then, will the possibility of concrete multiplication be proved.

Further, if concrete multiplication were a possibility as "an arithmetical dodge," why should there be any more difficulty in multiplying pounds by yards than by pounds. The real explanation is, that concrete numbers are only susceptible of addition and subtraction, and then only as compared with the same concrete object. You cannot add, for instance, a pint of water to a pound of flour, and produce anything which a number compounded of them will represent; as with feet you must use a new unit—paste.

SIGMA.

SOMETHING WRONG WITH JUPITER.

[4189.]—HAD Mr. R. A. Proctor deferred his article, written for *St. Paul's Magazine* about a year ago, on "Something Wrong with Jupiter," he would have had some strong additional evidence to support the title after reading Mr. Ralph Lowdon's letter (4071, p. 176), and might have reasoned on the probability of the "giant planet" becoming one day transparent.

As I have paid attention to the phenomena of Jupiter's satellites for some time past, I regret I was prevented by cloudy weather from witnessing the extraordinary "transit of the shadow of satellite 4" on Jupiter's face on 14th March, 1872, described by Mr. Lowdon with a woodcut, while the satellite itself was at the back of the planet as viewed from us; or, in other words, it was under occultation from 6.46 until 10.56 on that evening, as given in the "Astronomical Notes for March" by "F.R.A.S."

We had lately some correspondence about the "retrogression" of the shadow of satellite 4, and we have now received evidence of it with a vengeance. From the woodcut of the belts of Jupiter, I presume a diagonal prism was used with inverting eyepiece, as the spot (whatever it was) appears on the northern hemisphere. In the description we are carried rapidly to Jupiter and back again. Altogether, the communication is very obscure, and is certainly amusing, if not instructive. I doubt not your contributor "F.R.A.S." little expected when he expressed his belief (let. 4047, p. 171) that we have not had a funnier communication in "our" columns for many a long day than Mr. R. Lowdon's letter (3966, p. 119) on a novel mode of taking the longitude at sea, that he would so soon have his risible faculties again excited.

LINEA.

THE IMPROVED SCALE FOR THE LENGTHS OF PIANO STRINGS IN No. 372.

[4140.]—THIS was drawn showing every string its full length, so that a workman should only have to copy those lengths when making working gauges. Considerations of space induced the reduction of those lengths one-third. Of course, when making his gauges he must add one-half to the lengths shown in the diagram, both above the hammer line and below it, which, with a pair of fine spring dividers he can do without difficulty.

THE HARMONIOUS BLACKSMITH.

WHERE IS THE WATER GONE TO?

[4157.]—VERY often have I speculated whether there may ever be found means of guessing or making some approach to a probable estimate of this important quantity in geology—an approximate figure to, I will not say the *depth*, whether in feet or furlongs, of the general cometary rainfall on the day and hour of our planet's last astronomical catastrophe,—I will not say approximating to the *number* expressing the depth of this added layer of water, but to the *logarithm* of that number,—how many digits the number of feet or yards would probably require—whether, in short, we should rather call the addition one of fathoms, or of poles, or chains, or furlongs, of fresh water. We seem quite without data, either from present traces, or from the Bible, Vedas, or any other tradition or record, for guessing whether furlongs or only a few fathoms would be the nearer measure to assume.

Apart from the work obviously done in scouring the hilly surface into sweep vales, and sweeping into its present deposits the newest "boulder-clay," or rather "drift-gravel"—effects affording no definite measure of the quantity of water unless we knew the exact force, impact of the first dash, and rate of decrease with time, as hour by hour, or minute by minute, the height of unfallen steam atmosphere above diminished; apart from this, the chief fact knowable or to be inferred from the strata is, that there was weight enough of newly-arrived atmosphere to so far equalise the pressure over the whole globe's film (falsely called crust)—so far approach equalising it on highlands and seabeds (which beds, observe, *now* bear scores or even hundreds of times the 6lb. per square inch that the backs of Andes or Himalayas bear)—weight enough so to modify this difference towards equality, as to disturb the whole film's equilibrium, and cause it to take a new form, sea-beds to rise and highlands to sink, by a simultaneous universal earthquake and plutonic movement, or as records (traditional or not) call it, breaking up, of "*all* the [fiery] fountains of the abyss"—whether "fountains of the abyss," or "foundations of the deep," *i.e.*, sea, as some translators say, be the right rendering. Just as now, over thin or tender regions of the film, such as the Caribbean Islands are upon, the mere removal of a tithe or a twelfth of the usual pressure, say 3 or 2½ barometric inches, over the space covered by a cyclone, is difference enough to disturb the crust's equilibrium; so that in scores of cases since Columbus' time, a hurricane has been instantly followed by, or has begun, earthquake shocks, and the last cyclone over St. Thomas set that island rocking for months, after years of quiescence; just so the arrival of the last new atmosphere (one evidently of steam) must have instantly done (all that the traditions or records relate it to have done)—initiated months at least of continental and general plutonic disturbance; but *at first* of a kind just opposite to the usual partial ones, whereby, as Herschel insisted (and as even "Sigma" has heard), plutonic action keeps our lands above water. Instead of weight taken from the land to the sea-bed, and added thus to the depressed scale of the balance, giving the raised scale from time to time a further lift, here the *first* action (whatever might follow) was a contrary one, equalising pressure, and so tending *for a time* toward general levelling of form and general inundation.

Now, if we ask what weight of steam sufficed for this?—an amount equivalent (say) to the air—that is, to 34ft. of water? or to ten present atmospheres, or a hundred? in short, to fathoms of water or furlongs?—I see no conceivable data for an estimate. Even if we knew, or assumed (which I see no sufficient grounds for doing), that the highest antediluvian peaks were at some moment covered, so that not only was every undrowned organism afloat (which, I think, was probably the case for a short time), but even no rock left unsubmerged, even then, what know we of the height of such antediluvian summits, either above the antediluvian or the present sea level? Our present highest ones, all the Himalayas, Andes, Alps, Elie-de-Beaumont, has proved to be the newest, and to date from this last disturbance. The Pyrenees are the highest (now) of all that are known to have had any considerable height *before* it: and *what* height? We know not, whether *double* or *half* their present. We know not, of any two hills 100 miles apart (say Snowdon and Malvern), *which was the higher*, the day before that "six hundredth year of Noah, the second month, the seventeenth day of the month;" though we can be sure both were *hills*, and so higher than the Andes, which then were *not* hills. But even if it were asked, what addition of water would suffice *now*, in a new deluge, to submerge our five-mile Himalaya peaks? we know not whether it would take one mile, or half a mile. For aught that any of us knows, even that "Sigma" knows, a furlong might do it; might have weight enough so to derange and reverse the relations of sea-bed and continent as to bring Dawalagiri's snows under its wave! They and we alike are on a fluid (not solid) globe, a ball of liquid lava with a film (not a *crust*) over it, and, even if we knew all about this, its thickness and structure everywhere, what possible means of ascertaining this weight can "Sigma" conceive but by *experiment?* And without a comet at command, where will he get the one or two trillion tons weight required for the experiment?

That "comets" have "a mass too small" (p. 196, let. 4086) is not only of all things I ever saw alleged in the ENGLISH MECHANIC, but of all myths in any mythology, the boldest venture, the most purely groundless, I ever heard of! "Comets!" Why, of the three or four hundred on record, I challenge him to prove a *single one* too small! Let "Sigma" bring us proof of *any single* comet yet seen having weighed as *little* as (say) a mile layer of water over the earth, 160 atmospheres, or a trillion tons. And comets, remember, have differed in their bulk, the largest and least of *this century* alone, as full a million to one! This variety in bulk, but in appearance as much variety as in *any* 300 things of one name—say a cabinet of 300 minerals! Just *two* very minor ones the spectroscope has been made long enough to examine. And on the strength of this "Sigma" tells you, "*they* (comets) do not contain or consist of water"! Who said they did? *Any* comet "Sigma" chooses to name, I will grant him, if he likes, to have been of rubidium vapour. For aught I know, Encke's is so; or thallium, if he prefers it. But, mind, we cannot allow many to be of like material. Their looks are too various. Moreover, if he likes, there shall never have been more than *one* of steam—none before the last that fell on earth, nor since. What I say geology shows is, that one fell 50 centuries ago (or between 45 and 55), enveloped the earth before falling, and that its material was steam; *that one*,—I know and say nothing of any other's materials.

Now, as "Sigma" asks, "Where is the water gone to?" he might ask the same of any other rainfall. Let me suggest the same respecting some mill tail-water, of which Prof. Ansted writes in his "Visit to the Ionian Isles," 1863, cap. XI., p. 322:—"A curious natural phenomenon occurs, and is taken advantage of, in the neighbourhood of Argostoli. At four points on the coast the sea, at its ordinary level, enters a very narrow creek, or broken rocky channel; and after running somewhat rapidly through this channel and among broken fragments of rock for a short distance, it gradually becomes sucked into the earth and disappears. By conducting the water through an artificial canal for a few yards, and so regulating its course, and forcing all the water that enters to pass in a single stream beneath an undershot wheel, power enough is obtained in two cases to drive a mill. Mills have, in fact, been placed there by an enterprising Englishman, and are constantly at work. The stream, after being utilised, is allowed to take its natural channel, and is lost among the rocks. It is common enough to drive a wheel by a current of water going from the land towards the sea; but it is certainly rare, and, as far as I am aware, peculiar to this locality, to find mills driven by a current of sea water, acting quite independently of the tide, the water constantly and steadily rushing in over the earth's surface, and finally disappearing. . . *Apart* from the facts that the water sucked into the earth is sea water, and that it enters below the sea level, there is *nothing* extraordinary or unusual (!); for numerous instances occur in every limestone country of streams, often of considerable dimensions, entering into open fissures and disappearing. . . . But it is certainly very seldom that we are able to satisfy ourselves of the empty state of the limestone caverns close to the sea and below the sea level, as we can at Argostoli [*satisfy ourselves of their* 'empty state' *by their perpetual receipts!*], and for this reason, if for no other, the phenomena are worthy of particular notice. The general condition of the surface is as follows:—The small harbour of Argostoli is inclosed on both sides by the hard broken limestone rock, so common in the islands. On the east side it rises immediately into hills of moderate elevation; and on the west side, behind the town, there is a plateau, scarcely above the usual level of the water, rising, about two or three hundred yards from the shore, into a low ridge, which, in fact, by its projection into the gulf, makes the harbour." According to his map of the island, p. 378, this "plateau" or peninsula is the only square mile that he represents flat (with no hill shaded), and its area is under a square mile—less than two miles by half a mile—that of the whole island being possibly 300 square miles. "Between the shore line and this low ridge, there is an evident depression of the surface in all that part over which the sea, when it enters, is sucked in. . . . But what, it will be asked, becomes of the waters of the sea thus pouring in continually to fill the cavern?" Let me commend this question to "Sigma." Instead of theoretical "comet's tail" water *once*, here is very practical mill tail-water *every day*, that has ground the Cephalonian's bread corn to the following tune.

Professor Ansted continues (p. 327): "The influx of water, however, is not small. It amounts, as far as I could make out, to *more than half a million of gallons per diem.*, for the two mills together." When "Sigma" has answered that, we will proceed to consider, perhaps, where the cometary water has gone to. . . . . "It will be evident that if sea water finds its way into any large natural cavity, from which it is afterwards evaporated, a deposit of salt must be taking place in this cavity, or in the rocks adjacent and connected with it. Assuming the influx to be at the rate already mentioned, this may be roughly estimated as equivalent to an area of ten or twelve acres of solid matter one foot thick, accumulated each year. It is an interesting question to consider where this deposit of salt is going on, and whether saline springs may not be thus fed. There are no known springs in the island of Cephalonia that present any large quantity of saline matter."

Remember it is not I, but "Sigma," that finds any difficulty about where the comet water of Noah's time has "gone to"? I simply hold it to have obeyed all the same laws as yesterday's shower. But as this does not satisfy "Sigma," probably it will assist him to consider and solve for us first this Cephalonian question, as it is not theoretical. The mills being ascertainably at work for years past (if not to this day), and the corn ground and eaten from them, I return his question as to these millions of tons of sea, "Where is the water (and the salt) gone to?"

E. L. G.

BELL PIANETTE.

[4158.]—MR. S. BOTTONE (reply 11893) says "a paten was taken out for this instrument towards the latter en of the last century." I have carefully looked over the list of musical patents before A.D. 1800, and cannot find it. Query, what was the name of the patentee?

Dr. Cleggat, A.D. 1788, patented—or rather proposed in his patent of that date to make tuning-forks with movable weights for altering their pitches, which familiar method was afterwards employed by Loeschman in the terpodian, patented A.D. 1820; although I have a specimen of that instrument bearing the name of Van Den Burgh and date 1817; and M. Hiles states, in his musical dictionary, it was invented by Buschmann, of Hamburg. Dr. Cleggat also proposed to construct a new instrument (of music) of a proper number of those tuning-forks, or of single prongs or rods of metal fixed on a sounding-board or box. In times of old, I believe all the sounds of stringed musical instruments were "boxed up," or at least supposed to be, and the performer, *à la* Pandora, let the often but too evil sounds out without, like that merciful young (female) person, leaving the hearers any hope of better things. Excepting that the proposed instrument had a sounding-board, I see no difference in principle between it and the terpodian. It can hardly be termed a bell pianette or a rod harpsichord, for Dr. Cleggat does not suggest the employment of either plectra or hammers for vibrating his forks or rods, but that "a celestina stop, made by an endless fillet, may be applied, producing the sounds on (*sic*) these bars as it does on strings." No doubt Dr. Cleggat was familiar with Adam Walker's instrument, the celestina, patented A.D. 1772, also with the application of its mechanism to the harpsichord—viz., the celebrated celestina stop of that instrument, not to mention the lyrichord of Plenius, A.D. 1741. I append a verbatim copy of a broadsheet or handbill containing statements very interesting to all who desire to obtain continuous sounds from the strings of keyed instruments, concerning which I may remark that, excepting in the instances of Hawkins's claviol, R. Mott's sostinente pianoforte, and perhaps the modern tetrachordon piano, we do not seem to have gone much ahead of the musical capabilities of the productions of that clever inventor, always assuming the said handbill to state the truth; but, alas! all statements in advertisements must be taken *cum grano salis*, the said grain of salt being fully understood to be as big as a bushel.

Rutergius Plenius was by no means the first in the field. As early as A.D. 1600 John Heyden produced the clavicin viol; and Kircher, in his "Musurgia Universelle," mentions the possibility of constructing such an instrument. In A.D. 1664 Evelyn relates he saw one with gut strings—a veritable lyrichord—at a meeting of the Royal Society, the bow of which was formed of parchment; and in 1717 Marius constructed a model of a similar instrument (alias mechanical fiddle), which model is, or at least was, in the museum of the Académie des Sciences.

The only thing I can find which seems to resemble the bell pianette was patented by Groll (1812), who proposed to construct a musical instrument of metal bars (bell metal by preference) attached to a sounding-board at one or both ends. Hammers applied to this instrument would have made it a veritable pianoforte, but the inventor does not suggest their use; in fact, he only claims improvements on the class of musical instruments which "afford their tones by friction applied to metallic substances." The said friction he proposes to obtain by the violin bow, the endless web or riband of horsehair or other fibrous material, or by a rosined wheel, *à la* hurdy-gurdy. He, however, also proposes a very important practical improvement—viz., "applying the said friction to a small stem, stud, or protuberance on one or both of the (unisonous) bars."

The earliest musical instrument I remember in which metal bars are struck by hammers is the design of Mr. Goldsworthy Gurney (A.D. 1833), and it is also one of the very simplest, cheapest, and best I have seen. Several patents have since been obtained for modifications of the bell, or rather bar, pianoforte, of which that of Crawford (1862) is one of the most modern. Mr. Crawford, besides hammers, proposed to employ plectra similar to those of the harpsichord for vibrating his elastic bars or springs, probably in imitation of those very pleasing instruments the musical-boxes, some of which yield really powerful sounds, and all of which are rendered considerably louder by being laid on a resonant surface. I find the soundboard of a piano before the strings are put on—or, yet better, the thin belly of an unstrung harpsichord—answers this purpose admirably. It may be a wrinkle well worth knowing—especially to dealers in musical-boxes—that a soundboard (about 30in. long by 20in. wide, only ⅛in. thick, strengthened by three bars ½in. thick, about ¾in. deep at the middle, tapered to one-sixteenth of an inch at their ends) enormously augments the loudness of their sounds. A late friend of mine, who dealt rather largely in those made by Nicol Frère, had a soundboard of the above dimensions constructed to my design, which, being stained mahogany colour and raised on short pillars, had the appearance to his simple customers of a simple show-board standing on his counter. He told me this simple contrivance sold him many musical-boxes; and when I asked him if it was not true that it also "sold" their buyers, he only answered "caveat emptor," which, as he was an Evangelical Churchman who swore by Lord Shaftesbury, was, I suppose, the Christian (practical) rule for "doing your neighbours as they would do you" (if they could).

Should "Valve," or any fellow reader, desire to try his prentice hand on the amateur construction of a bell, or rather a bar, pianoforte—which is far easier and cheaper to make than one with strings, for in the former no framing to resist tension is needed, and no provision of means for retuning required, as it never gets out of tune—I think it would be no more than common prudence to purchase the following patents: Groll (No. 8531), price, with drawing, 4d.; Gurney (No. 6483), price, with drawings, 6d.; and Crawford (No. 1543, A.D. 1862), price, with drawings, 8d. The total sum (1s. 5d.) is not very large, and their perusal would render him familiar with most of the more important things which have been done in this direction. Having suffered "pretty considerable" from the folly of independent investigation and the re-inventing of old things myself, I can appreciate the advantages of starting from the 'vantage ground of the experiences of those who have helped (as the French wit put it) to fill up the many pitfalls in the road to improvement and discovery by falling into them, although I fear they but too often perished on the way. I would also suggest that the intending constructor purchase—I use the word in its strict legal sense of obtaining by any means, and not merely as buying—one of Messrs. Cramer's instruments, which he may obtain on hire at a very small cost. He can then see, or rather hear, how he likes it on further acquaintance, and may—if his conscience does not rebuke him—like a manufacturer, copy all that seems worthy of imitation. I may add if a good treble be desired I would advise him to employ very light hammers, and to drive them with great velocity, for the reasons stated in my recent articles on "Pianoforte Actions," printed in Nos. 367, 368, and 370 of the ENGLISH MECHANIC.

Mr. Bottone says "no dampers are required." I am very sorry to hear this, for, if true, the vibrations of the steel springs or bars which generate its sounds must be addicted to that great evil—laziness, or at least "retiring early to rest." The defects of most pianofortes are manifold, among them the too early cessation of the vibration of their strings is a common one, and this is what renders their tones "short;" but I never yet heard any piano with strings whose tones were so short as not to require dampers, which are necessary in the old harpsichord even when "buff stop" is on. Shortness of tone is to me an utter abomination, and, if not a very great evil in a piano used exclusively for quadrille playing, renders the instrument quite unfit to render properly Mendelssohn's "Lieder ohne Worte" and similar music; in a word, you cannot make such a piano "sing" anyhow.

Verbatim Copy of Broadside (Handbill) in the Chetham Library Relating to the Lyrichord of Plenius, A.D. 1741.

By his Majesty's Royal Letters Patent, granted to Rutgerus Plenius, Harpsichord Maker, for the sole Making, Use, and Benefit of a new invented Musical Instrument called a Lyrichord, which imitates a Violin, Violoncello, and Double Bass; but when play'd full, it resembles a perfect Organ of a most delightful Tone, altho', by catgut strings only, without Pipes. It admits of playing Forte and Piano; as also of swelling any Single Note (or many notes, *ad libitum*), on ye same Key, by ye simple Pressure of ye Fingers: But what is most surprising, and indeed incredible, if not seen (yet plainly demonstrable to everyone), its strings never go out of Tune, as long as ye constituent Instrument remain entire; a Thing which has been so long wisht for and desir'd, and in all Ages, 'till now, by everyone, deem'd impossible to find out. This, therefore, is to inform ye Nobility, Gentry, and others, That ye aforesaid Rutgerus Plenius has now (after Ten years' painful study and Labour, accompany'd with no small Expence) brought ye above-mentioned Instrument to Perfection. And he humbly presumes, that all the Gentlemen and Ladies, who will do themselves ye pleasure, and him ye Honour of seeing and hearing it, will be fully convinced of ye Truth of ye foregoing Assertions; and at ye same Time be agreeably diverted by ye Harmony of ye Instrument, it being esteem'd and approv'd by all that have yet seen it; particularly by ye most eminent Masters of Musick in England, who allow it to be ye most curious Piece of Workmanship, and most wonderful Instrument they have ever seen or heard of. The Price of seeing and hearing it performed on at any Time between ye Hours of Twelve and Four o'clock, is Half a Crown each Person, at ye Inventor's House (ye King's Arms being over ye Door) in south Audley Street, Grosvenor Square; where a good hand is provided for ye Entertainment of ye Audience.

THE HARMONIOUS BLACKSMITH.

COMMUNICATING ROTARY MOTION TO BALL FIRED FROM SMOOTH-BORED GUN.

[4159.]—I IMAGINE that had the first inventors of rifles taken a piece of gas-pipe about the size and length of a gun barrel, and made it red hot for about a foot at one end, then placed an inch or two of that end in water, and looked down the inside of the pipe, we should never have departed from the use of the smooth-bore; for they would have seen the steam thus generated winding its way out spirally, which I take to be the course the gas evolved by the combustion of the powder in a gun does take. It would, therefore, become apparent to them that all that they had to do to obtain the spin for their projectile would be to provide a surface by which the rotary motion in the gas would be received by the projectile.

That surface would be obtained by leaving a projection extending a short way from the circumference to the centre at the butt of the projectile, or, perhaps, more than one projection. I should have tested this theory of mine some two years since, but being a working man I have not the power. Perhaps "Artillery Captain," or some other friend, could say how far I am right. PHILUS WARD.

HOW WE SEE A DISTANT OBJECT.

[4160.]—IN reply to "E. J. D." (let. 4063, p. 174), I would ask what he means by a pencil of rays. Rays from combustion issue and extend in every direction. The Rev. David Blair taught that a pencil of rays is a parcel of them proceeding from a point; but no particle of matter leaves the point and passes to the eye, a mere impulse is given to the ethereal millions of atoms which, from closeness of juxtaposition, almost instantly communicate with every eye in the line of radiation or in any line of reflection thereof; the ray, then, is but transmitted pulsation, and rays from every point of an object acting in every direction compel our acknowledgment that the ultra-microscopic diminutiveness of the ethereal atoms amaze us more with the infinity or smallness than we can be with infinity of extension in stellar space. On the diameter of what we call a "point," it were but guesswork to estimate the number of ethereal atoms that might repose. Reflection of light is but repulsion or rebounding of the infinitesimally small ether-atoms. Now a "pencil of rays" falling or striking on the eye is but a succession of these ether-atoms striking on the eye's outer convex surface, from whence the direction of the impulses converge towards a focus which they reach on the retina or on the optic nerve: the impulses are continuous as long as the combustion that they proceed from continues. Solar combustion is the power which imparts impetus to the ethereal pulsation, and so the distance of the sun is the distance of the power which produces reflection. Glass is porous to the ether-atoms, but mercury seems to reflect nearly them all when pulsating in periods in accord with the interchange of atoms in the gaseous molecules of the sun. We read of three sorts of pencils, cylindrical, divergent, and convergent, and, as Blair has it, they proceed from points. The cylindrical from a flat surface, the divergent from a convex, and the convergent from a concave, just as with the reflected chemical atoms of sound. We read, also (as in Chambers's "Educational Course"—Optics), that a pencil is a parcel of rays proceeding *to* (as well as *from*) a point; thus a concave mirror will converge reflected rays to a very brilliant point, but so immense is the sun that its rays are deemed parallel, the divergency being imperceptible. But the number of pulsations of ether-atoms that fall each second on a square inch of surface are evidently countless millions, and we do not see any object, colour, or shape so much because they reflect rays as because they do not reflect them. Where every ray is reflected, the colour is shadeless white, and we only perceive degrees of distance and shades of colour by non-reflection, some of the ethereal pulsations of larger or smaller amplitude being cut off by the, to them, non-repulsive (or absorbent) nature of the impinged surface. We see objects, therefore, solely by their non-reflection of rays, a red object being one that reflects none of the other rays of the spectrum but the red ones. Pencils of rays, if solar, are parallel, and do not converge till after they strike the convex surface of the eye, and pencils from a point (so far from coming to a focus) must be divergent when they strike the eye, the ether-atoms retaining the impulse transmitted at the surface of the sun, and unless reflected from concave surface, such rays cannot converge before they reach the eye. I cannot understand "E. J. D." when he talks of fresh pencils springing up to suit change of position; the undulatory vibrations are in every direction to and from every point that catches direct sun rays, and it is most absurd to suppose that rays must converge to a point before they enter spectators' eyes. A single pulsation will bestow light lasting the one-eighth of a second on the retina, so that eight ether-waves per second maintain constant light. I see, from where I sit, a placard: it is printed on "white" paper, but whether with red or black ink is hardly plain. I cannot read a word till I put on my concave glasses, and then I make out indistinctly the large letters in the word "Bazaar." Now, why cannot I read every line and letter in the placard? Simply because I am too far off; the ether-atom vibration-rays are too few to reach me unless the diameter of my convex eye were much greater, so as to catch more of the direct pulsations from the placard. I see the shape, size, distance, and colour of the placard; the pulsations from its exterior and interior are adequate for that; but the other pulsations from its interior are too few and too much crossed for me to gain more than a hazy, indistinct picture of the words it bears. No object provides any rays but solar and other fire, and were a very powerful lime or electric light thrown on our placard, I might be able with my concaves to read it all, it would so multiply the ethereal pulsations from each point.

We hear a band of musical instruments, and each of hundreds of hearers can perceive not only the tone of each note from each of all the instruments, but perhaps, also, its first, second, and third overtones, all blending in harmony as one note with numberless overtones, as note succeeds note to suit a well-balanced order of completeness. These pulsations on the drum of the ear are to each note from each instrument and to each of its overtones more or less rapid, or of varying amplitude and number, in accordance with the acuteness (or shrillness), or with the flatness (or baseness) of the sound conveyed. If one note give 256 pulsations in a second, another gives twice, and another three times as many, and so on (see Tyndall "On Sound"); and if all the heart-moving tunes we hear are conveyed by vibrations of the coarser atoms that the chemical laboratory can appreciate, we must cease to consider it impossible that every degree of distance and surface-quality of object in contact with sun rays is shown to us by the intervention and non-intervention of pulsations of what I venture to call the "ultra-microscopic" ethereal atoms (though the recognised chemical atoms may fall under the same name). Rates of speed in the transit of sound, varying to the different notes of music and the varying lengths of musical vibrators, I doubt not, offer us a first clue to the size, distance apart, and number of atoms or molecules in a line of specific length, certainly as to the total amount of interspace that separates them; and the same rule will apply to the otherwise wholly inappreciable atoms of illuming ether, whose closeness brings light to us from the sun in 192,500 seconds of time according to Herschel. If, however, different notes of the spectrum travel like different notes of sound, at very different speeds and amplitudes of oscillation, we need not wonder at speeds of light or of sound varying unless it be with reference to some specific tint or to some specific note.

We should look upon the light-giving vibrations of ether-atoms as moving in masses, rather than only in diverging lines, from each point of reflection, and as subject to cross vibrations in every direction; and as they convey impulse forward about 200,000 miles per second, whilst particles of air convey sound's impulse but about 1,000 feet, and those of glass but 18,000 feet, we should estimate the extreme closeness of the ether-atoms, which carry surrounding atoms wave-like along with them till such are diverted by cross-vibrations, and the motion is so rapid, and the atoms so sufficiently unattached, that crossing does not divert the straight line of motion. In Gutch's "Register," 1859 page 180, I find "Black has small atoms, and absorb light; white large, and reflects it. Reds are of oxyge character, according to Ellis; greens, nitrogen; an violet, hydrogen." An oxygen body combines wit hydrogen and reflects red rays; a hydrogen atmospher cuts off the red, &c., vibrations, and reflects the blue and indigo ones, and a nitrogen air cuts off red and violet, and reflects green or white, orange or blue. As a clue to the nature of any molecular constitution, the rays of sunlight or other light it cuts off is too important to be overlooked. J. BARWICK.

P.S.—Direct sun rays penetrate through porcelain as well as through paper; indirect or reflected rays do not, objects being thus shown as shadow by interception of rays, but no bright tint is seen, reflected pencils seeming to lack adequate force to penetrate through paper or porcelain.

[4161.]—IN reply to the kind letter of "F. R. A. S." (4049, p. 171), I am pleased to get a reply from one who does understand the theory of light, and the best proof that he does so is, that he carefully refrains from touching on the point that I want cleared up. He has omitted to answer the following part of my letter (3974, p. 120): "I cannot conceive how the reflections can be so numerous, and so conveniently arranged, that they flash in right lines from every physical point of the statue to the eyes of the spectators," &c. I said in that letter, "and that in front of them (the multitude) some conspicuous object is elevated." This was to show that a front view was only provided for. The experiment of the lenses only serves to strengthen my position as to the number of rays to be accounted for. I will now add some more points that require to be cleared up. The rays by which vision takes place must leave all parts of the object at different angles, converging to the eye; but if a mirror be placed where the eye was, the rays to it causing reflection proceed from the object to the mirror in right lines parallel to each other; for if they were reflected from the object in converging rays (as they proceed to the eye), the result would be either a confused image or a number of small images; and I am not aware of any power possessed by the mirror, or the eye, to change (as it were, at will) the order in which the rays shall be reflected. Thus, a man standing in front of a mirror resting on the ground, and a little higher than himself (the mirror being perpendicular), will see his eyes by direct rays, I presume, and all his body will be reflected by direct parallel rays; but if he still continues erect, but wishes to see his feet in the mirror, he turns the eyeball downwards, and of course can only see his feet by pencils of rays converging to the eyes. Here, then, we have direct rays for one purpose, and converging rays for the other. The latter, it would seem, must proceed from the phantom image in the mirror, or they must proceed from the observer to the mirror, and be thence reflected to his eyes. Will "F. R. A. S." please to account for this seeming paradox? and if he refers to my letter to Mr. Barwick (4063, p. 174), he will fully understand that I challenge a portion of the theory of light. I hope, therefore, in his next, that he will try and explain the various points I have raised. I feel that we should not take any theory for granted, but carefully analyse it.

Mr. Barwick says, in his letter (3973, p. 120), "A mirror's frame is visible, as 'Bobo' shows, by its shading off or not reflecting all the received rays; it reflects but those that denote its colour." I was under the impression that the prism could analyse light into the three primitive colours and secondary compounds (by some believed to be primitives also); or, in other words, the colours of the rainbow; but I was not aware that the prism or anything else could show the tertiary compounds. I presume, therefore, that olive, &c., must be added to the list. I am at a loss to understand the ether pulsations on the eye: I thought that belonged to the exploded old theory, which stated something about the eye having the power to reflect or direct some subtile ether on a distant object, and by that means see it. He says, "The fading of visibility of distant objects, I take it, is caused by increase of intervening ray-crossings, which obstruct more extensively as distance increases." Well, I should suppose

WHERE IS THE WATER GONE TO?

[4157.]—VERY often have I speculated whether there may ever be found means of guessing or making some approach to a probable estimate of this important quantity in geology—an approximate figure to, I will not say the *depth*, whether in feet or furlongs, of the general cometary rainfall on the day and hour of our planet's last astronomical catastrophe,—I will not say approximating to the *number* expressing the depth of this added layer of water, but to the *logarithm* of that number,—how many digits the number of feet or yards would probably require—whether, in short, we should rather call the addition one of fathoms, or of poles, or chains, or furlongs, of fresh water. We seem quite without data, either from present traces, or from the Bible, Vedas, or any other tradition or record, for guessing whether furlongs or only a few fathoms would be the nearer measure to assume.

Apart from the work obviously done in scouring the hilly surface into sweep vales, and sweeping into its present deposits the newest "boulder-clay," or rather "drift-gravel"—effects affording no definite measure of the quantity of water unless we knew the exact force, impact of the first dash, and rate of decrease with time, as hour by hour, or minute by minute, the height of unfallen steam atmosphere above diminished; apart from this, the chief fact knowable or to be inferred from the strata is, that there was weight enough of newly-arrived atmosphere to so far equalise the pressure over the whole globe's film (falsely called crust)—so far approach equalising it on highlands and seabeds (which beds, observe, *now* bear scores or even hundreds of times the 6lb. per square inch that the backs of Andes or Himalayas bear)—weight enough so to modify this difference towards equality, as to disturb the whole film's equilibrium, and cause it to take a new form, sea-beds to rise and highlands to sink, by a simultaneous universal earthquake and plutonic movement, or as records (traditional or not) call it, breaking up, of "*all* the [fiery] fountains of the abyss"—whether "fountains of the abyss," or "foundations of the deep," *i.e.*, sea, as some translators say, be the right rendering. Just as now, over thin or tender regions of the film, such as the Caribbean Islands are upon, the mere removal of a tithe or a twelfth of the usual pressure, say 3 or 2½ barometric inches, over the space covered by a cyclone, is difference enough to disturb the crust's equilibrium; so that in scores of cases since Columbus' time, a hurricane has been instantly followed by, or has begun, earthquake shocks, and the last cyclone over St. Thomas set that island rocking for months, after years of quiescence; just so the arrival of the last new atmosphere (one evidently of steam) must have instantly done (all that the traditions or records relate it to have done)—initiated months at least of continental and general plutonic disturbance; but *at first* of a kind just opposite to the usual partial ones, whereby, as Herschel insisted (and as even "Sigma" has heard), plutonic action keeps our lands above water. Instead of weight taken from the land to the sea-bed, and added thus to the depressed scale of the balance, giving the raised scale from time to time a further lift, here the *first* action (whatever might follow) was a contrary one, equalising pressure, and so tending *for a time* toward general levelling of form and general inundation.

Now, if we ask what weight of steam sufficed for this?—an amount equivalent (say) to the air—that is, to 34ft. of water? or to ten present atmospheres, or a hundred? in short, to fathoms of water or furlongs?—I see no conceivable data for an estimate. Even if we knew, or assumed (which I see no sufficient grounds for doing), that the highest antediluvian peaks were at some moment covered, so that not only was every undrowned organism afloat (which, I think, was probably the case for a short time), but even no rock left unsubmerged, even then, what know we of the height of such antediluvian summits, either above the antediluvian or the present sea level? Our present highest ones, all the Himalayas, Andes, Alps, Elie-de-Beaumont, has proved to be the newest, and to date from this last disturbance. The Pyrenees are the highest (now) of all that are known to have had any considerable height *before* it: and *what* height? We know not, whether *double* or *half* their present. We know not, of any two hills 100 miles apart (say Snowdon and Malvern), *which was the higher*, the day before that "six hundredth year of Noah, the second month, the seventeenth day of the month;" though we can be sure both were *hills*, and so higher than the Andes, which then were *not* hills. But even if it were asked, what addition of water would suffice *now*, in a new deluge, to submerge our five-mile Himalaya peaks? we know not whether it would take one mile, or half a mile. For aught that any of us knows, even that "Sigma" knows, a furlong might do it; might have weight enough so to derange and reverse the relations of sea-bed and continent as to bring Dawalagiri's snows under its wave! They and we alike are on a fluid (not solid) globe, a ball of liquid lava with a film (not a *crust*) over it, and, even if we knew all about this, its thickness and structure everywhere, what possible means of ascertaining this weight can "Sigma" conceive but by *experiment*? And without a comet at command, where will he get the one or two trillion tons weight required for the experiment?

That "comets" have "a mass too small" (p. 196, let. 4086) is not only of all things I ever saw alleged in the ENGLISH MECHANIC, but of all myths in any mythology, the boldest venture, the most purely groundless, I ever heard of! "Comets!" Why, of the three or four hundred on record, I challenge him to prove a *single one* too small! Let "Sigma" bring us proof of *any single* comet yet seen having weighed as *little* as (say) a mile layer of water over the earth, 160 atmospheres, or a trillion tons. And comets, remember, have differed in their bulk, the largest and least of *this century* alone, as full a million to one! This variety in bulk, but in appearance as much variety as in *any* 300 things of one name—say a cabinet of 300 minerals! Just *two* very minor ones the spectroscope has been made long enough to examine. And on the strength of this "Sigma" tells you, "*they* (comets) do not contain or consist of water"! Who said they did? *Any* comet "Sigma" chooses to name, I will grant him, if he likes, to have been of rubidium vapour. For aught I know, Encke's is so; or thallium, if he prefers it. But, mind, we cannot allow many to be of like material. Their looks are too various. Moreover, if he likes, there shall never have been more than *one* of steam—none before the last that fell on earth, nor since. What I say geology shows is, that one fell 50 centuries ago (or between 45 and 55), enveloped the earth before falling, and that its material was steam; *that one*,—I know and say nothing of any other's materials.

Now, as "Sigma" asks, "Where is the water gone to?" he might ask the same of any other rainfall. Let me suggest the same respecting some mill tail-water, of which Prof. Ansted writes in his "Visit to the Ionian Isles," 1863, cap. XI., p. 322:—"A curious natural phenomenon occurs, and is taken advantage of, in the neighbourhood of Argostoli. At four points on the coast the sea, at its ordinary level, enters a very narrow creek, or broken rocky channel; and after running somewhat rapidly through this channel and among broken fragments of rock for a short distance, it gradually becomes sucked into the earth and disappears. By conducting the water through an artificial canal for a few yards, and so regulating its course, and forcing all the water that enters to pass in a single stream beneath an undershot wheel, power enough is obtained in two cases to drive a mill. Mills have, in fact, been placed there by an enterprising Englishman, and are constantly at work. The stream, after being utilised, is allowed to take its natural channel, and is lost among the rocks. It is common enough to drive a wheel by a current of water going from the land towards the sea; but it is certainly rare, and, as far as I am aware, peculiar to this locality, to find mills driven by a current of sea water, acting quite independently of the tide, the water constantly and steadily rushing in over the earth's surface, and finally disappearing. . . *Apart* from the facts that the water sucked into the earth is sea water, and that it enters below the sea level, there is *nothing* extraordinary or unusual (!); for numerous instances occur in every limestone country of streams, often of considerable dimensions, entering into open fissures and disappearing. . . . But it is certainly very seldom that we are able to satisfy ourselves of the empty state of the limestone caverns close to the sea and below the sea level, as we can at Argostoli [*satisfy ourselves of their* 'empty state' *by their perpetual receipts!*], and for this reason, if for no other, the phenomena are worthy of particular notice. The general condition of the surface is as follows:—The small harbour of Argostoli is inclosed on both sides by the hard broken limestone rock, so common in the islands. On the east side it rises immediately into hills of moderate elevation; and on the west side, behind the town, there is a plateau, scarcely above the usual level of the water, rising, about two or three hundred yards from the shore, into a low ridge, which, in fact, by its projection into the gulf, makes the harbour." According to his map of the island, p. 378, this "plateau" or peninsula is the only square mile that he represents flat (with no hill shaded), and its area is under a square mile—less than two miles by half a mile—that of the whole island being possibly 300 square miles. "Between the shore line and this low ridge, there is an evident depression of the surface in all that part over which the sea, when it enters, is sucked in. . . . But what, it will be asked, becomes of the waters of the sea thus pouring in continually to fill the cavern?" Let me commend this question to "Sigma." Instead of theoretical "comet's tail" water *once*, here is very practical mill tail-water *every day*, that has ground the Cephalonian's bread corn to the following tune.

Professor Ansted continues (p. 327): "The influx of water, however, is not small. It amounts, as far as I could make out, to *more than half a million of gallons per diem.*, for the two mills together." When "Sigma" has answered that, we will proceed to consider, perhaps, where the cometary water has gone to. . . . . "It will be evident that if sea water finds its way into any large natural cavity, from which it is afterwards evaporated, a deposit of salt must be taking place in this cavity, or in the rocks adjacent and connected with it. Assuming the influx to be at the rate already mentioned, this may be roughly estimated as equivalent to an area of ten or twelve acres of solid matter one foot thick, accumulated each year. It is an interesting question to consider where this deposit of salt is going on, and whether saline springs may not be thus fed. There are no known springs in the island of Cephalonia that present any large quantity of saline matter."

Remember it is not I, but "Sigma," that finds any difficulty about where the comet water of Noah's time has "gone to"? I simply hold it to have obeyed all the same laws as yesterday's shower. But as this does not satisfy "Sigma," probably it will assist him to consider and solve for us first this Cephalonian question, as it is not theoretical. The mills being ascertainably at work for years past (if not to this day), and the corn ground and eaten from them, I return his question as to these millions of tons of sea, "Where is the water (and the salt) gone to?"

E. L. G.

BELL PIANETTE.

[4158.]—MR. S. BOTTONE (reply 11893) says "a paten was taken out for this instrument towards the latter en of the last century." I have carefully looked over the list of musical patents before A.D. 1800, and cannot find it. Query, what was the name of the patentee?

Dr. Cleggat, A.D. 1788, patented—or rather proposed in his patent of that date to make tuning-forks with movable weights for altering their pitches, which familiar method was afterwards employed by Loeschman in the terpodian, patented A.D. 1820; although I have a specimen of that instrument bearing the name of Van Den Burgh and date 1817; and M. Hiles states, in his musical dictionary, it was invented by Buschmann, of Hamburg. Dr. Cleggat also proposed to construct a new instrument (of music) of a proper number of these tuning-forks, or of single prongs or rods of metal fixed on a sounding-board or box. In times of old, I believe all the sounds of stringed musical instruments were "boxed up," or at least supposed to be, and the performer, *à la* Pandora, let the often but too evil sounds out without, like that merciful young (female) person, leaving the hearers any hope of better things. Excepting that the proposed instrument had a sounding-board, I see no difference in principle between it and the terpodian. It can hardly be termed a bell pianette or a rod harpsichord, for Dr. Cleggat does not suggest the employment of either plectra or hammers for vibrating his forks or rods, but that "a celestina stop, made by an endless fillet, may be applied, producing the sounds on (*sic*) these bars as it does on strings." No doubt Dr. Cleggat was familiar with Adam Walker's instrument, the celestina, patented A.D. 1772, also with the application of its mechanism to the harpsichord—viz., the celebrated celestina stop of that instrument, not to mention the lyrichord of Plenius, A.D. 1741. I append a verbatim copy of a broadsheet or handbill containing statements very interesting to all who desire to obtain continuous sounds from the strings of keyed instruments, concerning which I may remark that, excepting in the instances of Hawkins's claviol, R. Mott's sostinente pianoforte, and perhaps the modern tetrachordon piano, we do not seem to have gone much ahead of the musical capabilities of the productions of that clever inventor, always assuming the said handbill to state the truth; but, alas! all statements in advertisements must be taken *cum grano salis*, the said grain of salt being fully understood to be as big as a bushel.

Rutergius Plenius was by no means the first in the field. As early as A.D. 1600 John Heyden produced the clavicin viol; and Kircher, in his "Musurgia Universelle," mentions the possibility of constructing such an instrument. In A.D. 1664 Evelyn relates he saw one with gut strings—a veritable lyrichord—at a meeting of the Royal Society, the bow of which was formed of parchment; and in 1717 Marius constructed a model of a similar instrument (alias mechanical fiddle), which model is, or at least was, in the museum of the Académie des Sciences.

The only thing I can find which seems to resemble the bell pianette was patented by Groll (1812), who proposed to construct a musical instrument of metal bars (bell metal by preference) attached to a sounding-board at one or both ends. Hammers applied to this instrument would have made it a veritable pianoforte, but the inventor does not suggest their use; in fact, he only claims improvements on the class of musical instruments which "afford their tones by friction applied to metallic substances." The said friction he proposes to obtain by the violin bow, the endless web or ribbon of horsehair or other fibrous material, or by a rosined wheel, *à la* hurdy-gurdy. He, however, also proposes a very important practical improvement—viz., "applying the said friction to a small stem, stud, or protuberance on one or both of the (unisonous) bars."

The earliest musical instrument I remember in which metal bars are struck by hammers is the design of Mr. Goldsworthy Gurney (A.D. 1833), and it is also one of the very simplest, cheapest, and best I have seen. Several patents have since been obtained for modifications of the bell, or rather bar, pianoforte, of which that of Crawford (1862) is one of the most modern. Mr. Crawford, besides hammers, proposed to employ plectra similar to those of the harpsichord for vibrating his elastic bars or springs, probably in imitation of those very pleasing instruments the musical-boxes, some of which yield really powerful sounds, and all of which are rendered considerably louder by being laid on a resonant surface. I find the soundboard of a piano before the strings are put on—or, yet better, the thin belly of an unstrung harpsichord—answers this purpose admirably. It may be a wrinkle well worth knowing—especially to dealers in musical-boxes—that a soundboard (about 30in. long by 20in. wide, only ⅛in. thick, strengthened by three bars ¾in. thick, about ½in. deep at the middle, tapered to one-sixteenth of an inch at their ends) enormously augments the loudness of their sounds. A late friend of mine, who dealt rather largely in those made by Nicol Frère, had a soundboard of the above dimensions constructed to my design, which, being stained mahogany colour and raised on short pillars, had the appearance to his simple customers of a simple show-board standing on his counter. He told me this simple contrivance sold him many musical-boxes; and when I asked him if it was not true that it also "sold" their buyers, he only answered "caveat emptor," which, as he was an Evangelical Churchman who swore by Lord Shaftesbury, was, I suppose, the Christian (practical) rule for "doing your neighbours as they would do you" (if they could).

Should "Valve," or any fellow reader, desire to try his prentice hand on the amateur construction of a bell, or rather a bar, pianoforte—which is far easier and cheaper to make than one with strings, for in the former no framing to resist tension is needed, and no provision of means for retuning required, as it never gets out of tune—I think it would be no more than common prudence to purchase the following patents: Groll (No. 3531), price, with drawing, 4d.; Gurney (No. 6483), price, with drawings, 6d.; and Crawford (No. 1548, A.D. 1862), price, with drawings, 8d. The total sum (1s. 5d.) is not very large, and their perusal would render him familiar with most of the more important things which have been done in this direction. Having suffered "pretty considerable" from the folly of independent investigation and the re-inventing of old things myself, I can appreciate the advantages of starting from the 'vantage ground of the experiences of those who have helped (as the French wit put it) to fill up the many pitfalls in the road to improvement and discovery by falling into them, although I fear they but too often perished on the way. I would also suggest that the intending constructor purchase—I use the word in its strict legal sense of obtaining by any means, and not merely as buying—one of Messrs. Cramer's instruments, which he may obtain on hire at a very small cost. He can then see, or rather hear, how he likes it on further acquaintance, and may—if his conscience does not rebuke him—like a manufacturer, copy all that seems worthy of imitation. I may add if a good treble be desired I would advise him to employ very light hammers, and to drive them with great velocity, for the reasons stated in my recent articles on "Pianoforte Actions," printed in Nos. 367, 368, and 370 of the ENGLISH MECHANIC.

Mr. Bottone says "no dampers are required." I am very sorry to hear this, for, if true, the vibrations of the steel springs or bars which generate its sounds must be addicted to that great evil—laziness, or at least "retiring early to rest." The defects of most pianofortes are manifold, among them the too early cessation of the vibration of their strings is a common one, and this is what renders their tones "short;" but I never yet heard any piano with strings whose tones were so short as not to require dampers, which are necessary in the old harpsichord even when "buff stop" is on. Shortness of tone is to me an utter abomination, and, if not a very great evil in a piano used exclusively for quadrille playing, renders the instrument quite unfit to render properly Mendelssohn's "Lieder ohne Worte" and similar music; in a word, you cannot make such a piano "sing" anyhow.

Verbatim Copy of Broadside (Handbill) in the Chetham Library Relating to the Lyrichord of Plenius, A.D. 1741.

By his Majesty's Royal Letters Patent, granted to Rutgerus Plenius, Harpsichord Maker, for the sole Making, Use, and Benefit of a new invented Musical Instrument called a Lyrichord, which imitates a Violin, Violoncello, and Double Bass; but when play'd full, it resembles a perfect Organ of a most delightful Tone, altho', by catgut strings only, without Pipes. It admits of playing Forte and Piano; as also of swelling any Single Note (or many notes, *ad libitum*), on y^e same Key, by y^e simple Pressure of y^e Fingers: But what is most surprising, and indeed incredible, if not seen (yet plainly demonstrable to everyone), its strings never go out of Tune, as long as y^e constituent Instrument remain entire; a Thing which has been so long wisht for and desir'd, and in all Ages, 'till now, by everyone, deem'd impossible to find out. This, therefore, is to inform y^e Nobility, Gentry, and others, That y^e aforesaid Rutgerus Plenius has now (after Ten years' painful study and Labour, accompany'd with no small Expence) brought y^e above-mentioned Instrument to Perfection. And he humbly presumes, that all the Gentlemen and Ladies, who will do themselves y^e pleasure, and him y^e Honour of seeing and hearing it, will be fully convinced of y^e Truth of y^e foregoing Assertions; and at y^e same Time be agreeably diverted by y^e Harmony of y^e Instrument, it being esteem'd and approv'd by all that have yet seen it; particularly by y^e most eminent Masters of Musick in England, who allow it to be y^e most curious Piece of Workmanship, and most wonderful Instrument they have ever seen or heard of. The Price of seeing and hearing it performed on at any Time between y^e Hours of Twelve and Four o'clock, is Half a Crown each Person, at y^e Inventor's House (y^e King's Arms being over y^e Door) in south Audley Street, Grosvenor Square; where a good hand is provided for y^e Entertainment of y^e Audience.

THE HARMONIOUS BLACKSMITH.

COMMUNICATING ROTARY MOTION TO BALL FIRED FROM SMOOTH-BORED GUN.

[4159.]—I IMAGINE that had the first inventors of rifles taken a piece of gas-pipe about the size and length of a gun barrel, and made it red hot for about a foot at one end, then placed an inch or two of that end in water, and looked down the inside of the pipe, we should never have departed from the use of the smooth-bore; for they would have seen the steam thus generated winding its way out spirally, which I take to be the course the gas evolved by the combustion of the powder in a gun does take. It would, therefore, become apparent to them that all that they had to do to obtain the spin for their projectile would be to provide a surface by which the rotary motion in the gas would be received by the projectile.

That surface would be obtained by leaving a projection extending a short way from the circumference to the centre at the butt of the projectile, or, perhaps, more than one projection. I should have tested this theory of mine some two years since, but being a working man I have not the power. Perhaps "Artillery Captain," or some other friend, could say how far I am right.

PHILUS WARD.

HOW WE SEE A DISTANT OBJECT.

[4160.]—IN reply to "E. J. D." (let. 4063, p. 174), I would ask what he means by a pencil of rays. Rays from combustion issue and extend in every direction. The Rev. David Blair taught that a pencil of rays is a parcel of them proceeding from a point; but no particle of matter leaves the point and passes to the eye, a mere impulse is given to the ethereal millions of atoms which, from closeness of juxtaposition, almost instantly communicate with every eye in the line of radiation or in any line of reflection thereof; the ray, then, is but transmitted pulsation, and rays from every point of an object acting in every direction compel our acknowledgment that the ultra-microscopic diminutiveness of the ethereal atoms amaze us more with the infinity or smallness than we can be with infinity of extension in stellar space. On the diameter of what we call a "point," it were but guesswork to estimate the number of ethereal atoms that might repose. Reflection of light is but repulsion or rebounding of the infinitesimally small ether-atoms. Now a "pencil of rays" falling or striking on the eye is but a succession of these ether-atoms striking on the eye's outer convex surface, from whence the direction of the impulses converge towards a focus which they reach on the retina or on the optic nerve: the impulses are continuous as long as the combustion that they proceed from continues. Solar combustion is the power which imparts impetus to the ethereal pulsation, and so the distance of the sun is the distance of the power which produces reflection. Glass is porous to the ether-atoms, but mercury seems to reflect nearly them all when pulsating in periods in accord with the interchange of atoms in the gaseous molecules of the sun. We read of three sorts of pencils, cylindrical, divergent, and convergent, and, as Blair has it, they proceed from points. The cylindrical from a flat surface, the divergent from a convex, and the convergent from a concave, just as with the reflected chemical atoms of sound. We read, also (as in Chambers's "Educational Course"—Optics), that a pencil is a parcel of rays proceeding *to* (as well as *from*) a point; thus a concave mirror will converge reflected rays to a very brilliant point, but so immense is the sun that its rays are deemed parallel, the divergency being imperceptible. But the number of pulsations of ether-atoms that fall each second on a square inch of surface are evidently countless millions, and we do not see any object, colour, or shape so much because they reflect rays as because they do not reflect them. Where every ray is reflected, the colour is shadeless white, and we only perceive degrees of distance and shades of colour by non-reflection, some of the ethereal pulsations of larger or smaller amplitude being cut off by the, to them, non-repulsive (or absorbent) nature of the impinged surface. We see objects, therefore, solely by their non-reflection of rays, a red object being one that reflects none of the other rays of the spectrum but the red ones. Pencils of rays, if solar, are parallel, and do not converge till after they strike the convex surface of the eye, and pencils from a point (so far from coming to a focus) must be divergent when they strike the eye, the ether-atoms retaining the impulse transmitted at the surface of the sun, and unless reflected from concave surface, such rays cannot converge before they reach the eye. I cannot understand "E. J. D." when he talks of fresh pencils springing up to suit change of position; the undulatory vibrations are in every direction to and from every point that catches direct sun rays, and it is most absurd to suppose that rays must converge to a point before they enter spectators' eyes. A single pulsation will bestow light lasting the one-eighth of a second on the retina, so that eight ether-waves per second maintain constant light. I see, from where I sit, a placard: it is printed on "white" paper, but whether with red or black ink is hardly plain. I cannot read a word till I put on my concave glasses, and then I make out indistinctly the large letters in the word "Bazaar." Now, why cannot I read every line and letter in the placard? Simply because I am too far off; the ether-atom vibration-rays are too few to reach me unless the diameter of my convex eye were much greater, so as to catch more of the direct pulsations from the placard. I see the shape, size, distance, and colour of the placard; the pulsations from its exterior and interior are adequate for that; but the other pulsations from its interior are too few and too much crossed for me to gain more than a hazy, indistinct picture of the words it bears. No object provides any rays but solar and other fire, and were a very powerful lime or electric light thrown on our placard, I might be able with my concaves to read it all, it would so multiply the ethereal pulsations from each point.

We hear a band of musical instruments, and each of hundreds of hearers can perceive not only the tone of each note from each of all the instruments, but perhaps, also, its first, second, and third overtones, all blending in harmony as one note with numberless overtones, as note succeeds note to suit a well-balanced order of completeness. These pulsations on the drum of the ear are to each note from each instrument and to each of its overtones more or less rapid, or of varying amplitude and number, in accordance with the acuteness (or shrillness), or with the flatness (or baseness) of the sound conveyed. If one note give 256 pulsations in a second, another gives twice, and another three times as many, and so on (see Tyndall "On Sound"); and if all the heart-moving tunes we hear are conveyed by vibrations of the coarser atoms that the chemical laboratory can appreciate, we must cease to consider it impossible that every degree of distance and surface-quality of object in contact with sun rays is shown to us by the intervention and non-intervention of pulsations of what I venture to call the "ultra-microscopic" ethereal atoms (though the recognised chemical atoms may fall under the same name). Rates of speed in the transit of sound, varying to the different notes of music and the varying lengths of musical vibrators, I doubt not, offer us a first clue to the size, distance apart, and number of atoms or molecules in a line of specific length, certainly as to the total amount of interspace that separates them; and the same rule will apply to the otherwise wholly inappreciable atoms of illuming ether, whose closeness brings light to us from the sun in 192,500 seconds of time according to Herschel. If, however, different notes of the spectrum travel like different notes of sound, at very different speeds and amplitudes of oscillation, we need not wonder at speeds of light or of sound varying unless it be with reference to some specific tint or to some specific note.

We should look upon the light-giving vibrations of ether-atoms as moving in masses, rather than only in diverging lines, from each point of reflection, and as subject to cross vibrations in every direction; and as they convey impulse forward about 200,000 miles per second, whilst particles of air convey sound's impulse but about 1,000 feet, and those of glass but 18,000 feet, we should estimate the extreme closeness of the ether-atoms, which carry surrounding atoms wave-like along with them till such are diverted by cross-vibrations, and the motion is so rapid, and the atoms so sufficiently unattached, that crossing does not divert the straight line of motion. In Gutch's "Register," 1859 page 180, I find "Black has small atoms, and absorb light; white large, and reflects it. Reds are of oxyge character, according to Ellis; greens, nitrogen; an violet, hydrogen." An oxygen body combines wit hydrogen and reflects red rays; a hydrogen atmospher cuts off the red, &c., vibrations, and reflects the blue and indigo ones, and a nitrogen air cuts off red and violet, and reflects green or white, orange or blue. As a clue to the nature of any molecular constitution, the rays of sunlight or other light it cuts off is too important to be overlooked.

J. BARWICK.

P.S.—Direct sun rays penetrate through porcelain as well as through paper; indirect or reflected rays do not, objects being thus shown as shadow by interception of rays, but no bright tint is seen, reflected pencils seeming to lack adequate force to penetrate through paper or porcelain.

[4161.]—IN reply to the kind letter of "F. R. A. S." (4049, p. 171), I am pleased to get a reply from one who does understand the theory of light, and the best proof that he does so is, that he carefully refrains from touching on the point that I want cleared up. He has omitted to answer the following part of my letter (3974, p. 120): "I cannot conceive how the reflections can be so numerous, and so conveniently arranged, that they flash in right lines from every physical point of the statue to the eyes of the spectators," &c. I said in that letter, "and that in front of them (the multitude) some conspicuous object is elevated." This was to show that a front view was only provided for. The experiment of the lenses only serves to strengthen my position as to the number of rays to be accounted for. I will now add some more points that require to be cleared up. The rays by which vision takes place must leave all parts of the object at different angles, converging to the eye; but if a mirror be placed where the eye was, the rays to it causing reflection proceed from the object to the mirror in right lines parallel to each other; for if they were reflected from the object in converging rays (as they proceed to the eye), the result would be either a confused image or a number of small images; and I am not aware of any power possessed by the mirror, or the eye, to change (as it were, at will) the order in which the rays shall be reflected. Thus, a man standing in front of a mirror resting on the ground, and a little higher than himself (the mirror being perpendicular), will see his eyes by direct rays, I presume, and all his body will be reflected by direct parallel rays; but if he still continues erect, but wishes to see his feet in the mirror, he turns the eyeball downwards, and of course can only see his feet by pencils of rays converging to the eyes. Here, then, we have direct rays for one purpose, and converging rays for the other. The latter, it would seem, must proceed from the phantom image in the mirror, or they must proceed from the observer to the mirror, and be thence reflected to his eyes. Will "F. R. A. S." please to account for this seeming paradox? and if he refers to my letter to Mr. Barwick (4063, p. 174), he will fully understand that I challenge a portion of the theory of light. I hope, therefore, in his next, that he will try and explain the various points I have raised. I feel that we should not take any theory for granted, but carefully analyse it.

Mr. Barwick says, in his letter (3973, p. 120), "A mirror's frame is visible, as 'Bobo' shows, by its shading off or not reflecting all the received rays; it reflects but those that denote its colour." I was under the impression that the prism could analyse light into the three primitive colours and secondary compounds (by some believed to be primitives also); or, in other words, the colours of the rainbow; but I was not aware that the prism or anything else could show the tertiary compounds. I presume, therefore, that olive, &c., must be added to the list. I am at a loss to understand the ether pulsations on the eye: I thought that belonged to the exploded old theory, which stated something about the eye having the power to reflect or direct some subtile ether on a distant object, and by that means see it. He says, "The fading of visibility of distant objects, I take it, is caused by increase of intervening ray-crossings, which obstruct more extensively as distance increases." Well, I should suppose that the confusion would be more likely to occur near the object, where the multiplicity of rays would be more condensed, and could hardly allow a ray at all to escape outwards; but, with due respect for this theory, I am at a loss to account for the fact that when objects begin to appear indistinct to unaided vision, the use of the telescope again renders them distinct. He further adds, "But also rays diverging," &c. I understood from the theory of light that the rays would converge; but perhaps there is some law I am not acquainted with causing them to diverge; but in this case the telescope, I suppose, has the power of bringing back the wanderers to the proper path. In his second letter (4061, p. 174) he says, "'E. J. D.' should know that the eyes only catch, proportionately to their size, the rays in contact with their surface, which impinge on them, neither more nor less than on every other object in space at an equal distance and equally uninterrupted." Does he mean that a man with a small pair of eyes can see less of the surrounding objects than a man with larger eyes? or does he mean that the rays are reflected in parallel lines, of which the eye can only take in its own breadth? If so, I cannot imagine how we could see more than an inch of an object at a time. I heard that recent computations in Germany, about the retardation of Encke's comet, had settled the question of the ridiculous theory of ether existing in space; and that, in fact, there is no such thing, the retardation of the comet being found due to planetary influence. The remarks about ascertaining the distance of combustion, &c., are too deep for me, and can only be appreciated by astronomers.

In reply to "Bobo's" letter (4062, p. 174), I beg to state that his remarks about contrast, light and shadow, are admirable; and, being an amateur artist, I fully appreciate them; but he forgets that if the black statue was placed in a room hung with black, and the sunlight admitted, the statue would be quite distinct in all its details, without a light background to contrast it; in fact, a light background would render the statue more indistinct, owing to the great preponderance of light reflected. Orange glass stops the chemical rays, and "Bobo" would find that he could not obtain a photographic picture by light transmitted through it. Blackened glass (with soot, for instance) will also stop the heat rays; but, as "Bobo" says, it reflects white light from a black bead. E. J. D.

"T. A." AND REPULSION.

[4162.]—I MUST decline to accept "T. A.'s" invitation (letter 4089) "to give a single instance of the action of a repulsive force in nature." My instance would not convince him, and his objections (judging from former instances) would not weigh with me. So we should argue fruitlessly,—one of the most repulsive things in nature. RICHARD A. PROCTOR.

A STUDENT'S COMPLAINT.

[4163.]—I THINK that "A Desperate Character" has not a sufficient cause to make him desperate. If he had two hours and a half for his paper he had ample time to enable him to pass first-class, if he only knew how to use it, and if he fail it will not be for want of time, but for want of knowledge. The Elementary Chemistry paper (subject X.) contained twelve questions, eight of which only were to be attempted. An ordinary intelligent student who had attended twenty-five times a properly-taught class, or who had gone through a similar course privately, could have answered the requisite number in one hour and a half. If six questions were properly answered a candidate would pass easily. "A Desperate Character" should rail at the local committee in the town in which he was examined, or rather at the local secretary, for he is responsible for almost everything. He can do no good in appealing to the columns of the ENGLISH MECHANIC. It is simply a local question. If the Government rules were obeyed a hundred candidates might begin their papers at five minutes after seven o'clock. As a science teacher of several years standing, I think that two hours and a half is ample time for most of the South Kensington papers.

Bradford, Yorks. J. HARRISON.

[4164.]—"A DESPERATE CHARACTER" (let. 4110) should have noted the facts on the examination paper in explanation of its brevity and shortcomings. A courteously drawn up protest to the Department of Science and Art, if sent before the results of the examination are known, would meet with careful attention, and probably lead to satisfactory results. H. P. H.

TERRESTRIAL GRAVITATION.

[4165.]—THERE is only one word to describe the proof sketched by "F. N." (let. 4115). It is charming. I fully concede that it is a simple proof, not involving the integral calculus. Looking over my papers on the subject, I find that in my search for a simple proof I have over and over again been close on this one. Worse luck that I failed to see it. Yet I need not be ashamed at my failure, since for nearly two centuries the proof was looked for and missed.

The proof involves the theorem that if the attracted particle is the vertex of a cone tangentially inclosing an attracting thin spherical shell, the part of the shell on the particle's side of the circle of tangency exerts the same amount of attraction as the remainder of the shell. This theorem is at once seen to be true, when we take the particle as the vertex of a series of cones of minute vertical angle, as in the proof for case of a particle *within* a spherical or spheroidal shell. I think it must have been this circumstance—the fact, namely, that the method of taking cones with minute vertical angle had already been once applied (in dealing with an external particle), which caused me to overlook the possibility that by applying it a second time the problem could be solved. At least, I find that in my papers I try more than a dozen ways of dividing the two parts of the spherical shell into elements, without once noticing that the centre of the circular section is the proper point to look to.

I do not mention this circumstance by way of excusing my failure, a failure which a host of eminent mathematicians from Maclaurin downwards have equally undergone; but to show what an advantage the integral calculus possesses over the most ingeniously devised geometrical considerations. I would venture to say that the mental effort given to devise a simple proof of this problem, *after* the integral calculus (or disguised integration) had solved it, has surpassed more than a thousandfold that requisite to supply the integral proof. Yet, because there is no certain rule to follow in such cases, that labour has been fruitless until a "happy thought" has shown how the egg is to be set on end. RICHARD A. PROCTOR.

[4166.]—I AM very sorry that my recommendation of the reasoning in Chap. 2, Book III. of Ganot's "Physics" should cause Mr. Proctor to suspect me of a desire to produce the impression of its author being on my side about the attraction of oblate spheroids, as nothing was farther from my intention. It was simply because my idea of obtaining resultants and ascertaining their magnitude seemed followed out in that chapter; not that I imagined myself correct, for here I fear the skiing error is on my side, and not Ganot's or Mr. Proctor's. This, however, all our readers can judge for themselves, as the suspicion has stimulated invention into solving this question by what may be called a method of geometrical integration, easily understood by any intelligent mechanic.

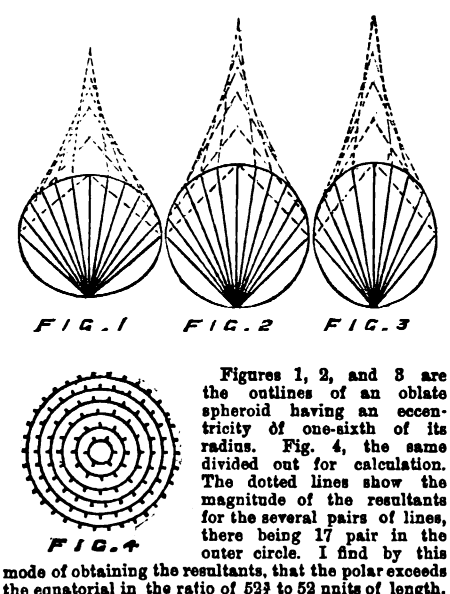

FIG. 1 FIG. 2 FIG. 3

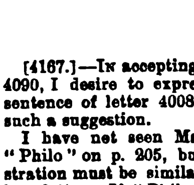

FIG. 4

Figures 1, 2, and 3 are the outlines of an oblate spheroid having an eccentricity of one-sixth of its radius. Fig. 4, the same divided out for calculation. The dotted lines show the magnitude of the resultants for the several pairs of lines, there being 17 pair in the outer circle. I find by this mode of obtaining the resultants, that the polar exceeds the equatorial in the ratio of 52¾ to 52 units of length. Would Mr. Proctor kindly say if this is correct? T. A.

[4167.]—IN accepting Mr. Proctor's apology in letter 4090, I desire to express my regret that the closing sentence of letter 4008 was so worded as to convey such a suggestion.

I have not seen Maclaurin's work mentioned by "Philo" on p. 205, but fancy his geometric demonstration must be similar to the one described in my last letter. If "Philo" examine the diagrams he will perceive that, although the summation of the joint attraction of all the particles in the spheroid is greater in Fig. 1 than in Figs. 2 and 3, yet the force directly exerted is that of a globe one-sixth less radius. To this inequality of attraction is due the fact of liquid matter exerting force in assuming the globular form. T. A.

ELECTRICAL SPARKS.

[4168.]—"PHILO'S" statement (let. 4105) that electrical sparks can be produced in the United States of sufficient force to light the gas by simply walking across the room is perfectly correct, and well known to all intelligent persons in the United States.

In 1855, being then in Troy, New York, my sister called my attention to the fact that she could easily light the gas by simply sliding two or three steps across the carpet. The experiment, although an old one, interested me, and I repeated these experiments with invariable success, when the conditions necessary to such success were fulfilled. These conditions were, that they should take place in winter during a sharp frost, or rather with the ground covered with dry snow. This occurs for at least three months in all the Northern States. The experiment succeeded better where the house was warmed by hot-air stoves, as they generally are at the North. I found that a sliding step gave the best results, two or three of such steps being sufficient to produce a spark three-sixteenths of an inch long, and quite sufficient to light the gas at any burner instantly

Ladies generally could perform these experiments with more success than men; but this was simply from the fact that they had remained longer at home, and consequently their slippers were perfectly dry. In my own case I found that by putting on a perfectly dry pair of slippers, or even boots, I could produce fully as good sparks as the ladies. Ordinary slippers, however, always gave the best effect, a larger rubbing surface being then exposed to friction upon the carpet.

Sparks could be easily given from one person to another, and I have been "shocked" by some young lady with "malice prepense," sliding up to me, and touching my forehead. I have charged a Leyden jar by this means, and, in fact, all static electrical experiments could be produced where the spark of one-eighth to a quarter of an inch sufficed. These results can be obtained during winter in any of the Northern or Western States. I have tried to reproduce them in England and throughout the Continent, but without success—in Russia during the winter of 1864, I observed a few traces of this high electrical or insulating powers of the atmosphere. I did not, however, succeed in lighting the gas, but I found great difficulty in combing my hair with an ordinary indiarubber comb, the hair all raising on an end with constant shower of sparks from teeth of comb; this, however, I found much more disagreeable in the United States than in Russia, as during many winters I had to wet my hair before combing—else impossible to get it to lay straight or even. Without this remedy, or by using oil or pomade on the hair, my hair, which is very thick, would rise up, and would be some minutes before I could get the "porcupine" appearance to disappear.

I have never in England seen these effects, though Professor Wheatstone has already observed them, and read a paper before the Royal Society (two years since) upon the great care necessary in making electrical experiments, as he had found many errors, for which he could not at first account, had been produced simply by the friction of his feet upon the floor. He also observed that in the United States he had been informed by the best scientific authorities that by simply walking across the floor electricity of sufficient tension to light the gas at a burner could be produced. Therefore "Philo's" statement is perfectly true, and I inclose my card, not for publication, but as a guarantee of the good faith of yours TRAVELLER.

[This letter is well authenticated.—ED.]

[4169.]—FRIENDS of mine, on whose truthfulness I feel complete reliance, assure me that they have witnessed electrical phenomena substantially the same as those described (let. 4104, p. 199) as witnessed by friends of "Philo." I am not yet at liberty to publish their names; but if any one is desirous of more precise information I think I could procure it privately.

13, Great George-street. P. H. HOLLAND.

[4170.]—IT is neither right nor wise of "Philo" (let. 4105, p. 199) to force his own misapprehensions and deductions therefrom upon other readers. Why should he persist in asserting that a certain supposed fact which he believes in is "treated as an impossibility by one correspondent at p. 62"? At p. 62 I expressed the "trust that 'Philo' is able to distinguish between the two mental states of not denying yet not believing." It appears I gave credit to "Philo" for more perception than he possesses. I said, "I do *not* deny the possibility of gas being lighted by a spark from the finger, the electricity being unintentionally excited." If that is treating it as an impossibility, as "Philo" is pleased to say, it is time some of us went to school again. I do not believe the event has happened—that is, I wait for evidence; I am accustomed to test facts, even when I witness them myself, and often find that my first impression was mistaken; and does "Philo" suppose I am going to accept the secondhand testimony of one or twenty ladies, young or old, pretty or plain? Why, I have fifty times better evidence that Mr. Home has floated out of window, round the face of a house, and in again, and I actually do not believe that. To speak plainly, I should require any testimony coming from America to be very thoroughly supported. Whether the air there facilitates the production of electricity of high tension I do not know; but that something facilitates the development of enormous falsehoods, intentional or otherwise, we do know very certainly, because the peculiar feature of American wit actually consists in the giving of some vraisemblance to outrageous exaggerations, and that is sure to react upon national character for truthfulness. We electricians of the ENGLISH MECHANIC have not yet forgotten Paine's electro-motor engine.

"Philo" may further be assured that our electrical theories do not fail to correspond with well-authenticated facts; but his facts do not come under that description in the first place, and in the second, no theory that I am acquainted with is opposed to them. We well know that such sparks could be generated under certain conditions: what is doubtful is whether such conditions are ever attained. As to his last word and recommendation, does it not occur to him that misrepresentation of others is not the likeliest mode of drawing out "polite" replies? SIGMA.

"E. L. G." AND PHYSICAL GEOLOGY.

[4171.]—I CANNOT help contrasting "E. L. G.'s" style of argument with the words of Murchison (who was both the friend and opponent of Lyell), that the question between the uniformitarians and the catastrophists was only one of degree, and that by means of fair discussion the truth would at length be eliminated. Why should not "E. L. G." be more eclectic, and select the good grains of uniformitarianism at the same time that he rejects the chaff? Surely none will deny that there is truth in uniformitarianism as well as in the theory of the catastrophists. Let us neither be too "prodigal of violence," nor too "parsimonious of time." The reasonable uniformitarian admits the necessity of occasional catastrophes (not connected with comets, though), while, on his part, the unbiased catastrophist will uphold the necessity of enormously long undisturbed periods to account for the formation of thick and slowly deposited formations like the chalk.

Turning to letter 4068 (p. 175), I find that "E. L. G." there makes three assertions, with none of which I can agree, viz.:—(1) That causes "now in action" can only account for the present condition of one-hundredth part of the globe (putting aside all alluvial and recent deposits); (2) that the form of the remaining part of globe has been determined by deluges; and (3) that the deluges were the result of comet-falls. Now, undulating country has been formed by causes now in action, and it is just the kind of phenomenon that a deluge does not produce. Catastrophal deluges can only account for the condition of a small part of the earth's crust.

To prove the above assertions, let us first consider the beautifully-moulded waterless coombes of the chalk, to which "E. L. G." specially refers. These are due, in the opinion of Murchison, Lyell, and a host of other geologists, to the long continued erosive action of atmospheric influences—such as wind, rain, and frost, which would denude a soft material like chalk, or even oolite, in time, short in comparison to that required to reduce some of the granite mountains of Wales and Scotland to their present weathered condition. These coombes could not have been formed by a deluge which would make a clean sweep, and leave a long trough with sweep sides just as it has done in the Weald and at Woolhope, which are known as valleys of elevation, and are referable to this cause. In these cases the superior strata have been elevated and shattered by a series of seismological convulsions, and the débris then brushed off by a torrent of water. Then, again, small watered "sweep" valleys which are now unfloored mostly began with a floor, the river eating its way down, not all at once, so as to form a canon with steep sides, but gradually, and leaving a series of raised beaches on either side, thus forming a terraced valley. Atmospheric action in many cases has crumbled away these terraces, and formed a gentle slope.

Now for "E. L. G.'s" experiments with mud, fine clay, and sand. These go for nothing, because the materials employed do not resemble those of which the majority of strata are composed. All geologic rocks are more or less consolidated. Try the effect of continual droppings on a piece of soft and unequal sandstone or chalk. The result will be a series of miniature coombes and rounded hills. Now, take another piece of the same material, and chip up a portion of it with a chisel. This represents, though imperfectly, the effect of elevation and earthquakes splitting up the rocks. Now pour on it quickly a jugful of water. The crushed and rent débris is swept clean away, and we have a model Weald left behind.

Lastly, as to the cause of these deluges. They were in all probability partial, and of short duration, doing their work by mere velocity and impetus. Deep seas and other still waters are well known to have no erosive action. The late Sir R. Murchison considered that these deluges were the effects of the sudden upheaval of large tracts of land in mid ocean. Such elevations must have displaced large masses of water which would pour over the then existing continents. OSA.

REVOLVING PUDDLING FURNACES.

[4172.]—IN let. 4064 "G. S.," I regret to see, brands Mr. Danks "as a mere copier of the inventions of Mr. Walker and Mr. Tooth." This must have been written without due consideration, for Mr. Danks's furnace has been carefully tested both in England and America, and the almost unanimous verdict of the trade is that it is a complete success. Surely, then, it must be something more than a mere copy of unsuccessful inventions; if, however, it is not it will share their fate, whatever that may be. If the inventions were alike so would be the results produced; but this is not the case. Mr. Danks has produced a furnace which, in my humble opinion, is destined to supersede all others; and whether his success be attributable to the materials used in fettling, to the mode of applying those materials, to the arrangement of metal plates which secure the fettling in its position, to the contrivances for facilitating the extraction of the puddled ball, to improvements in the construction of the furnace, or to all these points combined, I hope he will ere long reap the reward which all honest men must admit is his due. And let all praise be given to Mr. Walker, Mr. Tooth, and other gentlemen who have endeavoured to ameliorate the condition of the puddler.

I pass over the strictures upon "scientific institutions in England" with the remark that the earnest manner in which the investigations of the present state of mechanical puddling and of the merits of the Danks furnace have been conducted by the Iron and Steel Institute proves that this society, at any rate, is not an "egotistic sham." R. S.

PHOTOGRAPHICAL.

[4173.]—IN the articles on "Photography for the Uninitiated," three solutions are given for sensitising albumenised paper. To No. 1 there may be little objection, but the addition of muriatic acid to any silver solution, as given in No. 2, must be to convert so much of the silver into a chloride, rendering it useless for the purpose for which it was intended. In No. 3 it is mentioned there is a heavy precipitate. What is precipitated? If the author of the articles thinks the uninitiated will find pleasure and profit in purchasing silver to see it precipitated in that manner, I think he will be mistaken. I for one will prefer a plain 60 grain solution, allowing the albumenised paper to convert what is required into a precipitate on the face of it where it is required. I would recommend black enamelled pins for paper.

If "R. M. H.," query 11791, will look at page 137 of present Vol. he will find what he asks for. If he succeeds, perhaps he will let his success be known. Several professionals I know have got the length of shadows. If he would like a cheap dry process, which a friend of mine gets on so well with that he can calculate on eleven out of the dozen being good, I will be delighted to give him the details.

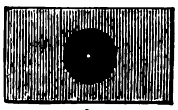
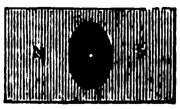
[Please send it.—ED.]

MAGNETISM.

[4174.]—I BEG to say a few words in answer to "Conatus" (query 11761, p. 184). Your correspondent, referring to some lectures on "Magnetism" I have recently been delivering to science students in Liverpool, by the invitation of the Town Council of that town, asks a question relating to some of my experiments. In one of the lectures referred to I showed that the magnetisation of iron or steel causes a molecular change in those bodies, whereby, among other results, the conduction of heat in magnetised iron is swifter in a direction across than along its magnetic axis. Around a central hot rod, wax spread over the iron will be melted in a circle if the iron be unmagnetised (A), but in an ellipse if magnetised (B).



A



B

Further, it was shown that if a cylinder with glass ends be filled with water containing magnetic oxide of iron in suspension, such a medium becomes more transparent along its axis when magnetised by an electric current. These experiments are well known. Your correspondent asks whether the magnetic oxide of iron should not get more transparent across than along its axis. This is not the case, for in magnetisation the particles of iron approximate sideways, and probably place themselves end to end lengthwise, arranging themselves somewhat like soldiers when a scattered field forms its ranks, and closes in. Iron, therefore, slightly lengthens when magnetised, but its total bulk does not alter, as it diminishes proportionally in its cross section.

I hope shortly to find time to publish, in one of the scientific journals, a lecture on the "Molecular Structure of a Magnet," which I delivered last week before the Dublin Royal Society, and where your correspondent will probably find the fuller information he needs. He further speaks of "the conduction of light and heat." I need hardly tell him that there is no such thing known as the conduction of light. Light, as far as we know, is only transmitted in one way—namely, as a wave-like motion of the ether. Heat is chiefly transmitted in two ways—by ethereal undulation like light, and by molecular vibrations like electricity. In the former it is radiant heat, in the latter it is conducted heat. And, further, heat may be carried or convected by causing lighter currents in a liquid or gas. Inasmuch, therefore, as the conduction of heat is totally different from the transmission of light, your correspondent must not expect to discover any phenomenon common to both. In radiant heat he will, however, find in every instance a most perfect analogy to light.

Woodland Grove, Isleworth. W. F. BARRETT.

INCUBATORS.—To "M. O." AND OTHERS INTERESTED.

[4175.]—I WAS glad to see another letter from "M. O." on the above subject, being one in which I take an interest; for I do not see why eggs should not be hatched with certainty and success artificially. In reply to his query, "Whether I have hatched any with the machine I made?" Yes. But if asked whether it is a success—No, as about 90 per cent. of the eggs set are lost on the nineteenth or twentieth day. I have no difficulty in producing full-grown and remarkably fine chickens; certainly remarkable for their size, and fine, strong, and well developed limbs—quite perfect; but when the time comes for the yelk to be drawn up, and, in fact, at the last hour or two before hatching, in my opinion, the chickens die in the shells—frequently after having broken through sufficiently to protrude their bills. The same remarks apply to ducks' eggs. My machine can be set at any temperature, and will remain steady, by the thermometer, and will hatch and bring forth some chickens, which, contrary to the prophesies of the croakers, are strong, healthy, and lively, and eat well. I have been thinking over the matter, and it occurs to me that the drying and evaporating action of the machine heat, leaves the yelk in too thick or glutinous a state for the chicken to draw up into the abdomen. I suggest this for the consideration of others interested, and "M. O." in particular, and shall be glad of opinions upon the subject. Should I be right in my conclusions a question will arise as to the best method of supplying the moisture necessary to effect the best results. It is evident that the hen is not an evaporating machine, but rather inclined in the opposite direction, and that any moisture supplied by her is supplied in a most subtle manner. I am about making some further alterations in my machine, and shall be very glad to exchange results with "M. O." and others practically interested, and working. I think artificial hatching is especially applicable to ducks' eggs, the young from which require no care, and may be turned out next day, and that the matter is sufficiently important as a food question to warrant a little trouble, especially when young ducks a month old are selling for 2s. each in the market of the town in which I live. HATCHER.

THE DELUGE.

[4176.]—THE book of Colonel Greenwood, about which Mr. Gosse inquires in his very flattering but encouraging note (4097, p. 193) was published by Longmans, Green, and Co., the first edition in 1857, the second in 1866, with 237 pp. and some very good coloured maps of the Weald and some French districts. What I intended to praise in the book is independence of thought and fitness to stir up thought in the reader. I must beg to disclaim, if any of my words conveyed such an idea, any acceptance of the Colonel's chief doctrines. In fact, he is a thorough Lyellist in principle, wasting himself in futile attempts on the insoluble problem of accounting for all we see by "causes now in action," though all the while exposing the delusiveness of Lyell's similar attempts. His attack throughout is on Lyell personally, and not at all on what I call "Lyellology." The above false dogma that Lyell (I am told) invented—that, at any rate, made its appearance here in England some thirty to twenty-five years ago—has hardly yet deluded any foreigners, because they generally see that it is utterly disproved by all *known* facts in the heavens or earth (as baseless and as multifariously disproved as ever the Ptolemaic astronomy has been); and yet here—in the very birthplace of geology, the very land whose villages and districts have supplied nearly every name accepted for the world-wide formations throughout the world's schools of science, here it has driven out the true science (except as regards the *older* strata, deep or underground geology) absolutely banished to France and less sophisticated lands all *science* of the later tertiary and human periods, to supersede it by sheer *faith* in the miracle stories of a new *priesthood* that, instead of reasons or arguments, write (like Professor Tyndall in one of his Alpine books) when something is to be swallowed against evidence, of what "*we ought to believe*" Exactly as any Popish Council, or rather provincial or heretic synod of the dark ages, or of Brahmins, laid down their creeds; this new dogmatic *faith* (for such it is, and no science), being just as anti-scientific, reason-scorning, sacerdotal, myth-and-miracle-swallowing, and superstitious, as any form of Popery or Brahminism ever was! Now, of all acceptors of this baseless faith, Colonel Greenwood seems, to judge from his book, the most freethinking, and therefore least likely to swallow it permanently. But his temper towards the perfectly proved fact (as I consider it) of a cometary deluge, in this his last edition, Mr. Gosse may see from this quotation I will make from Chap. III. "Mantell tells us that at Hastings 'a *diluvial valley* intervenes between the white chalk and the west cliff, where the ruins of the castle are situated.' *Diluvial* Beautiful! A valley made by Noah's flood doubtless!" This will show you that if I commend the Colonel's book, it is not for diluvialism, but because its general frankness and breadth of admission of easy and difficult facts alike (very like Darwin's method) enables the reader to see where and wherein its reasoning breaks down, and how completely and solely through this error. In the table of contents all the positions are tersely put, including, with scores of excellent and novel maxims, such plain fallacies as these:—"Rivers may cut deep channels, rain makes wide valleys"! "Aqueous denundation is universal, and is not confined to the lines of torrents and rivers"! "Absurdity of the doctrine of the original incandescent fluidity of the globe"! Readers far inferior to Mr. Gosse may be trusted to see how entirely the book fails to make out the two former, or that there is anything absurd in the latter. As for the second, I maintain, with De Luc (Letters V.) that most vegetation, especially the lower, as moss, grass, heath, bushes, jungles, *totally* protects the ground below from suffering *any* balance of loss, and, in fact, wherever vegetation continues from age to age, it shows the balance (if any) to be on the side of gain, that at least *as much* new soil is added as is carried down and away into gutters, rills, and finally rivers by the rain; all of which has to sink into such ground at first, because the drops, falling only from a few inches above, have not impact to run and wear the surface. Denudation, therefore, by any present known rain, *is* "confined to lines," to the beds of rills and rivers, which it can only lengthen and deepen, never *widen* beyond a fixed small limit (except in those rare flats where a stream shifts its bed from time to time). *Furrowing* is all the effect possible, whether on the hardest or softest, richest ground or bare rock, by any modern rain, or any conceived even 100 times heavier, say, instead of the three inches per hour that is, perhaps, about the maximum of tropical storm fall, a deposit of a foot per minute (or an inch in five seconds). It is doubtful if even that would suffice to denude more than the lines of gutter, into which it would (on any considerable slope) have time to collect without flowing as a sheet on the whole surface, which is what we require to "denude universally." No mere atmospheric rain can or ever could approach aught like general *surface* denudation; and yet every acre (not of modern ground) testifies that such denudation it has had. Moreover, it is easily reckoned that not only the above rate of stormfall, but one *ten times greater*, say, depositing ten feet per minute (supposing you have store of steam enough above to supply it) need neither acquire in the air velocity enough for the drops to hurt or kill animals, nor displace enough of the air to affect their breathing in the least. Of course, the first dash of such a rain would scour to clean rock, all hills, and highlands; the first minute would uproot all timber, even in valleys and flats, would sweep off mankind and their habitations (Job xxii. 16, Matthew xxiv. 39, Luke xvii. 27), and before the sea level had been raised a yard (supposing the land and hills to retain their form rigidly, which however they could not), before, I say, a yard of water had fallen (which it might in one minute), every floatable thing on all continents would be afloat, and either over the old sea, or approaching it with sevenfold railway speed, all ice of both poles, and of all Alpine glaciers, and thousands of square leagues of matted forest timber, rather floating *continents* than the "floating islands" that navigators now see issuing from the Niger or Gambia. But in all this tremendous minute there would be nothing to kill necessarily *every* animal clinging to a tree. Individuals of many species might thus both float and find food on some of these millions of natural rafts of uprooted but still living forest for days or even weeks, till the driftwood landed on some of the newly rising hills that the general plutonic movement would certainly *begin* to upheave into air before *many* days from the first shock; though others, even of such as are now highest, and lowlands and vast portions of our continents might not emerge or reappear for much longer —we have no means of guessing how long. And as Magalhaen was carried, during above half a year, across all the most island-studded part of the Pacific, without once seeing land; so at the time of the Deluge, abundance of land might re-emerge in a few days, and become nearly restocked with most of its former vegetables and many of its former animal species, and yet a human navigator so drift as for months and months to find, like Magalhaen, "all hills that were under the whole heaven covered;" and even, if happening to ground and stick fast on a newly rising cone as solitary as Teneriffe, Pico, or Ararat, might see no other land till his vessel was hoisted above the clouds, whether such hoisting occupied days or months or years. If prevented descending, or afraid to do so, all nature might be teeming over these whole continents through a more sweltering summer (owing to the heat of the condensed steam) than centuries upon centuries had known before, and the renascent vegetable and animal kingdoms be in full swing before the generality of the rocking crust would be settled enough, or the lowland air healthy enough, to make it safe for such human navigators to descend from their lonely box on the cool peak above the clouds (supposing them there provided for).

Colonel Greenwood has, before the above first quoted position, a true one strangely contradicting it. "If valleys," he well says, "were widened by erosion of river banks, their sides would not *slope*, but must be *cliffs* with intervening *table*-land." Quite so, and such is the case on any known *modern*, that is, *undiluviated* land. But then he distinguishes between rain and rivers, which elsewhere he insists are all one action, and for once opposes them, thus—"*Rivers* may cut deep channels, *rain* makes wide valleys." It does no such thing. *Some* rain did so *once*, but no modern rain is capable of this. On the contrary, it collects into hills and rivers, and only acts by them, on their beds. It *furrows* more and more, an effect the very reverse of that of the diluvial *smoothing* rain. The widening and sweep-vale-making effect requires rain too great and rapid to furrow or form torrents. Instead of our *torrential* rain, it requires *diluvial* rain, such as to form a moving *sheet* over the whole of a steep hillside at once. The Colonel evidently met with objectors perceiving this difference, for at the end of Chapter II., he says, "In general the philosophic and the unphilosophic are terribly put out by the powers here claimed for the '*wash of rain*.' Yet when the word '*flood*' is used, they will allow you to wash away articles of any size or description, natural or artificial." A flood, however, is simply the effect of rain, as "*the flood*" was the same. A flood means rain collected in quantity enough to wash, but to do this any *modern* rain must be collected and concentrated greatly. By washing a thing we always imply exposure of the whole surface to water moving with regard to it at once. Modern rain washes the channels it flows in, when collected, but not the mere collecting surface it drops upon. I must, therefore, agree with "the philosophic and unphilosophic," against the Colonel, that "wash of rain," as he uses the phrase, as surface wash apart from wash of rills or torrents, is a thing now unknown. There has been no real washing (whole-surface-washing) rain since what made Mantell's "*diluvial* valley" that so amuses him. No millions of years of any present rains can form any such valley; but a washing rain might do so in less than a day. The motto on his title-page is

Multa renascentur quæ jam cecidere, cadentque
Quæ nunc sunt in honore.

He evidently reckons not Mantell's diluvial valleys among things that "renascentur." Men choose mottoes that occasionally "come home to roost" in unexpected ways. E. L. G.

VERDE ANTICO.—WORKING IN METALS, &c.

[4177.]—"ETHEL" (let. 4088) is mistaken in thinking me one of the gentler sex. Her mistake was, perhaps, caused by my making moan over the state into which filing and finishing metals puts my hands. But I suppose my doing so must be ascribed to early training and prejudice: the remains of the superstition which made Lord Chesterfield and Lord Byron say, "Show me a man's hands and I will tell you whether he is a gentleman or not"—a miserable mistake. Show me his heart, say I, or his head, or both, before I can decide. As to the colour of antique bronzes, I did not mean to say there was no green colour given to bronzes artificially in ancient times. I only meant that it probably was, though verde, not verde antico when freshly manipulated. "Ethel's" own things may be in existence 2,000 or 10,000 years hence, and the verde moderno, which she now laments, be turned into the true antique hue. As to colouring metal before casting that I fear is impossible; any colouring matter would be destroyed by the heat required to melt bronze —unless, indeed, some of the colours used by enamellers, which become green by a heat as intense. Perhaps some of our chemical brethren will tell us. Enamelling, by-the-by, is a thing which "Ethel" might easily add to her metallic pursuits. I used, in a very far-off land, often to see a jeweller friend of mine enamelling pins and things with a mouth blowpipe, and enamel in powder, or rather paste. I believe that enamel powder adheres, when fused, to copper without any preparation, except brightening the copper surface. If "Ethel" has gas where she is, the best blowpipe she can use is the one made of two balls of vulcanised rubber. The first ball, when pressed by the foot, fills the second, and, keeping it full, causes a continuous blast. It costs 15s., and is, I believe, a French contrivance, though I bought mine in London. I have melted with it on charcoal a piece of brass as big as a nut. I don't believe there is any book—in England at least—on working in gold and silver, but there is a *Goldsmiths' Magazine* published monthly, I think, which ought to be useful to "Ethel." Perhaps some of "our" readers will kindly mention the exact title. I once tried one of the spirit blowpipes, and after lighting it the whole inside caught fire and blazed furiously. I put it out at once with the rug, and on taking it back to the man he showed me a hole in the spirit lamp which he assured me was the cause. But having gas and the vulcanised rubber blower I did not again try it. In Ure's "Dictionary" there is a very elaborate table of the various alloys, but I have left mine in London, and shall not get back for months. Will some brother who has access to it kindly answer our fair correspondent's question (p. 560, Vol. XIV.)? PROVEN.

NEW DOUBLE STAR IN VIRGO.

[4178.]—I WOULD call attention to the following double star found two nights since, which appears to be new, so far as I can learn:—

VIRGINIS = L 23106. 12h. 18m. 29s., N 14° 25′: 7, 11½: 110°: 4″.—About 1½° *s.f.* 6 Comæ, and easily found from that star. At the time of the discovery of this pair (and I have not seen it since), it seemed a very delicate and rather difficult object; but as it was in the same quarter of the heavens with a full moon, and the seeing only moderately good, it may, under more favourable circumstances, be quite easy. This is Weisse XII., 197. The spiral nebula, M 99, should, from its place in "Celestial Objects," be about ⅔° *n.* of this pair.

A few days since I forwarded a note in reference to a new double near 17 Hydræ, giving its distance at 1·5″. Later observations indicate that the distance is rather less, if anything, and probably will not exceed 1·25″. I hope to hear from Mr. Knott and Mr. Bird in reference to these matters, and if any of these supposed new pairs have been observed before, I shall be glad to have it stated.

I may repeat, for the encouragement of others having small telescopes, that all the new double stars communicated to the ENGLISH MECHANIC and many others, have been discovered in every instance, and observed only with a 6in. aperture, so that they are all within reach of an instrument of that size, and for many of them a much smaller aperture is sufficient; while with an 8in. or 10in. mirror, all of them, I should expect, would be quite easy objects.

Chicago, April 24. S. W. BURNHAM.

BRIDGE CONNECTING ENGLAND AND FRANCE.

[4179.]—IT appears to me very simple as to the reason why the pump had to work for "three minutes before there was any indication of a vacuum." When the shroud, closed at top and open at bottom, was forced by weights to a depth of 4ft. 7in. of sand and gravel, as well as 1ft. 8in. of water, there would be a very considerable pressure upon the air contained therein, and until the pump had exhausted all this pressure it would not begin to show any tendency to a vacuum. I would imagine that it would be preferable to have an aperture at top, so as to let the air out and water in, until it reached a suitable depth in bottom to commence the the exhaustion. By this means there would not require to be such a quantity of weights to sink it at first.

Liverpool. A.

ATOMICITIES AND ELECTROLYSIS.

[4180.]—THE question which "Eclecticus" (let. 4109, p. 200) has once or twice before raised as to the relationships of the phenomena of electrolysis to the old and new notations is one of interest and importance; like most other natural problems, too, it cannot be decided by studying it only from that point of view. It gave me a great deal of trouble at one time when passing from the old to the new notation, but for me that difficulty has long since vanished. I will not attempt to go into the matter now, as I have it prepared for necessary papers on "Electrolysis," but a few remarks will show, I hope, how it may be explained. As I pointed out in my papers, the electric current appears to support the old equivalent notation; it does so partly because our knowledge of it grew up under that system, and most experiments are on record in it; but the true explanation is that we cannot escape from what are diatomic elements, such as zinc, copper, sulphuric acid, &c., and, therefore, we are bound to get an action represented by H_2 on the atomic notation, and H on the equivalent system, which, therefore, appears (but only appears) to best match the facts.

The principle which clears the difficulty will be found in Section 240 of my papers. "Energy equivalent to 4,673 foot pounds exerted upon a chain, each link of which is a chemical equivalent of matter, weighed in grains, converts that chain into an electric circuit under a tension of one volt at the source of the force . . . It has a further meaning—for applied to the atomic notation it expresses the force transmitted through the centres of attraction or of 'atomicity' by which the molecules are constituted."

We may find here the explanation of several curious facts which have puzzled electricians, and led to the setting up of some imaginary laws of electrolysis. Copper furnishes an example of several such anomalies. It can be deposited either at the anode or cathode, and it can be deposited in the same circuit, in one and two equivalents, a fact I have never had explained by an electrician who held to the equivalent system.

We may form a circuit of three cells—1 containing dilute acid, for what is called the electrolysis of water; 2, cupric chloride; 3, fused cuprous chloride—forming a binary chain of attractions starting from the zinc and sulphuric acid in the battery; the lines below show this:—1, the circuit; 2, the equivalent expression of the products; 3, the atomic expression, remembering that for the same actual quantity the equivalent numbers would be doubled throughout—

1.	$\begin{matrix} H \\ H \end{matrix}{>}SO_4$; $H_2 = O$	$Cu{<}\begin{matrix} Cl \\ Cl \end{matrix}$	$\left\{\begin{matrix} Cu-Cl. \\ \mid \\ Cu-Cl. \end{matrix}\right.$
2.	H O	Cu Cl	Cu_2 Cl.
3.	H_2 O	Cu Cl_2	Cu_2 Cl_2.

Now, all this is quite clear when we adopt its atomic notation, and the idea of the atoms or radicals possessing certain mutual attractions or valencies, or, what is the same thing, class acids or acid radicals as monobasic, bibasic, &c.

Of course, I quite agree with "Eclecticus" in regarding radicals—such as cyanogen, ethyl, &c.—as exactly corresponding to elementary atoms; in fact, this doctrine is a pure "radical" theory. According to my diagrams above, and the atomic notation, one atom of copper exerts its bibasic powers as a radical upon two atoms of chlorine in cupric chloride, while it is capable of uniting with a second atom of copper, so as to form not a molecule but a still unsatisfied radical still uniting to two atoms of chlorine to form cupreous chloride, from which, therefore, the same current deposits two equivalents. Now, until "Eclecticus" can explain this he really must not quarrel with Mr. Davis because platinum is capable of claiming either two or four atoms of chlorine according to the conditions and forces to which it is subjected. SIGMA.

OBSERVING ASTRONOMICAL SOCIETY.—OBSERVATIONS MADE BY THE MEMBERS.

[4181.]—JUPITER.—MR. H. W. Hollis, of Newcastle, Staffordshire, reports that on January 14, 9h., the disc of the planet appeared very sharp, and he counted twenty-two different bands of colour. "Those visible in the equatorial parts of a beautiful delicate pinky brown. I am certain that the belts are visible up to the very edges of the disc, but there is an apparent increase of brightness for a considerable distance round the edge of the planet—probably an effect of contrast—which obliterates the extremities of the belts unless carefully looked for. Several well-marked and beautifully defined irregularities in the belts showed the rotation most clearly, even in half an hour's watching. Jan. 23, 8h. 15m., satellite 1 just entered on disc of Jupiter, and appears as an intensely white spot; 9h. 20m. shadow of 1 on centre of disc black and sharply circular; the satellite itself cannot be seen." Mr. T. W. Backhouse, of Sunderland, observed the transit of satellite 1 on January 14. At 13h. 54m. it "appeared as a faint white spot." On February 3, 6h. 7m., he examined satellite 3 and its shadow when in transit. The satellite itself was, at the time mentioned, nearly half across Jupiter on a darkish belt. "It is much darker than the darkest part of the planet." At 7h. 30m. it was "still very plain, but only the same shade as the darkest part of Jupiter. It was smaller than its shadow, which was very black."

T. CORONÆ BOREALIS.—Mr. T. W. Backhouse says:— "A change has taken place in this star. On its fading the second time it became stationary in brightness about the middle of the year 1867, since which time up to the beginning of this year it continued the same.

but with frequent slight fluctuations, which, however, ceased, so far as I could judge, at the end of 1869. I have suspected fluctuations since 1869, but they were doubtful. On Jan. 14, this year, I looked at the star, and found it about its usual brightness, or perhaps a little fainter, but certainly not fainter than it had been at times previously. I did not look at it again till March 5, when I found it much fainter than I ever saw it before, perhaps half a magnitude less than usual, and it was the same on the following day."

NEBULA IN THE PLEIADES.—Mr. H. W. Hollis has looked for this nebula with his 8in. achromatic, but cannot find it. He says:—" There is something peculiar about all the brighter stars of this group which for months past have appeared to me as if surrounded with nebulous light. Can the nebula have been distributed amongst them ?"

METEORS.—The Rev. S. J. Johnson, of Crediton, witnessed the appearance of "a splendid meteor at 7h. 37m., April 6. Its course was in a straight line downwards from about 15° above the N.W. horizon to about 5°. Colour, white with a greenish tinge. Duration, about 5 sec. Seen against a dark sky this meteor would have equalled, if not exceeded, the brightness of Venus or Jupiter. I was looking for Mercury at the time." On April 19, 11h. 10m., Mr. William F. Denning, of Bristol, saw a brilliant meteor. It passed downwards in the NN.E. sky. It was starlike in appearance, and left no train of light.

MERCURY.—The Rev. S. J. Johnson observed Mercury both with the naked eye and telescope on the evenings of March 25 and April 5. A power of 100 on a small telescope brought out the phase.

W. F. DENNING, Hon. Sec.

EARWIG IN EAR.

[4182.]—ANY insect is immediately killed if its spiracles be filled with oil. A dog of mine was once driven nearly distracted by a flea that had fixed itself so deeply in the dog's ear that neither he nor I could reach it. I gave him immediate relief by dropping a little oil into his ear, which killed the flea. What became of the corpse of the deceased I did not observe. Oil is more easy to use than tobacco smoke, and as effectual. M. R. C. S.

ERRATUM.—In let. 4068, p. 176, line 30, for "probably also the *last*," read "probably also the *east*, of any mountainous tropical island," &c.—E. L. G.

EXTRACTS FROM CORRESPONDENCE.

Communicating Rotary Motion to Ball Fired from Smooth-Bored Gun.—In reply to M. Paris' witty and clever letter (4051) my idea, I fear, seems more likely to cause man's laughter than manslaughter. If it be possible, "with such a ball to shoot round a corner," I must take out a patent and sell it to the Fenians. However, it has done more. "Philanthropist's firework" has recoiled on himself like a boomerang, not to use the stronger language of the poet. However, joking aside, I am obliged to M. Paris for explaining the matter to me; he says, "the rotation might be at any angle to the line of flight." I fear this is the real difficulty, it occurs to a very small extent in rifles of high trajectories at long ranges, as the rotation ceases to be identical with the curvilinear path of the ball.—PHILANTHROPIST.

Experimental Borings for Coal.—An experimental boring in search of coal has been commenced in the centre of the Weald of Kent, but is now postponed till after the meeting of the British Association at Brighton. A desire has been generally expressed that a boring should be made in the Thames Valley to test the hypothesis of Mr. Godwin-Austin and Mr. Prestwich; a considerable sum has already been subscribed for this purpose, and sufficient will probably be provided at the Brighton meeting.

Harbour Scheme for Calais.—Another new scheme for making Calais Harbour available for steamboats of 3,000 or 4,000 tons at all times of the tide has been brought before the authorities. The engineers are Messrs. Liddell and Richardson. Their proposition is to construct a landing and embarking pier about three-quarters of a mile into the water from Calais, and to connect this pier by a subway from the railway station. By going so far out into the Channel they will avoid "silting up," and by making a basin for the steamers at the extreme distance they will be able to land in shelter at any time of tide, wind, or weather. It is estimated that the cost will amount only to about £400,000.

Durability of Framed Timbers.—The durability of the framed timbers of buildings is very considerable. The trusses of the old part of the roof of the Basilica of S. Paul, at Rome, were framed in 816, and were sound and good in 1814, a space of nearly a thousand years. These trusses are of fir. The timber work of the external domes of the Church of S. Mark, at Venice, is more than 840 years old, and is still in a good state. And Alberti observed the gates of cypress to the Church of S. Peter, at Rome, to be whole and sound after being up nearly 600 years. The inner roof of the Chapel of S. Nicholas, King's Lynn, Norfolk, is of oak, and was constructed about 500 years ago. Daviller states, as an instance of the durability of fir, that the large dormitory of the Jacobins' Convent, at Paris, has been executed in fir, and lasted 400 years.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

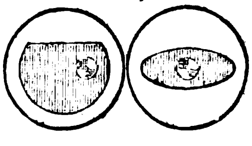
1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[10478.]—**Pork Diet.**—I am a believer in the profound wisdom which dictated the old Jewish laws and rules; one of these is the disuse of pig meat. The same regulation prevails in Mahommedan countries, and I have read the assertion that in non-pork-eating lands the disease we call consumption is absolutely unknown! Many medical men object to its use in common; some say that well-cured bacon toasted hanging before the fire may be eaten by delicate people, but not any other description of the animal's flesh. If all pigs were well fed and healthy, there would be but little objection, perhaps, to our using them for food, but there is no animal more liable to disease, and no meat in which such state of disease can be so easily disguised and concealed from the consumer.—A MOTHER.

[10664.]—**Angle of Reflection and Incidence.**—There is a slight error in the diagram on page 205. The line A H should pass through a point in B F, the same distance from F as G is from A, and the line A K through a point the same distance from F as J is from A.—BILLIARDIST.

[11108.] — **Tilt Hammer.** — I have been very carefully examining the drawing of tilt hammer sent by me. (See page 128.) It was carefully studied, and may be made free use of by any of your numerous readers. Two further diagrams will explain all that is needed. No. 1, the eccentric drawn separately; No. 2, a separate action, so that it will be easily perceived. My drawing is correct, and can be made adjustable to any weight or purpose.—JOSEPH WILLIAM FENNELL.

FIG. 1 FIG. 2



[11120.]—**A Question of Sight.**—J. Barwick must really go to the rudiments of the subjects he is attacking, which are to be learnt from school primers. And why does he not try the experiments on shadow and penumbra? He has no right whatever to occupy your space with speculations on points open to experiment, and which he refuses to learn either from nature or books. The shadow of a globe in sunshine extends just as far at all hours of the same day, he might readily find. What does he mean by air "except under special mechanical pressure"? Who has ever experimented on air not under some special pressure? Where can he get uncompressed air? or what is its density? If he could have a steel "needle" reaching to the sun, any pulsation would be communicated in not less but far longer time than light; in fact, according to him, only 17,000 feet per second; 56,000 times slower than light, and would take about two years and a half!—E. L. G.

[11207.]—**Siphon Bottle Caps (U.Q.).**—A greater pressure by making your runner longer, or rather higher, will stop the "drawing into holes;" if this does not do, make the runner bigger. I can't tell about the kind of metal.—ANGLO-AMERICA.

[11209.] — **Making Gold Malleable (U.Q.).**—Perhaps lead was melted in the crucible, which would cause it. A clean crucible is required for gold; melt it again.—ANGLO-AMERICA.

[11223.]—**Stereotyping.**—"A Country Printer" will find the paper process far more economical and convenient than the plaster. He will find all the information he requires on p. 231 of Vol. XIII., and diagrams and description of casting-box on pp. 16 and 36 (Nos. 813, 814, and 323). In answer to his questions the metal may be and is generally "poured over" the mould in the "paper" process; that is, it is poured into the casting-box. A similar proceeding might be successful with plaster moulds, but I think they require rather more pressure than the weight of the small quantity of metal thus used would give. The paper process "injures" the type more than the plaster, but it leaves the forme comparatively clean, whereas the plaster method always entails a large amount of labour in clearing out the small pieces left in the spaces between the words, unless "high spaces" are employed. At times, too, if every crevice is not properly oiled, letters will be filled up, and they are generally damaged (at least) in picking them clean. The cheapest and best metal to use is old type-metal. "A Country Printer" should read the letters I have mentioned, and if he intends to do his own stereotyping adopt the "paper" or papier-mâché process. It is cheaper, easier, and quicker than the plaster; the apparatus is not so expensive, and does not occupy so much room; while, with the exception of woodcuts, the casts are as serviceable for most purposes as those obtained by the plaster method.—SAUL RYMEA.

[11275.]—**Darkening Walnut (U. Q.).**—I have found Stephen's wood stains very useful for darkening oak, mahogany, &c., and I have no doubt that S. Paine will find Stephen's walnut stain answer his purpose. Mix the powder (which can be sent by post), with at least double the quantity of warm water recommended for staining deal. When the stain is dry the work can easily be varnished, French or wax polished in the usual way.—SACRISTAN.

[11275.]—**Darkening Walnut (U.Q.).**—Lime water will darken oak or walnut about $^1/_{10}$in. in depth. The application of steam might drive it in further, but this is only conjecture.—F. G. T.

[11288.]—**Hardening Iron Plates (U.Q.).**—Would not the application of prussiate of potash supply this want?—F. G. T.

[11289.]—**Flexible Oil Painting (U.Q.).**—To make a calico waterproof coat flexible, if the same recipe would answer requirements of this querist, paint the calico or canvas in hot weather in the sun. With every brushful of paint take a rub on a good-sized piece of brown soap, not too dry, so as to take up a moderate quantity of soap each time. It will take a long time to dry, some weeks, and should have free access to sun and wind; but it will turn out perfectly waterproof, and quite flexible.—F. G. T.

[11294.]—**Dividing Metal Disc.**—ERRATUM.—Sixteenth line read: C B, D B, E B, A B respectively.—THETAMU, Horsham.

[11320.]—**Marking Leather for Ornamental Stitching by Machine.**—How will blacklead from a soft dark pencil rubbed well into the back of your pattern answer as a transfer? I always use it for my purposes.—G. W. C. H.

[11359.]—**Casting Brass Solid.**—Put a good tall head on it, and skim clean; if too much copper is used to the spelter, that may account for it; there must never be less than 4oz. to the pound of copper for anything.—ANGLO-AMERICA.

[11385.] — **Crystals in Gas Tar.** — In attempting to correct me "Ethyl" has himself fallen into error. If he will kindly refer to my reply he will see that I stated that naphthaline is used in the preparation of artificial (not real) alizarine. Real alizarine was first prepared synthetically by Messrs. Graebe and Liebermann. From an examination of the substances obtained during the decomposition of alizarine it had been conjectured that it was connected with anthracene, $C_{14}H_{10}$; and the above-mentioned chemists actually obtained anthracene from alizarine by heating it with zinc-dust. The reverse operation was then attempted; and by acting on anthracene with nitric acid, so as to convert it into anthraquinone $C_{14}H_8O_2$, treating the anthraquinone thus produced with concentrated sulphuric acid, which gives rise to disulphoanthraquinic acid, and, lastly, by fusing this with caustic potash, they succeeded in building up the molecule of alizarine, the formula of which is $C_{14}\binom{H_6}{H_2O_2}O_2$. It is also worthy of note that Anderson has prepared alizarine from opianyle; but it is still doubtful whether, when thus prepared, it is exactly similar to that obtained from madder and anthracene. But the artificial alizarine to which I referred in my letter is a body of entirely different composition; its properties are somewhat similar to real alizarine, hence its common name. Schützenberger, who has studied it much, calls it naphthazarine to indicate at once its derivation and its similitude to alizarine. He gives its composition as $C_{10}H_4O_4$. Several other fine colouring matters have been obtained from naphthaline; I need only mention naphthylamine violet, dinitronaphthol, naphthamëine, &c. The reader, who may be desirous of following out this interesting branch of applied organic chemistry, cannot do better than consult "Couleurs à l'Aniline," in Roret's "Encielopédie."—S. BOTTONE.

[11398.]—**Stinging of Bees, Hornets, and Wasps.**—The pain of these poisoned wounds is relieved by either ammonia or tobacco juice, but a writer in the *British Medical Journal* says the very intense pain he suffered from the stings of two bees in his ear was instantly relieved by injecting into the wounds a drop of a solution of carbolic acid 1 to 100, by means of a hypodermic syringe. I never found ammonia relieve instantly, but perhaps it might if injected into, instead of being dropped on to the wound. It would be well for any one who has an opportunity to try the comparative effect of each of these remedies used in the same way. A hypodermic syringe is one with a very fine pipe for injecting medicaments beneath the skin; a fine pointed blowpipe might be used if no better instrument be at hand, but it must be a very fine point to inject into a bee-sting wound, which may not be necessary in common cases.—M. R. C. S.

[11438.]—**Vegetable Marrow Preserve.**—Does your correspondent, "A Young Housekeeper," require a recipe for preserving marrow in imitation of ginger, or simply for a general preserve? If the latter I cannot supply one, but for the former, the following, taken from Francatelli's "Cookery," will no doubt answer. Peel a vegetable marrow and cut into shapes in imitation of preserved green ginger, simmer very gently for a few minutes in syrup prepared as follows:—To 1lb. of loaf sugar add a tablespoonful of Savory and Moore's essence of ginger, the juice of a lemon and half a pint of water; boil three minutes. The syrup should be boiled up twice, adding each time a teaspoonful of essence of ginger.—E. O. J.

[11440.]—**Double Bass and Violin Stain.**—Mr. Davidson will probably furnish "Benson" with the dimensions of a good double bass, and here is a recipe for "stain." Boil a pound of Brazil wood in two quarts of water for about an hour; strain, and add ½oz. of cochineal; boil gently, and it is ready for use, giving a crimson-tinted stain. If a darker colour is preferred, wash with saffron water previously. If a purple is desired, boil a pound of logwood in three quarts of water, add 4oz. of pearlash and 2oz. of indigo in powder.—E. M.

[11442.]—**Old Wives' Science.**—The reference by two of your correspondents to Dr. Brewer's "Guide to Science" for a solution of a scientific question must have amused any of your readers who are acquainted with that work. The specimen quoted from it was characteristic. "Why do the sun's rays shining on a fire tend to quench it or retard its burning?" (Or something to that effect.) Hear the learned reply, so instructive and convincing to the pupils of the young ladies' academies in which the book is used as a scientific "cram." "Because the heating and actinic rays are detrimental to combustion"! That is to say, the sun's rays have such and such an effect because—because they have! What could be more logical and conclusive? The only misfortune is that the fact so ably explained is not a fact at all; as your correspondents, S. Bottone, and "Shu Fly," have clearly demonstrated. Pray don't let us have any more of "Brewer's Guide" in "our" columns.—G. W. K. L.

[11448.]—**Warming Greenhouses.**—My method with my conservatory is to hang a long tarpaulin all along the front and sides of greenhouse in very cold and wintry weather, just taking down, if possible, for a little sun. Valuable plants I remove to my house, and I have a small stove at the end to light in day time, and two or three patent crystal lamps, well suited to the purpose, suspended from roof for night time.—H. B. E.

[11461.]—**Reviving Black Cloth Coats, &c.**—If "A. Despoire" wishes to make a good job in improving an old coat he must first give it a good beating till he has got the dust out. Then he must get the grease out with ammonia, or soap and water and turpentine, and wash the places clean. Fuller's earth is the best for grease. Having got the coat clean, he must brush or sponge it over with a solution, not too strong, of sulphate of iron, till it is well soaked in. Then take a decoction of logwood and galls, and while hot, sponge or brush the coat over with that. Hang it out to dry, and give it a good brushing the right way of the cloth. He must mind the solution of iron is not too strong for the logwood, &c.—E. T. S.

[11482.]—**Algebra.**—Let "A New Subscriber," who finds fault with my solution on p. 180, consider the number 24929, whose internal evidence is, that the four biquadrates which compose it are not fractional, for had any of them been fractional the total would have had a decimal, which must have been even, for it must have terminated in 2, 4, or 0, which is not the fact here; therefore neither of the roots (x, y, z, t) is anything but an integer; moreover, only one of the terms of the analogy can be odd, which can be proved; therefore (n) must be an even number, and (d) must be odd, and both of them integers, and thus 5 and 5 are shown to be the only integral divisors of 25, and thus ($n + 1$) and ($2a + d$) are determined. It may be added the theorist taking advantage of this principle may often avoid a press of calculation. In working equations, where diminution or augment of the root is necessary, a skilful substitution (call it guess) is a vital matter.—THETAMU, Horsham.

[11554.]—**Pedestrian Tour.**—The advice given by "Hedera," at p. 181, is good, but not, I think, quite as complete as desirable. A shooting jacket, if well provided with pockets, will enable a pedestrian to dispense with a knapsack, which to one unused to it is a burden, as is also anything to carry in the hand, except an umbrella to serve as a walking-stick when not needed as a protection from rain, or, as I chiefly use it, from sun. I have a very convenient garment made of an oblong piece of light repellant cloth with a slit cut in the middle, like that of a poncho; it hangs down to my knees behind and just below them in front, and protects me well from a shower. When folded up it is easily carried by a strap over the shoulder, and serves as a cushion to sit on if the grass be damp, as it often is. The shoes I like best are made of No. 3 canvas, with stout but not very thick soles, well supplied with nails, to give secure footing on grass or slippery ground, which is essential to safety and comfort on the mountains. I take care that the shoe soles are cut rather wider than my foot, so that I may walk on the sole and not on the welt. Shoemakers, like other mere practical men, are always wrong, and will make the sole too narrow if we let them. They think the foot should be forced to fit the shoe, not the shoe made to fit the foot. I prefer having too day shirts, one on and one off, to wear day and night alternately, or to change if damp, this saves the necessity of carrying a night-shirt; I need besides only a spare pair of stockings, knitted worsted, soft slippers, pocket-comb, hair and tooth brushes, and a piece of yellow soap. Note, if the stockings are well soaped to keep them pliable, the piece of soap may be left in the portmanteau. All of which can be carried in the pockets of the jacket. A good map, with a telescope, a compass, a purse with some money it, and an amusing book to read when resting, completes the walker's outfit. As "Hedera" advises, the portmanteau should be sent on to where it can be met when wanted. I strongly advise all unpractised pedestrians to avoid the common error of trying to do too much; do not make a toil of a pleasure; you take a tour for health and enjoyment, do not over-tax your strength, or try to walk so far that you cannot properly see and duly appreciate the scenery you pass, simply that you may boast how far you have walked in a day. I find about fifteen miles from the start to the end of the day's walk about enough, not that a healthy man cannot easily walk more, but to allow time and strength without exhaustion, to make diversions by the way, or to push on to another inn if that first reached prove full. It is no great hardship to add, say, five miles to a walk of fifteen, but it is no joke to add it when already dog tired.—PHILO.

[11566.]—**Equisetum.**—I fancy M. Paris must mean the seeds, not pollen, of the equisetum. They make an interesting object with a low power. Each has four kinds of threads or elaters. They appear at the right time as a kind of powder. They should be put on a piece of glass, and while looking though the microscope, gently breathed on for a moment; the threads will then be seen contracting and expanding as they get first damp and then dry. It is curious to watch them and their movements.—E. T. S.

[11572.]—**Compressing Water.**—I will admit that there are leaky joints, but not to the great extent of leaking gallons; if so, it would be impossible to get the pressure required. After a certain strain it would be pumping in and forcing out again, therefore the ram would remain motionless. I should like to ask "C. S." one question: How is it when the pressure is pumped up, the indicator showing three or four thousand tons pressure with what we term weeping joints—*i.e.*, just spotting—the pressure being allowed to remain on for a quarter of an hour—that the indicator never alters? That proves to me it is the compression of water. In reply to "Tubal-Kain's" suggestion, I do not think cast iron has much elasticity, and, depend upon it, the elasticity of the cylinder was inappreciable, or it would allow the water to escape between the ram and the cylinder, also the columns and nuts being so massive, the elasticity would be a mere nothing. Therefore, I think the water does not go in that way; I am also aware that metals are porous to a lesser or greater degree, but I think there is a slight difference between a ball of gold and a cylinder of well hammered steel 8in. thick.—J. WESTWOOD.

[11580.]—**Soda Ash in Boilers.**—No definite quantity can be fixed, as it varies according to the quality of the water. Therefore try a moderate dose first for your 8 horse-power boiler; say 1lb. per day of 24 hours, of strength from 48° to 52°. It is a good plan to dissolve it in the feed-tank, and it is pumped into the boiler without any trouble.—BUSY BEE.

[11589.]—**Dry Steam.**—"A, Liverpool," p. 157, makes an attempt to answer a question which he evidently does not quite comprehend. Superheated or dry steam is not necessarily high pressure steam, although he seems to assume such to be the case. I have seen steam generated in a boiler under a pressure of only 3lb. on the inch, passed through a coil of pipes bent over a furnace, and when issuing into the open air show no appearance whatever of visible or condensed steam. "J. L.," p. 181, thinks that the steam is decomposed into its elements of oxygen and hydrogen; but, were such the case, it would then have become an explosive mixture, which it certainly is, otherwise the flame of paper, timber, &c., which it so readily kindles, would inevitably cause an explosion. I should feel greatly favoured if some one of the talented chemical correspondents of "ours" would give a true solution of this query, which I doubt not they can.—CALORIC.

[11602.]—**Ligurian Bees.**—"G. M.'s" question, p. 131, not having been replied to, I venture to assert that ligurian bees are in every respect far superior to black bees, and that in neighbourhoods where the former are kept in large numbers, the latter cannot get a living. In early spring, when provision is scarce, the ligurians may be seen abroad two hours before the blacks make a move, and when the latter do try their luck, they find that all the sweets have been taken from the few flowers that yield any, and they literally starve. The long tongue of the ligurian enables it to dip much deeper into the nectaries of flowers than it is possible for the black bee to reach, so in scarce times the poor native deserves to be pitied. The long tongue also enables the ligurian to obtain large supplies from flowers that the native never visits, for instance, the red and alsike clover, and enables it to store very much more largely for its master. The queens are very much more prolific, and breed earlier and later than the blacks, the bees are more gentle under treatment than any others, but they are awfully fierce in defending themselves against robber bees, and a little handful will hold their own against large odds of marauders. As to the breeding power of the ligurian, Elisha Gallup, one of the first and most practical of American apiarians, finds 4,000 cubic inches of space not enough for the breeding apartment of a good ligurian queen. My own experience is in that direction, and from a hive containing 2,244in. of space, my first natural swarm issued on Saturday, April 27th, but returned, and on the following Monday came forth again and were safely hived. The same hive sent out a cast on May 8th, which nearly filled a skip which was used to take them, although thousands were lost in the storm of hail and rain which came on before they had alighted. The black bees in my neighbourhood have nearly all perished, in fact, I may say have quite departed, for none exist but those in which their queens have met Italian drones, as may be proved by their worker progeny, but, alas! their drones are all rascally blacks. The mode of introducing Italian queens was fully described by me in No. 333 of the MECHANIC, Aug. 11, 1871, and as it occupies nearly a page, I must refer "G. M." to that number, and am sure he will find the information desired. Now, as to "why Italian swarms are so expensive" I can only give a general answer that the supply is not quite equal to the demand, and point to the difficulty of breeding pure queens, and the necessity for importing them, and when I assure "G. M." and all others whom it may concern, that pure tested queens cost 10 francs each in the Grisons, Italian Switzerland, during the past and present months, perhaps he and they will not think the prices he quotes unreasonable. Italian queens and swarms, too, would be cheap enough and common enough if bee-keepers would take a little trouble and get rid of the black element, but there is the fact that although the Italian drones improve the worker bees of black stocks, the drones of those stocks remain black, and blacken and taint the ligurian blood even at distances of five or six miles from their homes. My answer to "One Interested," referred to above, points out how with one queen a whole apiary may be ligurianised, so that black drones may be exterminated, and a little care and liberality on the part of large bee-masters in seeing that the bees of their little neighbours were Italianised would render the raising of pure queens easy work, and consequently they would soon become cheaper. The best time to insert a ligurian queen is now, before the bees swarm, as the young queens, which will be reared in the hive, will then be all Italians, and the chances are that the drones also will be of that nationality, unless "G. M.'s" bees are more forward than blacks usually are this year. The process of driving is very simple, and is correctly described by "E. D.," p. 158, No. 370, and a very little practice will insure success, and the finding of a queen after driving is only a question of patience (if you know a queen from a hornet), when clad in bee-proof head-gear. Another way in which ligurianising may be performed throughout a whole apiary in one summer is as follows: Suppose the apiary to consist of twenty stocks in straw skips, and one of them (which I will call No. 1) contains a pure Italian queen, and the bee-master has made himself, by practice, an adept at driving or drumming, he will first drive out all the bees he can from the ligurian stock and fumigate the few remaining either with puff-ball, or chloroform, leaving the stupefied bees on their own floor-board. He will then perform in the same manner with the black stock he intends to ligurianise, say No. 10, and will take care to catch and remove the black queen. He will then change places with the hives Nos. 1 and 10, but will always return the bees to their own stance. Thus the Italian brood will be on No. 10 stance for the bees of No. 10 to raise a queen from, which, being of pure breed, will insure a supply of pure drones in future, even supposing she is wicked enough to marry beneath her; and the Italian queen will be at the head of the hive of black brood, and if very ordinary care has been used scarce a bee need have been killed, and the valued Italian queen not even endangered. After the lapse of five or six days the black brood in No. 1 (formerly No. 10) will have become too old to raise into queens, but the Italian queen will have deposited any number of eggs in the hive, and on the seventh day it will be quite safe to go again through the performance, driving out the Italian queen and her motley crew (for her beautiful progeny will have a strong mixture of young niggers), and again exchanging hives with another black stock (say No. 11), after destroying the black queen therein. Then No. 11 will have the stock in which the Italian queen has deposited eggs while on No. 1 stance to raise their queen from, and the Italian queen will in a few days have deposited eggs in No. 11 while on No. 1 stance, and so the whole apiary may be ligurianised, the whole secret of the thing lying in this, that each black stock is successively supplied with pure ligurian eggs from which the black bees must raise their queens. The chief care is required in seeing that no living black bees are left in the hives into which the Italian queen, with her gradually blackened followers, is successively introduced. The only disadvantage attending this system lies in the fact that each stock has to raise a new queen for itself instead of simply having to hatch out a sealed queen cell; but I greatly question if this is not compensated for by the fact that almost every stock having raised queens' cells will cast a first swarm with a young Italian queen at its head as if it had swarmed before; but, of course, the season will have its influence on that matter, and as it will take twenty weeks to operate on the twenty stocks, the time of swarming will be past with some of them. However, by selecting the strongest black stocks successively the swarms will all be headed by young Italian queens; and although some of them may be lost in seeking fertilisation, the majority will do well, and amply repay their owner for his cost, time, and trouble.—C. N. ABBOTT, Hanwell, W.

[11604.]—**A Task for Chemists.**—I must apologise to Mr. Davis for not replying earlier. Having been absent from home, this is my first opportunity. Referring to my reply to query 10510, I find a misprint which altogether alters the sense. I keep press copies of my letters, and find the words I used were "a simple one would be," &c., instead of which it appears as "some simple ones would be," &c., so that my remarks referred to one process including three or more operations, instead of three distinct operations, as it appeared in print. There still remains one omission on my part, which I must now correct, that is that the boiling should be conducted under a pressure of 150lb. per square inch. I note that "Devonshire" says 184lb. pressure, but on this point there is a difference of opinion. I think if Mr. Davis gives thin pieces of wood this boiling, then thoroughly washes out all the resinous and siliceous matters that may still be adhering to the wood, and after that steeps it in the chlorine solution, he will get the wood pliable as desired. This subject is well illustrated in the Exhibition now opened, the various processes adopted for the conversion of wood into par-being shown, and, as I understand (for I have not yet seen it), the machinery used also appears in the Exhibition. I may take this opportunity of suggesting to Mr. Davis that there is here a fine field for original research; and I cannot help thinking that a chemist of such abilities might discover some more expeditious and cheaper process of removing resinous and silicious matters from vegetable fibres. At present it is alkali and steam pressure, and nothing else. Hydrofluoric acid has, I believe, been experimented with, but I have not heard of any useful results.—BUSY BEE.

[11615.]—**Teeth.**—A very simple way of taking tincture of iron and quinine is to suck it through a small glass tube, slightly curved, and flattened at one end to fit the mouth. I believe they are to be obtained from any respectable chemist.—H. C.

[11627.]—**Gilding Strips of Wood.**—W. H. Hey's ineffectual plan (page 146) is not the "golden" rule, which I subjoin as plainly as possible. After the wood has been planed give three or four coats of whiting and size, mixed together to the consistency of paste, rubbing down after each coat while wet with pumice-stone, till you have a smooth and sharp surface, then apply the "body," consisting of gilding clay and chrome yellow mixed with common size, after which give a "clearing coat," consisting of thick common size; it is then ready, when dry, for the oil gold size, which, after applying, gild when sufficiently dry, and size again after gilding. "Ironsides" must get the necessary tools, which can be bought for a mere trifle, consisting of knife, cushion tip, &c., flay for gilding. Common and gold size can be bought ready for use at any compo. shop.—H. B. E.

[11628.]—**Violin.**—In reply to T. R. Willis, the maker he mentions is unknown to me, never having seen any of his instruments. The instrument can be of no particular value, I should say, but it would be impossible to pronounce upon a sum unless one saw the violin in question. The only maker of the name I am acquainted with was a Samuel Collier, who lived in London about 1758, of no particular repute.—P. DAVIDSON, author of "The Violin."

[11632.]—**Debility.**—The answer of "Amateur" on p. 182 is an imposition on your good nature. Its statements about allopathy and homœopathy are so untrue as to show that the "Amateur" is either entirely ignorant of both systems, or worse. Where did he learn that "allopathists think they can cure by the administration of an unlimited number and quantity of drugs and counter-drugs"? Or "homœopathists by the finding of a medicine suitable for each separate malady, and for that only"? Truly each of these theories is "an absurdity;" but they are his own, or he gets them second-hand from some such source as the *Anti-Lancet*. And as to homœopathy having no medicine to relieve constipation, this is also grossly untrue, and a weak invention of the enemy. What is the "altera-tonic system" in praise of which he writes? He does not choose to say, but refers again to the *Anti-Lancet*. If you will get a copy of that work (which is scattered broadcast through the land gratis), and will read it from beginning to end, you will know as much of the matter as you did before. All you will learn is, that every system of treatment is wrong and hurtful except that practised by a certain doctor at Scarborough—which, of course, he does not divulge, though he describes lots of cases of "wonderful cures" he has effected upon "the victims of each of the above systems—that is, of "allopathy, homœopathy, hydropathy, etcætera." (Don't omit the "Amateur's" sweeping "etcætera.")—G. W. K. L.

[11632.]—**Debility.**—Before bringing a charge of quackery, "Saul Rymea" should read the *Anti-Lancet* himself. Perhaps he "would be surprised to learn" how many eminent physicians have agreed with the author's views. I once was as sceptical as he is, but instead of throwing the work aside unread, I gave it a calm impartial investigation, and was convinced of the truth of its arguments, the practical result of which I see in every day's experience. I would also commend to his notice the following, from the *Athenæum*, November 28, 1846. It is a review of a work of Liebig: "From him will be dated those investigations which promise to make medicine a more certain science, if science that can be called which has not yet determined a single main principle of action." "The occult erudition" by which I was convinced may be found in the *Anti-Lancet*, the work of an eminent M.D. and author, whom even the readers of the ENGLISH MECHANIC need not be ashamed to own. But I will give a few extracts: "The artificial arrangement of diseases and their infinite multiplication is much to be deplored, and leads to the administration of countless remedies, with countless intentions. To me such fanciful systems have always appeared utterly repugnant to truth. Indeed, he who considers every affection of the body as a distinct disease resembles the Indian or African native, who regards dew, ice, frost, and snow, as distinct essences, instead of considering them so many different modifications of water, derived simply from the absence of heat." Surely "Saul Rymea" has seen the long train of phials and boxes which follow in the wake of the allopath, so that he need not inquire whence I have derived my peculiar idea of their system. But our author shall again speak: "Seeing that all diseases arise from depression of nervous power, and beholding, moreover, the inutility and danger of the popular practice of medicine, which, not being founded on any fixed principles of science, is purely experimental and conjectural, consisting in administering a multitude of different drugs, and ten thousand times ten thousand different combinations of drugs, and with as many diversified intentions, and, consequently of hurrying multitudes to premature graves, I bent my studies unremittingly for some years towards the attainment of a unity of purpose, or general plan of treating diseases; and the result is the discovery of two most noble medicines, which have already established their power and efficacy in the cure of diseases, beyond all others which have yet been discovered in any age or nation."—AMATEUR.

[11639.]—**Rock Inscriptions.**—I cannot, with "A. D. H.," regard the remarks of "H. E. H." as the least exaggerating the extraordinary neglect of these Sinaitic relics. The few sketches (of 100) by various old travellers under difficulties, collected by Beer in 1840, might mostly be, as he tried to make out, mere names of Christian pilgrims, or even, as another Leipzig professor, Tuch, maintained, of pre-Christian but Nabathean ones! We might almost guess, without any learning, that so famous a desert must contain innumerable such scribblings by visitors of all ages and alphabets; and all accounts agreed that it does so, in Biblical Hebrew, Samaritan, the Egyptian popular (of the Rosetta stone and later), Nabathean, and down to modern Arabic. A few are Greek, including (as Forster thought he made out) that in which poor Cosmas "Indicopleustes" (or the "Wanderer to Ind") asks to be prayed for. He lived about 500 A.D., and left the first extant description of them at any length (according to Dean Stanley), though by no means the first author to name them. As early as B.C. 10, the geographer, Diodorus Siculus, could mention such inscriptions as a characteristic of that country as numerous, "extremely ancient," and "in unknown characters"—which certainly neither Nabathean nor any kind of Hebrew were in his day—the former was a living dialect. Cosmas was told by Jewish guides that those he saw were Hebrew, and stated merely "the departure of such a man, of such a tribe, in such a year, such a month;" and doubtless the majority, especially of the short ones throughout the country, those most easy to sketch, and likely to be brought away, are no more than this. Probably, also, Dean Stanley, in his few days hurried transit, would meet with no others. But would he, or will "A. D. H.," parallel them at all with inscriptions, one of sixty-five lines, another of forty-two, and its first line in characters a foot high? And these moreover, which must necessarily be on rock walls too high to be approachable but by ladders, windlasses, or such appliances peculiar to a numerous population in a "howling wilderness," and "back side of the desert," most remarkable in all historic time for its non-production of human food—much pasture indeed, and even shittim wood, gums, and incense, but so little for man, beyond date-groves few and far between, that even the few herdsmen pasturing there have to carry all their own food. Moreover, these great inscriptions (whereof but one line has been sketched by the Comte d'Antraignes), and all the long ones, or those in the Sinaitic alphabet proper, the only "unknown characters" are, by all accounts, both much larger than the letters of Nabathean, Greek, and other known alphabets, and in a totally distinct and quite peculiar style of execution. Instead of incised letters, that in sandstone would necessarily be chiefly or wholly of straight lines (as even our Roman B, C, D, O, S were made on stone). These are what we should call dotted outline letters, and wholly curved, as if a superintendent had first marked them with a brush of paint or whitewash (on the red sandstone) and then workmen had drilled little deep holes all round the outline, and in some few cases filling the surface of the letter as well, this especially (according to Forster) when particular letters pass, as they often do in a most singular way, into illustrative outlines of the camel, goat, horse, wild ass, ibis, and ostrich, all very correctly and carefully drawn. These evidently are part of, or added force and meaning to the words, whereas the sketches of these same animals accompanying (as they often do) the short pilgrim inscriptions, are quite independent thereof, and mere idle scrawls, no better than boys now chalk on our walls. Again, all the holes thus drilled, we are told, are quite indistinguishable in colour from the weathered rock, whereas incisions now made remain glaringly bright for years, and all the lesser inscriptions give some scale of age by their colour, the Greek and Nabathean even being still perceptibly paler, in that extraordinary climate, than the natural surface. It seems that in 1753 an Irish bishop (Clayton) having heard of these inscriptions, from monks at Cairo, offered large rewards for their transcription—or, as our friend "F.R.A.S." would say (p. 171, let. 4048, par. 4), "offered to bet," in the *Bell's Life* of that day that no one would transcribe any. This seems to have elicited a few of the sketches republished by Beer. But in these photographic days, when no sketching is needed, and the earth might truly more than ever be lightened by any angel "with a little book open in his hand," we have no Bishop Claytons, nor so much as a word of attempts even to re-find either the 42-line or 65-line inscriptions, but, as "H. E. H." says, much otherwise.—E. L. G.

[11661.]—**Photography (Background).**—Wet the canvas you intend for background and wring out well, then tack tightly as possible on to a frame, say 7ft. 6in. by 5ft. When dry, paint over with the following: white lead, 1lb.; driers, 2oz.; black paint, sufficient to give it the desired shade; turpentine, ½pt. Mix thoroughly and allow to stand a day, when the lead will settle down. Pour off turps carefully, which will rid it of the oil; bring to proper consistency by adding fresh turps. Then add 1oz. scraped yellow soap, strain through calico and it is ready for use. The quicker it is brushed over the canvas the better. If done over again it will be improved.—GAMBA.

[11677.]—**Rendering Wood Incombustible.**—I have often wondered that we have no companies for making difficultly combustible timber (as well as rot-proof), by inclosing it in large vessels of boiler-plate, making a vacuum therein, so as to exhaust the sap, and then admitting metallic solutions more fireproofing than alum (as tungstate of soda) to replace the sap. A company had a patent many years ago, and imbued timber thus with sulphate of iron and some lime salt (that decomposed one another and made gypsum within the fibres), in a receiver 40ft. long and 4ft. in diameter, wherein a vacuum was made by condensing steam.—E. L. G.

[11687.]—**Speeding Machinery.**—"A Reader" thanks "Philanthropist," and as he kindly offers to give further information, will be much obliged if he will illustrate by a few examples the rules by which the dimensions of wheels and pulleys are determined for correctly speeding machines.—A READER.

[11694.]—**Green Fly.**—"H. S. C.'s" conservatory must certainly be of extraordinary dimensions for tobacco smoke not to be of any good in exterminating the above and other such-like pests. I have some very large glass-houses, but always smoke with success. "Saul Rymea's" plan for syringing with tobacco water would only answer to a certain extent, not so well, I fear, as the smoke. I imagine sulphur fumes would do better followed by a general clean and paint; but first remove all plants on the slightest approach of sulphur. But autumn is my time for cleaning, not spring.—H. B. E.

[11695.]—**Succession Duty.**—The duty is calculated on the value, according to Government tables, of an annuity equivalent to the net annual income of the property for the life of the successor, thus:—Supposing the net income, after allowing for repairs, insurance, and ground rent, is £70, and the successor to be thirty years of age, the value of the annuity would be £1151 1s. 3d.; if aged forty, £1041 5s.; and if aged fifty, £870 1s. 7d; and the succession duty in this case will be 1 per cent. on such value. I have given the values for these ages to enable your correspondent to estimate within a little the amount he will have to pay for duty.—E. C. J.

[11699.] —**Organ Cleaning.** —The rewiring, cleaning, and tuning of the 24 stopped organ would cost £25, and to alter to equal temperament would cost £5 extra.—S. TAYLOR.

[11704.]—**Rats.**—Melt hog's lard in a bottle, plunged in water, heated to about 150° Fahrenheit; introduce into it ½oz. of phosphorus for every pound of lard, then add a pint of whisky; cork the bottle firmly after its contents have been heated to the above degree, taking it at the same time out of the water till the phosphorus becomes uniformly diffused, forming a milky-looking liquid. This liquid being cooled, will afford a white compound of phosphorus and lard, from which the spirit spontaneously separates, and may be poured off to be used again, for none of it enters into the combination, for it merely serves to comminute the phosphorus, and diffuse it in very fine particles through the lard. This compound on being warmed very gently may be poured out into a mixture of wheat flour and sugar, incorporated therewith, and then flavoured with oil of rhodium. This dough being made into pellets, lay it in rat-holes. By its luminousness in the dark, it attracts the rats, and being agreeable to their noses and palates, it is readily eaten, and proves certainly fatal. This remedy has been tried scores of times, and found to be perfectly effectual.—H. B. E.

[11710.]—**Cleaning Oil Paintings.**—Rub the picture over with a piece of cotton wool, dipped in sweet oil, then rub with dry cotton wool. You must not put too much oil on, nor use too much elbow grease.—H. C.

[11711.]—**Time at our Antipodes.**—I have referred to your Vol. XIII. as recommended by "A Fellow of the Royal Astronomical Society," but, unless I have by accident missed any of the letters, I find they chiefly consist of queries and suggestions rather than of satisfactory explanation. I do not want to know that a day is lost or gained by sailing round the world from east to west, or *vice versâ*, but what the existing difference of time really is. Supposing two telegraphic cables were laid to our antipodes, one by the east, the other by the west, messages sent simultaneously would arrive together, but would they arrive 12 hours earlier or later than the time of dispatch? If a message sent from London on Tuesday 12 o'clock (noon) could be dropped at Calcutta, it would find the time there to be 6 p.m., and therefore continuing its journey eastwards should arrive at the Antipodes 12 p.m. On the other hand, the western message, if dropped at New Orleans, would find the time 6 a.m., and so further westward at the Antipodes still 6 hours earlier, or break of day Tuesday morning. This question has, I have no doubt, been asked scores of times before, and the solution of it a very simple matter to "A Fellow of the Royal Astronomical Society;" but if he would kindly let me know where I can find the matter clearly elucidated, I should feel extremely obliged to him.—T. S.

[11711.]—**Time at our Antipodes.**—Can there be at the same moment the commencement of *two* civil days at the meridian of 180° east or west? The earth rotates on its axis from west to east, *i.e.*, considering the sun to be stationary in the heavens, every portion of her surface passes him in this direction. Before noon (say) Tuesday, London, is west of the *upper* solar meridian, or the line on the earth's surface at which the sun culminates; after noon London is east of the same meridian. In the first case our antipodes are east of the *lower* solar meridian, drawing towards midnight of Tuesday in the second they are west of the same meridian, having commenced Wednesday morning at the time of transit. The following diagrams will show that a misapprehension may arise from an erroneous conception of the time westward of the upper solar meridian:—

No. 1.

London ...... 0° astr. time, Monday, May 6, 18 hours.
civil „ Tuesday, May 7, 6 morn.
Antipodes ... 180° astr. „ Tuesday, May 7, 6 hours.

civil „ Wed. May 8, 12 noon.

No. 5 recommences the series.

—W. R. Birt.

[11718.]—**Composition for Moulding.**—Compo. is made of whiting, size, and glue, which has been stated over and over again in "ours." Will not querists search back vols.?—H. B. E.

[11715.]—**Testing Acetic Acid.**—Though a precipitate from vinegar by barium chloride is almost certain proof of the presence in it of sulphuric acid, it is no proof or even presumption that that acid has been used for adulteration, for it may, and very probably does, exist in the form of a sulphate, naturally existing in the water used in making the vinegar, or, if it be wood vinegar, for diluting pyroligneous acid. To distinguish whether the sulphuric acid, if present at all, exists as free acid, or combined with lime or other base, there should be boiled with a little of the suspected vinegar a few grains more of pure carbonate of lead than it will dissolve, adding a little more vinegar until the acid is in excess; most of the carbonate of lead will be converted into acetate, but if free sulphuric acid be present, sulphate of lead, which is insoluble in acetic acid, will remain. To prove that the white insoluble powder is sulphate, wash it well and suspend it in water, decompose it with a slow stream of sulphuretted hydrogen, filter and test the clear liquid for sulphuric acid with chloride of barium. If a white precipitate falls, which when decomposed with charcoal and a blowpipe flame gives off sulphuretted hydrogen, known by its smell and by blackening lead paper, there can be no doubt that sulphuric acid was present.—Philo.

[11721.]—**Assayers' Duties.**—"G. T. H." must excuse my long delay in giving him the information promised. All ores sold under "private treaty" are sold on an agreed assay, and sometimes on an agreed standard; hence it is not an easy matter to give any general rules applicable to particular cases. However, the account of copper ore sales, published in the *Mining Journal*, contains sufficient data to enable one to ascertain the value of any copper ore offered for sale by public ticketing. Given the produce and price per ton we can easily find the standard for ore of that produce by the simple proportion sum:—As the produce: to the price :: 100 : the standard. The price per ton may be found from the standard and produce in a similar manner:—As 100 : to the produce :: standard : price per ton. The produce may, of course, be determined from the standard and the price.—As the standard : the price :: 100 : the produce. As I have had but little practical experience in valuing ores of copper, I shall not attempt to go further into the subject (having a sincere regard for Montaigne's maxim), but content myself with hoping that "G. T. H." may find something useful in the few hints I have been enabled to give. *Lead Ores, and Lead Ores containing Silver.*—The assay value for lead is determined by "dry assay," with or without fluxes, in an iron crucible, and from the percentage yield thus found, a deduction is made for loss in smelting. This loss increases with the lowness of the produce. In determining the proper deduction to be made, the following table will be found useful:—

Produce of ore per cent.	Loss in units.
82	2
80	3
78	4
76	5
74	6
72	7
70	8
66	10
58	14

The silver in the ore is calculated at 5s. per ounce, and a deduction of (say) 2oz. 10dwts. made for loss in desilverisation. The following example will make the method of valuation clear:—An ore, after making the deduction for loss in smelting, gives 75 per cent. of lead by assay in an iron crucible, the price of common pig lead being (say) £20 per ton. The ore also contains 10oz. 10dwts. silver, to be valued at 5s. per ounce troy:—

Lead in a ton of the ore, 15 cwt. (20s.) per ton	£15
Silver in ditto, minus 2½ oz., = 8 oz. at 5s......	2
	17
Deduct returning charges........................	2
Value of ore per ton..............................	£15

"G. T. H." must, of course, be aware that, as these ores are sold by "public ticketing," the bids must necessarily vary, although they do so only within narrow limits. *Silver Ores.*—These ores are valued on scales devised by buyers and sellers on the basis of the price of standard silver per ounce, and as the other metals (such as gold, copper, and lead) have also to be paid for when existing in notable quantity, valuing these ores is a rather intricate matter, and when we consider the amount of money which might be involved by an error, one on which I would not care to advise through the columns of a magazine like "ours." In the valuing of a rich auriferous silver ore, "G. T. H." might perchance find to his cost that more knowledge is required than could be easily imparted through the columns of the English Mechanic by—Un Irlandais.

[11724.]—**Discharge of Water Over Weirs.**—The quantity of water falling over a weir is proportional to the square root of the cube of the depth measured from the top of the weir to the level of still water in the pond above it. The exact quantity depends somewhat on the form of the weir; but, as far as I understand its construction from the question put, I should think the number 5 would be very nearly the proper co-efficient, and in any case it will not be far from that number either way. If Q represent the quantity in cubic feet per minute, l the length of the weir in feet, = 4 in this case, d the depth of water (measured as above described) in inches, and c a co-efficient proper for the particular construction of the weir. Then $Q = c\sqrt{d^3} \times l$. The depth being, as stated, 2¾in., the quantity in cubic feet per minute is 5 × 4·55 × 4 = 91, and that is 819,000 gallons in 24 hours.—C. S.

[11731.]—**Hair Wash.**—Nothing better have I found, or more refreshing to the head, than equal amounts of glycerine, honey water, and spirit of rosemary. Add soft water to your mind, begin with 10 or 15 times the quantity of water, or even 20, and make a small bottleful at a time. I have used this for years in the morning after washing, and still continue to like it. At some times in the year I think hair is dryer than others, I then use a little so-called lime and glycerine after the other, when required.—F. G. T.

[11731.]—**Hair Wash.**—Your hair wash is generally considered to be excellent. Perhaps you do not prepare it rightly. Reduce half an ounce of camphor and one ounce of borax to fine powder, and dissolve them in one quart of boiling water. When cool, the solution is ready for use. The camphor will form into lumps after being dissolved, but the water will be sufficiently impregnated.—H. C.

[11731.]—**Hair Wash.**—A simple and effectual remedy. Into a pint of water drop a lump of fresh quicklime, about size of a walnut, let it stand all night, then pour the water off clear from deposit, add a quarter of a pint of best vinegar, and wash head. Tried. Perfectly harmless; you need only wet roots of hair.—H. B. E.

[11731.]—**Hair Wash.**—A small tooth comb, taken once through the hair every day, and persevered in, will do more for removing scurf and preventing its return than any hair wash known, whether prepared by hairdresser or "old wives' science." I can recommend it thoroughly, having tried it. It is a good plan, when brushing the hair, to lightly dip the brush into cold water, so as to carry a little moisture to the roots of the hair without wetting the head completely. This is very refreshing. No oil or grease should be used.—Sarah.

[11731.]—**Hair Wash.**—Let "Excelsior" try the Chile or Chili hair wash. Take a large fresh egg, beat up well the white and yelk, rub well into the roots of hair and whiskers (don't laugh), wash with three or four changes of water, and you will find it leaves the head very clean, and hair beautifully soft and glossy, not oily or greasy as one would suppose.—Chambon.

[11733.]—**Cotton Spinning.**—Try and procure "A System of Practical Arithmetic: containing the fundamental rules and their application to mercantile cotton spinning, &c.," by Samuel Young, 1833, published by Cowie and Co., Poultry, London, and in Manchester by W. and W. Clarke, price 4s. 6d., key 5s. This book gives all the computations in cotton spinning. I don't know of any book containing the practical theory. Get some friend to inquire in Manchester or Leeds.—E. J. D.

[11736.]—**Extracting Iodine from Seaweed Ashes.**—The ashes of burnt seaweed (kelp) contain iodine in the state of iodide of sodium. This (iodide of sodium) is mixed with peroxide of manganese and diluted sulphuric acid, and put in a retort and distilled; the iodine passes in the form of a vapour into the receiver, and condenses into lead-coloured crystalline spangles of solid iodine.—T. T. Greg.

[11737.]—**Fairbairn's Ventilating Bucket.**—"Philanthropist" will find a paper by Mr. Fairbairn upon this subject, at page 232 of Part 148, Vol. XII., August, 1849, of the *Civil Engineer and Architect's Journal*.—C. W. M.—[This publication is not now published.—Ed.]

[11738.]—**Cyanide of Potassium.**—Potassium heated in cyanogen gas (a compound of carbon and nitrogen) takes fire and burns in a very beautiful manner, forming cyanide of potassium(KCN). The same substance may be prepared by fusing potassium ferrocyanide with potassium carbonate. It is a white salt deliquescent in air, and exceedingly soluble in water; its solution always has an alkaline reaction, and when exposed to the air exhales the odour of hydrocyanic acid (prussic acid). At high temperatures cyanide of potassium combines with oxygen, forming potassium cyanate. It is decomposed by the feeblest acids, even by the carbonic acid of the air, hydrocyanic acid being liberated. It is a violent poison, and is said by some to be as poisonous as prussic acid. For an antidote an emetic should be taken, and cold water and ice applied to the spine. The other questions I am unable to answer.—E. A. K.

[11739.]—**Economy of Fuel.**—"X. Y. Z." would effect no saving of fuel by increasing the pressure of steam used for heating purposes. As the temperature of steam rises, its latent heat diminishes, so that equal weights of steam thrown into water produce about the same heating effect, although the temperature of the steam in one case may be much higher than in another. This, I believe, is known as Watts' law.—Shylock.

[11741.]—**Boot and Shoe Making.**—First make the sole smooth by scraping; then run the iron round cold. Next, get some ink, and make the soles black, then dry them; now get your heel ball, rub round your sole, and apply the iron hot enough to melt your heel ball, and not too hot to burn the leather; after that rub round with a bit of old cloth.—S. H. L.

[11744.]—**Shorthand.**—I am an oldish practitioner of "Pitman" (getting on for a quarter of a century now since I first used the system as a newspaper reporter), and have also for a number of years used an abbreviated longhand for reporting meetings, trials, &c., to save time and the trouble of transcribing from shorthand notes. With steady practice and lithe fingers it is possible to write very full reports in this way, which are so legible that they can be handed at once to the compositors of a newspaper office to set from. Of course, they must learn the system of abbreviation, but it takes no time to speak of to do this; and the compositors who have done my work were the uneducated (and often stupid) boys who are so plentiful in country newspaper offices. The method is an extension of one which is very commonly in use by reporters—its main feature being to abbreviate to the utmost, and sometimes omit altogether, the frequently recurring particles, prefixes and affixes, which form fully one-third, or more, of ordinary spoken language. In fact, it is founded on the same principle as almost every practical system of shorthand. I have heard, and believe, that some of the best newspaper reporters who ever existed knew nothing of shorthand, but used only abbreviated longhand. I would willingly give a specimen or two, but fear it would entail the expense of a little engraving.—G. W. K. L.

[11744.]—**Shorthand.**—It is generally admitted that Pitman's system is preferable to all others. Those more easily learned are easily forgotten, whereas Pitman's is as readable by the writer himself or by any other Pitmanite ten years after as the day it was written; and there is no living public speaker that ever I heard of whose delivery is so rapid as to baffle a writer in that method.—An Ex-Practiser.

[11744.]—**Shorthand.**—"Wood Sawyer" might write his notes in the ordinary English character, but would very considerably shorten the time by setting down the consonants only, and rejecting the vowels. The articles, conjunctions, &c., that are of such frequent recurrence might be omitted also, as they could be filled in afterwards, or some quickly-written symbol might easily be devised to represent words of that class.—SWAN.

[11749.] — **Cementing Iron in Wood.**— Let "F. S. G." try white lead; I have seen it used for the same purpose.—T. T. GREG.

[11749.]—**Cementing Iron in Wood.**—Make a strong solution of sal-ammoniac in water. Introduce a few drops of this into the hole before putting in your screw. The iron will speedily rust in, and you will find it almost impossible to extract it without breaking the wood.—S. BOTTONE.

[11751.]—**Bugs, Lice, and Parasites.**—Oil of rosemary, or sprigs of ditto, are said to be prophylactic. I know they are useful in warning off mosquitos.—G. W. C. H.

[11751.]—**Bugs, Lice, and Parasites.**—It is a curious fact that there is a sort of "elective affinity" in the proceedings of these pests. Certain of them affect certain persons, in spite of scrupulous cleanliness on the part of the latter, and victimise them fearfully; whilst they either utterly neglect or are innocuous to other persons—either clean or dirty. My duties take me much into public places, and the members of my family are pretty attentive to their church-going; and rarely does either of us come home without a flea—not in the ear, but on the clothes. The worst of it is that the wretch invariably makes his way to the "neckhole" or wrist of myself or my youngest boy, and punishes us horribly. The stings inflicted are nearly as bad as those of a wasp, and so rapidly repeated on every accessible portion of the cuticle that the torture is intolerable; and it soon becomes necessary to rush to a private apartment, strip, and hunt out the persecutor, who has left as a memento of his visit a series of hard white swellings, surrounded by inflamed patches that do not subside for an hour. At the same time, my spouse, eldest son, and daughter, never know when they have one of these parasites about them, unless they see it or feel a slight titillation. But, whilst the F sharps persecute me so fearfully, the B flats and gnats never trouble me at all, although I am occasionally in places where I am sure they abound. Yet, passing by me harmlessly, they vehemently attack and hurt the very persons who are exempt from annoyance by the F sharps aforesaid. Will some learned friend explain what good and wise purpose the tortures I have so often undergone (from no fault of myself or my connections) serve in the order of providence or economy of nature? Why the very persons who from their dirty habits originate and extend the nuisance frequently escape the penalty, which falls so heavily on those who are wholly innocent? As to "prophylatics" the revelation of one which shall be effective, and yet in itself harmless, would indeed be a godsend. There is a plant called "fleabane," from its supposed virtues—but whether preventive or curative, and where it is to be gotten, I do not know. "M. A. B." should try a lump of camphor in a small porous bag, worn next the skin, unless he uses homœopathic medicines for any purpose. If so, avoid the camphor, as it is a powerful antidote to all the medicines except itself.—G. W. K. L.

[11756.]—**Power of Water Wheel.**—You do not state the fall. The modulus of the breast wheel is ·6, that is, it utilises three-fifths of the power applied to it. Your dam contains 40 × 7 × 2 = 560 cubic yards of water, or 560 × 27 = 15,120 cubic feet of water. The power is more at the beginning when the dam is full, as the effective fall is greater. Let me know if it is a breast wheel, or, as I suppose probable, an undershot wheel; and if so, whether the buckets are straight or curved as in Poncelet's wheel; also the height of the fall, and I will send a calculation. If the water ran 4, 6, or 8 hours, the theoretical power would be ½, ⅓, or ¼ of that for 2 hours; however, the practical proportions would be greater, as the buckets of a wheel, if filled full, lose a considerable amount of power by the spilling out of the water before the level of the tail race is reached.—B. A.

[11761.]—**Magnetism.**—For answer to "Conatus" see Professor Barrett's letter.

[11761.]—**Magnetism.**—I fear that your correspondent "Conatus" has not understood the rationale of the experiment he has described. The use of a tube of water with oxide of iron was not to show the increase of transparency of iron when magnetised, but to illustrate by analogy the probable molecular change which a solid bar of iron undergoes when a current of electricity circulates round it. The cause of the increase in the amount of transmitted light was, that under the magnetising influence of the current the particles of oxide arranged themselves longitudinally—that is, parallel to the axis of the tube—and consequently the transverse spaces between the particles were larger than when those particles were indiscriminately mixed together. The arrangement of the particles is precisely analogous to the structure of the so-called Derbyshire egg, which is made of fibrous gypsum, and is much more transparent through its longer than through its shorter axis, because its fibres are parallel to the former.—PI.

[11764.]—**Scrubber for Gasworks.**—The scrubber I am using is composed of iron pipes 3ft. diameter, and 2ft. 6in. long, socketed together, stood upright, and charged with large stones (but I think coke is best, between which the gas passes. I do not think there are any pipes inside except when the scrubber is charged with drain-pipes.—A GASMAN.

[11767.] — **Horsehair.** — Nothing to do with galvanism; simply a consequence of unequal absorption and evaporation of the water. A piece of paper will do the same much more rapidly, but not for so long a time.—S. BOTTONE.

[11768.]—**Cheap Filter.**—Procure the sponge much closer in texture, and about four times as large as the present piece; then compress the new sponge into the hole now occupied by the small piece; this will make the water ooze through instead of pouring.—H. O'B.

[11777.]—**Postage Stamps.**—Sell them for remanufacture into paper. They ought to be worth a penny per pound.—BUSY BEE.

[11777.]—**Postage Stamps.**—I feel due thankfulness and profound gratitude for being the chosen and 'umble instrument permitted to reply to this important question, and have great pleasure in informing "F. A. E." that his postage stamps, although very unpromising material, may be applied to use, provided they resemble the writer and most other blacksmiths in being "werry dry." With great care and attention, the great assistance afforded by a pair of hand bellows and sundry fragments of ligneous materials, I feel quite confident "F. A. E." will be enabled to light his fire with his postage stamps, provided he proceeds *secundum artem*, but (a word to the wise) I may just remark the unpleasant adhesive matter on their backs is a very serious obstacle to ready combustion, and that I am very confident (from long experience in the art) that he will find a large handful of wood shavings, which may be often obtained with facility, for a consideration, at a neighbouring carpenter's shop, far more efficient, and in every way preferable for that important purpose, considered from the domestic stand-point of the feminine satisfaction of "Our Mary Hann."—THE HARMONIOUS BLACKSMITH.

[11784.] — **Restoring Colour to Marble Mantelpiece.**—Clean with diluted muriatic acid, or warm soap and vinegar; afterwards, if you choose, heat a gallon of water, in which dissolve one pound and a half of potash; add a pound of virgin wax, boiling the whole for half an hour, then suffer it to cool, when the wax will float on the surface. Put the wax into a mortar and triturate it with a marble pestle, adding soft water to it until it forms a soft paste, which, laid neatly on your marble mantelpiece, and rubbed, when dry, with a woollen rag, gives a good polish. This, too, is a capital furniture polish.—H. C.

[11784.]—**Restoring the Colour of Marble Mantelpiece.**—Mix up a quantity of the strongest soap-lees with quicklime to the consistence of milk, and lay it on the stone for twenty-four hours; clean it afterwards with soap and water.—G. W. C. H.

[11785.]—**London Blackbeetles.** — Take a common washing-stand jug well glazed, strew the bottom of it with cucumber rind peelings, and place it against the wall: touching it, in fact, so as to enable the beetles to reach the end of the jug, which, if well glazed and cleaned, affords a very treacherous footing, and once in no beetle can get out. They can be destroyed with boiling water at leisure, I have destroyed numbers in this manner.—G. W. C. H.

[11785.]—**London Blackbeetles.**—Let "J. L." try a pot of white phosphorus paste. We tried, when in London, everything, but nothing else appeared to hurt the beetles, a few pots ridding us entirely of these pests. This is not only our own experience, but that of several friends, who found it as effectual as we did. The paste was bought in threepenny pots, but I cannot remember the maker's name.—EMILY.

[11788.]—**Bunions.**—Cold cream applied on a linen rag and bandaged on is often very effectual.—G. W. C. H.

[11788.] — **Bunions.** — The following is recommended:—Bunions may be checked in their early development by binding the joint with adhesive plaster, and keeping it on as long as any uneasiness is felt. The bandaging should be perfect, and it might be well to extend it round the foot. An inflamed bunion should be poulticed, and larger shoes be worn. Iodine 12 grains, lard or spermaceti ointment half an ounce, makes a capital ointment for bunions. It should be rubbed on gently twice or thrice a day.—H. C.

[11789.]—**Effect of Temperature upon Ale.**—"A. N." is evidently unacquainted with the commonest laws of physics, and I would suggest the following answer to him:—The effect of a decreasing temperature on a beer is to render it of a greater specific gravity, and if the cold is sufficient to render the beer of the same density as any of the insoluble matter that was near the bottom of the cask, a portion of this will remain suspended in the beer if it is shaken, or will even rise in the beer of its own will. The water is not the cause of the thickness. If he were to use some of Beane's patent material, this suspended matter would not be there, as the material prevents its being dissolved out into the mash.—AUGUSTUS AVAME.

[11790.]—**Photography.**—If your markings are thick wavy lines of collodion, I have met with the same difficulty myself. After running the surplus collodion off your plate, hold the plate up by one corner in a vertical position, and rock it slowly from side to side, looking through it at the same time, and these wavy markings will gradually disappear, giving a smooth and nearly transparent surface.—PHILANTHROPIST.

[11790.]—**Photography.**—If "Camera" will, after coating his plate with collodion, pour off the surplus and immediately rock the plate to the left (keeping it quite perpendicular), and hold it in that position for a second, and then to the right for the same time, repeating the motion until the collodion is sufficiently set, he will be rid of the lines he speaks of. The reason he has not succeeded is, I think, because he rocks the plate too quickly. With respect to the washings, I find the following plan a very good one: Get two stone jars holding about two gallons each, into which pour the washings alternately day by day: after pouring in throw in about a tablespoonful of salt; every other day pour off the clear liquid from the jar that has been undisturbed the longest. When the jars are about half full of precipitate I begin the evaporation, and save the residue, which finally finds its way into the crucible. I generally use a "positive fixing-bath" twice, and then strengthen by adding a little more hypo. It will keep good in summer about four days, and longer in winter: when bad it will have an unpleasant smell. After the print has laid in the fixing-bath (say) five minutes, hold it up between the eye and near a gas or other light, and if it looks clear the bath is active, but if cloudy it requires strengthening, and the print is not fixed. With respect to the time for exposure in the studio and open air; it all depends upon the aspect and the amount of light "Camera" has in his studio. I have taken views out of doors in less than a second, when I had to expose from five to eight seconds in the studio. Again, I have succeeded in getting a good negative in the studio in three seconds, and with the same chemicals, but a few minutes later have had to give the same time out of doors; this I attribute to the continual change taking place in the light.—C. S. W.

[11797.]—**Preserving Moths and Butterflies.**—Camphor will certainly effect this if the cases be perfectly closed. To arrest decay (or rather insects), inject tobacco smoke by blowing through the bowl of a clay pipe, the stem to be inserted into the case containing the insects. Close the glass and allow the smoke to be well absorbed. This is an effectual remedy.—S. BOTTONE.

[11800.]—**Electrical.**—The processes required by "T. A. D.," are given in No. 359, p. 523 of last vol.; process 4 for electro-motive force, and 2 or 3 for internal resistance. To obtain the result in terms of a certain length of wire of course the measures needed for use in these processes would be simply lengths of that wire.—SIGMA.

[11806.]—**Power Loom Weaving.**—"Lancashire Lad" will find a work written by George White, and published by Simpkin and Marshall, London, or Joseph Thompson and Son, Market-street, Manchester, which will supply the desired information.—WILLIAM ASHPLANT.

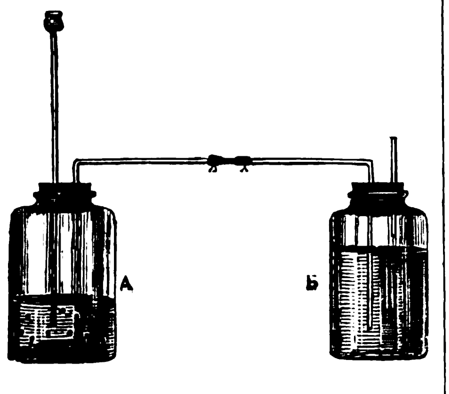
[11809.]—**Cool Air in Hot Climates.**—The plan proposed by "C. H. B." of cooling apartments by the sudden expansion of compressed air is perfectly possible. But I, for one, should never advise any ordinarily constituted mortal to subject himself to the sudden changes of temperature as such cool rooms would involve. I remember that when I first went to reside in Italy sixteen years ago, I thought I was going to be very clever, and carried my impediments into a fine large airy dry and cool cellar, where the daily temperature was about 60°, while in the rooms and out of doors it ranged from 100° to 120°. My peasants warned me that I should have a fever, but wise in my own conceit, I pooh-poohed them. Before the first week was out their prediction was verified, and since then I have taken great care, when in a warm climate, to avoid remaining in cool rooms, and to eschew the use of cold water.—S. BOTTONE.

[11810.]—**Colds in the Head, &c.**—I have much pleasure in recommending "X. Y." the following, as an effectual and speedy remedy for influenza:—Take a pennyworth of carbonate of ammonia and dissolve it in an ordinary wine bottle full of water. I have known a wine glass of this mixture taken three times a day cure a troublesome cold in one day.—WHITAKER.

[11810.]—**Colds in the Head, &c.**—These are not simple colds. Consult a medical man, as there appears to be some organic lesion which might increase.—S. BOTTONE.

[11814.]—**Lathe Queries.**—This is exclusively addressed to "J. K. P.," but having manufactured lathes at a former period, and given the subject some consideration, I would observe that the double cone is very troublesome to make, and only necessary for slide lathes, which, if not perfectly accurate, are worthless. The method which I adopted was to bore the hole for cone in front of headstock slightly taper, and a hole in the back of headstock, say ⅛in. diameter, and perfectly cylindrical, at the one operation. When you have turned the steel collar inside and outside a shade larger than hole, heat the headstock in forge until nearly red hot, slip the hardened collar in quickly, lay a piece of iron upon it, strike tenderly, and cool as quickly as possible. I think Whitworth uses composition metal for his cones. Into the ⅛in. hole in back fit a piece of turned steel, one end with hole in to hold it steady whilst adjusting, the other with taper point and a pinching-nut at each side of headstock.—A., Liverpool.

[11825.]—**Testing Bleaching Powder.**—The quantity of available chlorine in chloride of lime, may be easily ascertained as follows:—Weigh up a given weight of chloride of lime, and place it in a gas bottle. (See Fig. A.) Connect this with a second bottle, B, containing a solution of nitrate of silver. (The quantity of nitrate of silver in this solution must be equal to the amount of chloride of lime to be tested.) Now add gradually dilute sulphuric acid, through the thistle funnel C, as long as gas is given off. At the end of the operation, a heavy white precipitate will be found in the bottle B, consisting of chloride of silver. Filter off the liquid, dry, and weigh the powder. On comparing different samples of chloride, you will find that you will get different weights of this precipitate; and the richer the chloride of lime in available chlorine, the more chloride of silver will you get. Should you desire to know the exact quantity of available



chlorine your bleaching powder contains, you need only make a calculation, remembering that every 143·5 parts of chloride of silver represent 35·5 of chlorine.—S. BOTTONE.

[11826.]—**Tinning and Soldering.**—Having considerable experience in the art of soldering, I have arrived at the following conclusion, which is, as far as I am aware, novel—viz., that if two metals are brought to a certain heat and then a substance applied which will free their surfaces from oxidation, that union will take place, through the partial vacuum produced by the expansion of the air contained amongst the particles of the metals. Now, in order that the joint shall be successfully made, it is necessary that we use a body which will not burn before the metal is hot enough to produce this condition. Therefore, if it is lead or zinc which is to be soldered, scrape the surfaces scrupulously clean and free from grease, and use pounded resin, but, as lead is such a good conductor of heat, many fail from not using a large enough copper bit. To solder steel, iron, brass, copper, tin, or any of their alloys, spirits of salts, with as much zinc as it will dissolve, is all that is required, but, of course, the part to be soldered must be previously filed to a clean surface. How "A. B." proposes to unite by melting wrought iron, which takes such a high degree of heat, with tin, which takes so much less, I don't know, but if he succeeded it would destroy its most valuable property—viz., that of being readily welded. He surely does not suppose that the surface of the steel or iron itself is partially melted in the act of soldering. I have omitted to state that when the spirits of salts has ceased to act upon the excess of zinc I add nearly one-half of water to it to render it fit for use, and I would feel obliged if some of "our" chemists would state whether there is anything of the nature of resin in chloride of zinc, as, after a day's use of it I find that my hands are as difficult to clean as if I had been using resin.—A., Liverpool.

[11827.]—**Sight.**—"W. P." had better go to some oculist at once. If he cannot afford the fee, I should recommend him to go to the Eye Infirmary, Blomfield-street, near Broad-street Station of the North London Railway, between 8 and 10 a.m., where he will, without a letter of recommendation, get the best of advice free of cost, as to the number and kind of spectacles he requires. Invisible spectacles are ordinary convex or concave glasses, with very thin gold, or other wire rims, &c.—SACRISTAN.

[11827.]—**Sight.**—This is a case of myopia. The pin-hole in the card acts as the "stop" in a lens, and enables "W. P." to focus distant objects. Invisible spectacles are "bosh." Go to any respectable optician, state your case, and he will give you a pair of concave glasses that will suit you. Do not begin with glasses which are too concave.—S. BOTTONE.

[11828.]—**Duration of Boiler.**—The life of a boiler depends on the treatment to which it has been subjected, and the kind of water with which it is supplied. A saddle boiler of good material ought to last more than 11 years, but only a practised hand can form any idea of its condition without unsetting it for a thorough overhaul. There is no "insecurity" about a horticultural boiler in the sense of "explosion" unless the pipes are blocked up. The "saddle" is the best boiler for all moderate lengths of piping; the "tubular" for anything more. The "double L," as it is called, is so far an improvement on the saddle that it gives a larger heating surface; but the economy in fuel thus obtained would not, I think, be appreciable except in long lengths of pipe, and in this case nothing has yet beaten the tubular. I am not singular in this opinion; but possibly the coming trials at Birmingham may throw a little light on the subject, if properly carried out.—SAUL RYMEA.

[11831.]—**Thermometer.**—Most likely the air was not completely expelled from the thermometer. A similar case happened once to me, and I got my thermometer in good working order by applying a gentle heat to the bulb.—F. T.

[11835.]—**Arsenic in Wall Papers.**—Scheele's green is a copper arsenite. The presence of arsenic will be easily detected by the Marsh apparatus. Let "G. C. C." scrape off some particles of the paint used for colouring the paper, and mix these particles with the materials required to prepare hydrogen gas—that is, with pure granulated zinc, and pure diluted sulphuric acid. Arseniuretted hydrogen will evolve; on burning the gas, and on putting before the flame a piece of cold porcelain, a kind of gray metallic ring will be deposited.—F. T.

[11839.]—**Plates Chemically Clean.**—You were quite right to say you "fancied" that washing the plates under the tap would grease them. It is sheer fancy. If you wash your plates carefully, either with nitric acid, sulphuric acid, or cyanide of potassium, &c., and rinse them afterwards in abundance of water, drying carefully with a clean diaper washed with soda (not soap), you will have your glasses "chemically clean."—S. BOTTONE.

[11839.] —**Plates Chemically Clean.** — Well rubbing the plates with a piece of felt carpet dipped in a mixture of nitric acid and rotten stone (taking care that it does not get on the clothes or fingers), and then thoroughly washing them under the tap, is much better than a bath of cyanide of potassium. Varnished plates require to be soaked for a short time in a hot solution of common washing soda, to remove the film before using the acid.—WILLIAM.

[11840.]—**Whooping Cough, &c.**—I can't tell "T. C. H." how to make balsam of horehound, but I can tell him that change of air is the very best remedy for whooping-cough. I have found with my own children that even a run down the river to Greenwich and a blow round the Observatory has had a wonderful effect in ameliorating this malady, while a few days in the country has effected a cure. The only medicine advisable (except under competent advice) is some one of those domestic remedies which do no harm if they fail to do good.—SAUL RYMEA.

[11841.]—**Human Relics.**—In the Etruscan Vase Room in the British Museum the oldest human relic is to be seen. This relic is the skeleton of Pharoah Mykerinus. It is decently encased in burial clothes, also surrounded by pieces of the coffin. On one of these fragments is the name of the occupant, which can be deciphered by Egyptologists, affording conclusive evidence that it once contained the body of an Egyptian monarch who reigned more than a century prior to Abraham's time. From the *Gentleman's Magazine*, April, 1866, we find that Herr Dümichen, an explorer of the Egyptian monuments, discovered on the buried walls of the temple of Osiris, Abydos, a large tablet containing the names of the ancient Pharoahs from the time of Mizraim, grandson of Noah, to that of Pharoah Seti I., the father of the well-known Rameses the Great. This tablet shows that Pharoah Mykerinus, whose remains are to be seen in the British Museum, succeeded the builder of the Great Pyramid with only two intervening kings. — HENRY T. MATTHEWS.

[11848.]—**Conic Sections.**—I beg to refer "Rusticus" to any elementary book about conic sections, treated geometrically. He will easily find then the following propositions:—(1) Every section of a cone, by a plane meeting the conic surface on every side—that is, neither a parallel nor a subcontrary section—is an ellipse. (2) If a cone be cut by a plane parallel to another, touching the conic surface, the section is a parabola. (3) Every other section of a cone is a hyperbola. For the demonstration of the above propositions, he will get it as complete and short as possible from Chambers's "Solid and Spherical Geometry."—F. T.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "Anglo-America" has answered 11207, 11209; "Sacristan," 11275; "F. G. T.," 11275, 11288, 11289.

11439	Cost of Chamber Sulphuric Acid, p. 80
11441	Dyeing Cotton Thread Jet Black for Polishing, 80
11447	Blundered Coin, 80
11449	Angelet, 80
11452	Rainwater Tanks, 80
11458	Carmine Staining, 80
11463	Working Engines, 80
11477	Lamplough's Pyretic Saline, 80
11494	Utilising Slack, 81
11496	Lotion of Hydro.-Sulphate of Soda, 81
11501	Exhalations and Consumption, 81
11503	Wollaston's Differential Barometer, 81
11509	Adapting Barrel to Pianoforte, 81

Refined nickel is worth three dols. a pound. The ore is found in Pennsylvania and Missouri. The Pennsylvania mines furnish the principal supply at present, and are said to be very profitable.

The best fireproof safe is a hole in the ground, properly lined with brick and cement. If it must be above ground, it must be a double one, with the interval filled with fire-clay and sand; plaster of Paris is much used for this purpose.

QUERIES.

[11857.]—**Gelatine Moulds for Plaster Ornaments.**—Can any of "our" readers inform me how to make the gelatine moulds for casting undercut plaster ornament?—G. W. P.

[11858.]—**Nickel Spoons.**—Will some brother reader kindly give me the mixture of the above, to keep their colour.—ARSENAL WORKMAN.

[11859.]—**Dyeing Raw Cotton.**—Could any of my brother readers inform me the cheapest and quickest way to dye raw cotton black, and, if possible, with one dipping?—F. E.

[11860.]—**Magnetic Machine.**—I beg to inquire further about the magnetic machine for making oxygen, mentioned on p. 49 of this present volume. I have called at Mr. Browning's, No. 111, Minories, and was told there is no such machine. We make our oxygen from the usual mixture of chlorate of potass and black oxide of manganese, and then purify it; then the price is about 1s. per cubic foot. I wish Mr. J. T. Sprague would undertake to devise the required machine, and publish it in detail in the ENGLISH MECHANIC. I have no doubt that many would feel thankful for such information.—A POOR MACHINIST.

[11861.]—**Glove Cleaning.**—I have a pair of valuable American buckskin gloves, in a very dirty greasy state, having worn them across the Atlantic. Will some kind reader oblige by informing me how I can best clean them, without injury to the leather?—CONSTANT READER.

[11862.]—**Charcoal.**—How much charcoal should I get from a ton of tops and edgings of oak and elm? and, if I convert it in a retort, should I get any gas or oil worth saving? I use it for cleaning sewage water, and re-heat it occasionally. Of what use are the gases I drive off?—PRENTICE.

[11863.]—**Barrow-in-Furness.**—No doubt some of "our" readers are residents of Barrow-in-Furness, Lancashire. Having heard some good reports concerning the place, and also having a desire with a companion to get northward (being carpenters and joiners), I should like to know from some brother mechanic, a resident there, what sort of place it is, and if he thought that there would be a chance of getting employment. Should we make our way there? Such a description would perhaps interest other readers besides—AN ENGLISH MECHANIC.

[11864.]—**Rabbit Disease.**—Could one of your correspondents inform me the best way of curing tame rabbits of a disease in the neck? It is something similar to the mange. All the hair comes off from the top part of the neck and back.—JAMES KING.

[11865.]—**Fish.**—Can any of "ours" inform me if there be any foundation for the opinion held by some anglers that fish, such as roach, dace, bream, &c., are attracted by means of oil of aniseed, oil of cloves, rum and honey, when mixed with the bait used. I have been told by enthusiastic amateurs that such is the case, but I never believed in it, trusting rather to fine tackle, clean baits, and my own skill.—PISCATOR.

[11866.]—**Splitting Wood.**—Will some of your correspondents inform me how I can split straight deal in the most expeditious way the following sizes—5in. long, $\frac{5}{8}$in. wide, and $\frac{1}{8}$in. thick? I have been told that matches are stamped out in a peculiar way. Would that process answer, or is there anything better? An enormous quantity wanted, so must be done quick. Perhaps some of your correspondents can inform me where such a machine can be obtained, and the price.—DEAL TIMBER.

[11867.]—**Separating Tar from Wool.**—Will any subscriber kindly inform me the cheapest method of dissolving tar or pitch, and paint, from wool?—Z.

[11868.]—**Ash Timber.**—I have lately purchased some young ash timber, felled this last winter. How must I proceed to keep it in the best condition? Let it be in the open with the bark on, exposed to the weather, and for how long? or saw it into plank? or place it in a shed secure from wet, without sawing it? I may not require to use it for a year or two. What is round ash timber worth per foot (good ash)? How is ash plank sold? I have heard it is sold by the inch.—ASH.

[11869.]—**Zinc v. Coal.**—In Dr. Ferguson's volume on "Electricity," p. 234, it is stated zinc cannot compete with coal as a source of mechanical action—nothing, however, is mentioned as to the means of comparison. Can any reader inform me (1) what data has been obtained on this point? (2) Might the weight consumed per hour of zinc be assumed proportionate, as of coal, to the mechanical action developed?—S. I. G.

[11870.]—**The Sun.**—To MR. RICHARD A. PROCTOR.—Would Mr. Proctor kindly give his reasons for his opinion expressed some time back in the ENGLISH MECHANIC, that the sun is not part of the milky way?—L. J. V. G.

[11871.]—**Deluges.**—Mr. Darwin, in a foot-note in his "Origin of Species," rejects the Adhémar theory on periodical deluges. Would a subscriber, or Mr. Darwin himself, who is very likely a reader of "ours," kindly give the author's reasons?—L. J. V. G.

[11872.]—**Carbonic Acid Gas and the Atmosphere.**—1. How many million tons of carbonic acid does the atmosphere contain? 2. How many million tons of carbonic acid is the atmosphere capable of containing without the animal kingdom being seriously affected by it?—WILLIAM THOMPSON.

[11873.]—**Magic Lanterns.**—Will any correspondent inform me how to japan tin bodies for magic lanterns, to stand the heat without softening or flying off, what sort of japan to use, and where to get it?—A. B.

[11874.]—**Bryant and May's Matches.**—Bryant and May's matches are sold with the warranty that they "ignite *only* when rubbed on the side of the box." I find, however, that many of the matches will light readily on linoleum. Will any kind reader explain to me the chemistry of this?—HIPPARCHUS.

[11875.]—**Spectrum Colours.**—I wish to paint upon a disc of card 18in. diameter, the colours of the spectrum, so that when caused to revolve rapidly it will show pure white. What pigments must I use to obtain pure colours? or could I obtain paper of those coloured? Any advice on the subject will oblige—UTILE DULCI.

[11876.] — **Hydraulic Press.** — Will some kind mechanic help me? I wish to make a model hydraulic press. Any information would be thankfully received by —RICARDO.

[11877.]—**Slide Valve Question.**—Will any reader of "ours" kindly explain how the to-and-fro motion is communicated to the slide-valve (of Cameron's patent steam-pumping engines, manufactured by Tangye Bros.) without the aid of eccentric cranks, &c.? A diagram showing the steam passages in the cylinder, and how the valve is acted upon, will be most kindly received by —HYDRAULICAN.

[11878.]—**Photography.**—Will some kind reader tell me how to retouch negatives, what colours to use, how to varnish the retouched part, and any other particulars? Also why do my landscape negatives flash into view the moment the developer is applied, and afterwards go dull and opaque—when indoor portraits, taken with same camera, come gradually and get more and more distinct.—CAMERA.

[11879.]—**Thermopile.**—How can I make the bars of antimony and bismuth and put them together for a thermopile, to use with radiant heat, &c.? I cannot succeed in doing this because of the brittleness of the bars.—ARTHUR CAXTON LOWE.

[11880.] — **Armature.** — How may I construct a Siemen's armature for a magneto machine? Smiths charge me high for forging the core, and I wish to know how to make one cheaply for a small machine?—ARTHUR CAXTON LOWE.

[11881.]—**Velocipede to be Driven by the Hands.**—Would some reader furnish me with a drawing of a velocipede to be driven by the hands instead of the feet. I have seen several excellent plans, but they will not suit me, as I cannot use my legs. I want one which could be driven up a moderate incline with tolerable ease. Speed is not so much an object as ease; say four miles an hour. I don't mind whether it is a three or four wheeler.—A CRIPPLE.

[11882.]—**Webs of Cranks for Model Engines.** —Will "Jack of All Trades," or some other of our numerous correspondents, be kind enough to inform me how to forge the webs of cranks for model steam-engines? The size I want to make is this: Diameter of shaft ⅜in., throw 1⅛in.—W. B. W.

[11883.] — **Sustaining Weight of Cast-iron Column.**—What weight would a cast-iron column of the following dimensions sustain:—Length 8ft., diameter (outside) at base 7½in., at top 7¼in.—VULCAN.

[11884.]—**Power of Water-wheel.**—Will any one kindly tell me the horse-power of a water-wheel, of which the diameter is 24ft. 5in.; length of bucket, 8ft. 4in.; and fall 19ft.?—R. S.

[11885.]—**Power of Boiler.**—What boiler power would it take to keep at nearly boiling point a tank full of water, measuring 15 × 6 × 4ft.?—R. S.

[11886.]—**A Thick Soled Shoe.**—I am about to make a boot for a person whose leg is so contracted that the foot is considerably risen from the ground, and, in consequence, will want a very thick sole. I wish to know what is the best material for the soles, and also the mode of fastening them to the upper?—WEE PET.

[11887.]—**Hair Dye.**—Nitrate of silver is used in some form of solution as a hair dye. Will any reader inform me how the solution is prepared, the quantity of nitrate and of solvent, and if any other ingredient is included?—GRAY BEARD.

[11888.]—**Astronomical.**—I wish to call the attention of my fellow readers to an article in this month's *Cornhill Magazine*, entitled "A Giant Planet," in which the theory is propounded that Jupiter is at the present time about as hot as red-hot iron. The name of the writer is not given. I should like to hear what our valued friend "F. R. A. S." thinks of this. Can any reader inform me if Sirius is pronounced "Sirius" or "Sirius"? Also is there a planet Vulcan, between Mercury and the Sun?—WHITAKER.

[11889.]—**Hedgehog.**—Will Mr. Pope, who recommends a hedgehog as a destroyer of kitchen beetles, give me a hint about the management? Will he take to a box or basket? and does he require milk?—F. S.

[11890.]—**The Lathe.**—How can I mount a centre knife edge at perfect right angles to the plane of the beam of a delicate balance, the beam of which gets thinner as it approaches towards the ends, that is, the thickness is a gradual slope from centre to ends, so that a square laid on beam will not give the right angle, which it is necessary for the knife edge to have.—C. SMITH.

[11891.] — **Contents of Cistern.**—I should feel obliged by some of the readers of the MECHANIC informing me of some accurate method of ascertaining the number of gallons of water contained in a stone cistern of a shape something like a D.—J. K.

[11892.]—**Steel Combs.**—Will any brother reader kindly inform me how to make steel combs such as those used by weavers? Also what kind of metal the tops of the combs are made of?—DUSTY MILLER.

[11893.]—**B. Sc. of London.**—Will any of "our" readers tell me what is a good book from which to get up the botany for this examination, especially as regards the examples required from British plants? Lindley's books do not seem to meet this quite. Also what is a good book for the zoology, with hints as to the kind of specimens provided in that examination?—J.P.P.

[11894.]—**Lamp for Incubator.**—Will any of your readers be kind enough to tell me what sort of lamp is best for an incubator? I want one that will keep alight 14 hours without touching. Will a double-wick colza oil lamp do this?—OVO.

[11895.]—**Making Templates or Moulds.**—Will some fellow subscriber give me some instructions how to make the templates or moulds for marking out planks for chairs and other furniture in a practical manner?—ANXIOUS.

[11896.]—**Taking Copy of an Engraving or Lithograph.**—Can any fellow reader give me a simple method of taking a rapid impression of an engraving, lithograph, or print?—ANXIOUS.

[11897.]—**Fastening Fret Saw.**—Will some fellow reader tell me how to fasten a fret saw to the end of an arm spring, so as to obtain a perpendicular motion? The spring describes a segment of a circle.—G. W. C. H.

[11898.]—**Tempering Cast Steel Chisels.**—Could any of "our" readers inform me how to temper chisels made of old rasps and files, used for cutting cold iron?—U. V. U.

[11899.]—**Etching on Glass.**—Would some of "our" readers kindly inform me how to propare the hydrofluoric acid in solution for the purpose of writing on glass? I often graduate my ordinary flasks to hold measured quantities, such as 300 c. c., 400 c. c. &c., by exposing the flask to the vapours of hydro-fluoric acid, but I believe that it is much more convenient to use the acid in weak solution, and am anxious to learn the details of the process.—UN IRLANDAIS.

[11900.]—**Electro-Plating.**—Would "Sigma" be so good as to describe for me a battery best suited for the purpose of electro-plating small articles, with other essential pieces of apparatus required? I would also feel obliged by his recommending me some cheap manual on the subject.—UN IRLANDAIS.

[11901.]—**Grip Chuck.**—I want to make a grip chuck how am I to manage the left-hand screw? I have Whitworth's set of four right-handed screws, ½in. largest size. Can I get a set of three taps and dies to one of his pitch, left handed? or had I better get the jaw and screw made by a regular machinist? I had rather do it myself if I can.—F. G. T.

[11902.]—**Chlorine.**—Is chlorine (when evolved from chloride of lime) injurious in a sleeping room?—WM. HAMILTON HEY.

[11903.]—**Quinine.**—(1) What is used to adulterate quinine? (2) How may it be easily detected? (3) Does quinine cause salivation? (4) How is amorphous quinine prepared?—WM. HAMILTON HEY.

[11904.]—**Suitable Spectacles.**—I usually devote the evening to writing, and find that my sight—naturally long-sighted—is rapidly failing, and would be obliged for any information as to the most suitable spectacles to procure.—A., Liverpool.

[11905.]—**Miniature Turbine.**—The following appeared in the *Society of Arts Journal* for March 8, 1871:—"The *Berg und Huettenmaennische Zeitung* describes a small turbine, the diameter of which is only 3in. There are 24 passages of the water, each of which has an area of one-tenth of a square inch. It is driven by a fall of 85ft., the water being led by a small pipe, having a sectional area of half of a square inch. This turbine is used for driving a lathe, in which an iron shaft of 4in. diameter can be turned. The turbine, when not loaded, makes 2,288 revolutions per minute. Can any of our readers furnish fuller particulars, as I think it might prove very useful to many of us?—H. H. MASON.

[11906.]—**Spectroscope.**—Will "F. R. A. S." or Mr. Proctor kindly give me some advice about purchasing a spectroscope? What price one would be most suitable for a beginner? Would it be best to have it fitted to a microscope or not? I shall feel greatly obliged for any information on the subject.—W. H. H.

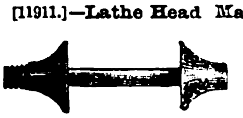
[11907.]—**Hebrew Music.**—Can any one give me any information about Hebrew sacred music. How is it written? Does it at all resemble Gregorian?—KAPPA.

[11908.]—**Drilling Boiler Plates.**—Will some practical boiler maker inform your readers in America, what kind of tools or machines are used for drilling the rivet holes in boiler plates, and state whether it is done before the plates are bent, or after they are fitted or lapped over each other? and whether the holes in each plate are drilled at once, or the one plate drilled first, and the second one from the holes in the first? In this country boiler plates are never drilled, but always punched; and any details about the best practice in England in boiler construction would be of service here, and, perhaps, help to prevent some of the sad accidents unfortunately now so common on this side of the Atlantic.—AMERICAN MECHANIC.

[11909.]—**Loud Whistle.**—Wanted, to know the way to make a very loud-sounding whistle, a regular "ear splitter," to be heard at a distance. Any information thankfully received.—ANGLO-AMERICA.

[11910.]—**The London Encyclopædia.**—Wanted, to know if the London Encyclopædia was ever completed, and, if so, if obtainable? It was begun in 1826, and was to be finished in 8½ years, in 40 parts. I have up to G, 20 parts.—ANGLO-AMERICA.

[11911.]—**Lathe Head Mandril.**—Will "J. K. P." kindly give his opinion on a lathe head mandril, with bearings the shape of the sketch, for an eccentric chuck, or anything else, so as not to have the least shake, the back bearing being a brass bush screwing into head with gas thread, and a nut on inside for a keeper?—ANGLO-AMERICA.



[11912.]—**Chemical.**—Can any contributor inform me of the best book to use in order to acquire a thorough knowledge of the chemical theory in its present complicated form?—ONE WHO IS PUZZLED BY THE LATE ALTERATIONS.

[11913.]—**Fixing Pins in Barrel.**—Will Henry Newman inform me how to fix pins in barrel, for the purpose of playing any tune that may be desired? Also how are the pins tightened?—RICHARD LINTON.

[11914.]—**Expansion Joints in Steam Pipes.**—What is the best kind of expansion joint for 10in. steam pipe, also for 4in. steam pipe? Steam usually 50lb. per square inch, but occasionally let down and shut off.—BUSY BEE.

[11915.]—**Corn Screen.**—I was greatly disappointed to see the correspondence that was carried on by millers a short time ago had been allowed to come to a standstill. I should take it as a great favour if some of my more experienced dusty brothers would give me their opinion as to what they think is the best sort of corn screen to use for general purposes. The number of brushes and what kind, and any other useful information will be thankfully accepted by—A YOUNG TYKE.

[11916.]—**Octave Coupler.**—Will any contributor kindly furnish a drawing or description of octave coupler for organ? or, if such has appeared in the ENGLISH MECHANIC, please give number and volume.—GAMBA.

[11917.]—**Organ Construction.**—Are there any books published on the construction of organs? if so, will any reader please give the name of a cheap and good one?—GAMBA.

[11918.]—**Fumes from Gasworks.**—Will "Sigma" kindly tell me of what the fumes, or "perfumes," which escape from gasworks consist; and what alteration, if any, they undergo in traversing a quarter-mile of air during rainy and dry weather?—SAUL RYMEA.

[11919.]—**Trigonometrical.**—The following theorem occurs in the "London Encyclopædia," article "Trigonometry": "The secant of an arc is equal to the sum of its tangent and the tangent of half its complement." A geometrical solution is given. Will some one give a trigonometrical solution? It will be propounded thus—

$$\text{Sec. A} = \tan. \text{A} + \tan. \frac{90^\circ - \text{A}}{2}.$$

—THETAMU, Horsham.

[11920.]—**From "Jack of All Trades."**—Having had a very protracted bout of ague, from which I was very debilitated, troubles set in thick and fast, which were a cause of great anxiety to me. I caught a violent cold, which ended in a violent attack of erysipelas in the head, and for a fortnight the question was "to be or not to be." Since my partial recovery I have been troubled with a tenderness of the interior of the nostrils, upper part of throat, and the inner ears. One of my eyes seems as if it was seared with a hot iron, which will ultimately end in the loss of sight, there is not the least doubt; and my brain is so affected that if I try to collect my ideas, read, write, or put my considering cap on, I receive a shock in the back of my head as if I had been stunned with a violent blow. At the same time, everything seems to vanish from my sight; in fact, total darkness supervenes for a minute or two. At one time, if I partook of a cup of hot tea or coffee after my daily labour I felt invigorated and equal to a good evening's work, but now, if I partake of a cup of *anything* hot, it debilitates me by producing a huskiness in the throat, and fever, and if cold it produces all the symptoms of a violent cold in the head, and I have been, since I have been able to get about, troubled with a species of fever in my feet. They are painfully tender, as if they had been scalded. Knowing that there are medical subscribers to "ours" that are capable of answering my query, I hope they will answer this candidly, and state whether this is likely to be a permanent affection or wear off in time. It at present leaves me almost a perfect drone, as study or the least excitement or exertion produces the above-mentioned shock to the head, and for the life of me I cannot see or think of what I am seeking.—JACK OF ALL TRADES.

[11921.]—**Curing Sprats.**—Can any of your readers describe a good method of curing sprats in oil, so as to form a substitute for sardines?—WAYNFLETE.

[11922.]—**Sewage Pipes.**—Are iron pipes fit for sewers? and if used as sewers, are they serviceable, or do they quickly corrode when in contact with ordinary town sewage? What difference in price (about) is there between earthenware and iron pipes of equal diameter?—SUGGESTOR.

[11923.]—**Potatoes.**—May I ask "Inquiring Mind" (let. 8888, p. 66) how he can manage to keep the disease from late potatoes by mowing the tops off, seeing that the disease uniformly comes about the beginning of August, when late potatoes are not ripe, neither are the second early; and if potatoes are not allowed to get full-grown they get soft, and are not really good? He is quite right about wide setting and whole potatoes, but he is wrong in wanting to insure large potatoes. They are never so good, or convenient, or nice looking for a gentleman's table, as moderate-sized ones, and he insures a hollow to them. The very best potatoes are always the very small ones, which most people throw to the pigs as good for nothing.—E. T. S.

[11924.]—**To Millers.**—Will some of our miller friends answer the following:—Which is the best size millstone to work as regards power, speed, &c.—a 4ft. 6in., or a 4ft. stone? I shall feel obliged by any of our miller friends answering this or any other items connected between the two sizes of French burr millstones.—M. C.

[11925.]—**Beef Fat.**—Can any of your numerous readers inform me how marrow fat for cooking can be best made out of beef suet, and give it a colour similar to butter? I have tried aunatto, but I think something cheaper for quantities could be got. Also what process will make it soft and seedy like the original marrow?—COMMUNE BONUM.

[11926.]—**Malleable Iron Castings.**—Will any one describe the process through which malleable iron castings are obtained, referring principally to the kind of iron used.—J. T. LITTLE.

[11927.]—**Ants.**—In my kitchen, about the chimney, somewhere, there is a nest of very small brown ants. They have been there some time, and are very troublesome. I should feel very much obliged if any of your numerous readers would inform me how to destroy them. I have tried several things, but have not succeeded in destroying them.—A. N. T.

[11928.]—**Microscope.**—"A Canadian Subscriber" will take it kind of brother subscribers to give him a few hints upon purchasing a first-class microscope. The strength or powers and merits and demerits fully specified, and the names of the different kinds, and, if permitted, the names of makers, with prices.—CANADA

[11929.]—**Chemical.**—Will any one inform me of what iron retorts are lined with for distilling nitric or other acids?—C. M. J.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, May 14, and unacknowledged elsewhere:—

Robert Tongue.—Epps and Co.—Thos. Evans.—C. H. Stott.—Wm. Pearson and Co.—John Murphy.—Wm. Tyred.—T. Barnard.—John Abrahams.—J. E. F. Wilson.—J. B. W.—J. H. Heywood.—Col. Staces.—Sigma.—Rev. W. H. Morgan.—"To the Manor Born."—J. H. P.—The Harmonious Blacksmith.—A Paper Maker.—F. C. S.—Roland.—T. J. Ridge.—Whitkirk.—J. S. Wood.—Ebury St.—Samuel Smither.—W. H. Hey.—E. L. G.—The Welsh Shepherd.—Boo.—H. O'B.—A Philanthropist.—J. Barwick.—A Country Tinker.—F. B.—William.—G. R. S.—Nil Sine Labore.—In a Difficulty.—Jas. Renworthy.—S. Brown.—W. H. N.—C. W. M.—A Pupil.—Economy.—Glare.—Hard as Stone.—An Apprentice.—Weather.—S. J. D.—Teachable.—Ashtonian.—J. E. Hale.—Waller.—Boongate.—A. C. S.—Glatton.—Speight.—Ashworth Bros.—W. H. Gaines.—J. Starling.—R. Singleton.—T. P. Barkas.—J. M. Elder.—W. H. Lockwood.—R. A. Proctor.—A Colonist.—J. W. J. Manners.—S. Bottone.—Jannifred.—W. M. S.—A Young Butler.—Sigma.—Lindsey.—R. E.—Artillery Captain.—Optical Bricklayer.—J. W. H.—Barbaros.—W. P. Clarke.—Soper.—Charlie Brown.—W. H.—Nil Desperandum.—One in a Fix.—F. H. Smith.—E. H.—A Sufferer.—W. R.—J. H. S.—Piano.—G. W. C. H.—M. Paris.—Saul Rymes.—Halifax.—W. H.—James Hughes.—B. D. T.—Zoo Andra.—Old Cheeseman.—A Cambridge Graduate.—Spider Wheel.—T. Greenway.—A Welshman.—Mechanician.—A Paper Maker.—W. T.—J. H. T.—Screw Cutter.—W. D. Evans.—J. C. J.—W. D. Roberts.—J. Gilbert.—Master of Arts.—Growing Wiser.—W. H. Hibbert.—The H. B.—Confidential.—American Subscriber.—Obby Oss.—G. R. G.—Henry Jackson.—G. H.—Oyster Eater.—Henry Hall.—Speculator.—W. H. Davis.—Amateur.—E. B. Hurley.—G. F. B.—Watts.—H. B. E.—An Old Subscriber.—F. Greenway.—Learner.—J. T. Maurock.—Wm. John Hay.—Walter Keeble.—Richard Jorman.—W. F. Denning.—Fiddler.—J. Swift.—Capt. Crozier.—A. W. Brewtnall.—Nathaniel Waterall.—Whitley Partners.

Communications which can only appear as advertisements to hand from G. E. G., A Draughtsman, John Robinson, Hamlet, O. J. P., Montre, C. L. A., A New Reader, E. L. J., An Old Subscriber, Achilles, J. H. E., W. Copeland.

GAMBA, Bed of Stone, Screw-cutter, W. B. V., Aspirant, Amateur, A Sufferer, F. S. B., Gloster, W. W., B., Experto Crede, T. H. F., Alfred, and David Williams are referred to indices to back vols.

VENTILATION.—"E. L. G." was mistaken in letter 4087, in saying "Philo" ran away from his challenge. His letter in reply to it was not inserted for want of room and other reasons. "Philo" shows no fear of a fight, whatever his other shortcomings may be.

N. J. G. C.—Write Mr. Browning, 111, Minories.

MORNING.—Because your query was an advertisement.

QUI QUÆRIT.—It meant that we do not receive answers to advertisements and forward them to advertisers. See "Hints to Correspondents," over Replies to Queries.

SUFFIRE.—Query 11454 was answered in due course.

SHADY SIDE OF FIFTY hopes we shall adopt the suggestion of J. Rae, and use a little larger type.

C. E.—See a little book on Dilapidations, by Mr. B. Fletcher; published by E. and F. N. Spon.

VULCAN.—You ask a question and send a drawing that would cover half a page, and would cost about £8 to engrave. Did it occur to you that you were asking too much of our space and our money? Try and put your question without the drawing, or with a small one, and we will insert it.

S. J. STAFFORD.—If a "regular subscriber" you are an irregular reader, as we have said dozens and dozens of times that we do not answer querists by post, neither do we insert queries that only minister to *individual* benefit.

W. ROBERTS (Stonehouse).—You begin your rather long query thus: "Will any of our competent mechanical readers give an opinion on the accompanying sketch, which I presume is so simple," &c., &c. We do not insert illustrated queries on speculative notions to elicit the "opinions" of readers. Why not try the experiment yourself, and then, if you think well, give the ENGLISH MECHANIC the results of your experience?

WEE PET.—Consult in such a case a shoemaker. It will save you trouble and expense.

BED OF STONE.—Query about "lame hen," too trivial.

J. RAWDIN.—See "Hints to Correspondents," No. 6.

H. B. E.—We hope to say something soon about the mechanical inventions at the International Exhibition.

JAS. WADDINGTON.—Please say whether your drawing is a design for a steam tricycle or an illustration of a fact.

H. C. JONES.—It was not "Zoo Andra" who inserted the advertisement you refer to.

ARTHUR BOOTY.—Trübner and Co., Paternoster-row.

S. H. L.—Send.

T. F. S. M. R.—Send description for the benefit of others besides "Modeller." If you want to communicate with him privately, you must advertise.

ONE WILLING TO LEARN.—Pianoforte-tuning is a trade, and can scarcely be taught by a few hints, even to "one possessing a little knowledge of music."

RICHARD HOLDEN.—Have the tooth properly stopped by a dentist.

ANGELO.—You can have any back numbers sent to you at the rate of 5d. each, including postage.

CHICAGO.—The number of the current volume is denoted in the left-hand bottom corner of the first page. See reply to "Angelo."

METEOR.—The proposed monthly record would take too much of our space.

AN OLD PRACTICAL MINER.—We think you hardly touch the side of the question with which we have to deal, viz.—the scientific means available for the prevention of explosions.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING MAY 7, 1872.

1286 H. Myerns, Liverpool, for a solution for joining vulcanised indiarubber.

1287 G. Edwards, Park-road-villas, Battersea, for improvements in cabs and other vehicles or carriages.

1288 J. Walker, James-street, Saint Luke's, and A. E. Ragon, Upper Westbourne-terrace, for a new or improved method of constructing public and private buildings, bridges, and other similar structures practically fireproof by the combination of wood and iron in the framing thereof.

1289 L. Cooper, Manchester, for improvements in machinery and apparatus for transporting passengers, goods and other articles. A communication.

1290 H. A. Bonneville, Piccadilly, for a new or improved medical injecting or irrigating apparatus. A communication.

1291 J. Smith, Manchester, for improvements in machinery or apparatus for beetling woven fabrics.

1292 D. Hebson, Liverpool, for improvements in steering gear.

1293 C. Duff, Wandsworth-road, for improvements in the treatment of fibrous substances to be used in the manufacture of pulp for paper, and for conversion into spun and textile fabrics.

1294 T. H. Blamires, Huddersfield, for improvements in machinery for spinning or twisting yarn.

1295 B. A. L. Hautrive, Shrewsbury, for an improved apparatus to facilitate drawing and sketching.

1296 R. Boyle, Glasgow, for improvements in ventilators and smoke extractors.

1297 J. Firth, Sir C. H. Firth, and E. Firth, Heckmondwike, Yorkshire, for improvements in looms for weaving.

1298 Sir J. Whitworth, Manchester, for improvements in gun carriages.

1299 J. Bending, Oxford-street, for improvements in apparatus for producing vapours for medicinal purposes.

1300 J. T. Griffin, Upper Thames-street, London, for improved arrangements of reaping machines to facilitate their transport by road or from place to place. A communication.

1301 W. G. K. Breavington, Regent-street, and T. I. Isaacs, Archer-street, Middlesex, for improvements in reed organs.

1302 J. H. Johnson, Lincoln's Inn-fields, for improvements in the manufacture of steel. A communication.

1303 W. S. Fish, Glasgow, for improvements in locking nuts on the bolts used in the fish-joints of rails and other situations, and in means employed therefor. A communication.

1304 W. R. Lake, Southampton-buildings, for improvements in roofing and in apparatus employed in the manufacture of the same. A communication.

1305 H. Hirsch, Craven-street, Strand, for improvements in the form and construction of ships and other vessels.

1306 C. Lund, Fleet-street, for an improved cutting instrument particularly intended for opening tins of preserved food.

1307 L. Bradley, Park-place, Regent's-park, for improvements in the manufacture of cement.

1308 C. H. Southall, Leeds, for improvements in machinery for finishing the bottoms of boots and shoes, and for paring the edges of the soles and heels.

1309 W. W. Box, Crayford, Kent, for improvements in apparatus used in the manufacture of gas.

1310 M. Henry, Fleet-chambers, Fleet-street, for improvements in reeds, sleys, or combs used in the manufacture of textile fabrics. A communication.

1311 W. Jackson, Caroline-street, Pimlico, for improvements in sewing or stitching machines consists of a guard which prevents the under cotton or thread from being caught by the hook, and an improved system for fixing the needle.

1312 F. A. Gatty, Accrington, Lancashire, for improvements in printing and dyeing cotton fabrics.

1313 C. A. de Laskarzewski, Coventry-street, Middlesex, and H. Kehrmann, West Brompton, for improvements in the manufacture of pianofortes.

1314 G. B. Smith, Kennington, for improvements in manger logs or balls.

1315 J. S. Hughes and C. E. Spooner, Carnarvon, for improvements in the means of obtaining motive power for working railways and tramways.

1316 J. Fielding, Liverpool, for improvements in steam and water rotatory engines, applicable also for pumping purposes.

1317 J. Hodgkinson and T. Thornley, Bolton, for improvements applicable to bobbin and fly frames for preparing cotton and other fibrous materials for spinning.

1318 W. H. Percival, Aldershot, for improvements in camp bedsteads.

1319 R. Coddington, Chancery-lane, for improvements in printing presses, partly applicable to other machines. A communication.

1320 W. A. Lyttle, The Grove, Hammersmith, for improvements in the means and apparatus for attaching telegraph wires to insulators, and for protecting such and other insulators from breakage.

1321 W. A. Lyttle, The Grove, Hammersmith, for improvements in the construction of ships and boats.

1322 A. Clark, Rathbone-place, Oxford-street, for improvements in corrugated metal revolving shutters.

1323 H. R. Fanshawe and M. Bird, Southampton-buildings, for improvements in cigars, cheroots, and cigarettes, and in their manufacture, and in the manufacturing apparatus employed.

1324 J. Piddington, Gracechurch-street, City, for improvements in breech-loading fire-arms. A communication.

1325 G. T. Mackley, Shoreditch, for improved apparatus for supplying cotton and other fibrous materials to the shuttles of lock-stitch sewing machines.

1326 E. Craddock, Fowkes'-buildings, City, for improvements in the manufacture of pipe wrenches.

1327 T. Christy, Jun., Fenchurch-street, City, for improvements in the treatment of ammoniacal and other liquor of gas-works, sewage, and other waters containing foreign matters in suspension or solution in order to obtain useful products therefrom. A communication.

1328 H. A. Dufrené, South-street, Finsbury, for improvements in watches. A communication.

1329 J. H. Johnson, Lincoln's Inn-fields, for improvements in apparatus for disengaging ships' boats. A communication.

1330 F. Finlay, Camden-grove, Peckham, for improvements in the further application of asphalte.

1331 A. Smith, Manchester, and E. Kenyon, Hollinwood, Lancashire, for improvements in the manufacture of velvets, velveteens, and other piled fabrics.

1332 W. R. Lake, Southampton-buildings, for improvements in the construction of metallic springs. A communication.

1333 J. Richards, G. Lawrence, and J. W. Lingard, Birmingham, for an improved spring flower or bouquet holder.

1334 W. Darlow, North Woolwich, for improvements in the construction of portable magnets for curative and other purposes.

1335 N. Ager, Grosvenor road, Pimlico, for improved machinery for the manufacture of stock and other bricks and similar bodies from plastic materials.

1336 M. Henry, Fleet-chambers, Fleet-street, for an improved box. A communication.

1337 J. James, Princes-street, Lambeth, for improvements in part of the process of manufacturing cartridge cases and in apparatus therefor.

1338 W. Hammant, Bouverie-street, Fleet-street, for a new or improved method of propelling carriages with or by compressed air.

1339 W. E. Kochs, Manchester, for an improved boiler for generating steam.

1340 S. Vigoureux, St. Denis, France, for an improved means of forming threads and the production of fabrics therefrom.

1341 A. P. Stephens, Brooklyn, U.S., for improvements in vises for machinists and others.

1342 R. B. Stephens, Langrish, Hants, for a new or improved milk-condensing apparatus.

1343 J. Briggs, High Holborn, for a new or improved apparatus, arrangement, or method for giving, receiving, and taking votes by ballot.

1344 W. R. Hodge and R. R. Hodge, Millwall, for improvements in the construction and arrangement of boilers for generating steam and economising fuel.

1345 J. H. Johnson, Lincoln's Inn-fields, for improvements in carding engines. A communication.

1346 D. Bentley and J. B. Jackson, Bury, Lancashire, for improvements in the construction of cylinders or drums for paper-making and other machines.

1347 T. J. Denne and A. Hentschel, Cambridge-road, Mile-end, for improvements in materials for dyeing raw, felted, and woven fabrics, and printing fabrics.

1348 T. J. Denne and A. Hentschel, Cambridge-road, Mile-end, for improvements in materials for finishing and currying leather.

1349 E. T. Hughes, Chancery-lane, for improvements in the manufacture of pianofortes. A communication.

1350 W. M. Brown, Southampton-buildings, for improvements in centrifugal machines. A communication.

1351 A. M. Clark, Chancery-lane, for improvements in rotary engines. A communication.

1352 H. E. Newton, Chancery-lane, for an improved composition to be used for the manufacture of drain pipes and other articles, and as a substitute for artificial stone. A communication.

1353 T. T. Macneill, Warwick-street, Cockspur-street, for improvements in subterranean railway or tramway intercommunication for cities and towns, and in the structures and apparatus employed therefor.

1354 J. Imray, Southampton-buildings, for improvements in interlocking apparatus of railway points and signals.

1355 W. Brookes, Chancery-lane, for improvements in means for communicating motion and pressure to parts of presses, cocks and valves, vices and jacks, which improvements are also applicable in communicating motion and pressure to parts of other apparatus. A communication.

1356 R. M. Marchant, Kirby-street, Hatton-garden, and B. J. Angell, Lubenham, Leicester, for improvements in horse-shoes.

1357 R. W. Marshall, Owlerton, Sheffield, for improvements in the manufacture of bearings.

1358 R. Waygood, Falmouth-road, Surrey, for improvements in the construction and arrangement of steam and other engine governors, and in valves to be used in connection therewith.

1359 G. H. Carter, Eltham, Kent, for improvements in the construction of gas stoves, applicable for heating public and private buildings, pineries, hot-houses, graperies, and such like buildings and purposes.

1360 W. Ellis, South Lambeth, for improvements in or applicable to machinery or apparatus for cutting wood to any required shape, pattern, or design.

1361 W. R. Lake, Southampton-buildings, for improvements in the manufacture of knitted fabrics, and in machinery employed therefor. A communication.

1362 R. Fish, Hornsey, for improvements in the method of and apparatus for revivifying materials used in the purification of gas.

1363 W. Mitchell, Waterford, Manchester, for improvements in the manufacture of felt carpets.

1364 E. Slaughter and A. L. Sacré, Bristol, for improvements in the construction and coupling of locomotive engines.

1365 J. E. Walker, Sunderland, and J. W. Cole, Newcastle-upon-Tyne, for improvements in apparatus for screening coals.

1366 J. Parks, Northwich, Cheshire, for improvements in fixing salt pans and in arranging the furnaces under the same.

1367 F. J. Sweeting, Rotherhithe, for improvements in apparatus for lowering boats from vessels.

1368 J. P. Fison, Cambridge, for an improved lifting and steering gear for double and three furrow ploughs.

1369 P. Couper, Edinburgh, for improvements in motive-power engines.

1370 H. Lomax and J. Lomax, Lancashire, and G. F. Bradbury and T. Chadwick, Oldham, for improvements in sewing machines.

1371 T. Turton, Liverpool, for improvements in spring safety valves.

1372 W. D. Player, Birmingham, for improvements in machinery for the manufacture of buttons.

1373 T. J. Denne and A. Hentschel, Cambridge-road, Mile-end, for preserving meat.

1374 W. L. Wise, Chandos-chambers, Adelphi, for improvements in musical instruments. A communication.

1375 C. [illegible], Compton-street, Brunswick-square, for a new washing fluid for obliterating marks or stains in white linen.

1376 D. G. FitzGerald, Loughboro'-road, North Brixton, and B. C. Molloy, Elm-court, Temple, for improvements in treating compound substances by the agency of electricity, and thereby decomposing them or resolving them into their components.

1377 J. D. Culp, Santa Clara, U.S., for an improved process for drying and curing leaf tobacco raised from Havanna seed, and to be used for the manufacture of cigars, in order to impart to it the colour and flavour of real Havanna tobacco, independent of the soil and climate in which it is raised.

1378 W. R. Lake, Southampton-buildings, for improvements in electric torches for lighting gas. A communication.

1379 R. J. Edwards, Shoreditch, for improvements in the manufacture of sand, emery, and glass papers and cloths, and in the machinery and apparatus employed therein.

1380 B. Hunt, Serle-street, Lincoln's Inn, for improvements in the manufacture by rolling of straight axles for waggons, tenders, locomotives, and other wheeled vehicles. A communication.

1381 B. Hunt, Serle-street, Lincoln's Inn, for improvements in the manufacture of metallic wheels for railways. A communication.

1382 J. H. Johnson, Lincoln's Inn-fields, for improvements in the treatment of corn and other grain, and in the machinery or apparatus employed therein. A communication.

1383 J. H. Johnson, Lincoln's Inn-fields, for improvements in the treatment of coal and in the preparation of artificial fuel. A communication.

1384 B. J. B. Mills, Southampton-buildings, for improvements in apparatus for heating air to a high temperature for use in furnaces and for other purposes. A communication.

PATENTS SEALED.

2955 W. H. Tooth, for improvements in breech-loading small arms.

2976 A. Jaynor and S. F. Smith, for improvements in night signals for naval, military, and other purposes where night signalling is required.

2978 J. Blakey, for improvements in brakes.

2981 H. Denton, for improvements in actuating and constructing the rakes of reaping and mowing machines.

2993 G. Heywood and G. Whewell, for improvements in steam boilers or generators, and in the arrangement of the furnaces and flues thereof.

2999 J. C. Mewburn, for improvements in machines for embroidering.

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

FRIDAY, MAY 24, 1872.

ARTICLES.

AIR AND RAIN.*

UNDER this title Dr. Angus Smith has gathered together and published the results of his investigations into air and rain, and of the experiments made to determine their relative purity or impurity in various parts of the British Isles and on the Continent. As a first step towards establishing a chemical climatology the book will undoubtedly be extensively read; and although a tentative effort to place the analysis of air and rain as affecting the health of the community on a more scientific basis, it must be regarded as the standard text-book of the present time, and in all probability for a long period in the future. Dalton, it is said, considered that chemical experiment could not distinguish the air of Manchester from that of Helvellyn, but the progress made in scientific knowledge since that time has shown that he was mistaken, and that it is not only possible to exhibit a distinction between the air of our manufacturing towns and that of Ben Nevis, but also between the different parts of those towns themselves, and, further, to draw important conclusions from the results thus exhibited. Chemistry, says Dr. Angus, has not hitherto done enough in sanitary inquiries, though it ought to be able to relieve medical men of much of their heavy responsibility, and it is chiefly with this view that he has gathered together the papers and reports written by him, the latter being furnished to the Government in his capacity of Inspector-General of Alkali Works. Besides the two principal gases found in atmospheric air we know that there are others which, though small in quantity, are nevertheless powerful for evil, and in the neighbourhood of towns, and particularly of those which are the seats of special manufactures, ocular demonstration is afforded of the deleterious nature of some of the vapours and gases thrown into the air in unknown quantities and numbers, while others, probably not the least hurtful, escape detection both by the eye and nose. We know also that there are innumerable solid particles, consisting of common salt, sulphate of soda, nitrate of ammonia, and sometimes lime-salts and iron, as well as phosphates, iodides, and, in fact, probably a little of nearly everything at times. Besides all these we have organic substances given off from animals and vegetables, and, finally, living things themselves, capable of propagation wherever they may find suitable conditions and food. It may possibly be true that some of these latter are useful, many inert, but it cannot be doubted that a very large proportion are positively hurtful—conveyers of disease, if not actually the producers.

Numerous observers have experimented on the air and calculated the amount of oxygen it contains, and although formerly results differed, owing probably to defects in the modus operandi, latterly the analyses have come much nearer agreement and to minute accuracy. Gay-Lussac and Humboldt gave the mean as 21·0 volumes per cent. of oxygen; De Saussure, after numerous experiments at Chambeisy, found a mean of 21·0; and Dalton found the air at Manchester to contain from 20·1 to 21·5 per cent. Bunsen, at Heidelberg, however, found an average of several trials to give 20·924; and Regnault, whose results are probably most reliable, from the number of experiments he made in different parts of the world, obtained a mean of 20·949, while 100 specimens of Paris air gave 20·96. Priestley, when oxygen was first recognised, imagined that the amount varied to the extent of 6 per cent., and Scheele is said to have obtained as much as 30 per cent.; but Cavendish, by making a series of 500 analyses, arrived at the conclusion that 20·833 was the mean amount, and later experiments have shown that he was not far out, Graham and Liebig both giving 20·9. Dr. Angus Smith found, from repeated analyses, the following percentage, which we extract from his table as characteristic situations :—

On the N.E. shore and heaths of Scotland	20·999
Outer circle of Manchester (not raining)	20·947
Open places, London, summer	20·950
In a sitting-room, which felt close, but not excessively	20·890
In a small room with petroleum lamp	20 840
Theatre gallery, 10 30 p.m.	20·860
Theatre pit, 11.30 p.m.	20 740
Backs of houses and about closets	20·700
Court of Queen's Bench	20 650
Under shafts of metal mines (average of many)	20·424
When candles go out	18 500
Worst specimen found in a mine	18·270
Difficult to remain in	17·200

The cursory reader who does not stop to examine what these figures really mean will probably exclaim, What difference capable of affecting health can there be in the air of London and that of Scotland—20·999 against 20·950 per cent. of oxygen! It is quite true that a mere deficiency of oxygen to the extent of 49-10,000ths may affect us but little, but that deficiency means something more than a mere absence to that extent of oxygen; it involves a question as to what has taken its place. Even so slight a difference as that between 20·999 and 20·980 is equal to 190 in a million, and if we put impurity into water at this rate it amounts to 13·3 grains in a gallon. This amount, says Dr. Smith, would be considered enormous if it consisted of putrefying matter, or any organic matter usually found in waters. But we drink only a comparatively small quantity of water, and the whole 13 grains would not be swallowed in a day, whereas we take into our lungs from 1,000 to 2,000 gallons of air daily. We must remember, too, that the blood receives the air and such impurities as are not filtered out in its passage, whereas the stomach has powers of disinfection and destruction which render harmless many organic impurities contained in water. But if we take the air found in the pit of the theatre we find that the difference amounts to 2,590 in a million, and the importance of the minute analysis becomes evident. It is rather curious that in the atmosphere of towns more oxygen is found after rain has washed out the carbonic acid than before, some analyses giving more than 21 per cent., the experiment being frequently repeated to guard against what at first was supposed to be an error.

The experiments carried on at Dr. Smith's laboratory in Manchester furnish in a conclusive manner, the proof of the statement enunciated above; for, from a number of trials on air taken from the front of the laboratory and from the back near an ash-pit—in which the means were respectively 20·943 and 20·70—it was found that not only was there a diminution of oxygen in the less pure spot, but that the carbonic acid was not in sufficiently increased proportion to make up for the loss of oxygen. Dr. Smith thinks, therefore, that wherever there is a diminution of oxygen from the standard that is a proof of impurity. "We see putrid matter laid on the ground, and find it disappearing rapidly, and yet we are told that it is not accompanied by loss of oxygen: it is not credible, and the results given show it to be incorrect." Those of our readers who are curious to know the percentage of oxygen found in different parts of London and in various parts of the kingdom and the Continent, must refer to the book; but we may mention that the average of six samples taken on the Metropolitan Railway give, as might be expected, a result as low as that found "about backs of houses and closets"—viz., 20·70—one specimen taken at the open window at 10 a.m. only giving 20·60. We may also mention that the amount of carbonic acid from air at the top of the Monument was considerably in excess of that found at the Duke of York's Column, or at Small Alley, Smithfield.

Not the least interesting of Dr. Smith's experiments were those undertaken to ascertain the amount of impurity in metalliferous mines, the air of which is contaminated by the candles and the breath of the miners, as well as by the gases given off in the explosion of gunpowder. Besides the impurities proceeding from these sources, there are, of course, small quantities of organic substances derived from tallow, tobacco, the human skin, and from putrefaction: it was found impossible to separate these, and in order to obtain a reliable idea of the separate effect of the principal agents, a lead chamber was constructed in which the experimenter could shut himself up from the external air. This chamber contained 170 cubic feet of air when furnished with a table and chair, and occupied by one person. On a day when the temperature was 45°F. no difference in the air breathed was perceptible for 25 minutes, but when drawn from the top by moving an umbrella up and down, it seemed like a soft wind capable of producing a slightly pleasant feeling, being, however, utterly without the property of producing that cheering and exhilarating effect to which we are accustomed in a gentle breeze. The air was moist, and a specimen of it deposited water. After an hour the well-known organic smell noticed in a crowded school-room was perceptible on moving about rapidly; and at the end of the experiment, which lasted 100 minutes, had a very unpleasant flavour and smell, and persons who entered immediately the door was opened, pronounced it very bad. Still, Dr. Smith says he did not feel uncomfortable, although the percentage of oxygen must have been reduced below the average found in the ordinary circumstances of daily life, showing the seductive and insidious character of breathed air. After a stay of 2 hours 20 minutes in the chamber, however, long inspirations became more frequent, and the air was found much less agreeable when breathed at the upper part by standing on a chair; at the end of three hours the amount of oxygen was reduced to 19·61. In an experiment with burning candles it was found that the amount of light was sensibly diminished, and when the candles went out the percentage of oxygen was found to be 18·80*, and of carbonic acid 2·28. On entering the chamber with candles and a spirit lamp the lights were speedily extinguished, and it was found impossible to re-kindle them with matches, the ordinary wooden ones refusing to ignite. Still, it was possible to breathe without difficulty, although a feeling of discomfort was soon experienced. Afterwards gas was lit and burnt brilliantly, but on entering with candles after the gas had gone out they were instantly extinguished. Nevertheless, it was still possible to breathe, although when Dr. Smith stood on a chair he experienced a feeling similar to incipient faintness; "but the senses were not annoyed by anything beyond a feeling of closeness, by no means so unpleasant as a school-room." This is an important fact, as Dr. Smith says, showing almost conclusively that organic matter is the cause of the unpleasantness to the senses on entering a school-room; for there was comparatively little organic matter in the chamber, and the school-room would have more oxygen than the chamber, the percentage found in the latter, after allowing the door to open for three persons to enter, being found to be only 17·45. The conclusion to be drawn from these experiments, therefore, is that the senses are bad and inefficient guides to the wholesomeness of air as regards the amount of oxygen and carbonic acid, save when the former is reduced and the latter increased to such an extent that the lungs seem to refuse to expand, and the whole vital action is threatened with paralysis. This was clearly proved in an experiment, in which a young lady entered the chamber as the candles were giving indications of going out, so that there could not be over 19 per cent. of oxygen nor less than 2·1 of carbonic acid. As no one had been breathing in the chamber there was no organic matter from the human body in the air, and for five minutes the young lady found no difficulty in breathing, and experienced no unpleasant sensation, but at the expiration of that period she became suddenly pale, and had to be assisted out of the chamber. It will thus be seen within what very narrow limits the amount of oxygen necessary for healthy life is confined, and the importance of the figures given in the table above is clearly shown. Rooms badly ventilated which contain less than 20·7 per cent. of oxygen are very unwholesome, and the necessity of taking into consideration the proportions of oxygen and carbonic acid in the sanitary inspection of factories and workshops is abundantly evident from the results obtained by Dr. Smith. We must postpone our remarks on the portion of the work devoted to analyses of rain to a future time; but meanwhile we may say that these "beginnings of a chemical climatology" should be studied by all sanitarians, and their teachings thoroughly grasped by those whose duty it will be to direct legislation on the subject.

ELECTRICITY—WHAT IS IT?

By B. Thompson.

I.—Electricity a Form of Motion.

I KNOW, to those tolerably well acquainted with the science of electricity, few arguments would be required to make them believe that electricity is a form of motion as much as heat or light; but since the object of this communication is more especially to show the difference between the motion of electricity and that of heat, light, or sound, I think it advisable to go through the principal arguments for supposing electricity to be motion, as they all bear directly upon the subject which is as follows.

Electricity is a force which resists all direct analysis on account of the difficulty which is experienced in retaining it, and the great restrictions one is under when dealing with it, which are greater and more numerous, I think, than those required in the examination of any of the other physical forces; we can, therefore, only judge of its nature by noting the laws which govern its development and phenomena; these, again, are very numerous and complicated, many of them, however, are identical with the laws governing other branches of physical science, and I think we shall be able to obtain clearer conceptions of the nature of electricity by studying this connection, together with the exceptions, than it appears we are enabled to by direct experiment.

We will first consider in what respects especially it differs from the ordinary physical forces of sound, heat, and light, as the coincidences of the laws regulating these and electricity are very significant, and point to an intimate connection, if not common origin.

Sound, we know, is propagated and made sensible to us by the undulations a vibrating body has imparted to the surrounding air; the molecules of air in immediate contact with the sounding body deliver the pulse they receive to other contiguous molecules, and so the motion is carried on until expended. And, so far as can be ascertained, heat and light are propagated by the same wave-like motion, which, however, does not use the air as a medium, but a (hypothetical) ethereal substance called ether. This is supposed to pervade all space and surround the atoms of all bodies, preventing the atoms themselves touching each other. The rate of vibration in the case of light and heat is, however, immensely greater than that producing sound, as the substance which conducts them is immensely rarer than that which conducts sound.

Apparently, electricity bears most resemblance to the former of these forces in requiring a substance more ponderable than ether to conduct it—as we shall see by after experiment—yet it is more intimately connected with heat than sound; as is shown by the ready and reciprocal transmutation of the one into the other, so that a full explanation must be one founded on a property common to both sound and heat. The most evident common property, and, I think, the one upon which all the other resemblances depend, is, that they are both modes of motion. Therefore, we may with some reason infer that electricity, also, is a mode of motion, and this will appear more evident as we proceed.

It is now generally admitted by philosophers that the dynamical theory of heat is most in accordance with the present state of scientific knowledge; especially since the exhaustive investigations of Professor Tyndall; and the belief, too, is growing fast that all the physical sciences are connected, and require a dynamical theory to account for their behaviour; therefore, it cannot be regarded as presumption on our part to attempt to prove that electricity is a mode of motion, in opposition to the conventional fluid theories, especially when we see the very intimate connection with heat, which we know is a mode of motion.

We will first investigate the phenomena which called forth the remark at the commencement, that electricity apparently requires a substance more ponderable than ether to conduct it. It is impossible for us to conceive of force apart from matter, as it is only manifest to us by its effects in nature, and we are compelled to recognise the existence of a something pervading all space, by which the waves of light from distant stars reach us, and this assumption receives verification from the observed retardation of some planetary bodies from resistance. So electricity requires matter to act upon, otherwise it is not manifest to us, nor does it exist. This leads us to inquire immediately into its relation to the substance which conducts it; the inquiry is attended with difficulty, and we are apt to be misled, for we find that a solid conductor, such as copper, enables electricity to pass freely through it; but we also find that a comparative vacuum, such as that in the vacuum tubes (so called) of Geissler, &c., seems to facilitate the conduction of electricity; in the latter case, we are led to attribute the conduction of electricity to the ether contained in the tubes (absence of air, if you please); but to suppose that the conduction in the case of copper is due to the ether surrounding its atoms is untenable, for as Faraday remarks, "ether exists alike in conducting and non-conducting bodies; it would, therefore, in the case of a conductor, be conducting, and in the case of a non-conductor, non-conducting." So we have every reason to believe that it is the substance of the conductor itself which affects its conducting power for electricity, and not the ether. The following experiments I have selected to still further prove this point.

If a tube—fitted with two platinum wires in its ends, so as to be a very short distance from each other in the tube—be connected with a good air-pump, so that it can be exhausted whilst electricity is passing between the two electrodes; then heated to a dull redness, and the exhaustion continued; in a short time the sparks will cease to pass; the tube may now be sealed, and although there is a very slight distance between the platinum points, the passage of electricity is completely stopped. Indeed, a vacuum sufficient to effect this is not at all difficult to obtain, for if three tubes of the kind described above be filled with chlorine, and the gases of bromine and iodine respectively (three simple substances), and a current of electricity allowed to pass through them, the gases, will combine with the platinum electrodes, from the negative pole of the battery, and in a short time so completely exhaust the tube that electricity will cease to be conducted. Also, if caustic potash can get at the gas in carbonic acid vacuum tubes, it absorbs the carbonic acid (CO_2) by degrees, until electricity will not pass, seeming to show that a substance of a ponderable nature was necessary for the conduction of electricity, for the quantity of ether would certainly be increased by the removal of the air.

Reasoning from the above experiments does it not appear singular that a comparative vacuum should conduct electricity well, when one more perfect will not conduct it at all? but the fact may be we are mistaken in supposing that an attenuated medium conducts (in the sense I am now speaking of conduction) better than a solid conductor, and it will be my next duty to prove that it does not, both by experiment and reason, but that the effect we see is due to the incandescence of the particles of ponderable matter between the electrodes, which, if it be so, implies increased *resistance* rather than conduction, for we know the greater the resistance in a conductor, so long as it will allow a current to pass at all, the greater will be the heat developed in it.

For the determination of this point the aid of the spectroscope is very valuable. If the spectrum of a luminous body is examined by a spectroscope, it is found to contain certain bright bands across it, characteristic of and peculiar to the substance or substances which are incandescent. If we allow the spectrum to pass through the incandescent vapour of any of the elements burning the rays of like refrangibility are absorbed by it, and on now examining the spectrum the lines characteristic of the absorbing vapour are there, but are now dark instead of light. This explanation is, I think, sufficient to enable any one to understand the reasoning founded on it.

Now, if on examining the spectrum of the light we observe in a vacuum tube when a current of electricity passes, we discover the bands are such as would result from the incandescence of the gases or vapours in the tube, and that the lines are bright ones, can we resist the evidence forced upon us that the contents of the tube have been rendered incandescent by the electric current? That the lines are bright and characteristic, and the deductions drawn therefrom justifiable, will, I think, be evident from the following quotations of experiments.

Professor Roscoe, in one of his lectures at the Apothecaries' Hall, gave some experiments with Geissler tubes with which to demonstrate the various characteristic lights emitted by incandescent hydrogen, carbonic acid gas, nitrogen, &c. The nitrogen lines are seen in the spectroscope when the electric spark passes through air, together with those of oxygen and hydrogen, owing to the presence of aqueous vapour.

From the latter experiment, I think, we may form a reasonable and important hypothesis—namely, that when electricity manifests itself to us as light by spark, or otherwise, it is due to incandescent matter, whether it takes place in a vacuum tube or not. This idea is also supported by the fact that electricity passing through air gradually converts some of the oxygen into ozone, an allotropic form of oxygen. Sulphur, selenium, phosphorus, chlorine, bromine, and all the carbon compounds, &c., also give different and characteristic spectra when the electric current passes through them. If the spark takes place through a compound gas or vapour the spectra are those of the elementary constituents of the gas. It seems as if at very intense temperatures chemical combination was impossible, and oxygen, hydrogen, chlorine, and the metals, &c., could exist in a separate state, although mechanically mixed together.

It has also been shown that when the electrodes of a battery are composed of metals, coloured sparks are obtained characteristic of the metals, and by which their presence can always be detected, if not directly from the colour, by means of the spectroscope.

All these facts, I think, give great additional support to the hypothesis before expressed, that it was not the electricity we saw in a vacuum tube or as a spark, but that there had been a transmutation of electricity into light, by its rendering the intermediate substances incandescent.

And it is important for us to notice that the light and heat (the light being a consequence of the heat) produced are *directly* due to the electric current, and not to ordinary combustion, for they are produced in gases and vapours which will not support combustion in the least, or it might be supposed that the current's only function was to heighten the affinities of the elements.

In the above experiments we have the force of electricity producing the motion of heat, which must be the result of some form of motion accompanying the current of electricity, and inseparable from it. We will, however, continue the proof of this motion further, and in another direction.

When electricity is invariably sent through the same pole of an induction apparatus, through the wire of a telegraph, in a very short time the wire is torn or divided into small sections, which destroy its continuity; but when the current is sent alternately through each pole, the conducting wire remains uninjured. As each atom of the wire has its own electricity the same as each atom of the wire has its own heat (motion), it seems to indicate that during the passage of the same kind of electricity the pole of each atom is forced more and more in the same direction, till at last they are not able to return to their normal condition; the coercive force is completely overcome, and a rupture takes place, the more readily if there be any imperfection in the wire.

Faraday was led to believe that the conduction of electricity might be only a consequence of decomposition, for he found that ice would not conduct electricity at all (friction, would, however, overcome the resistance), whatever the power of the battery. Water, however, was readily decomposed by a powerful battery, and this behaviour he found almost universal—that bodies which do not conduct electricity when solid acquire that property when fluid, and are generally decomposed as soon as conduction begins. He also informs us, I think, that there are but two exceptions to this rule—sulphuret of silver and fluoride of lead, and his belief was that electricity was conducted in the same manner in the metals, in lacks, or in gases, but in different degrees.

Looking at the preceding experiments, we shall find that the deductions drawn from them are of universal application in the science of electricity. Thus, when a person completes the circuit of a powerful battery he feels a shock, but only on making and breaking contact, because when the current is circulating continually in one direction, the conducting atoms or molecules lying between the electrodes do not return to their original state, but continue in a polarised one, because the successive polarisations are too rapid to permit of it. So long as there is quiesence no shock is felt; when, however, the current is stopped the return of the polarised molecules to their original state causes a shock equal to that felt when they became polarised, and if the current were to circulate continually in one direction in a human body, analogous results to those noticed in a conductor of metal would occur—*i.e.*, the intermediate matter would suffer slow decomposition. Indeed, induction or medical coils have complete superseded the battery alone as curative agents, because of the evil results from electricity when applied direct from the battery alone. These coils have contact breakers to continually make and break the connection, and as often reverse the current.

I have not been particularly careful in the use of molecule or atom, but may say at this point that it is pretty evident it is the molecules which take the polarised state, as this assumption will enable us the better to understand the action of decomposition when the conductor is a compound, but at present it is a very difficult matter to deal with, as there is no strict electrical distinction of conduction which can be drawn between elementary and compound conductors when solid, although fluidity is not always essential to decomposition.

Turning, however, to the more immediate object of this communication, perhaps the greatest proof of motion in a conductor when a current of electricity is circulating in it is contained in the following:—

When a current of electricity is traversing a wire, so long as it is readily conveyed, there is little heat caused by it, but if the current be increased, the heat is likewise increased, and, therefore, we have the actual and direct transference of one kind of force into another, which certainly cannot be admitted without recognising a great similarity of nature. So, I think, we are bound almost to regard electricity as a modification of the force of heat, and, therefore, a mode of motion, as heat is.

(To be continued.)

CEMENT FROM SEWAGE.

THE new method of disposing of sewage by making it into cement, which has been practically and successfully tested during the last six months at Ealing, a village to the west of London, formed the subject of a paper read at a recent meeting of the Society of Arts by Major-General Scott, the inventor and patentee of the process. From this we gather, although the details have not yet been published, nor the process carried out in the most economical manner, that a cement equal to the best Portland or an excellent hydraulic lime can be made from the ordinary water-borne sewage at a cost which does not exceed that of Portland cement prepared in the usual manner, while the offensive nature of the fecal matter is completely destroyed. The principle of the process consists in mixing with the sewage quantities of lime and clay, the former ingredient combining with the carbonic acid of the fecal matters to form carbonate of lime, which is precipitated with the other solid ingredients in the form of an impalpable powder. The lime and clay are preferably thrown into the main sewer some little distance before reaching the outlet, so as to insure a more complete incorporation of the different matters while at the same time destroying the slimy glutinous character of the sewage "sludge," and keeping the drain clean and free from the festering and putrefying deposit which otherwise tends to choke it. The clay and the lime do not merely facilitate the deposition of solid matter, but, as is well known, they tend to purify the supernatant water. Now, lime and clay are the chief constituents of those limestones, which on calcination yield the best hydraulic limes and cements, and it is claimed for this process that there is a sufficient gain of cement-making material abstracted from the sewage to make the operation profitable, independently of the advantages gained by thus deodorising and defecating the excrementitious matters of towns, which must otherwise be disposed of in a manner more or less unhealthy, and very often at great expense. Hitherto it has been found impossible to clarify liquid sewage at once satisfactorily and profitably. The grosser particles, it is true, are deposited, when it is simply allowed to stand in tanks, but the supernatant water still holds in suspension a very large amount of solid matter which renders it unfit to be turned into any river from which a supply of potable water is drawn. There are chemicals capable of purifying the liquor and precipitating all the solid matter, but the expense attendant on their employment is too great to permit of their use. Of all the chemicals hitherto employed for this purpose ime and clay are the least costly, and now that it is shown that a useful material can be made from the resulting deposit the problem of sewage disposal seems in a fair way to be solved.

The success of the new process depends in no small degree on the fact that the precipitated matter supplies to a considerable extent the fuel necessary for the burning operation. The sewage being allowed to settle in tanks, and the supernatant water drawn off, it is found to be thoroughly deodorised, and may be exposed to the drying action of the air for an indefinite period, without giving rise to any offensive or deleterious vapours. It is then dried on tiles, beneath which the heated gases of the furnace are made to pass, and is then calcined in the ordinary manner. The fecal matters which subside in the settling tanks are found to consist to a large extent of organic compounds, which when dried and distilled, yield large quantities of inflammable gases; and although the proportion of carbon may be small, the hydrogen gives a most intense heat, the sewage thus supplying the greater portion of fuel required to turn it into cement. The experimental kiln at present used by Major-General Scott, is only about 4ft. 6in. in diameter, and 12ft. high, and the working of the process on this small scale requires from three to five bushels of coal per ton of material, yielding a heat sufficient to keep the drying floor red hot, as well as burning the mixture to cement. It cannot well be doubted, therefore, that on a larger scale more economical results would be obtained; but even as at present carried out, a useful article is manufactured and the sewage is disposed of in the least offensive manner yet devised. General Scott does not suppose that his process will entirely relieve the inhabitants of a small place like Ealing from a sewer-rate, but it will reduce the expense lower than any system yet proposed, save the plan of utilising it upon land, which is not always that *summum bonum* which its advocates would have us believe. It was urged in the discussion that followed the reading of the paper, that cement might become a drug in the market, if the sewage of towns was extensively utilised in this manner; but even supposing this to be the result, the expense of carrying on the process would not exceed that of the present costly and wasteful system, while the sewage would be disposed of in a far more satisfactory manner than that at present in use for getting rid of the refuse of the metropolis. As a matter of fact, however, the value of Portland cement has been considerably augmented of late years. Experiments have proved that it is a most serviceable material when employed as concrete for building purposes, and we look for a much more extended utilisation of its valuable properties in time to come. Anything, therefore, that will cheapen its production, even if that result is attained by making it a drug in the market at the expense of the rates, must be hailed with satisfaction, for from the evidence of Mr. Hawksley, Dr. Odling, Dr. Frankland, Dr. Voelcker, and Professor Abel, the sewage is most effectually deodorised, and while the solid ingredients—those most difficult to deal with—are utilised, the liquid portion can still be employed for irrigation. The general opinion of those best capable of judging, was in favour of the new process, as a means of getting rid of an intolerable nuisance, the only objection being the large quantity of cement produced—estimated by Dr. Letheby at a ton per day for every 10,000 persons. The plan is, of course, only applicable to towns where a system of sewerage is in existence or in course of construction.

KEROSENE AS A CURE FOR RHEUMATISM.

ALL the way from New Zealand comes the intelligence that the administration of kerosene has had a most decided and marked effect in the cure of chronic rheumatism. Mr. W. G. Kemp, L.R.C.P. and M.R.C.S., of Wellington, N.Z., sends to the *British Medical Journal* an account of six cases of rheumatism, in which kerosene appears to have acted almost as a specific. The dose is a teaspoonful in a wine-glassful of water every other night. It produces no unpleasant symptoms, no loss of appetite, and has no effect upon the bowels or kidneys. Mr. Kemp says:—"Although kerosene cannot be called a specific for rheumatism, I think that the cases cited are quite sufficient to induce medical men to give it a fair trial. I am unable to find any unpleasant symptom caused by taking kerosene. The great objections with many people to taking it, are the unpleasant taste and smell. Some have taken it in water or milk; but I have lately heard a patient say he could take it best with salt; a pinch of salt being put into the mouth and allowed to dissolve, and the oil then swallowed, mixed with about its bulk of water. I am not aware of the remedy having ever been used internally; but I trust some medical men will be found who will give it a trial and record the results of their cases. Externally, it is of great use in cases of burns, whether severe or slight; it seems to relieve pain more than any other application, especially if resorted to as soon as the injury is received. I have known cases of severe burn to heal up rapidly under its use alone."

LESSONS ON CHEMISTRY.*

BY SELIMO R. BOTTONE.

(Late of the Istituto Bellino, Novara, Italy.)

(Continued from p. 215.)

c2. SULPHURIC ACID. *Synonym: Hydrogen Sulphate.*† *Symbol:* $H_2'S''O_4''$. *Combining weight:* 98.

166.—PROPERTIES.—Pure sulphuric acid is a transparent, colourless, oily liquid, of a specific gravity of 1·854 at 32° Fahr. It is extremely corrosive, owing to its powerful attraction for water. For this reason it chars and decomposes most animal and vegetable substances (which may be looked upon as compounds of carbon and water), by abstracting their water and leaving their carbon. Such is its action upon sugar, wood, paper, &c. Taking the case of sugar as an illustration, the following equation will give an idea of the reaction:—

$$\underbrace{C_{12}H_{22}O_{11}}_{\text{Sugar.}} + \underbrace{11H_2SO_4}_{\text{Concentrated sulphuric acid.}} = \underbrace{11H_2SO_4H_2O}_{\text{Dilute sulphuric acid.}} + \underbrace{C_{12}}_{\text{Carbon.}}$$

In practice the elimination of water from the organic substance is seldom found to be so complete as that represented by the above equation; and owing to the heat generated during the action, part of the unaltered sulphuric acid is decomposed by the carbon produced, and a quantity of sulphur dioxide is consequently evolved.

Sulphuric acid boils at about 638° Fahr. When boiled, a small quantity of sulphur trioxide is evolved, and a liquid remains behind which contains only 98·5 per cent. of the pure acid. At this strength the acid may be boiled without being farther decomposed, its boiling point being then constant at 620° Fahr., and its specific gravity 1·846. A temperature of 15° Fahr. causes sulphuric acid to freeze to an ice-like mass. When mixed with water sulphuric acid gives rise to the evolution of great heat, the degree depending on the relative quantities of acid and water employed. For instance, with 4 parts of sulphuric acid to 1 of water, the temperature produced is 300° Fahr. N.B.—We would impress on the reader that on mixing sulphuric acid with water it is prudent *to pour the acid into the water*, for if the opposite mode of procedure be adopted, the contents of the vessel are sometimes ejected, such is the violence with which combination takes place.

Great cold is produced on mixing one part of sulphuric acid with four parts of snow, and this apparent paradox is owing to the fact that as sulphuric acid on mixing with snow reduces it to the liquid form, so the heat necessary to transform snow into water is abstracted from the surrounding bodies, *id est*, cold is the result.

167.—Sulphuric acid possesses in the highest degree the typical properties of the class of bodies known under the name of *acids*, hence it may not be amiss here to enumerate them.

Sulphuric acid is endowed with an extremely sour taste, so sour that 1 part of acid will give a distinct taste to 1,000 parts of water, hence it is often used to adulterate vinegar. It reddens litmus paper strongly, and can combine with nearly all metals and metallic oxides, with the production of a series of bodies called sulphates. When it acts on metals these generally replace and expel the hydrogen contained in the acid, thus:—

$$M'' + H_2'S''O_4'' = M''S''O_4'' + H_2'.$$

If a metallic oxide be used, a similar expulsion and replacement of hydrogen takes place, but the oxygen of the metallic oxide combines with this hydrogen to form water, as may be seen by the following equation:—

$$M''O'' + H_2'S''O_4'' = M''S''O_4'' + H_2'O''.$$

† Hydric sulphate.

168.—The generic name for compounds resulting from the combinations of metals with acids is *salts*. A salt may therefore be defined as being "an acid in which part or all the replaceable hydrogen has been substituted by a metal or body playing the part of a metal."

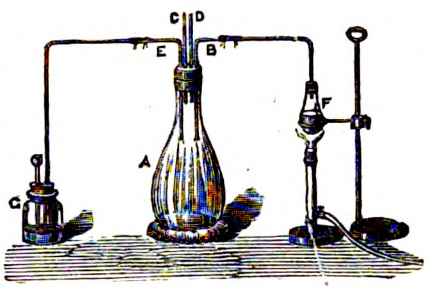
Salts may be divided into two grand classes—viz., 1. Those in which all the replaceable hydrogen of the acid has been replaced by the metal: these are said to be "neutral" or "normal" salts. *Potassium sulphate*, $K_2'S''O_4''$, will serve for an example of this class. 2. Those in which *only part* of the replaceable hydrogen is removed and substituted by a metal: such are called "acid salts," and *hydrogen potassium sulphate*, $\left.\begin{matrix}K'\\H'\end{matrix}\right\} S''O_4''$ may be taken as the type.

169.—Bodies which are thus capable of uniting with acids, whether they be metallic oxides or the oxides of bodies resembling metals, go by the general name of *bases*. The terms "acid," "base," and "salt," are by no means very accurate, or capable of very exact definition; but they are very convenient to point out the general properties of three large classes of bodies, hence they are often employed by the chemist.

of commercial importance, the preparation of sulphuric acid is of the highest interest and import to the scientific and practical chemist. We shall, therefore, enter somewhat into details, beginning by the experimental mode of preparing it, and after having traced the causes on which its production depends, terminate by noticing the several appliances employed in its manufacture on the large scale to bring these various causes into operation.

173.—We have seen (165) that when sulphur

FIG. 18



This nitric oxide absorbs oxygen readily from the atmosphere, being thereby converted into a higher oxide of nitrogen, known as nitrogen tetroxide. The mode in which this takes place is illustrated by the following equation:—

$$N_2'''O_2'' + O_2'' = N_2'''O_4''.$$

The sulphur dioxide issuing from the generator F meets with the nitrogen tetroxide formed by the action of the nitric oxide evolved from the bottle G on the atmospheric air in the flask. Though not able to absorb oxygen directly from the air, sulphur dioxide, by virtue of its deoxidising power, is able to take half the oxygen from the nitrogen tetroxide, thus:—

$$N_2O_4 + 2SO_2 = N_2O_2 + 2SO_3.$$

But the nitric oxide thus reproduced cannot exist *as such* in the presence of atmospheric air; it immediately absorbs oxygen from the air, and is reconverted into the tetroxide. Thus it acts as a *carrier* of oxygen between the atmosphere and the sulphur dioxide, which is therefore rapidly converted into sulphuric anhydride, and this body in contact with water gives rise to sulphuric acid.

Though other bodies, which part readily with their oxygen, might certainly be substituted for

FIG. 19

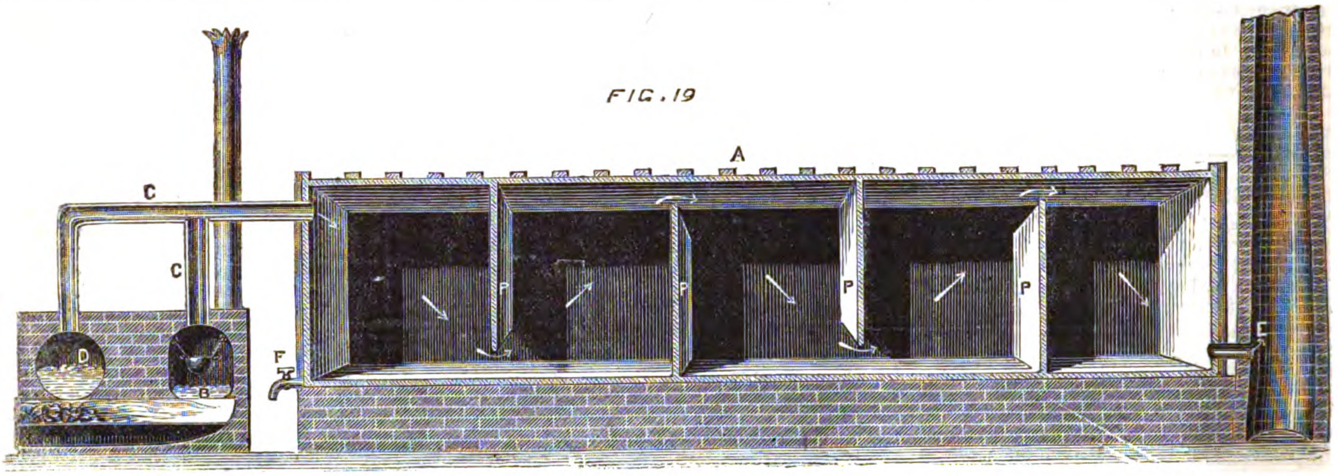


FIG. 20

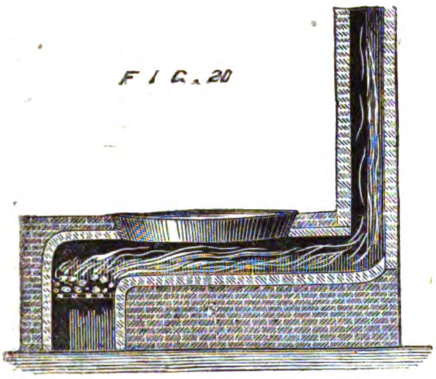

FIG. 21

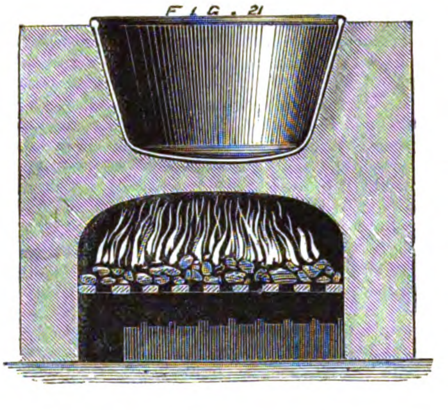

FIG. 22

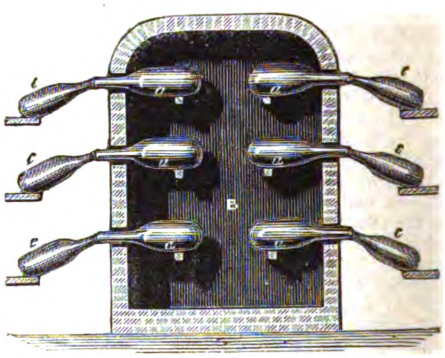

170.—Sulphuric acid is one of the most useful chemical products employed in the manufactures and arts. Owing to its superior affinity for bases it is in daily use for the liberation of other weaker acids from their salts, hence its employment in the preparation of hydrochloric, nitric, acetic acids, &c. In dyeing, bleaching, and the manufacture of soda, sulphuric acid plays an important part, and a very useful application has been made of its effects on paper (when slightly diluted), in the preparation of *parchment paper*. Of the multifarious manufactures to which Great Britain owes her commercial prosperity, few could exist without the employment of sulphuric acid, hence enormous quantities are annually produced here, and very considerable imports of the Nordhausen acid (from the Harz Mountains, Germany) are also made.

171.—STATE IN NATURE.—Sulphuric acid is sometimes met with in certain volcanic springs. In the mineral kingdom it is largely found, in combination with various metals, in the form of *sulphates*. Sulphates are also found in the animal and vegetable kingdoms.

172.—PREPARATION.—Whether we regard it from a theoretical point of view, or from a point

is burned at high temperatures, in air or oxygen, sulphur trioxide is produced; we also have learnt that sulphur trioxide in presence of water gives rise to sulphuric acid (see 164). It might, therefore, appear that this would be a good method of preparing this body, but in practice the heat required is found to be so great, and the product so small, as to render it impracticable. But though we cannot conveniently cause sulphur to unite with the required amount of oxygen at one operation, yet by taking advantage of the attraction which sulphur dioxide has for oxygen, and its power of abstracting it from bodies containing it, we can do so in two operations, which may be made to take place simultaneously.

Let A, Fig. 18, be a glass flask, closed with a cork carrying four glass tubes, B, C, D, E. A small quantity of water is to be placed in this flask. The tube B is made to communicate with an apparatus from which sulphur dioxide is being evolved, while the tube E is connected with a bottle G, from whence a compound of nitrogen and oxygen, called *nitric oxide*, is issuing.

Nitric oxide may be considered as consisting of two atoms of nitrogen united to two atoms oxygen, as the following formula indicates:—

$$N_2'''O_2''.$$

nitric oxide as oxidising agents, none have as yet been found which possess at once the power of successively absorbing and parting with the absorbed oxygen in the manner above described.

This property enables a relatively small amount of nitric oxide to convert a large quantity of sulphur dioxide into sulphuric acid. The presence of water is absolutely necessary for the conversion of the sulphur trioxide produced into sulphuric acid, and should the supply be limited, a white crystalline compound, in which the elements of water contained in sulphuric acid are replaced by nitrogen tetroxide, is produced. This body, however, is immediately converted into sulphuric acid and nitrous anhydride when placed in contact with water. The water contained in the flask A becomes therefore gradually charged with sulphuric acid. The use of the two tubes, C and D, is to admit atmospheric air without incurring loss of the gases evolved from the two generators, F and G.

174.—In the above experiment, nitric acid, consisting of HNO_3, may be substituted for nitric oxide, for it is speedily reduced by successive steps to that state, as may be seen by the following equations:—

Nitric acid.		Sulphur dioxide.		Sulphuric acid.		Nitrogen tetroxide.
$2HNO_3$	$+$	SO_2	$=$	H_2SO_4	$+$	N_2O_4

But on meeting with a fresh supply of sulphur dioxide, nitrogen tetroxide is immediately converted into nitric oxide, thus:—

$$N_2O_4 + 2SO_2 = 2SO_3 + N_2O_2.$$

Consequently, whether we inject nitric acid or nitric oxide, the contents of the flask A are soon the same—viz., sulphur dioxide, nitrogen dioxide (nitric oxide), and atmospheric air. The round of interchanges is continuous, for as fast as the nitric oxide absorbs oxygen from the air to become tetroxide, it yields it to the sulphurous anhydride constantly supplied, which is thereby converted into sulphur trioxide, and dissolved by the water with the production of sulphuric acid.

175.—Figs. 19, 20, and 21, may serve to elucidate the means employed on the large scale to bring about these various results. A, Fig. 19, represents a large leaden chamber, divided into several communicating compartments by means of the partitions, *p, p, p, p*. Sulphur dioxide is produced in the furnace B, either by burning iron pyrites or sulphur. Directly over the space in which this burning is going on is placed a stone box or cast-iron crucible, containing materials for the production of nitric acid. Sulphurous anhydride, along with nitric acid vapour, passes from the furnace into the leaden chamber, through the short wide conduit C. Steam, from a boiler at D, is also thrown into the chamber, the floor of which is covered to the depth of a few inches with water.

A moderate current in the direction of the arrows is insured by the chimney E, which also serves to carry off the spent gases, &c. During its passage through the chamber this mixture of nitric acid, steam, and sulphur dioxide, is converted into sulphuric acid, as explained in paragraphs 173 and 174, and collects in the water on the floor of the chamber. When this has attained a certain strength, with a specific gravity of about 1·6, it is drawn off by means of the leaden pipe F. This dilute sulphuric acid is placed in large shallow leaden tanks, seen in section at Fig. 20, where it is evaporated to get rid of the excess of water. It cannot be concentrated in these tanks beyond a specific gravity of 1·72, as at that point it begins to act on and corrode the lead. At this point it is known in commerce under the name of "brown oil of vitriol." It is further concentrated by being cautiously evaporated in glass or platinum vessels (see Fig. 21) till it acquires a specific gravity of 1·854. It is then allowed to cool, and when cold drawn off by means of siphons, and stored in carboys. This is known as "double oil of vitriol."

Whatever be the exact composition of the nitrogen oxide employed to effect the oxidation of the sulphur dioxide, whether it be injected into the leaden chamber as nitric acid HNO_3, as nitrogen trioxide N_2O_3, or finally as nitrogen tetroxide N_2O_4, it is speedily deoxidised to the state of nitric oxide (N_2O_2), when the "carrying" effect begins, and the operation can proceed continuously without requiring any farther supply of nitrous compounds than that which is needed to make good the waste which takes place through the chimney E. The formation of the white crystalline body mentioned at 173 is a sign that the supply of aqueous vapour is insufficient. Binitro sulphuric anhydride, or De La Prevostaye's crystals, as this body is called, is composed of sulphur, oxygen, and nitrogen, linked together probably, as expressed by the following formula:—

$$N_2O_2 . SO_4 . SO_3.*$$

176.—As thus produced, sulphuric acid or oil of vitriol is a heavy, oily, slightly brownish liquid. This colouration is owing to the presence of charred organic matter. This commercial acid contains many impurities, which must be removed if the acid be required for analytic or other delicate processes. The usual impurities are lead, arsenic, iron, &c., and these may be removed by diluting the acid with its own weight of water, passing a current of hydrogen sulphide through it, and after repose decanting the clear liquid. This treatment removes the metals under the form of sulphides. By cautious evaporation in a platinum or glass vessel the acid may be once more brought to its highest strength, while any volatile impurities, such as nitric acid, &c., are simultaneously got rid of.

177.—Sulphuric acid unites with water to form two definite hydrates. One, having the composition of $H_2SO_4 + H_2O$, may be obtained in rhombic crystals by cooling a mixture of 86 parts pure acid and 24 of water down to 44° Fahr. Another hydrate, $H_2SO_4 + 2H_2O$, has also been obtained.

178.—When sulphuric acid is exposed to very high temperatures it is resolved into water, oxygen, and sulphur dioxide, thus:—

$$H_2SO_4 = H_2O + O + SO_2.$$

(See paragraph 86.)

178.—When certain metallic sulphates are well dried, to expel their water of crystallisation, and then placed in an earthen retort, the application of a bright red heat causes the evolution of a mixture of sulphuric acid and sulphuric anhydride, known in commerce as Nordhausen sulphuric acid. The composition of this acid may be represented as being—

$$H_2SO_4SO_3 = H_2S_2O_7.$$

The process followed in the Harz Mountains for the production of this body is the following:—Dried iron sulphate, having the composition of $Fe''S''O_4'' + H_2'O''$, is placed in a series of earthen vessels of the form represented in Fig. 22 (*a, a, a, a, a, a*), which are ranged in three tiers in a peculiarly-constructed furnace B. Wood is the fuel employed. When sufficient heat has been applied dense white fumes of the body in question begin to appear. This is the signal for attaching the receivers (*c, c, c, c, c, c*), made of the same material and shape as the retorts, only a trifle smaller. The acid condenses in these receivers, and is found in commerce under the name of "fuming" or "Nordhausen" acid. It is a viscid light brown liquid, having a specific gravity of 1·896. At 0° it solidifies, forming colourless transparent crystals. It fumes strongly in the air. Its principal uses are in the preparation of sulphur trioxide and the solution of indigo for dyeing purposes. The effect of heat on iron sulphate may be understood by the aid of the following diagram:—

2 molecules of iron sulphate	=	H_4	F_2	S_2	O_{10}
Yield by heat:—					
1 molecule of fuming acid	=	H_2		S_2	O_7
1 molecule of iron peroxide	=		Fe_2		O_3
1 molecule of hydrogen	=	H_2			
		H_4	F_2	S_2	O_{10}

179.—The following table, compiled by Dr. Ure, gives the amount of real acid, H_2SO_4, contained in oil of vitriols of different specific gravities:—

180.—Table showing the amount of sulphuric acid contained in oil of vitriols of different specific gravities, at 60° Fahr.:—

ADJUSTABLE SPANNERS AND WRENCHES.

THE improvements in the construction of adjustable spanners, wrenches, &c., recently patented by Mr. James Hosking, of Stratford, which we illustrate in the annexed engraving, are worthy of a short notice, as spanners constructed on this plan may probably be found handy by many amateur mechanics. Fig. 1 illustrates the application of the improvement to an ordinary spanner, with a sectional view of the same. In this case a fixed head on a shank of the usual length has a rectangular mouth similar to the ordinary tool, but deeper in proportion to its width between the jaws. This aperture is made sufficiently wide to take in the largest sized nut or other body the spanner is intended to operate upon, and is filled up with a number of plates or tongues T of any required thickness, such thickness being regulated so as to agree with the different sizes of nuts for which the spanner is to be used. These tongues are centred on a pin, so that they may all be turned back or out of that part of the mouth which operates on the nut into the recess at the back of the pin, so as to rest on the web F, which prevents them falling through, as shown in the section, Fig. 1. Thus, if all the tongues are turned back into the recess the mouth of the spanner will be at its largest, and may be reduced as required to take in smaller sized nuts by turning one or more of the tongues into the mouth. It will be seen that when the tongues are turned into the mouth to reduce its width, they are prevented from falling through by their corners coming in contact with the edge of the web F.

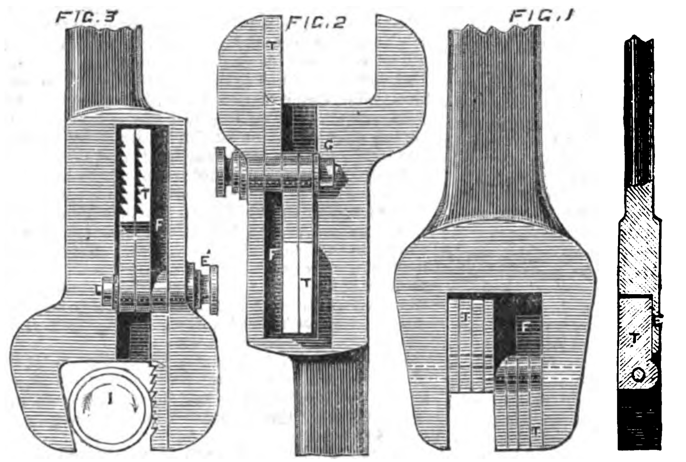

Fig. 2 shows a modified form, in which it will be observed that the mouth of the spanner is not wholly filled up with the tongues, but it is so arranged that when the whole of the tongues are turned into the mouth it will be of a size to take in and act upon the smallest sized nut it is intended for, other sized nuts being operated upon by turning one or more of the tongues back or out of the mouth. It will also be observed that in this design the pin on which the said tongues turn terminates in a screw which takes into a nut G let into a recess in one of the sides of the reserve recess F. Thus, by turning the pin by means of the thumb-stud, the nut G will be drawn against the tongues, tightening them together, and against the side of the reserve recess, and preventing them falling out, even if the spanner be turned over, thus enabling it to be used either side uppermost. The washer H is inserted to reduce friction.

Fig. 3 is a wrench, specially designed for grasping round surfaces, such as those of pipes, bars, or studs; it will also grasp oval, rectangular, or other surfaces. The action of this wrench is as follows:—I is a pipe that it is required to turn in the direction indicated by the arrow. After the

* Some chemists, while admitting that the above formula represents correctly the number of atoms of each element contained in the molecule of this compound, suppose the *arrangement* of these atoms to be different, and prefer giving the formula as being:—

$$\left\{\begin{matrix} SO_2\,(NO_2) \\ O \\ SO_2\,(NO_2) \end{matrix}\right\}$$

It would appear, however, that the constitution of this body varies, according to whether water is present in small quantity or totally absent. In the latter case the composition given above is probably the correct one; but if water be present, an intermediate body is formed, the composition of which is $SO_2\left\{\begin{matrix} NO_2 \\ HO \end{matrix}\right.$, or what amounts to the same, $\left.\begin{matrix} NO \\ H \end{matrix}\right\} SO_4$.

tongues have been turned back into the reserve recess, F, the mouth of the wrench is placed upon or over the pipe, allowing the smooth inclined surface to rest upon it, and then after turning as many of the tongues into the mouth as there is room for, the pipe will be jammed by drawing back the wrench, and can be turned as desired.

REPORT OF THE COMMITTEE ON THE PATENT LAWS.

THE Report of the Select Committee appointed to inquire into the laws and practice, and the effect, of grants of letters patent for inventions, was issued on Wednesday week. The committee contend that the law and its administration are defective, and they recommend the following alterations of the laws:—

That protection be not granted to any invention, except on the report of a competent person that certain conditions are fulfilled, those conditions being that protection for a limited period, and dating back to the time at which it is applied for, should only be granted for an invention on its nature, and particular points of novelty, being clearly described in a provisional specification, and upon the report of a competent authority that such invention, so far as can be ascertained by such authority, is new, and is a manufacture within the meaning of the law.

That no warrants for sealing letters patent be issued until the following conditions are fulfilled:—That letters patent ought not to be granted for any invention so protected until the provisional specification has been open to inspection, nor until a complete specification has been deposited, fully describing the means of carrying it into effect, and such complete specification has been found by the same authority to accord in all essential particulars with the description of the invention in the provisional specification.

That in the case of several concurrent applications for a patent of the same invention, the patent be granted to the first applicant, unless it be shown that he is not the first inventor.

That all trials of patent causes should be before a judge, with the assistance of skilled advisers (who may be Commissioners of Patents), and, as a rule, without a jury, but with power for the court to order a jury for the ascertainment of facts in exceptional cases requiring the same.

That the commissioners be reinforced by the appointment of competent persons of legal, scientific, and technical experience, whose time is not occupied with other engagements to such an extent as to prevent their giving full attention to such administration.

That the commissioners should make rules, relegating to some of their body, together with competent assistants, amongst other duties, that of ascertaining as to every invention for which a patent is sought to be obtained, whether it is properly the subject matter of a patent; whether its nature, and the particular points of novelty, have been clearly described in a provisional specification; and whether, so far as can be ascertained by them, it is a new invention; and, as to the complete specification, whether it fully describes the means of carrying the invention into effect, and accords in all essential particulars with the description thereof in the provisional specification.

That all letters patent should contain the following conditions not hitherto usually inserted therein, viz.:— That the manufacture be carried into effective operation within a reasonable time within the United Kingdom by the patentee or his licensees so as to supply the demand therefor on reasonable terms, and that licenses be granted by him to competent persons on fair conditions, such conditions, as well as the fact of competency, to be determined in the event of disagreement by the commissioners, due regard being had in such determination to the exigencies of foreign competition.

That besides the assistance afforded to intending patentees by the examination of their specifications, and by the reference library of the Patent Office, more satisfactory indices and abridgements of specifications be provided, and more particularly that the practice of accepting, without control or revision, the abridgements prepared by the patentees themselves be abandoned.

That the court or judges having discretion in patent litigation should avail themselves of the assistance of the commissioners for the better definition and limitation of the matters in dispute in respect of particulars of breaches and of objections respectively.

That in all future appointments of officers concerned in the administration of the patent law, remuneration by fees should (as it has been in the recent appointment of her Majesty's Solicitor-General) be discontinued.

The committee are of opinion that there should be an assimilation in the law and practice in regard to inventions amongst the various civilised countries of the world, and that her Majesty's Government be requested to inquire of foreign and colonial Governments how far they are ready to concur in international arrangements in relation thereto.

A GIANT PLANET.*

[From the *Cornhill Magazine*.]

THE planet Jupiter has been selected even by astronomers of repute as an abode of pleasantness, a sort of paradise among the planet-worlds. There exists, we are told, in that distant world, a perennial spring—"A striking display of the beneficence of the Creator," says Admiral Smyth; "for the Jovian year contains twelve mundane years; and if there were a proportionate length of winter, that cold season would be three of the earthly years in length and tend to the destruction of vegetable life."

Even those who have denied that Jupiter can be the abode of life, and have formed altogether unfavourable ideas of his condition, have pictured him, nevertheless, as the scene of continual calm, though the calm is, according to their view, the calm of gloom and desolation. They recognise in Jupiter an eternal winter rather than a perpetual spring. Whewell, for example, in that once famous work "The Plurality of Worlds," maintained that if living creatures exist at all in Jupiter, they must be wretched gelatinous monsters, languidly floating about in icy seas. According to him Jupiter is but a great globe of ice and water, with perhaps a cindery nucleus—a glacial planet, with no more vitality in it than an iceberg.

But when we begin to examine the records of observers, and to consider them with due reference to the vast proportions of the planet, we recognise the fact that whatever may be Jupiter's unfitness to be the abode of life, it is not of an excess of stillness that his inhabitants (if he have any) can justly make complaint. Setting aside the enormous activity of which the mere existence of the belts affords evidence, and even regarding such phenomena as the formation of a disappearance of a new belt in two or three hours as merely indicative of heavy rainfalls or of the condensation of large masses of invisible aqueous vapour into clouds—there have been signs on more occasions than one of Jovian hurricanes blowing persistently for several weeks together at a rate compared with which the velocity of our fiercest tornadoes seems utterly insignificant. During the year 1860, a rift in one of the Jovian cloud belts behaved in such a way as to demonstrate the startling fact that a hurricane was raging over an extent of Jovian territory equalling the whole surface of our earth, at a rate of fully 150 miles per hour. It is not too much to say that a hurricane of like velocity on our earth would destroy every building in the territory over which it raged, would uproot the mightiest forest trees, and would cause, in fact, universal desolation. At sea no ship that man ever made could withstand the fury of such a storm for a single minute. And yet this tremendous Jovian hurricane continued to rage with unabated fury for at least six weeks, or for fully one hundred Jovian days.

But during the last two or three years a change of so remarkable a nature has passed over Jupiter as to imply the existence of forces even more energetic than those at work in producing atmospheric changes.

In the autumn of 1870, Mr. Browning (the eminent optician and observer) called the attention of astronomers to the fact that the great equatorial zone, usually, as we have said, of a creamy white colour, had assumed a decidedly orange tint. At the same time it had become much less uniform in outline, and sundry peculiarities in its appearance could be recognised, which have been severally compared to port-holes, pipe-bowls and stems, oval mouldings, and other objects of an unocelestial nature. Without entering into descriptions which could only be rendered intelligible by means of a series of elaborate illustrations, let it suffice to say that the bright edges of the belts bordering on this ruddy equatorial zone seemed to be frayed and torn like the edges of storm clouds, and that the knots and projections thus formed often extended so far upon the great orange zone, from both sides, as almost to break it up into separate parts.

Now, without inquiring into the particular form of action to which these remarkable changes were due, we can see at once that they implied processes of extreme energy. For, every one of the projections and knots, the seeming frayed edges of narrow cloud-streaks, had, in reality, an extent exceeding the largest of our terrestrial countries. Yet their aspect—and, indeed, the whole aspect of the ruddy belt, whose extent far exceeded the whole surface of our earth—changed obviously from night to night.

Strangely enough, these interesting observations, though they were presently confirmed by several well-known students of the heavens, did not attract that full attention from the senior astronomers of the day which they appeared to merit. Several, indeed, of our leading astronomers were disposed to deny that anything unusual was in progress, though none asserted definitely that they based this opinion on a careful re-examination of the planet's face. But quite recently one of the most eminent of our modern observers—Mr. Lassell, lately president of the Royal Astronomical Society—(having been led to observe the planet by the fact that certain phenomena of interest in connection with the satellite system are now in progress), found his attention attracted by the marvellous beauty of the colours presented by Jupiter's belts. After describing the appearances he had intended to observe in the first instance, he proceeds. "But this was not the phenomenon which struck me most in this rare and exquisite view of Jupiter. I must acknowledge that I have hitherto been inclined to think that there might be some exaggeration in the coloured views I have lately seen of the planet; but this property of the disc, in the view I am describing, was so unmistakable that my scepticism is at last beginning to yield." Nor will this statement be thought to express more than the truth, when we add that in the picture accompanying his paper, Mr. Lassell presented the equatorial zone as brown-orange, and three neighbouring dark zones as purple; one of the intermediate light belts being pictured as of a light olive-green.

Let us compare these observations made in our brumous latitudes with those effected by Father Secchi with the fine equatorial of the Roman Observatory. "During the fine evenings of this month," he wrote last February, "Jupiter has presented a wonderful aspect. The equatorial band, of a very pronounced rose colour, was strewn with a large number of yellowish clouds. Above and below this band, there were many very fine zones, with others strongly marked and narrow, which resembled stretched threads. The blue and yellow colours formed a remarkable contrast with the red zone, a contrast doubtless increased by a little illusion. The surface of the planet is actually so different from that which I have formerly seen, that there is room for the study of the planet's meteorology."

It appears to us that when these remarkable changes are considered in combination with the circumstance that on *à priori* grounds we should expect the sun to have very little influence on the condition of the planet's atmosphere, the idea cannot but be suggested that the chief source of all this energy resides in the planet itself. The idea may seem startling at a first view, but when once entertained, many arguments will be found to present themselves in its favour.

For instance, it does not seem to have been noticed heretofore, as a very remarkable circumstance, if the Jovian belts are sun-raised, that they pass round to the nocturnal half of Jupiter and reappear again, with the same general features as before, and this often for weeks at a stretch. Even that remarkable feature whose changes led to the conclusion that mighty hurricanes were in progress, yet changed continuously and regularly during the Jovian nights as well as during the Jovian days, for one hundred such days in succession. This is perfectly intelligible if the seat of disturbance is in the planet itself, but it is perfectly inexplicable (as it seems to us) if the sun occasions all these meteorological changes in Jupiter, as he occasions all the changes which take place in our earth's atmosphere. The alternation of day and night, which is one of the most potent of all the circumstances affecting the earth's meteorological condition, appears to have no effect whatever on the condition of Jupiter's atmosphere!

Now, as respects the alternation of summer and winter, we can form no satisfactory opinion in Jupiter's case, because he has no seasons worth mentioning. For instance, in latitudes on Jupiter corresponding to our own, the difference between extreme winter and extreme summer corresponds to the difference between the warmth on March 12 and March 28, or between the warmth on September 15 and on September 31. Yet we are not without evidence as to seasonal meteorological effects in the case of the sun's outer family of planets. Saturn, a belted planet like Jupiter, and in all other respects resembling him so far as telescopic study can be trusted, has seasons even more markedly contrasted than those on our own earth. We see now one pole now another bowed towards us, and his equatorial zone is curved now downwards now upwards, so as to form two half ovals (at these opposite seasons), which, taken together, would make an ellipse about half as broad as it is long. As no less than fourteen years and a half separate the Saturnian summer and winter, we might fairly expect that the sun's action would have time to exert itself. In particular, we might fairly expect the great equatorial zone to be displaced; for our terrestrial zone of calms or "doldrums" travels north and south of the equator as the sun shifts northwards and southwards of the celestial equator, accomplishing in this way a range of no less than 3,000 miles. But the Saturnian equatorial zone is

* In a leading article (Saturday, May 4) the *Spectator* remarks that readers of Mr. Proctor's "Other Worlds" will entertain little question that the above essay on Jupiter is from his pen. The arguments in the essay are, indeed, for the most part new, relating as they do to recent observations; but the theory in support of which they are advanced, is that which Mr. Proctor advocated in the first edition of "Other Worlds." It may be added that in the second edition of that work, other arguments not mentioned in the first, or in the above article, are adduced in support of Mr. Proctor's theory. In particular, a remarkable phenomenon observed simultaneously by three astronomers (Smyth, Maclear, and Pearson)—viz., the appearance of a satellite outside Jupiter's disc ten minutes after its transit had commenced, finds an explanation if we accept the theory advocated in the above article.

not displaced at all during the long Saturnian year. It remains always persistently equatorial! Nothing could be more easy than the detection of its change of place if it followed the sun; yet no observer has ever suspected the slightest degree of systematic change corresponding with the changes of the Saturnian seasons. Or, rather, it is absolutely certain that no such change takes place.

It appears, then, that night and day, and summer and winter, are alike without influence on the Jovian and Saturnian cloud zones. Can it reasonably be questioned that, this being the case, we must look for the origin of the cloud zones in these planets themselves, and not in the solar orb, whose action must needs be largely influenced by the alternation of night and day and of the seasons?

But further, we find that a circumstance which had seemed perplexing when we compared the Jovian belts with terrestrial trade-wind zones, finds an explanation at once when we regard the belts as due to some form of action exerted by the planet itself. For let us suppose that streams of vapour are poured upwards to vast heights and with great velocity from the true surface of the planet. Then such streams starting from the surface with the rotational movement there prevailing, would be carried to regions where (owing to increase of distance from the centre) the movement due to the planet's rotation would be greater. They would thus be caught by the more swiftly-moving upper air and carried forwards, the *modus operandi* being the reverse of that observed when an engine leaves a trail of condensed steam behind it; or, rather, it may be compared to what would take place if a steam-engine were moving in the same direction as the wind but less swiftly, so that steam-clouds would be carried in front instead of behind.

Now, heat is the only form of force which could account for the formation of the enormous masses of cloud suspended in the atmosphere of Jupiter. And it seems difficult to conceive that the clouds could be maintained at a great height above the real surface of the planet unless that surface were intensely hot—as hot, perhaps, as red-hot iron. If we supposed this to be the case we should find at once an explanation of the ruddy aspect of the dark belts. Nor would the change of the great equatorial belt from white to red imply more than that, owing to some unknown cause, clouds had not formed during the last two years over the planet's equatorial zone, or, having formed, had been dispersed in some way. We need not even imagine a complete dispersion, since the best telescopes—and notably Mr. Buckingham's fine 21in. refractor—have shown always a multitude of minute cloud-like objects over the ruddy equatorial zone.

But the idea of a red-hot planet, or of a planet partially red-hot, will appear at a first view too bizarre to be entertained even for a moment. We have been so accustomed to regard Jupiter and Saturn as other worlds, that the mind is disposed to reject the conception that they can be so intensely heated as to be utterly unfit to be the abode of living creatures.

This unwillingness to accept startling ideas is not o be altogether reprehended, since it prevents the mind from forming rash and baseless speculations. Yet we must not suffer this mental habitude, excellent though it may be in its proper place, to interfere with the admission of conclusions which seem based on trustworthy evidence. Let us, then, inquire whether the startling hypothesis to which we have been led by the study of observed facts may not be found to be in agreement with other facts not yet considered.

It will be obvious that if the real globe of Jupiter is thus intensely heated, a portion of the planet's light must be inherent. Therefore, we might expect that the planet would shine somewhat more brightly than a globe of equal size and similarly placed, shining merely by reflecting the sun's light. Now, two series of good observations have been made upon the luminosity of Jupiter. One was made by the late Professor Bond, of America, the other by Dr. Zöllner, of Germany. According to the former, Jupiter shines more brightly than he would if he reflected the whole of the light falling upon him! According to the latter, and more trustworthy series, Jupiter does not, indeed, shine quite so brightly as Professor Bond supposed, but the planet yet shines *three times* as brightly as a globe of equal size would shine, if similarly placed, but constituted like Mars, and *four times* as brightly as such a globe would shine if constituted like our moon. Jupiter shines, in fact, very nearly as brightly as though he were constituted like one of our terrestrial clouds!

This result is highly significant. If Jupiter showed no belts, and shone with a pure white colour, we could explain it at once by simply regarding Jupiter as wholly cloud-covered or snow-covered (for snow and cloud shine with nearly equal lustre when similarly illuminated). But the great dark belts which occupy so large a proportion of the planet's disc altogether negative this supposition. We seem compelled to believe that some considerable portion of the planet's lustre is inherent.

Let us, however, proceed carefully here. We have to inquire first how far Zöllner's results can be trusted, and secondly, whether they are corroborated by any independent evidence. Now Zöllner carefully estimated the weight of his observations,—we may say he jealously estimated their weight, for it must be remembered that he was in no way interested in securing a greater or less result, while he was greatly interested in so stating the value of his results that those who might succeed him in the inquiry should not detect any serious error in his estimate. But his opinion of the probable degree of error in his observations was such as scarcely to affect to an appreciable extent the statements we have made above. Taking Zöllner's lowest estimate of Jupiter's brightness, that statement remains appreciably correct.

And next as to corroborative evidence.

It happens that we have a very delicate means of measuring the degree of Jupiter's luminosity, as compared with that of other orbs similarly placed, for his satellites pass across his face, and nothing can be easier than to observe whether they appear darker or brighter than his surface.

It was an observation such as this which Mr. Lassell had made on the night when he noticed the ruddiness of Jupiter's great medial belt. By a singular chance Father Secchi made a similar observation during *his* researches, and the reader will see, when we have quoted the narratives of both these observers, that the comparative darkness of all four satellites will have been established. "The fourth satellite," says Lassell, "has begun again for a season to cross the planet's disc, and I have looked out for opportunities of observing its passages, and was favoured on the night of the 30th December last by witnessing a part of its passage under circumstances more than usually propitious. On its first entrance it was scarcely to be distinguished from the edge, not appearing at all as the others do, as a round bright spot. As it advanced it grew gradually manifestly darker than the surface of the planet, and by the time it had advanced a fourth of the way across it had become a very dark, if not a *black*, spot—so dark, indeed, that if I had looked at Jupiter without knowing anything of the positions of his satellites, I should have said that a *shadow* (of a satellite) was passing. I remember having seen the like phenomenon many years ago; but my impression is that I had never seen the disc of the satellite so near to absolute blackness before. Of course, it is only by contrast that it can possibly so appear; and we have in this fact a striking proof of the exceeding brilliancy of the surface of the planet. In the same way the solar spots, if not surrounded by the marvellous splendour of the sun's surface, would doubtless appear as brilliant objects."

Next let us hear Secchi's account. "On the evening of February 3rd," he says, "I observed the transit of the third satellite and that of its shadow. The satellite seemed almost black when it was upon the middle of the planet's disc, and notably smaller than its shadow, which was visible at the same time; one would have estimated it at only one-half. In approaching the edge the satellite disappeared, and reappeared soon after, close by the edge, but as a bright point. This fact is not a new one for the other satellites, but for the third it is unique. This result shows also the great difference of luminosity at the centre and near the edge of the planet, a difference already confirmed by photography."

It is hardly necessary to point out how strikingly these facts illustrate and confirm Dr. Zöllner's observations. But they also supply fresh evidence of a very interesting nature.

Although a part of the difference dwelt on in Secchi's closing words may be ascribed to the oblique incidence of the light near the planet's edge, yet it does not appear to us that the whole difference can be thus explained. A difference so great that a satellite appears as a bright point close by the planet's edge, and almost black near the middle of the disc, suggests that the light near the edge is not reinforced by the inherent luminosity of our theory, that luminosity adding only to the brightness of the central parts of the disc. We would not insist too strongly on this inference, because the darkening due to oblique incidence is, under certain circumstances, very obvious to direct observation. But it seems to us that a portion of the difference should be referred to the inherent luminosity of the central parts of the disc. This being admitted, it would follow that the real solid globe of the planet is much smaller than the globe measured by astronomers; and that, therefore, instead of that amazingly small density which is so perplexing a feature of the planet's physical condition, Jupiter's globe may have a density equalling or exceeding that of the earth.

And after all, let us remember that the theory that Jupiter is an intensely heated globe—a theory to which we have been led by the consideration of many observed facts, and which in its turn suggests very satisfactory explanations of other observed facts — would merely show that, as Jupiter and Saturn hold an intermediate position between the sun and the minor planets in respect of size, so those giant orbs hold a corresponding position in respect of inherent heat. Roughly speaking, the earth is 8,000 miles, the sun 840,000 miles, in diameter, and Jupiter, with his diameter of 82,000 miles, comes midway between these orbs. Now, the sun is at a white heat, and the earth gives out only what is called obscure heat; and if Jupiter's globe is at a red heat, he again comes midway between the sun and the earth.

We should be led by the theory here maintained to regard the major planets which travel outside the zone of asteroids as in a sense secondary suns. So viewed, they could not be regarded as orbs fit for the support of living creatures. Yet, as each of them is the centre of a scheme of dependent worlds, of dimensions large enough to supply room for many millions of living creatures, we should not merely find a raison d'être for the outer planets, but we should be far better able to explain their purpose in the scheme of creation than on any theory hitherto put forward respecting them. Jupiter as an abode of life is a source of wonder and perplexity, and his satellites seem scarcely to serve any useful purpose. He appears as a bleak and desolate dwelling-place, and they together supply him with scarcely a twentieth part of the light which we receive from our moon at full. But regarding Jupiter as a miniature sun, not indeed possessing any large degree of inherent lustre, but emitting a considerable quantity of heat, we recognise in him the fitting ruler of a scheme of subordinate orbs, whose inhabitants would require the heat which he affords to eke out the small supply which they receive directly from the sun. The Saturnian system, again, is no longer mysterious when thus viewed. The strange problem presented by the rings, which actually conceal the sun from immense regions of the planet for years together in the very heart of the winter of these regions, is satisfactorily solved when the Saturnian satellites are regarded as the abodes of life, and Saturn himself as the source of a considerable proportion of their heat-supply. We do not say that, in thus exhibiting the Jovian and Saturnian systems in a manner which accords with our ideas respecting the laws of life in the universe, we have given irrefragable testimony in favour of our theory. That theory must stand or fall according to the evidence in its favour or against it. But so long as men believe that there is design in the scheme of the universe, they will be readier to accept conclusions which exhibit at once the major planets and their satellites as occupying an intelligible position in that scheme, than views which leave the satellites unaccounted for, and present the giant planets themselves as very questionable abodes for any known orders of living creatures.

THE PREPARATION OF TELEGRAPH POLES.

WHEN the telegraph system was transferred to the Government, arrangements were made with various contractors for providing the trees necessary for supplying the demand of the prospective increase of telegraph communication. In the north of Ireland the preparation of the trees which are to serve as telegraph poles is under the superintendence of a Government official, and a large staff of workmen are engaged in the process. The manufactory, as it may be termed, is situated in the middle of an extensive field, and consists, in the first place, of a quadrangular structure; four strong poles, some 60ft. in height, forming the angular points. Within 6ft. of the top is a platform, on which are two or three vats, each capable of containing 200 gallons. In the bottom portion of this structure are pumps for the purpose of forcing a liquid, chemically prepared, into the vessels above. The principal ingredient, besides water, is sulphate of copper. From these vessels two systems of tubing are carried downwards to the ground, and continued along the surface forward to a distance of a couple of hundred yards, in a direction at right angles to the front of the rectangular structure already mentioned. Raised at a slight elevation from the ground, and placed at right angles to these tubes, lie the trees to be operated upon, with their thicker ends inwards; at intervals of 12in. or 15in. in this horizontal tubing is placed a series of taps, each connected by a short indiarubber tube to the end of a tree, to which it is secured by means of cramps and screws, and rendered water-tight by a sort of nozzle. By means of cocks at the upper end of the horizontal piping the solution in the vats is permitted to descend. The pressure exerted from above forces it into the pipes through the indiarubber tubing and into the trees, traversing them in the direction of their fibre. In a short time the sap and a portion of the chemical solution are seen to ooze slowly from the smaller end of the tree, when it falls into a sort of wooden gutter, inclined at such an angle as causes it to run back to a cistern near to where it had been originally prepared. After undergoing some filtration here it is placed along with the yet unused liquid, and again performs the circuit of the vats above and trees below. The time necessary for the complete saturation of the trees varies from ten days to three weeks, according to their quality and age. In this way an application of the principles of hydrodynamics, combined with what is little more than a mechanical chemical knowledge, enables the manufacturer to provide poles for telegraphic purposes which will resist the action of the atmosphere for at least five times as long as the telegraph poles formerly in use.

SAND-PAPERING MACHINE.

WE this week illustrate a machine designed for facilitating the sand-papering of flat surfaces, which has been recently patented by Mr. Joseph Barker, of Chicago. It consists in principle of a horizontal wheel, formed with a series of blocks on which the glass-paper is secured, these blocks being supported on the arms or spokes and rim of a wheel in such a manner that the underside or working face of the wheel is furnished with what the inventor terms "tangent furrows," the object of which is to remove the dust by permitting a current of air to pass through the furrows. The arrangement will be readily understood from the illustration, in which Fig. 1 is a plan and Fig. 2 a longitudinal section. The upper surface of the wheel is shown in Fig. 1, and consists of a centre, through which the air-holes P are formed, of a series of arms or spokes *g* connected to the rim K. It is also provided with bars or levers L, the inner ends of which are attached to the centre, and the outer ends are secured to the rim K by set screws. The blocks N, on which the sand-paper is secured, are made to fit between the spokes *g*, the centre, and the rim K, and are clamped in position by the levers L, by means of the set screws at their outer ends. The rim K and the spokes *g* are provided with bevelled flanges corresponding to the shape of the under side of the blocks, by which means the lower surface of the blocks is kept below the under surface of the rim, the spokes, and the centre of the wheel, as shown in Figs. 2, 3, and 4, the latter, also, showing the formation of the furrows for the removal of the dust. Sand-paper (*f*, Figs. 3 and 4) of the requisite shape being laid on the blocks N, covering the face and the bevelled edges, the blocks are then placed in the wheel and clamped down by the levers or bars L, which are secured by the set screws to the rim K, the sand-paper being thus firmly held between the bevelled flanges of the spokes *g* and the rim K and the corresponding edges of the blocks. The surface of the sand-paper thus projects below the framework of the wheel, leaving the furrows formed by the spokes *g* in connection with the air-holes P in the centre, so that when the wheel is in motion a current of air passes through and carries away the dust, while the glass-paper, not being fastened to the blocks, is readily removed when worn out, though it is claimed that it lasts much longer than is usual under the arrangements in use at present.

The method of carrying the wood to be finished under the wheel will be understood on reference to Fig. 2, where B is a table provided with rollers R, J J being two rollers supported above the two end lower ones. The work W to be sand-papered is fed in as shown, and is supported on the rollers, R, which have bearings in blocks so mounted on rubber as to yield to a slight difference in thickness of the stuff to be finished. To accommodate greater differences the table B is made to slide on inclined planes *a a*, so that when either of the hand wheels T is turned, the distance between the rollers R and the sand-paper wheel can be regulated to suit the thickness of the articles to be operated on. For this purpose the table is connected by a rod to a block working on the screw *c*. A hopper is provided underneath at E to receive the dust. A in Figs. 1 and 2 shows the position of standards for supporting cross-beams through which the vertical shaft of the wheel passes to the driving pulley, as shown in Fig. 2. The machine appears to be an improvement on the ordinary discs used for sand-papering, and the principle on which it is constructed may possibly be found available for other purposes.

PHOTOGRAPHY FOR THE UNINITIATED*.

(*Continued from p.* 191.)

THE albumen paper, having fully dried after silvering, has now to be fumed with ammonia. This operation should be conducted in a room distant from that in which you may be performing the negative-making process, otherwise, the fumes may raise "old scratch" with that part of your operations. In handling the liq. ammon. conc., care should be exercised, as its great strength will, if too freely inhaled, give you much physical inconvenience and suffering, even should it not dangerously affect you. The bottle should always be kept very tightly stoppered, and in a cool place. The stopper, when removed should be pointed away from you, as the force gained by the confined gas often ejects it with great violence; a disregard of this precaution has led to most serious injuries. So much for my lecture. Now let's fume the paper.

Provide a box, some old case, or large old trunk; if the last stand on end so that the lid or cover may be easily opened and closed; on each side, a few inches from top, nail a narrow strip of wood, so that upon such you can easily lay other strips of wood, stretching across the trunk or box, to which the dried sensitised albumen paper can be fastened by a pin in one corner. When you have so fixed these strips of wood, with paper fastened thereto, pour into a saucer or flat dish an ounce or two of the ammonia, and close the door. The dish should be placed upon the bottom of the trunk or box, and at least 6in. (better twelve) below the lower corners of the paper. The paper must be allowed to hang in the fumes of ammonia for about ten minutes, and must be well opened to allow free contact with all portions of the silvered surface. Upon opening the door, first remove the dish, being careful not to inhale the fumes too freely.

The paper is now ready for printing, which operation, as you know, simply consists in placing its silvered side next to the film side of the negative, and exposing, while so held, to the action of light. No general rule can be given as to how long to allow this action of light to continue. This is alone to be governed by the quality of the light and the character of the negative. Most generally the best prints are those made from what are known as thin or weak negatives, full of detail, and which are printed either in diffused light, or shielded (if printed in the sun) by tissue paper. After all your paper has been printed, you have the various operations of toning, fixing, washing, &c., to which we will now proceed.

Before toning, you will need to wash the prints for about half an hour in at least three changes of water, or until the milkiness produced by the free nitrate of silver is no longer noticeable. This water should be saved by throwing into a tub, where it, with many other of the washings of your various processes, can be treated with salt, and the resulting chloride of silver utilised. While our prints are washing, the toning-bath can be made.

I do not intend to give you but one formula; it is a good one, in my hands quite good enough:—Water, 32 fluid ounces; chloride of gold, $\frac{1}{4}$ grain to ounce; acetate of soda, 64 grains; sal. soda solution, enough to make the bath just alkaline.

If you use the ordinary gold, which you will find with the dealers, it may be that more will be required than $\frac{1}{4}$ of a grain to each ounce of water. It is often very poor, as photographers are not unlike other people: they too often buy that which is lowest in first cost, not considering that the highest priced is most often the best and most carefully manufactured. The bottles of gold referred to are supposed to contain, I believe, 15 grains, which is, probably, somewhere about half gold and half salt. Procure a bottle, in which measure 60 fluid drachms of water ($7\frac{1}{2}$ fluid ounces), remove the cork from a 15-grain bottle of gold, and put gold, bottle, and all, into the water; you now have a solution of gold of $\frac{1}{4}$ of a grain of gold to each fluid drachm. Eight fluid drachms (1oz.) of this would then be the proportion to add to your 32oz. of water intended for the toning bath.

One grain of gold is enough for each sheet of paper to be toned, so that if you know how many sheets of paper you have printed, you can always estimate how much toning solution you should make up. It is important that the amount of gold should be in proportions given; if more is used, the prints tone faster; if too much is used, the action is likely to be irregular; if much less, the operation is tedious; if too little, the prints lack richness, and lose rapidly in the subsequent fixing operation. The sal. soda solution can be made and kept for use of about 5 grains of sal. soda to an ounce of water. This must be added to the bath cautiously, and carefully tested with litmus paper upon each addition; if too much is added, the prints are flat, dull, wanting in vigeur; if too little, the action of the bath is irregular and slow. This bath solution should stand fully half an hour before use, and should be of about 80° to 90° Fahrenheit. But few prints should be placed in it at one time, so that you can closely watch the changes, and from ir, when toned to your liking, at once remove them to a dish of clean water.

No rule for toning can be given, for each print depends much for its tone upon the quality of the negative; some may be pushed to a rich purple red; others never would reach that point, but would become flat, and be over-toned; therefore I will not attempt to direct in a matter in which experience alone can teach. I willl only say that it is better to be on the side of under-toning than to push so far as to over-tone.

After careful washing in several changes of water, proceed to fix in a bath of soda as follows:—Water, 8oz.; hyposulphite of soda, 1oz. In this be careful not to place so many that they become matted together, and keep them moving, so that the solvent action of the soda may have an opportunity to perform its part. Ten to fifteen minutes will be required to properly "fix" your prints, after which place them in water, which should be changed at least a dozen times, and in which they should all night, and be treated with two or three more changes in the morning before you hang them up to dry. If possible, a stream of water should pass through them; with this the washing can be well done in three or four hours.

In either of the operations of toning, fixing, or washing, care must be taken to prevent the matti[ng]

* From the American *Photographic Times.*

together of the prints, otherwise the chemical changes of toning and fixing will be irregularly conducted, the results of which will be miserable work. The final washing is also of the greatest importance, for upon it largely depends the permanence of your prints.

With a few general remarks I will close this letter. In the summer, reduce strength of silvering solution, or float a shorter time. A freshly albumenised paper requires less time for silvering than old and hard dried paper, and is, consequently, more liable to render the solution cloudy. Paper a long time albumenised is often repellent to the solution of silver, such as standing out upon it when hung up to drain like the moisture on a window-pane. This can be remedied by rubbing over the face of the paper with a pad of cotton, to absorb the oily surface, before silvering.

A print, before "fixing" in hypo., presents, when held to a strong light, a mottled appearance in its white parts or high-lights. When properly "fixed" and examined as before, this mottling has gone, and only the even grains of the paper is seen. I have thought at times that the addition of about five per cent. of alcohol to the hypo. solution was of benefit; yet am scarcely prepared to assert that it is of any material value.

We have now passed hastily over the whole subject of negative making by the "wet" process, and the production of prints from the same. I have aimed to write plainly, and have tried to avoid confusion by giving but few formulæ. If I have been at all successful in making a somewhat intricate science more plain than it was before, or in giving any hints of value, my purpose has been accomplished.

In practising our beautiful art, allow me to advise you never to be too hasty in making changes in formulæ which work well in your hands; they are generally less to blame for any poor work you may make than you are. Brains, patience, cleanliness, and system, with almost any of the thousands of formulæ published, will give good work. In formulæ there is but little practical difference. In the men who work them the difference is greater than any words of mine can express.

AN IMPROVED BLOWPIPE.

THE following description of a simple method of constructing a useful form of blowpipe is given by Messrs. Arnim, Junge, and Mitzopulos, of Freiburg:—All workers with the blowpipe are well aware how much the work is facilitated by a good blowing apparatus. In qualitative operations it can be dispensed with, but there are certain assays, such as concentrating cupelations for poor silver ores, which cannot be carried on without a blower, save with great exertion. For this reason, nearly every one who has quantitative assays to make provides himself with a blowing apparatus. The ordinary blowing apparatus consists of three parts, the caoutchouc bellows, the regulator, and the stand for the nozzle. The part which most easily gets out of repair is the caoutchouc regulator, for the operator, looking at his assay, often does not perceive that the regulator is too much stretched by the blast; the consequence is that the regulator often bursts. When we recollect that such regulators are not to be had everywhere, and that a reserve stock is often useless, from the caoutchouc getting hard, it becomes important to find a substitute which will give as regular a blast, and can be made of a more lasting material. The regulator designed by the inventors gives a perfectly constant blast, which can be used either for the oxidising or the reducing flame, and after numerous trials it is found to be in no way inferior to the caoutchouc regulator; at the same time it is so simple that it can be constructed with great ease and in a very short time. The arrangement is as follows:—A common wide-mouthed bottle is carefully fitted with a caoutchouc cork bored with two holes, into each of which passes a piece of glass tube bent at a right angle. On to one of these tubes is slipped the caoutchouc tube coming from an ordinary caoutchouc bellows, whilst the other is put in communication with the blowpipe nozzle by means of four pieces of caoutchouc tubing joined by three pieces of glass tube, drawn to a fine point at each end. This forms the main peculiarity of the arrangement. When air is forced into the bottle by the blower in jerks, it finds a difficulty in escaping as fast as it comes in, on account of the six fine openings in the glass tubes that it has to pass through on its way from the bottle to the nozzle, and it thus acquires a certain pressure in the bottle and flows out towards the nozzle as a regular blast. The bottle may be about 6in. high by 3¼in. wide, with a neck 1¼in. diameter; but of course the dimensions are of no great importance. On the whole, a somewhat large bottle is better than a small one. The pieces of glass tubing we use are 2in. long by ¼in. in diameter. The apparatus will be stronger if instead of a glass bottle a tin cylinder is used, about 4in. high by 2in. diameter, with two tin tubes opening into its top. Small metal cylinders, with a fine hole at each end, may be used instead of the little glass tubes. A blowing apparatus constructed in this manner will deliver a perfectly regular blast, and will be of practical interest to those who are thinking of working in places where it is difficult or impossible to repair the ordinary instruments.

ON CERTAIN PHENOMENA ASSOCIATED WITH A HYDROGEN FLAME.*

PHENOMENA of much interest, and possibly of future usefulness, are associated with the combustion of ordinary hydrogen.

1. To study these phenomena free from disturbing causes three things should be attended to, although the effects to be described can be obtained without any special precaution. (1) The gas must be stored and purified in the ordinary way—namely, by passing into a gas-holder through a solution of potash, and then through a solution of perchloride of mercury or nitrate of silver. (2) From the holder the gas must be led through red or black indiarubber tubing to a platinum, or better, a steatite jet. (3) And then the gas should be burnt in a perfectly dark room, and amid calm and dustless air.

2. In this way the flame gives a faint reddish brown colour, invisible in bright daylight. Issuing from a narrow jet in a dark room, a stream of luminosity, more than six times the length of the flame, is seen to stretch upward from the burning hydrogen. This weird appearance is probably caused by the swifter flow of the particles of gas in the centre of the tube. The central particles as they shoot upward are protected awhile by their neighbours; metaphorically, they are hindered from entering the fiery ordeal which dooms them finally to a watery grave. Dr. Tyndall has shown that the radiation from burning hydrogen is hugely ultra-red, and moreover, that it has not the quality of the radiation from an elementary body like hydrogen, but practically is found to be the radiation from molecules of incandescent steam. So that, except at its base, a hydrogen flame is a hollow stream of glowing water raised to a prodigious heat.

3. Bringing the flame into contact with solid bodies, in many cases phosphorescent effects are produced. Thus, allowing the flame to play for a moment on sand-paper and then promptly extinguishing the gas, a vivid green phosphorescence remains for some seconds. The appearance is a beautiful one, as a luminous and perfect section of the hollow flame is depicted. Similar phosphorescence is produced by the flame on white writing paper, or on marble, or chalk, or granite, or gypsum, &c. But no such effect is produced by coal gas, or olefiant or marsh gas. It is evidently a question of temperature, as oxygen driven through coal gas shows the phosphorescence well.

4. Far exceeding in generality the effect just noticed is a really magnificent blue image of the flame that starts up on almost every substance with which the flame is brought into contact. I have already drawn attention to this effect in the *Philosophical Magazine* for November, 1865, and the same effect has more recently formed the subject of a memoir, presented through M. Wurtz, of the Paris Academy of Sciences, the author of that paper evidently being unaware that the subject had already been investigated by myself.

The appearance is as follows:—When the hydrogen flame is brought either vertically or sideways, say, upon a white plate or a block of marble, there instantly appears a deep blue and glowing impression of the exact size and shape of the hollow flame. The moment the gas is extinguished, or the flame removed to the slightest distance from the solid, the effect as instantly ceases. If the flame be brought successively to the same spot on the solid, the effect grows fainter and finally vanishes, but instantly reappears upon an adjoining portion.

Other combustible gases, such as carbonic oxide, or marsh gas, or olefiant, or coal gas, do not yield this effect, nor does any lamp flame, luminous or otherwise; nor is it obtained in the oxidising flame of an ordinary blow-pipe; but it is imperfectly produced in the reducing flame when coal-gas is used; it is not seen when oxygen is driven through coal-gas, unless the latter be in excess; and it is poorer and vanishes more quickly with the oxyhydrogen flame than with hydrogen alone. This blue luminosity is, therefore, not a question of heat, but some property depending either on (*a*) the chemical nature of hydrogen, or on (*b*) the physical effect of its radiation. At first I thought it was the latter, and that it was a new form of fluorescence, so closely did it resemble those phenomena. But after a week's incessant experimenting, the true cause was hunted down and found to be dependent on the former effect (*a*), and in every case ultimately due to the presence of sulphur. A chemically-clean body, or a freshly-broken surface, did not show the blue coloration; but after exposure for a short time to the air of London, the substance invariably yielded the blueness; this, however, was not the case when the clean surface was covered by a shade, or exposed to the air of the open country. The combustion of coal-gas and coal fires yields sulphate of ammonia, a body often deposited in acicular crystals in the glass tubes in a laboratory. Sulphate of ammonia is decomposed by a hydrogen flame, and when that salt is brought into contact with burning hydrogen, it permanently yields the blue colorescence. Hence this body is probably the main source of the blueness seen whenever a hydrogen flame comes into contact with glass tubes or a dirty surface. This effect must repeatedly have been seen by every one who has experimented on singing flames.

When the blueness, as is so often the case, is seen tinging the flame itself, without contact with any body, the sulphur is derived either from the vulcanised tubing, the dust of which is taken up by the passing gas; or, if the hydrogen be burnt from the bottle generating it, the blueness is due to the decomposition of the sulphuric acid spray, as will be shown further on.

As a chemical re-agent for detecting sulphur, the delicacy of a hydrogen flame is extraordinary. This fact was estimated as follows:—Pure precipitated silica yields no blueness with the flame; 500 grains of silica were intimately mingled with one grain of milk of sulphur. Less than a one-hundredth of a grain of this mixture was thrown on the surface of pure water or placed upon chemically clean platinum foil. The water is best, but in either case the blue colour (absent before) now shot forth on bringing the hydrogen flame down. Tried again and again with fresh portions, the effect was very evident, but quickly vanished. The sulphur in a similar portion of the mixture could not be detected chemically by nitro-prusside of sodium. The wonderful sensitiveness of the flame may be still better seen in another way. Immediately after washing, the fingers show no colour when brought for a moment into the flame, but if a white indiarubber tube be touched ever so lightly, the fingers not only show a vivid blueness, but for some time any clean object touched by them, such as platinum foil, shows traces of sulphur by the appearance of the blue coloration with the flame. A block of melting ice continually weeps itself free from dust, and thus presents an excellent surface upon which to try the foregoing experiment. Or a plate of platinum, after heating to redness, may be written over with a stick of sulphur. If kept covered, the invisible letters may long after be traced out by sweeping the hydrogen flame over the surface of the platinum.

Examined through a prism, the blueness derived from any source shows blue and green bands, similar to the spectrum of sulphur, but I have noticed also a red band. This mode of obtaining a sulphur spectrum suggests further inquiry. White marble smeared over with a bit of sulphur, or with vulcanised rubber tubing, is a convenient source for obtaining the effect at pleasure.

Some sulphates and sulphides show the blueness with the flame, and are evidently decomposed by the hydrogen. Thus sulphate of soda gives no blue appearance, whilst sulphate of ammonia, or alum, does.

Various liquids were tried in contact with the flame. Sulphuric acid was very notable. Here a magnificent blue effect was observed. For persistence and brilliancy of the colour, this experiment leaves nothing to be desired; the spectrum is very fine. If the liquid is in a glass dish when the flame is brought vertically down, the blueness lights up the glass in a lovely manner.*

6. But the presence of sulphur is by no means the only body that a hydrogen flame reveals. The least trace of phosphorus is detected by the production of a vivid green light. It is striking to notice the wonderful sub-division of matter in these experiments, and how an immeasurable trace of an element can evoke pronounced and apparently disproportionate effects.

Might not this ready detection of minute quantities of sulphur and phosphorus be of use in the manufacture of iron? and might not hydrogen introduced into the molten metal be employed for the removal of these great enemies of the iron worker? I speak ignorantly.

7. Among the range of substances I have tried, tin was found to yield the most conspicuous effect, after the bodies named. A fine scarlet colour is almost instantly produced when the hydrogen-flame is brought into contact with tin or any alloy of tin. Tin is somewhat volatile, and its spectrum is rich in red rays. The tin must be clean; or the sulphur blue, which is much brighter, will mask the effect. A charming experiment may be made by partially scraping a soiled surface of tin; the blue and the scarlet colours mingle, and a lovely purple is the result. When a trace of phosphorus is present there may be obtained a green belt encircling a rich blue, then a purple zone, and finally a glowing scarlet at the root of the flame. These colours, it must be remembered, are not imparted to the flame, but reside on the surface of the body which the flame touches. And where the combustion of the hydrogen is complete, as in the upper part of the flame, or in the luminous stream referred to (2), these effects are not produced: they are best developed at the root of the flame.

* By W. F. BARRETT, F.C.S., Head Science Master at the London International College, &c.

* With all liquids, but best with mercury, a fine musical note can be obtained by causing the jet to dip just below the surface of the liquid.

8. Passing from liquids and solids, I next tried gases in contact with the flame of hydrogen. Many gases imparted a colour to the flame, but here the effect was different to that previously noticed. The whole flame was tinged with the colour imparted to it. A mere trace of hydrochloric acid gas imparts a reddish brown to the flame; ammonia gas gives a yellow, and burns freely. It is striking to note the combustion of ammonia gas rising from an unstopped bottle that contains the usual solution and which is placed below the flame.

But carbonic acid gas yields the most striking result in contact with the flame. A pale lilac tinge is instantly produced by a stream of this gas. This, I imagine, is due to the decomposition of the carbonic acid by the hydrogen, and the production and combustion of carbonic oxide. For it is at the lower part of the flame that the effect is most marked. One per cent. of pure carbonic acid admitted to a jar of air can be detected on holding the jar over the flame. The breath, of course, shows the effect most strikingly.

9. Here then is an eminently practical method of noting the presence of vitiated air in rooms or public buildings. A continuous hydrogen apparatus might be employed with a wash bulb attached. The flame might be burnt from a brass burner or lava jet, placed within a blackened tin cylinder. Opposite the flame a hole might be pierced in the cylinder, and closed by a lens for better viewing the flame within. As soon as the atmosphere in a room becomes unpleasantly vitiated the flame would indicate the fact by its changed colour. A similar apparatus might likewise be employed by miners: in metal mines as a warning against impure air, and in coal mines as a detector of fire-damp. In this latter case the ends of the cylinder could be covered with wire gauze. To this practical aspect of the question I am now giving such little leisure as I possess.

The results thus briefly described demonstrate—

1. That a hydrogen flame exhibits some physical peculiarities, and produces phosphorescence on many substances with which it comes in contact.

2. That the blueness so often seen in a hydrogen flame is due to the presence of sulphur, derived either from the vulcanised rubber tubing, or from atmospheric dust, or from the decomposition of the sulphuric acid spray from the generator.

3. That a flame of hydrogen forms an exceedingly delicate re-agent for the detection of sulphur or phosphorus, and possibly also of tin.

4. That many sulphates, and also carbonic acid are apparently decomposed by a hydrogen flame.

5. That a hydrogen flame is further a test for the presence of some gases, notably carbonic acid.

6. That these results are capable of practical application.

THE STAR DEPTHS.

MR. RICHARD A. PROCTOR, Honorary Secretary of the Royal Astronomical Society, gave the fifth and last of his course of lectures on the above subject on Saturday, May 11. That day being the anniversary of Sir John Herschel's death, Mr. Proctor paid a tribute to the memory of the great astronomer before entering on the subject of his lecture. He passed then in review the various theories which have been advanced in explanation of the phenomena of the sidereal universe by the ancients, by Corpernicus, Kepler, Wright, Kant, Lambert, the Herschels, and the elder Struve. In discussing the work of Sir W. Herschel, the lecturer pointed out that that astronomer's observations extended over a very long period, and that in the course of that period Herschel's ideas respecting the constitution of the universe underwent certain well-marked changes. The theory which he had advocated in 1785, a travestie of which appears in our text-books of astronomy, was definitively abandoned in 1802, and the principle on which it had been based was as clearly abandoned in 1811. The views which Herschel had entertained respecting the nebulæ were in like manner modified, it being impossible that any terms could be clearer than those in which he announced his change of opinion. Yet again, in 1817, he adopted a totally new principle for gauging the profundities of space. Notwithstanding these circumstances, the views belonging to the different periods of Herschel's observing career are as carelessly intermixed in our books of astronomy as though they had all been expressed in one and the same paper. The lecturer proceeded to sketch his own views, and the principle on which his researches had proceeded, which was simply this, to make all the relations he discussed—whether referring to the distribution of the stars or of the nebulæ, to the stellar proper motions, or to whatever else they related—*palpable to the eye* by the selection of suitable modes of charting or picturing them. He announced in passing his firm conviction that his theory of star-drift would be placed beyond dispute by the spectroscopic labours of Dr. Huggins. The lecture closed with a summary of the wonders presented to our contemplation by the star depths.

HINTS ON PAINTING.*—VI.

(*Continued from p. 168.*)

Scrolls.

THIS work requires the good taste and perfect outline of a draughtsman. But an insight into this art may be gained by copying the work of others, by processes described in these papers. When a copy has been made on the copying-paper, take a piece of stout wrapping-paper, and laying it on a smooth board, place the copy over it, and fasten all down to the board with a few tacks or pins; then with a pin prick the outlines with small holes through the copy and wrapping-paper. Having done this, lift all from the board, and by placing the wrapping-paper copy on the panel, and dusting on fine whiting with a pounce-bag, you will transfer the copy to the panel. Next proceed to fill in the outlines with gold size; lay on the gold, and then clean all off nicely for shading. This is done with asphaltum, but a very fine effect can be made by glazing some parts with carmine or blue. Copy the shading of the original as near as possible; put in the lights or white fine lines, and with a little practice and the use of pattern, you will soon gain a knowledge of scrolling sufficient to enable you to perform ordinary work. Scrolling in colours can be learned in the same way, but it is a more difficult art, as it requires good taste in the application of colours—harmony of colours being the greatest desideratum in good scrolling.

Stenciling.

Stenciling is an art by which the painter can execute ornamental work quickly, and when thoroughly understood it will often be called into requisition in the waggon paint shop. The articles required in making a stencil are a sheet of well-sized writing paper, a lead pencil, and a sharp pen-knife. Fold the paper, allowing the edge of the fold to form the centre of the pattern; then draw any design you wish, leaving bars to hold the parts together, then lay the paper upon a piece of glass and cut out the figure with the penknife. The tool used for this work is a camel's-hair brush or pencil, with air not over ½in. long, bound with quill and wire on a round wooden handle. The small sizes are preferable. The colour may be mixed in Japan and turpentine, as for striping, but colour mixed with vinegar and sugar will be found best. The paint must be quite thick, and a small quantity only must be taken on the brush, and then well rubbed out on a dry place before applying it to the work. Laying the stencil on the panel as desired, hold it down firmly, and rub over with the brush carefully until the cut portions of the figure are well coated. Then lift off the stencil and the work is completed.

To Transfer Ornaments for Carriages, Waggons, &c.

This beautiful art is now practised by many painters, who are either in a hurry with their work, or for economy's sake. Pictures expressly designed for carriages are now sold at the leading periodical stores, and the amateur painter is enabled thereby to finish a job of carriage painting in fine style. These pictures may be stuck on, and the dampened paper carefully removed, leaving the picture intact upon the panel, requiring no touching with the pencil. The proper way to put on decalcomainie pictures is to varnish the picture carefully with the prepared varnish (which can be obtained with the pictures), with an ornamenting pencil, being sure not to get the varnish on the white paper. In a few minutes the picture will be ready to lay on the panel, and the paper can be removed by wetting it, as already described; and when thoroughly dry it should be varnished like an oil painting. Be particular to purchase none of these transfer pictures, except those covered with gold leaf on the back, for they will show plainly on any coloured surface, while the plain pictures are used only on white or light grounds.

The following items will be found of interest.

To keep striping pencils in good shape and ever ready for use, grease them with tallow from a candle, and spread the hair straight on a piece of glass, keeping the same in a box made for the purpose, so that they may be preserved from dust. Why do striping pencils curl up or "crinkle" when used in white (keg-lead) colour? Because the acid with which the lead is made acts on the hair, heating and contracting the fibre. To straighten them when thus crooked, I draw the pencil across or between a warm iron and the finger. Dry white lead mixed in varnish and turpentine is preferable for striping, but tube colours are best.

When it is desirable to glaze a job with carmine, why do you advise the workman to get up a colouring varnish surface, while some painters are in the habit of putting on glazing the same as if it were colouring varnish? Because I have then a chance to rub the job smooth, which I could not do so well over the glazing. Besides, the glazing being mixed with flowing varnish, will flow level and free from clouds, if put on a smooth surface.

* From the "Carriage Painter's Manual." By F. B. GARDNER. New York: S. R. Wells.

Paper Cups for Striping Colours.

Although I do not recommend the use of paper cups for holding striping colours, I am aware that many prefer them, as they are easily disposed of when no longer desired for use. The economical painter would have small tin cups to use for striping colours, as the paper cups cause a waste of sandpaper.

Bronze Paint for Iron.

Ivory black one ounce, chrome yellow one ounce, chrome green two pounds; mix with raw linseed oil, adding a little Japan to dry it, and you have a very nice bronze green. If desired, gold bronze may be put on the prominent parts, as on the tips or edges of an iron railing, when the paint is not quite dry, using a piece of velvet or plush with which to rub on the bronze.

To Paint Magic-Lantern Slides.

Transparent colours only are used for this work, such as lakes, sap-green, ultramarine, verdigris, gamboge, asphaltum, &c., mixed in oil and tempered with light-coloured varnish (white Damar). Draw on paper the design desired, and stick it to the glass with water or gum; then with a fine pencil put the outlines on the opposite side of the glass with the proper colours; then fill up and shade with black or Vandyke brown, as you find best.

Lettering on Glass.

Sign painting on glass is one of the beautiful branches of our art, and as there are but few who can make a good job, I will endeavour to explain the method which has always been found to answer the purpose admirably. The glass should first be thoroughly cleaned and dried, then lay out the lines for the letters with soap, a piece of hard scented soap being the best, then proceed to paint the letters on the *right* side of the glass with lampblack mixed with oil; this is to form a guide for the work; then, on the inside, lay on a thin coat of size—made with the white of an egg and water, or isinglass dissolved in water—with a camel's-hair brush, covering over the whole line of letters. Then lay on the gold leaf with a tip, until every part of the letters is covered well. Allow the leaf to remain until the size is dry, and you will find that the letters on the front side can be easily seen and traced. This is done with quick drying black, to which is added a little varnish. Paint over every part of the letter directly on the gold and allow it to dry; then wipe off with soap and water the lampblack letters from the front side, and with clean cold water and a soft sponge, wash the superfluous gold leaf and size from the back, and you will have a perfect gold letter on the glass.

Proceed now to shade the letters, which may be done in colours to suit the taste of the painter. Always shade to the edge of the gold, for by that means you have only *one* edge to make straight. The shade may be left rough on its extreme edge, and when dry a neat straight edge can be obtained by merely scraping with a knife.

Ornamental Designs on Glass.

In making scrolls, eagles, &c, on glass, some painters put on the outlines and shades first, and then lay the gold leaf over all. Another good way is to scratch the shades into the gold leaf after it is dry, and put the colours on the back of the gold. Silver leaf may be used in the same manner as gold, but it will not wear as well. A very pretty letter may be made by incorporating silver with gold. Take paper and cut any fancy design to fit the parts of the letter, stick it on to the size before laying the leaf, and then lay the leaf, allowing it to dry, and wash off as before; then with a penknife raise the paper figure, and the exact shape or form of the figure will be found cut out of the gold letter. Clean off nicely, apply more size, and lay silver leaf to cover the vacant spots. Wash off when dry, and a very handsome ornamented letter will be the result. Colours may be used instead of silver, if desired, or a silver letter, edged or "cut up" with gold, will look well.

The Metal Industry.—The following, according to Mr. Hunt, are some of the quantities and values of metals obtained from the ores raised in the United Kingdom during 1870:—Pig iron, 5,963,515 tons, of the value of £14,908,787; tin, 10,200, £1,299,505; copper, 7,175, 551,309; lead, 73,420, £1,452,715; zinc, 3,936, 74,096; silver, 784,562, 195,140; gold, 191oz., £750; other metals estimated, £3,500.

Granite Glass.—The *Baltic Journal* reports that there exists near several cities of Finland a kind of granite, called there cupakivi, of which the composition is this:—Silica, 74 per cent.; feldspar, 12; oxide of iron, 8; lime, 1; alkalies, with traces of magnesia, 9. This being evidently a good compound to make glass, the first experiment was consequently made by melting 500 parts granite, and 200 limestone, and a white glass was obtained. The second experiment was made with 500 granite, 150 lime, and 75 of soda. This glass was more fusible, and at the same time harder. Both kinds were blown without difficult at a bright red heat, while a dark glass was made by the addition of 70 parts of sulphate of lime or potash, and 7 parts of carbon.

SCIENTIFIC SOCIETIES.

ROYAL ASTRONOMICAL SOCIETY.

AT the monthly meeting of this Society, held on Friday, May 10th, the President, Professor Cayley, in the chair, several interesting papers were read, one of the most important of which, by Colonel Tennant, was on

The late Solar Eclipse.

In introducing the paper, the Colonel remarked that of the six photographs obtained during totality, the first three were very good, and from the appearances depicted, he felt quite satisfied that the corona is a solar phenomenon. This opinion is based on the *persistency of the rifts* during the progress of the dark moon over the bright sun, which, by the shutting out of the solar light, enables us so to view the coronal appendage as to determine if its essential features preserve their relative positions, now that we are becoming acquainted with them. This the Colonel succeeded in doing: he found that as the moon passed onwards the corona appeared to be unaltered; each rift, as seen last December, was certainly connected with a visible prominence. As a general result of the observations, it was stated that a connection between the corona and its rifts with the solar prominences was well made out; the corona did not extend more than a radius of the sun from the surface.

Another very important result of the observations made in connection with the Indian Government, was the *reversal of the dark lines* seen by Captain Herschel—*i.e.*, the ordinary dark lines in the solar spectrum were at the moment of totality seen as bright lines, and not only so, but these bright lines existed in enormous quantities; the impression, if we understood Colonel Tennant correctly, made by them on Captain Herschel's mind, was that they were successive in their appearance, but with such rapidity did they present themselves that it was next to impossible to note their sequence. The conclusion drawn from their number and brightness appears to have been that the lowest stratum of the corona in contact with the sun consisted of a mass of vapour in which the bright lines originated. The narrow and lower bright portion of the corona, which was seen by several observers on the occasion of the eclipse of 1870, was not seen by Colonel Tennant in 1871.

Mr. Brett stated, in reference to the narrow bright rim next the sun which he saw in 1870, that it did not extend more than two minutes' of arc from the dark limb of the moon.

Dr. De La Rue bore testimony to the excellence and value of Colonel Tennant's photographs, and observed that they furnished conclusive evidence that the corona is a true appendage of the sun. As in 1860 his own photographs had decided the question of the prominences, so in 1871 Colonel Tennant's photographs had decided that of the corona by showing that during the passage of the moon over the sun no change in the coronal features had occurred.

Captain Noble, in alluding to the thanks that the Fellows present would unanimously award to Colonel Tennant for the very valuable information communicated in his paper, took occasion to remark that the Colonel had embraced the earliest opportunity after his arrival in England to dispel the ignorance of the details of the eclipse which characterised the meetings of the society that had intervened between its occurrence and the present. Having stated that he joined heartily in thanking Colonel Tennant, he wished to direct particular attention to the fact that on the occasion of the eclipse of 1870 the coronal matter extended outwards over each prominence, the rifts appearing in those portions of the corona in the lower stratum of which prominences did not exist. In 1871 the rifts are described as occupying precisely the localities in which in 1870 the greater extension of the coronal matter was found.

Dr. De La Rue suggested that the appearance of the rifts in the late eclipse might be explained on the supposition that the light of the photosphere being so much more intense than that of the prominences the corona would not appear so bright behind them.

Mr. Ranyard called attention to certain features in Colonel Tennant's photographs, the positions of which were symmetrically related to the sun's poles.

In reply to a question by Dr. Huggins, Colonel Tennant stated that the corona exhibited strong radial polarisation.

Mr. Ranyard read a paper on the value of the stereoscope as applied to the examination of eclipse photographs, in which he pointed out that the appearance of relief depended upon the direction in which the light fell on the photograph, as well as on the objects, and exhibited photographs of a cut tumbler taken with the open part downwards, and also with the same part uppermost. In the photographs the relief was reversed, the appearance of the tumbler in its ordinary position being as usually seen, while in the photograph with the mouth downwards the raised portions appeared as depressed. He also called attention to the fact that drawings viewed through a lens presented the appearance of relief. From these circumstances he argued that in judging of the appearances of objects in three dimensions care should be exercised as to the presence of light and shade in the originals, otherwise an erroneous estimate might result from the combination of photographs in the stereoscope, and suggested that for the determination of the positions of important features micrometric measurements should be employed.

Dr. De La Rue, as we understood him to say, was not aware with whom the notion of three dimensions, as shown in the stereoscope, originated, but he was quite clear as to the stereoscopic combination of photographs in furnishing information relative to the disposition of objects in a picture.

An Improved Altazimuth.

Mr. Brett exhibited and explained the construction of an altazimuth mounting for a reflector, possessing portability combined with facility of manipulation, the essential principle being that of a tripod with a movable apex. The instrument, when not in use, presents the appearance of a neat mahogany box, which forms one leg of the tripod the other two, folding within the box, can be so arranged externally that the box itself, carrying the reflector, eyepieces, &c., may take any position as to altitude. The two legs, constructed upon the principle of steadying rods, are furnished with adjusting screws having a play of about eighteen inches. By the aid of these screws a slow motion either in altitude or azimuth is effected. The instrument, having been constructed with a view to portability, was stated to weigh about 40lb., and could easily be carried from place to place. For temporary purposes it was described as fairly steady. The compactness of the arrangements was very striking.

Vlacq's Tables of Logarithms.

Mr. Lee Glaisher read a paper on the errors in Vlacq's tables of logarithms, in which he drew attention to the circumstance that Vlacq's are the only tables that extend throughout the series of numbers to *ten* figures. The author entered somewhat extensively into the history of these tables as containing the completion of the seventy chiliads left uncompleted by Briggs; that in many instances the errors of Vlacq had been transmitted through later editions; that the English and Continental editions were printed from the same types, and contained the same identical errors, of which about 700 had been ascertained and published. Mr. Glaisher referred to a copy of Vlacq in the library of the Royal Observatory, Greenwich, in which the errors detected at the time of Maskelyne are corrected. About one-half of these errors are considered as unimportant.

Satellites of Jupiter and Saturn.

Mr. Proctor read a paper on the densities of the satellites of Jupiter, which he considered to be greater than given in our text-books, and urged upon the Fellows of the Society the importance of examining for themselves the statements they met with in print. He also communicated a note on the discovery of the second satellite of Saturn, reckoning from the primary, by Sir William Herschel, with the 40ft. telescope. The object of the communication was to correct an erroneous statement which Mr. Proctor had met with.

A few further papers having been read, and others announced, the society adjourned at a late hour.

INSTITUTION OF CIVIL ENGINEERS.

Explosive Agents applied to Industrial Purposes.

AT the last ordinary meeting of the session, a paper was read on this subject by Mr. F. A. Abel, F.R.S.

The nature and properties of gunpowder, and its special advantages and defects as an explosive agent for industrial purposes, were first briefly reviewed. The application of chlorate of potash to the production of mixtures more violent than gunpowder was discussed, their general susceptibility to explosion by friction or blows was pointed out, and some comparatively safe compounds of this class, such as Horsley's powder and a substance called tutonite, were specially noticed. The salts of an organic acid, called picric acid, now produced in large quantities by the action of nitric acid on the well-known antiseptic carbolic acid, were described as endowed with explosive properties, and as furnishing very powerful agents when mixed with chlorate of potash or saltpetre. Of these the "poudre picrate," or mixture of picrate of potash and chlorate of potash, was the most violent, but was far too dangerous, on account of the readiness with which it exploded by friction, to permit of its technical application. A mixture of picrate of ammonia and saltpetre, designated "picric powder" by the author, was described as certainly not more dangerous to manufacture and to use than gunpowder; considerable quantities had been produced with the ordinary appliances of gunpowder-works, and the material had received safe and successful employment as a violently explosive charge for shells.

Numerous other products of the action of nitric acid upon organic substances, endowed with explosive properties, were stated to exist, but only two of them—nitro-glycerine and gun-cotton—had hitherto received practical application, and these two constituted, at the present time, the chief rivals of gunpowder in many of its most important uses. Attempts were made to apply gun-cotton immediately after its discovery in 1846, and long before its properties were understood; but nitro-glycerine, which was discovered in 1847, had continued a chemical curiosity for sixteen years, its manufacture and application having been developed during the last nine years.

The early history of gun-cotton was briefly referred to, and it was shown that, even in the first days of its production and application, important results were arrived at, though the too hasty attempts to utilise it led to its speedy abandonment, as a highly dangerous material, by all but the Austrians. The improvements effected by Baron von Lenk in the application, as well as in the manufacture, of gun-cotton, which first became public in 1863, led to a resumption of the employment of this agent in England, and to its careful study by a special Government Committee and others. The advantages of the Austrian gun-cotton, as a mining, quarrying, and engineering agent were pointed out, as also the considerable improvements in point of power, economy, safety, and convenience in use, in facility and uniformity of production, which had been effected by the reduction of gun-cotton fibre to a finely divided condition, and its subsequent conversion into highly compressed homogeneous masses. The rigidity of the charges of gun-cotton, and their consequent occasional tendency to become jammed in irregularly-shaped blast holes were, however, shown to be occasional sources of accident; and the necessity for strongly confining gun-cotton, in order to develop its full explosive force, was a defect which existed until recently, and had, for a time, rendered the material decidedly inferior to nitro-glycerine.

An account was next given of the successful manner in which Mr. Alfred Nobel had developed the practical application of nitro glycerine. His discovery that the explosion of this liquid could be brought about through the agency of a detonation, and its successful manufacture, combined to furnish the industrial world with the most powerful explosive agent hitherto susceptible of application, and which agent, from its high specific gravity and insolubility in water, presented the special advantage that it could be used in positions whence water could not be excluded. The poisonous nature of the substance constituted an objectionable quality, and some uncertainty occasionally attended its employment, but its principal defects arose from the fact of its being a liquid, and from the comparatively high temperature at which it froze. The majority of the numerous fearful accidents which had occurred during the transport and landing of nitro-glycerine appeared to be caused by the accidental leakage of the liquid from receptacles in which it was confined. The liability of such leakages to escape observation, and to lead to accidental explosions which would be transmitted to the confined nitro-glycerine, and the reckless manner in which the frozen nitro-glycerine had been frequently dealt with, in consequence of its apparently inert condition, had been fruitful sources of disaster, which had rendered the liquid, in its pure condition, a very unsafe material for employment as a mining agent. But Mr. Nobel has succeeded in applying nitro-glycerine in a simple manner, by which its defects, arising out of the liquid nature of the material, were remedied. He mixed nitro-glycerine with a porous and finely divided silicious earth, and thus obtained a solid but plastic preparation, which could be conveniently handled and converted into charges of suitable dimensions, susceptible of application like any other solid explosive agent, and capable o detonation quite as readily as the pure nitro-glycerine. This mixture, called dynamite, and of which one or two varieties were prepared by Nobel, was stated to be one of the safest, most convenient, and most powerful blasting and mining agents. As now manufactured, in the form of compressed charges, it retained as much as seventy-five per cent. of nitro-glycerine, without exhibiting any tendency to a separation of the liquid during transport and storage.

Several other nitro-glycerine preparations of more recent production were referred to, all of which might be regarded as modifications of dynamite. In some of them, such as Horsley's mining powder, dualine and glyoxiline, solid explosive compounds or mixtures were employed instead of porous silica, as the absorbents of nitro-glycerine; in others, as in lithofracteur, the silicious earth and nitro-glycerine contained in dynamite were in part replaced by semi-explosive substances—for example, by gunpowder constituents. None of these newer preparations contained so high a proportion of nitro-glycerine as dynamite, and although some of them, such as lithofracteur, might vie with it in regard to safety, it was scarcely possible that the substitution of other explosive substances for a proportion of nitro-glycerine in the mixture could result in the production of an equally powerful explosive agent.

When it was found, by recent experiments, that gun-cotton, in the compressed form, could be exploded by detonation like nitro-glycerine and its preparations, that substance proved to be quite analogous to them in its behaviour, though the pure nitro-glycerine still remained somewhat the strongest explosive agent. The suddenness of the explosion developed by detonation permitted of the application of compressed gun-cotton and nitro-glycerine preparations to purposes of destruction without any confinement, and thus operations could be expeditiously and effectually carried out with comparatively small quantities of these materials, which could only be accomplished by exorbitantly large charges of gunpowder. The rapid demolition of military works, bridges, &c., the breaking-up of boulders, large masses of rock, guns, or castings or forgings, were quoted as operations of this class.

The author pointed out some of the causes of the great difficulty experienced in arriving at anything approaching a precise estimate of the relative power and effect of different explosive agents. Taking dynamite as the type of the practically useful nitro-glycerine preparations, and as certainly one of the strongest, experience had shown it and compressed gun-cotton to be about on an equality in point of power, and to exhibit, in their most advantageous applications, a strength which was estimated at six times that of powder. The plastic nature of dynamite and its power of resisting penetration by moisture, gave it advantages over compressed gun-cotton, as it could be used in wet blast-holes, and as very irregular holes, or holes terminating in fissures, could be more conveniently and heavily charged with it than with gun-cotton. On the other hand, the readiness with which dynamite froze and its inertness unless thawed, or fired by special arrangements, and the unpleasant effects experienced occasionally by those using it, were inconveniences not shared by gun-cotton. The advantages presented by these materials, in their general application as blasting agents, were shown to consist chiefly in saving of time and labour, especially in tunnelling or in blasting in hard rock. They were also susceptible of advantageous employment as auxiliaries to gunpowder, in the rapid removal of large masses of rock, or of submerged wrecks; the violent explosive agent being first used to produce extensive rending and shattering effects, and the superior displacing effect of powder being afterwards brought to bear. It was pointed out that gunpowder could not be satisfactorily replaced by these violent explosive agents in some kinds of work, where its comparatively gradual action was a specially valuable feature.

In conclusion, after referring to some recent interesting experiments of Dr. Sprengel, on the application of readily oxidisable and other powerfully oxidising liquids in the production of violently detonating mixtures, the author showed that, even in the application of gunpowder to industrial purposes, some decided advance had lately been made, for its violent explosion could be developed, like that of all other explosive mixtures and compounds, through the agency of a detonation, whereby its action might be considerably intensified, and its application to some important classes of work—*e. g.*, submarine operations, greatly facilitated.

Koumiss.—Dr. Townsend, of Cork, writes to the *British Medical Journal* that koumiss was used by his father many years since in the treatment of phthisis. The following is the manner in which he prepared it, and it answered well:—Take one quart of new milk, one noggin of good thick milk or fresh butter-milk, and three or four lumps of white sugar. Mix all together from jug to jug till the sugar is quite dissolved. Put it in a warm place to stand for ten hours. It will then be quite thick. Pour it again from jug to jug till it is smooth. Bottle it in soda-water bottles; let it remain in a warm place for thirty-six hours (twenty-four in summer). Use the best velvet corks; tie them down; shake the bottle well for five or six minutes before it is opened. It will have whey at the bottom when fit for use. It is to be made every day, and taken in quantities. Its fermentation is the test of its excellence.

Ashworth's Fine Pointed Flattened-Wire Cards.—Messrs. Ashworth Bros., of Manchester, have introduced some improvements in wire cards for carding cotton, wool, worsted, silk, &c., consisting in the manufacture of the teeth or staples out of a wire which has been flattened by passing through hardened steel rollers. The wire thus produced is similar in shape to an ordinary comb tooth, having two broad flat sides, and two narrow round sides. The breadth of the teeth in the direction of the working of the cards gives more than the strength gained by the use of round wire, and thus renders possible the production of cards equal to their work, with a less weight of metal, though with the same number of points as round cards. The cards have now been at work for twelve months in a number of mills, and are very well spoken of. A special "steel" card used extensively in covering lickerin rollers should be separately noticed. It is cut, pointed, and does not require grinding. It works quite clean, and therefore needs no stripping or even brushing. The advantage of an even and regular ..d is thus insured.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, 81, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

*** *In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"T. A." AND GRAVITATION.

[4183.]—"T. A.'s" method (let. 4166) is altogether unsound. It is based on two assumptions (tacitly made)—viz., first, that the length of a line drawn from the attracted particle in any direction through the spheroid represents the attraction exerted by the portion of the spheroid lying in that direction; and, secondly, that the lines thus drawn diverge (in "T. A.'s" construction) uniformly from the attracted particle—that is to say, that an equal number of them would fall on equal portions of any spherical surface having the particle at its centre. The second assumption is undoubtedly erroneous; as to the first, "T. A." should have substantiated it before proceeding with his proof.

It is impossible that there can be any simple proof for the attraction of a *spheroid* on an external particle, simply because the integral calculus has demonstrated that the expression for that attraction is not simple.

"T. A.'s" explanation of his reference to Ganot is quite sufficient to show that my apology was called for.

RICHARD A. PROCTOR.

THE SUN.

[4184.]—IT would not be easy for me to answer the question of "L. J. V. G." (query 11870) within compass of a letter, as the considerations which have led me to the conclusion that the sun does not belong to the stream of stars forming the Milky Way are based on researches which have occupied me during the last seven or eight years. I am compelled, in this instance, to refer to my published works, "Other Worlds" (2nd edition, p. 256, *et seq.*), "The Sun" (2nd edition, p. 464, *et seq.*); and, for an account of the researches themselves, the "Essays on Astronomy" (p. 240, *et seq.*), and appendix. It will, I fear, seem unsatisfactory thus to refer to books of my own; yet it must be remembered that if my views could be fully or properly exhibited in a letter I should probably not have cared to write books concerning them.

RICHARD A. PROCTOR.

PIANO CONSTRUCTION—To MR. SCHUCHT AND OTHERS.

[4185.]—"THE HARMONIOUS BLACKSMITH," with that modesty which is his normal characteristic, respectfully declines the honour (?) of being an inventor (?) of perpetual motion; also of being the designer of mechanism which—in the mechanical sense—gains power. Sooth to say, both are simply mechanical impossibilities, and their conceptions only exist in the absence of knowledge of mechanical laws. All machines being but transmitters, not generators, of force.

Mr. Schucht says "'The Harmonious Blacksmith' is trying to show the possibility of imparting to the hammer—in the treble of a piano—a greater power than we usually can get." Now this may be quite true, or "the thing which is not," for it all depends on our definition of the word power. If power and velocity be identical, yes; but if they don't mean exactly the same thing (and I have yet to learn they do), why then, no.

If I ever said anything from which it can fairly be inferred I expected my own, or any other man's, "mechanick" could give out a greater mechanical force than that which impelled it, I can only say, with the parrot (wiser than any "Harmonious Blacksmith," who had experience of the evil consequences of garrulity, "The Harmonious Blacksmith's" greatest fault), "Sorry I spoke" to so little purpose; but I guess I am rather "too old in the tooth" to have been guilty of uttering any such nonsense. What I did say (or intended to say) was, that from the change of its position, the hammer of a piano with an upright action has more and more of its weight supported on its centre as it rises, and (as a necessary consequence) less and less force becomes needed to continue its motion (supposing the velocity of that motion to be uniform), as it approaches the strings. This notorious fact may be ascertained experimentally by taking out the dampers, and finding the different weights required to balance the hammer of a common cottage action in various positions between the lowest and highest.

It is notorious that a continually diminishing resistance to the finger during the key's descent is neither desirable nor pleasant, but that, on the contrary, a perfectly uniform or even moderately increasing resistance produces the most pleasant touch—a fact well known to most makers of grand pianofortes, who purposely delay the contact of the key with the damper lever until the former has descended about half its path, for the purpose of diminishing resistance to the finger at the commencement of the key's motion. In imitation of their practice I designed the actions figured in No. 368, in both of which the resistance to the finger will be found slightly to increase as the key descends.

I might have effected this by other means; for instance, by a spring which, as its resistance increases when it becomes more bent, its reaction necessarily also becomes greater as the key descends. I might also have employed a lever carrying a weight, a contrivance employed in certain ancient machines for weighing bread, &c., which I remember in the—alas, long past—days of mine youth. In these machines the weight recedes from its support as its rises, so, of course, it requires a greater force to balance it the further it rises. Something like this in connection with the key would have compensated for the diminishing resistance caused by more and more of the hammer's weight becoming supported on its centre during its rise, but I thought it far preferable to effect the same result by imparting greater velocity to the hammer, and I did this by positing the sticker hinge (or butt shoulder) in relation to its centre, so that the arm of the lever which lifts the hammer—in other words, the distance from the vertical plane of that shoulder, or of the sticker hinge, to the vertical plane of the hammer centre—became less as the hammer rose. (See Fig. 2 and the description thereof in No. 868.) My reason for preferring to increase hammer's velocity I subjoin.

I presume neither Mr. Schucht nor any other man will deny that *cæteris paribus* the loudness of the sounds produced when the strings of a piano are struck is in proportion to the force of the blow. Also that that force will, *cæteris paribus*, be in proportion to the hammer's velocity. Now, had I adopted either of the former methods of improving the touch, the hammer's velocity—and consequently the force of the blow struck by it—would have remained unaltered: on the contrary, by adopting the method I did, which increased the hammer's velocity from three to six-fold, at the instant it struck the strings (N.B.—So far as regards the production of sound, its velocity during any other portion of its path is quite uninfluential), need I add the force of the blow was increased in proportion to the increase of the hammer's velocity? and although I am far from asserting the sound became six times louder, its power was very considerably augmented. That the sound should not respectively have become three or six times louder—so far as I am able to estimate the relative intensities of sound—need not very much surprise us, for the proportions between the force of the blow and the mass of material—strings and belly—by which the blow was resisted were considerably altered: in a word, *cæteris paribus* was not maintained, and to restore, or rather to approximate to, those original proportions, it became needful to increase either the length, the thickness, or the number of unisonous strings the hammer struck. All these methods were tried, as I before stated, and from the experience gained during those trials I opine the very best thing to do—supposing our object to be the production of a pianoforte capable of yielding the most powerful sounds of the best possible quality, without regard to its original cost or the expense of occasionally, but not very frequently, retuning it—would be to employ all three of these methods; but as regards increasing the lengths of the strings I fear we can hardly do so with safety, beyond those shown in the diagram and specification in No. 372, until the employment of wire of greater tenacity than can now be obtained, unless it be drawn extra hard to special order becomes general.

With regard to the positions of the dampers I may just remark that, *cæteris paribus*, they act quickest when at the middles of strings. Of course, it would be inconvenient, although far from impossible, to place them there; doing so would not be worth its cost, for if made pretty long (say, from one-twentieth to one-fifteenth the string's length) and soft, they act efficiently when properly pressed against the string at any convenient portion of its length, especially if their soft faces be grooved so that they embrace the string for about two-fifths of its circumference. If you desire to damp "werry dead" indeed, double dampers are the right thing. By double dampers I don't mean what the late Mr. Mott called by that title, but dampers before and behind the strings, which when opened allow them to vibrate, but when shut clip the strings like a pair of hollow-bitted forge tongs clip round rod iron, which the "Harmonious Blacksmith" avers is a very efficient clip indeed, but it is unnecessary; again, as their French hosts—who are now mercifully permitted to have the privilege (?) of feeding and entertaining a good many of Mr. Schucht's countrymen—would say "Le jeu ne vaut pas la chandelle."

THE HARMONIOUS BLACKSMITH.

MUCH EXPERIENCE IN FEW WORDS.

[4186.]—A CORRESPONDENT, who is a competent observer, has sent me the following pithy letter:—"A vessel of ink and water is better for solar observations than an oblique silvered glass; but your first surface prism for ever!"

J. B.

AN IMPROVED BEEHIVE.

[4187.]—BEING a constant reader of the ENGLISH MECHANIC, and of late having seen several articles on "Bees and Beekeeping," I thought a few words and sketch of an improved hive might interest a few of your readers. I have myself been a loser of these very interesting labourers in considerable numbers for want of a well-constructed hive, both in workmanship and principle, and after many trials with plain straw hives, those on the Neighbour system, as well as those on the Woodbury principle, both with bars and frames; but this last winter has convinced me that a hive constructed after the inclosed sketch is more practical, simple, and better than any of them.

The hive consists of a long box, most representing a cupboard. The extreme dimensions inside are: Height, 29½in.; width, 9½in.; depth 11½in. The body is of 1in. thick pine, with ¼in. thick crossing the grain again inside, and fastened by means of nails every three or four inches of the whole surface, thus making the sides and door 1¼in. thick. The bottom, or floor, is formed of two pieces, 1in. thick, with a space of 1in. between, which is stuffed with hay or other open material, as shown, and closed by a piece fitting in between the bottom boards. The top or roof of the hive is formed by a 1in. thick board; between this and the gable-roof boards, which are 1¼in. thick, the space is filled in with hay, as shown. The gable-roof is made weather-tight by means of painted canvas; the rest of the hive is painted dark ochre, and the whole varnished. The door is formed the same as the sides, and extends from top to bottom of the hive in one piece, and fits neatly into the recesses formed by the 1in. and ¼in. thicknesses. This completes the exterior of the hive.

It will be observed that the interior is divided, as it were, in three compartments; in reality, Nos. 2 and 3 are one compartment, so high that two frames can hang one above the other, with five-sixteenths of an inch space between them for the bees to travel through. The top room (No. 1), or super-room, is separated from the stock-room by means of a board ⅜in. thick, formed of three breadths, which slide easily from back to front of the hive in the recesses (*b*) at each side. The total breadth of these three boards should be five-sixteenths of an inch less than the total depth of the hive inside from back to front. In one of these boards should be bored a hole 1½in. in diameter to allow for a feeding-bottle to be placed over it, as shown in the sketch, the bottle being supported on a turned wooden base, as shown. The same hole can be used for setting a glass over in summer for honey taking; at other times a prop or cork can be inserted, through which a hot wire or needle has been passed several times; the prop then serves as a gentle ventilator. The objects gained by having this partition board in three pieces are that the position of the one with the hole in it can be changed to suit the requirements of the inmates at the different seasons for feeding; also, that when it is wished to take honey in the frames the one board is pushed in first close to the front, the other two are then put in, but kept close up to the door at the back; thus there will be left an opening of five-sixteenths of an inch between the second and third board, which will allow the bees to pass through and fill the frames, the queen never venturing to pass through such a small opening, thus we secure clear honey in these frames. When wishing to take one or all the frames out I merely press the two front boards gently and slowly back against the other, thus closing all communication between the super and stock-room; then, by removing the window (*c*) of the super-room, the confined bees can escape, and we can take the frames out with freedom. All the frames are of equal size, and can be used either in the super or stock-room. They are of the following dimensions: 9in. high, 8¾in. wide, and fifteen-sixteenths of an inch broad, outside measure. They are made of deal strips, fifteen-sixteenths of an inch broad by three-sixteenths of an inch thick, being joined at each corner by means of fine sprigs driven into ⅜in. square distance pieces. Each of these distance pieces project ¼in. at each side of the frames, and serve to hold the frames at a regular distance from each other—that is, ½in., so that the bees have clear access over the whole combs at each side. The top pieces of frames project ⅜in. over the sides that form a support on each side to fit in the recesses (*b*) that are worked out of the ¼in. lining at the sides of the hive. The recesses or grooves are made in the form shown, so that the bees can at all times have access to destroy moths or other intruders that may have entered the hive, as it is of the highest importance to avoid having any opening where the moths can lay their eggs, or other intruders hide, and where the bees cannot come at them to destroy them for this purpose there is left a space of ⅛in. at each side of the hive between the outside of the frames and side of the hive.

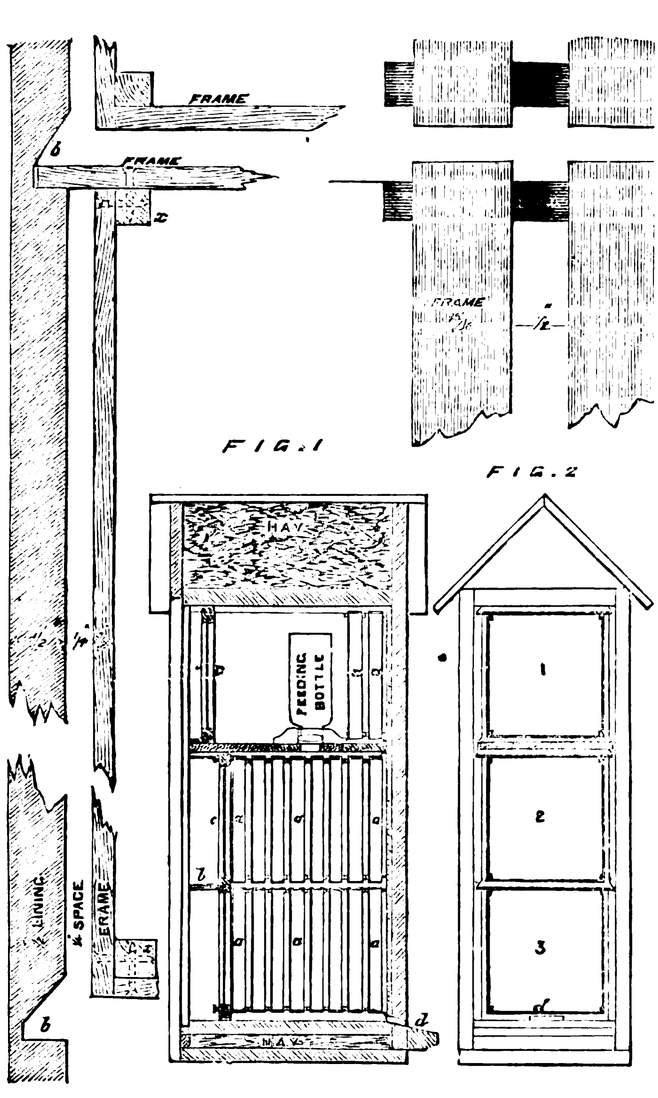

FIG. 1 FIG. 2

From the sketch it will be seen that there are sixteen frames in the stock-room; this is the full number intended, and in the super there can be eight frames. It will also be observed that there are two windows (*c*)—one for the super and the other for the stock-room. These windows fit nicely, and slide from back to front of the hive. By this means we can always limit the space for the bees' requirements. For instance, on having a swarm, six frames can be put in the stock-room (three under and three over); the window is then slid in close up to these frames. On our next examination, if we see that they have begun to fill the frames nearest the window, we immediately take the window out and place two more frames (one top and one bottom), pressing the window up as before, and so on progressively until the sixteen frames are inserted, when the hive will then be in good condition, and well populated. The same control can be exercised over the working space in the super. Inside the window of the stock-room a small thermometer is fastened to the window, by which means the temperature can at all times be observed. On looking at the sketch it will be noticed that when the full number of frames are in the stock-room, and the window close up to them, there is a space between the door and the window. This, in winter, after the frames have been seen to and found all in order and the window replaced, is well filled with some dry material, such as cotton waste, hay, or whatever may be found most convenient and warm.

After one has satisfied himself that there is no occasion to feed by means of the bottle or honey in the super, the bottle and frames should be taken out and the space well packed with a dry and, if possible, absorbing material that has been previously dried carefully in an oven, to destroy all eggs or larvæ that may come to life by the warmth from the hive. After thus packing, the window can be replaced, after opening a small sliding ventilator fitted into the frame of the window at the top, the ventilator being a plate, pierced with small holes, inside the frame. The door can then be carefully closed and fastened, and the little colony left safe and warm for their winter's rest, until a warm day in the early spring allows of their being examined, and they give a healthy buzz as sign of thanksgiving for their careful preservation during the cold winter. I may here state that on opening the super-room in the spring the packing material will be found quite wet or damp, and covered with a dew, thus showing that all this moisture otherwise must have remained in the stock-room, to the little colony's danger and discomfort.

The advantages of this hive are: Always being able to see all going on inside; able to take any frame out in a few minutes; able to feed at all times without enticing robbers from other hives; being able to obtain honey easily by three modes—viz., in a glass or in a beautiful square piece of comb, by merely passing a knife all round inside a frame, when the square comb is left on the plate as easily as a brick from a mould; or, if wished, by means of machine the frames containing the combs full of honey can be taken out, and in a few minutes the empty combs can be returned to the super to be again filled, thus saving the bees time and trouble of building fresh combs, as by use of machine half a dozen frames can be beautifully emptied, and the empty combs returned to the super to be filled again, the whole not occupying more than as many minutes of time.

In hives of this description there are no screws to take out or set in, and the bees are not annoyed by the roof of their dwelling being taken off every time one wishes to examine or see to their welfare. I reserve until another time a short description of a honey-taking machine, should any of your readers wish to make and try one, as I assure them they work admirably. I may add that such a hive costs me, complete in all respects for working, at the rate of English money, £1 2s.

REFERENCES TO DRAWING.—Fig. 1, side elevation in section; Fig. 2, back view with door removed. *a*, frames for combs; *b*, recesses for frames to slide in; *c*, windows to slide in and out; *d*, entrance; 1, super-room for honey in frames or glass and for feeding by bottle (Crosse and Blackwell pickle bottle); 2 and 3, stock-rooms; *x*, distance pieces.

CURIOUS CASE OF DOUBLE REFRACTION.

[4188.]—MANY years ago, observing to a philosopher how curious it was that Iceland spar should possess the property of giving a double image, he replied that the wonder rather was to find what had not this property. I had lately an illustration of this doubly-refracting power in the ordinary glass of a window. About 50ft. outside of my window a small iron ball is attached to an iron rod. When the background of the sky is not too bright, I clearly discern through the window glass a shadowy ball, like a photographic ghost, which I prove to be a secondary image by changing the position of my eye and angle of visual perception. The shadowy image moves, as it would do if a prism of Iceland spar were slowly rotated. I cannot see this secondary image on looking at the eaves of a house or the bare branch of a tree. At first I referred it to polarisation. Perhaps both have something to do with the phenomenon. THOMAS BUCHANAN.

DR. CARPENTER AND PERSPECTIVE.

[4189.]—THERE is such a conventional rule as "Cervus" mentions (let. 4118, p. 200), for limiting the horizontal angular range of pictures containing architecture; but it need not apply to their vertical extent, which need not be nearly so limited, as will appear the moment the reason of the rule is understood. No picture can possibly represent a scene with *real* accuracy when viewed from any other point than *one*, the "point of sight," the same at which the lens would be placed for viewing it as a "peep-show," or what was lately dignified as "cosmorama." But pictures to hang on walls for ornament (as the vast majority always must) are necessarily viewed with the eye constantly moved away from their true "point of sight," more or less; and if the angular range of scene represented do not exceed 60°, the eye can so allow, by habit, for the error of the foreshortened plane picture, as still to understand, and not find it distorted. But beyond 60° this correction is hardly in the eye's power, so that, when much removed from the point of sight, it will find the picture distorted in the perspective of its corners or extreme parts; though *at the point of sight* (let me remind "Cervus" and M. Paris), perspective is perspective, and absolutely true, however far extended, so that a picture to be viewed only cosmoramically, or from the right point, has no limit, but may be 100 times as wide or high as it is distant, and represent any amount of horizon possible, even 170° or 179°, with no distortion. Now, as the eye, in a room or gallery, moves away from the point of sight *horizontally*, but hardly at all *vertically*, only so much as arises from our unequal statures, "Cervus" will see why much closer limitation has to be observed in any picture's horizontal range than its vertical. The latter may be freely carried even beyond 45°, both above and below the horizon, while the former should never exceed 30° each way from the centre.

M. Paris says "all objects diminish as their distance from the eye increases," but forgets that the marks on his picture are no exception to this! If the top and bottom of his *representation* of a tower are at distances from the eye as two to one, and the top and bottom of the *real* tower are at distances in the same ratio, must not the top and bottom widths, if equal in one, the tower, be equal also in the representation? He sticks, like the Chinese before they had photographs to measure, to the metaphysical heresy against perspective, that the representation of outlines is to be matter of judgment instead of pure science; something subjective, physiological or psychic, instead of objective; but with more than Chinese obstinacy, he sticks to this after photographs have given tangible proof that the mathematical perspective (which is what I suppose he means by "Laputan") was always the sole right one!

If by "moving" the eye or the camera he means *locomotion* of them, of course there must be none, but if by "moving" he only means *turning*, the eye may always turn to any extent, in viewing the same picture (or panorama). The camera, however, if forming its images on a plane (as it usually does) may not turn at all, without altering the picture's forms, because the *plane of projection* is altered. If it threw the picture on a spherical watch-glass (as the eye on its spherical retina), then it might turn to any extent on the centre of sphericity, just as the eye does. The picture, though falling on different parts of the glass would always be identical. E. L. G.

[4190.]—IF M. Paris had read my letter (3944, p. 39, so as to understand it, before he wrote his replies (let. 3971, p. 119, and let. 4111, p. 200) he might have seen that his question about a long wall is answered; and that if he wants to delineate his wall of infinite length his canvas must be of infinite length also. If he has understood my letter and thinks that my definition of the reason for parallel perspective is wrong, he might as well explain where the error is. A sketch, also, of some simple subject, such as a row of houses, according to his ideas of perspective, would be interesting.

I am as sure as M. Paris is to the contrary that parallel perspective is the only true one; that pictures are something to go by, because they are not conventionally arranged, but are drawn as they are actually seen; that moving the eyes is not the same as moving the camera, because when the camera is moved the plane of delineation is moved also; and that "E. L. G." will not say anything so foolish as M. Paris supposes.

Ten minutes' drawing practice on a window, as suggested in my letter (p. 39), would teach M. Paris more of the true principles of perspective than reading or writing any number of letters on the subject, and he would also see that he has totally misunderstood the matter which was to be demonstrated. No one says that the summit of a tower, viewed from the ground, does not look narrower than the base, the question to which Dr. Carpenter gives one answer and I another is, why a tower with parallel sides, which appears to the eye tapering, should (or should not, if M. Paris likes) be drawn parallel? B. D. T.

SPINNING-TOP.—PERSPECTIVE.

[4191.]—THREE letters (4180, 4181, 4182, page 204) have drawn my attention to an earlier one (4040, page 151). "Philo" is right. A top has keen known to spin longer in a partial vacuum than in the atmosphere. As to "A." and M. Paris, they revive old fallacies about the gyroscope, of which the common spinning-top is but a variety; but may console themselves that they are in good company, since the Astronomer Royal for Scotland said that in the case of the gyroscope we must look to the action of gravity acting horizontally, or words to that effect. It is strange how often mistakes reappear, although corrected. At page 411 of your issue for January 7, 1870, your correspondents will find a figure and description of apparatus which demonstrates that "the effect of gravity is not nullified"—that the "force of gravity is not overcome."

The late Arthur Parsey published a book about twenty years ago, to endeavour to establish a system of perspective in accordance with Dr. Carpenter's unfortunate blunder, and a very curious book it was. The difficulty some people have about the point in question arises from their erroneously supposing that in a picture or drawing objects must be as the eye sees them. Now, the image in the eye is not identical with the objects, for it makes the more distant ones smaller than the nearer ones: it also corresponds to a spheroidal section of the rays from the objects. A drawing or picture is a contrivance (generally, although not necessarily, on a vertical plane) for producing in the eye the same image that the actual objects would do, which it could not do were it precisely the same as that image. It is geometrically demonstrable that parallel vertical lines in the object must be represented by parallel vertical lines in the picture, when the plane of the latter is vertical. But for all that, the picture will appear quite right to the eye, for the widths between the lines of the actual objects will appear to vary in a manner depending on the angles between the vertical lines and imaginary lines from the several points to the eye, and the widths between the lines of the drawing will appear to vary in precisely the same way. Thus the top of a tower in the picture must appear as much further from the eye than the bottom as the top of the actual tower seems further than the bottom.

Glasgow. E. H.

ECONOMY OF SMALL BIRDS.

[4192.]—I BEG to thank "Animals' Friend" (let. 4126, p. 208) for his defence of small birds. I am a gardener in a small way, and do all I can to prevent birds being driven away, being convinced that though they do some mischief, they prevent far more being done. Some years ago, when visiting a large establishment for the growth of grapes for sale, I noticed many birds flying about the houses, and was told by the owner that he had quite satisfied himself that though the birds did eat a good many grapes, they took no more than they were fairly entitled to, for they prevented a great many more being eaten and spoiled; he would not on any account have them excluded, even during the fruit season, while during the greater part of the year, their services as insect eaters are of unmixed benefit, and as to a few grapes they were welcome. The labourer is worthy of his hire. PHILO.

"E. L. G.'s" COMET.

[4193.]—ONE thing is certain. Whether there was a universal deluge 5,000 years ago or no, there is a deluge of words now. Four columns of "E. L. G."! However, there are some good grains of wheat among the large amount of chaff, and I hope our friend will not object if others add a little chaff also.

Lest we should get altogether swept away from any known position, let me lay down some fixed bearings. "E. L. G." is committed to two distinct propositions, not singly, but united, and it is the union of the two which caused this discussion; at all events that has brought me into it. These propositions are:—

1. That some 5,000 years ago there was a universal deluge which covered the whole then existing earth, necessarily destroying all its inhabitants except those specially preserved.

2. That this deluge was caused by contact with a comet.

The first of these propositions is difficult to debate without getting into a morass of theological squabbles, upon which I should firmly refuse to enter if "our" Editor were foolish enough to let me. But I heartily indorse the truly wise sentiment of "F. R. A. S.," p. 223; it *is* "playing deliberately into the hands of the infidel and the scoffer," when those who consider themselves the advocates of religion insist upon coupling together religion and statements set forth as facts which are not facts, and which can be disproved. That the early fathers of mankind were subjected to a great destruction by a deluge or flood is a fact testified to by most of our early records. That this deluge was a universal one covering the whole earth is the apparent verbal meaning of the account given in our sacred records. But those records are the history of a family and nation; they give a cosmogony and early history, but they do *not* give them on their own account. They are the grandest poem in the world, but they are but an episode; they are simply an incidental introduction to the history of the Jewish family and race, and all the rest of the world, and its history is ignored except where it is essential to that special history; even when touched upon in consequence of this, it is always dealt with in perfect accordance, not with late scientific discoveries, but with the ideas of the people to whom the narrative was addressed, and who regarded the earth as consisting of just the lands they were acquainted with, as a plane surface, the centre and object of the universe, to which the sun and moon were subordinate, and in relation to which the stars were utterly insignificant, ranging these bodies purely in the order of their apparent utility. To people with these ideas, a flood which covered the land their fathers were living in (probably a fertile river district) would be fitly described as covering the whole earth. But if because such words are used we must be bound to extend that idea to the whole globe such as we know it, we must also be bound to accept literally the similarly connected ideas of the sun and moon standing still, and the creation in six literal days, as to both of which, explanations similar to that which I have given are now universally admitted.

Turning now to "E. L. G.'s" remarks (for it would be a great stretch of courtesy to call them arguments), they are found to consist of such phrases as these: "Very often have I speculated whether there may ever be found means of guessing;" "The arrival of the last atmosphere (evidently one of steam) must have;" "If we ask what weight of steam sufficed, I see no conceivable data for an estimate;" &c., *da capo*, as the musicians put it.

Happily "E. L. G." in his letter (4176, p. 229) has furnished a few excellent words which, reversing their application, convey admirably the sentiments his doctrines excite: "They generally see that it is utterly disproved by all *known* facts in the heaven and the earth (as baseless and as multifariously disproved as ever the Ptolemaic astronomy has been);" "A new priesthood that instead of reason or argument, write when something is to be swallowed against evidence, of what *we ought to believe*;" "Exactly as any Popish Council, &c., laid down their creeds, this dogmatic *faith* (for such it is, and no science) being just as anti-scientific myth and miracle-swallowing," &c. It is not necessary to give in full the usual string of epithets in which "E. L. G." so delights.

Now, as to the first point, was there a universal deluge? Any single fact inconsistent with such an occurrence disproves it, despite of any quantity of facts or arguments which may be consistent with it. Such a fact is that distribution of life to which I referred (p. 196), for it is impossible that in the short space of 5,000 years, the whole of the marsupial races should have found their way to the great island of New Holland, and disappeared from all the rest of the earth; ergo, New Holland was *not* flooded, its inhabitants were *not* destroyed, and, corollary therefrom, the deluge was *not* universal.

It may be "obvious" to "E. L. G." that all surface undulations were caused by a flood, but to other minds it is equally obvious that these undulations are due to other causes. But the second paragraph of letter 4157, p. 226, is one of the richest things I have seen for some time past. We are to accept on "E. L. G.'s" pure dictum that the earth is covered with a film (falsely called crust). Of course, "E. L. G." has measured its thickness, and is prepared to show the error of those mathematicians who show that this crust or film is some 800 miles thick at least. The one evidence he appears to present is a connection between cyclones and earthquakes at St. Thomas's, as to which far too little is yet known for any one but "E. L. G." to dogmatise about. But the fun of the matter is, that if "E.L.G.'s" facts and doctrines are true, they disprove his theory of the deluge. A mass of water falling over the whole surface would certainly do exactly the reverse of what he states; all that fell on the sea would increase the liquid pressure on its bed; all that fell on the land would run off into the sea, and increase that pressure; so that the result, on his own theory, would be such a compression of the film under the sea as would force the land up higher and higher, instead of raising the sea bed. This would be further aided by that rapid denudation, and, therefore, diminished land pressure depicted p. 230, because although "E. L. G." speaks of the action occurring before the water could run off, that could only maintain a temporary equilibrium—not increased pressure on the land, as the "10 feet per minute" on the area of the land would be balanced by the same 10ft. per minute on the sea; but as soon as it began to run off it would add to the sea pressure, not its own weight only, but that of the land it swept away also.

But how is it possible to argue seriously with a man who coolly obliterates the Andes and the Himalayas at his pleasure?

Now, as to the second proposition, the comet as cause of the supposed deluge. I have never yet weighed a comet for two reasons. 1. My balance, being for chemical analysis, will weigh only small masses up to 1,000 grains. 2. I do not know how to get a comet into the pan. But astronomers suppose they have some means of weighing the heavenly bodies, and in reply to "E. L. G.'s" challenge to prove a *single one* too small, I quote from Roscoe's "Spectrum Analysis." "The mass of the comet, I believe, is, astronomically speaking, inappreciable. We do not know whether there is as much matter in this comet as would fill this room, or as much as would fill one's hat, and this amount of matter is spread over an enormous space." This may not be proof; but assertion against assertion, if I am to choose between Roscoe or Huggins and "E. L. G.," I have no hesitation as to where the preference is due.

Now, as to the great question, where is the water gone to? Probably, "E. L. G." thinks that by puzzling others with a small problem of this sort he may evade the great difficulty. But, unfortunately for him, the difficulty he proposes is a very slight one. I know nothing of the matter beyond the extract he furnishes, showing the disappearance of a quantity of water from the sea into a limestone cavern. Probably a visit to the spot and a careful survey would explain the matter at once. I will, however, suggest a very likely explanation. We know that in many seas (and particularly we know it of the Mediterranean) there are very strong undercurrents. Such a current sweeping along a shore perforated with an opening leading to the particular cavern in question would produce a strong eduction current, or suction sufficient to draw out the water entering the cavern, probably on the other side of the island. The account shows, apparently, that the fall of the water is very slight, for the mills are stated to be driven by an undershot wheel. I could furnish several other probable explanations, but it is needless.

"E. L. G." holds that the water of the deluge obeyed the same laws as yesterday's shower, but this is absurd. Yesterday's shower fell, and returns to the sea to be again raised in vapour; here is circulation of a fixed quantity. Our problem is to dispose of a sudden and vastly excessive quantity, taken, at the least, very much in excess of the power of the air to absorb as it does yesterday's shower; for we know that the whole weight of the atmosphere is only equal to about 34 feet depth of water over the earth's surface, and the water contained in that atmosphere is only a small fraction of the total weight.

"E. L. G." has undertaken a hopeless task: a believer in the universal deluge, by faith in the record of it, has a perfect right to assume a miraculous production and a miraculous removal of the water: that is consistent, and I know of no possible reply. But one who treats it as a scientific fact, to be accounted for by natural causes, whether providentially controlled for the purpose or no, is bound to show that the causes he relies on explain his doctrine. If he invents a comet to bring the water, he must invent some way of getting rid of the water when its work was done. That task can surely prove no difficulty to a man who can order in a ready-made steam comet when he requires it. This is all "E. L. G." has done, for he most certainly has not given one particle of evidence that "geology shows that one fell 50 centuries ago, enveloped the earth before falling, and that its material was steam." SIGMA.

INLAND NAVIGATION.

[4194.]—I AM much obliged to "Jack Tar" for his great concern on my behalf, but very much surprised that he should gather from my simple letter that I was going to be fool enough as to venture to attempt crossing the Channel in my canoe. The words I used were simply that I was desirous for information about the waters in England or in Ireland; but lest any one else may go wrong, I want particulars the waters, rivers, canals, &c., of the counties of Armagh, Monaghan, and Fermanagh (more especially in the province of Ulster), which come on the way to join the Shannon.

I may say I have carefully read all Mr. Macgregor's books relating to his various voyages. I intend to confine myself to river and lake or canal navigation—with the exception of our own river here, the Mersey.

When asking for particulars of outfit, I had hoped some of our readers would have described the shape, material, and number of their sails; the sizes and weights of their various spars; the make of painter; whether they used an anchor or boat-hook, or carried wheels to make portages, or trusted solely to the chance of friendly assistance, or dragged their craft over land. Such particulars as these will be gratefully received by AFLOAT.

[If "Afloat" had referred to the *number* of the query or reply he would stand a better chance of getting the information he is in search of.—ED.]

GOVERNMENT AND AMATEUR SCIENCE.—I.

[4195.]—AT a late meeting of the Royal Astronomical Society, Colonel Strange advocated very strongly the importance of establishing physical observatories for prosecuting original research, more particularly with regard to what he termed the "physics of astronomy," and urged that as it was out of the power of individuals to carry on those long-continued observations that are necessary to elucidate questions which have been raised in the present advanced state of science, national establishments should be founded for the purpose of conducting such observations.

In the present age of amateur activity it may not be unimportant thoroughly to canvass this proposition, and if, Mr. Editor, you will grant me the necessary space I shall be happy to lay before the readers of the ENGLISH MECHANIC my views of science, as it exists under Government patronage and support, and as pursued by enthusiastic and energetic amateurs.

With the remarks of the Astronomer Royal relative to the connection of an object of secular interest with a Government establishment I most fully concur. We are all, more or less, taxpayers, and we have an interest in the disbursement of public money for scientific purposes. This disbursement may at present be considered under the two heads of "Astronomy" and "Meteorology." During the existence of the Royal Observatory, from its foundation to the present time, I think we must all agree with Colonel Strange that in connection with navigation it has done its work nobly and well; it may, nevertheless, not be out of place to ask if during this interval it has fully executed *all* the work devolving upon it? If I mistake not, the distinguished astronomer who at present presides over the establishment found in the archives of the observatory certain *unreduced* observations of the moon, which in that state were unfit for use. These by the aid of a grant of money, have since been reduced, and rendered capable of being employed in one of the most important astronomical investigations, "The Lunar Theory."

This allusion to the lunar theory leads me to notice the five principal divisions of this part of astronomy. 1. The raw material, consisting of the observations as made with the necessary instruments, and recorded in the books of the observatory. 2. Of the prepared material or the reduced observations in a fit state for the use of the theorist. 3. The theory itself brought to its present state by the labours of gifted minds, aided by mathematics of a high order. 4. The construction of tables in accordance with the theory. 5. The application of these tables in the computation of our national ephemeris, the *Nautical Almanac*. In looking at these five divisions we find three that are the work of the Government, and could not be accomplished without its aid. The unbroken series of lunar observations made at the Royal Observatory is one of the scientific glories of England. Nowhere in the whole world is an observatory spoken more highly of in connection with the moon than the Royal Observatory at Greenwich. Although the accumulation of unreduced observations during an anterior period of the history of the observatory has been referred to, such is not the case under the present able management. All observations are now reduced and duly published. The two departments, observing and reducing, are most efficiently carried on, and represent astronomy as supported by the Government.

The work of building up and perfecting the lunar theory is altogether separate from that above described, and may be regarded as a high order of amateur effort. While Governments have contributed to furnish theorists with materials, it is only by such minds as those of Newton, Clairault, Euler, Mayer, Lalande, La Place, Hansen, Delaunay, Cayley, and others that a theory so important in its bearings on the well-being of mankind could be brought into its present state. It was said by the Astronomer Royal, at the meeting of the Royal Astronomical Society, that the observations of the moon so sedulously pursued at the Royal Observatory were not undertaken for the elucidation of the lunar theory, but for the determination of the longitude. Now these two objects are indissolubly bound up in one great enterprise, an enterprise in which a succession of master minds have engaged; an enterprise that has had a two-fold effect upon society, for it has developed and disciplined minds of the highest order, and it has contributed in an accelerating ratio to the spread of commerce and civilisation. Without the theory the determination of the longitude would still be an unsolved problem, and without the important incentives for discovering the longitude, the theory might not have been developed to the extent to which it is at present.

Of all the branches of astronomy, the lunar theory has been the most extensively employed, but to render it as efficient as possible it must be cast in a mould, it must assume a shape by virtue of which its results can immediately be turned to a practical account; in a word, tables must be computed which can be used in determining the position of the moon for any given time; accordingly, several of the astronomers who have engaged in investigations of the lunar theory have constructed lunar tables. It is at this stage that Government aid is again indispensable. For the mariner to compute from the lunar tables the position of the moon before he could from his "lunar" find his longitude, would be a work which few, if any, could accomplish, but by supplementing the observational work of the Royal Observatory with the results of computations embodied in the *Nautical Almanac*, as suggested by Nevil Maskelyne and continued since his time, the mariner goes to sea with the requisite means for finding his longitude furnished him by science.

I have in this letter endeavoured to direct attention to the important assistance which our Government has rendered to a portion of astronomy that has been of incalculable benefit to navigation in the departments of observing and reducing observations, and in the computation of data by which the mariner determines his longitude. The higher branch of this valuable work appears to have been beyond the reach of a Government establishment. The improvement of the lunar theory has not been worked out within the walls of the Royal Observatory, nor have the tables been constructed therein. Men unconnected with it have accomplished the higher objects—that of producing tables of the moon as accurate as existing data will permit. In my next letter I propose to notice more especially the labours of amateur astronomers.

W. R. BIRT.

LUNAR OBJECTS FOR OBSERVATION IN JUNE, 1872.

[4196.]—JUNE 8, Brom., Agarum, Hahn, Berosus, Condorcet (*a*). June 9, *Wrottesley*, a crater adjoining Petavius on the east, Snellius Stevinus. June 10, Mare Nectaris, the ridges on the western part. June 11, Mare Serenitatis, the ridges on the western part (*b*). June 12, Linné and craters west of it. June 13, *Piazzi Smyth, Rumker* (*c*), *Bond* (*d*). June 14, Abenezra, Azophi, Agrippa, Godin. June 15, *Teneriffe Mountains* (*e*), Archimedes, *Newton* (*f*), (Schr.). June 16, Delisle, Diophantus. June 17, La Place, Maupertius, Condamine. June 18, Hesiodus (*g*), Cichus, Wurzelbauer.

(*a*) There are two conspicuous craters (not in Webb) S. and SS.W. of Condorcet. They were well seen on March 23, 1871.

(*b*) With longitude of terminator at 60° north latitude, varying from 20° to 12° west, and from 24° to 12° also west on the equator, the ridges of the Mare Serenitatis may be studied to advantage.

(*c*) Piazzi Smyth and Rumker are two small but conspicuous craters between Archimedes and Plato.

(*d*) A group of fine formations exists on the north of the Mare Frigoris, in the neighbourhood of Barrow and Timæus. The fine lozenge-shaped formation between Timæus and Barrow has been named "Bond," in commemoration of the discoverer of the obscure ring of Saturn.

(*e*) The group of mountains on the Mare Imbrium south of Plato has been named "The Teneriffe Mountains," to commemorate "An Astronomer's Experiments."

(*f*) The ancient crater about as large as, and south of, Plato, described as "Newton" by Schröter. It is best seen just after sunrise.

(*g*) The cleft from Hesiodus to Capuanus is a fine study. It has lately been traced throughout its length by Mr. Knobel.

Possessors of the first sheet of my catalogue of "Lunar Objects," including Area I A β, are requested to add the following, which were observed on May 15, between 8 and 10 hours Greenwich mean time:—

I A β 38 An isolated mountain between Agrippa and I A β 9, shown by Schröter in T LXII., Fig. 2. and by Lohrmann in both Map and Section I.

I A β 39 A peak on the S.E. border of Agrippa, shown by Lohrmann only in his map and Section I.

I A β 40 A cleft extending from I A β 41 to I A β 31. It terminates at the northern part of the mountain I A β 31, is a bright conspicuous object, and forks about the middle of its course. It is not shown by Lohrmann, but is well given by Beer and Mädler in the new edition of the large map as *a mountain ridge*, forking as above described. Its character may be better determined under an earlier illumination than on the 15th of May. It is about double the width of the Higginus cleft, and brighter. It is perceptible on De La Rue's photogram of Feb. 22, 1858.

I A β 41 A small mountain N.E. of I A β 5. It is shown in Fig. 2 of my Notes and Illustrations to the Catalogue.

W. R. BIRT.

HOW THE TONES OF A VIOLIN MAY BE INCREASED.

[4197.—To state anything new concerning the violin is usually a difficult matter, and I suppose one may experiment for years before arriving at any new fact worth mentioning. In previous numbers of "ours" the construction of the violin has been freely handled, and the relation of string to bridge, and thence to the breast, commented upon. Savart went further, and compared breast with back, showing (I think) that they must be dissimilar in kind of wood, and in thickness or density. We may infer, then, that to make the parts of a violin the same or alike is a mistake. I thought at first (and do now in part believe) that the pressure of the strings on the bridge interfered with the vibrations of the breast, for by raising the strings on a piece of wood 1¼in. high, previously removing the nut, sensibly improved the tone; but alas! not when the bow was used near the bridge, but only near the nut, and, again, the tone was not the true violin tone. It will always be difficult to maintain the present tone and increase its power without a roughness or reediness as a consequence. So I have come to the conclusion that we may not change the rules already established, but must endeavour to carry them out further, if possible, and I beg to place before our readers the following fact for their consideration. It is known that the back of a violin is hard, and forms the sound reflector; now, if a piece of hard wood—mahogany, for instance—is placed against a violin, the tone is very much enlarged. The best way is to lay the instrument down on its back, on another sounding-board, made 14in. wide, 28in. broad, and 1in. thick, the grain of the wood running across. The inference is this: cannot a second back be made to fit the violin? Very easy, is it? But no pressure must be used in the fixing, or the tone is lost, a simple contact is only allowable. A piece may be cut so as to cover the back, and held under the chin with the violin in the usual position, and that would do very well if you could keep it there. Another sounding-post will not act; I wish it would, for then we might have a series of soundboards *ad libitum*. Some of our fiddlers may see their way through this difficulty, if so we shall be glad to know. Probably if the backs of violins were made thicker it might improve the tone, but not much, and it might act just the other way. I have communicated this very small piece of information in the hope that as the trial can be easily made, some of our friends will report on the same.

FIDDLER.

COMMUNICATING ROTARY MOTION TO BALL FIRED FROM SMOOTH-BORED GUN.

[4198.]—"PHILANTHROPIST" is quite correct in what he states is the object of rifling a gun (let. 4100, p. 198); but when he says the composition holes might point backwards, so as to be ignited by the fire of the gun, he shows a want of practical acquaintance with artillery work. In shells for smooth-bore guns, the projectile is fitted into a wooden bottom, and the fuze points forward, towards the muzzle, and is ignited by the flash lapping all round. All muzzle-loading shells have their fuses ignited in this way. Breech-loading shells have their fuses ignited by a fulminating composition, which is fired by the shock of the explosion, owing to there being no windage.

I have seen many contrivances for rotating projectiles fired from smooth-bores, but however plausible in theory, they have all utterly failed in practice.

If "Philanthropist's" gun had to be used to fire over the heads of infantry, I should very much object to being the "infantry."

ARTILLERY CAPTAIN.

HOW TO USE A BOOK WITHOUT HANDS.

[4199.]—THAT your readers may see how gratefully the consideration of your correspondents, and the special kindness and ingenuity of "M. O." have been appreciated by the railway men, I inclose extract from the *Manchester Courier*, and shall be glad if you can insert it, and accept our best thanks.

"HOW TO READ A BOOK WITHOUT HANDS.—This question was opened a few weeks back in the ENGLISH MECHANIC, on behalf of an engine-driver who lost both arms on the Lancashire and Yorkshire line about a year ago, and who was so successfully treated in the Manchester Infirmary. After many ingenious suggestions, the question has at last been solved by Mr. Morehen, of 18, Banner-street, St. Luke's, London. This gentleman has taken a most kindly interest in the case, and last week sent his invention to Mr. Inspector Davis, Victoria Station, free of all charges. After the usual porters' church service last Sunday, this neat little desk was examined and tested by the unfortunate engineer, John Shaw, and his sympathising comrades. The table is fitted with wire folders attached to pedals which turn up twelve pages in succession, the sloping book-rest being easily adapted to the thickness of the volume or magazine used, held in its place by elastic bands. The mechanism is compactly covered in between the knees, and not liable to get out of order. It is altogether a very creditable and efficient contrivance, and cannot fail to prove a valuable relief where such an affliction to a man of healthy mental power renders it necessary."

T. M. W.

ELECTRICAL BELLS ANTICIPATED.

[4200.]—GIBBON, in his "History of the Decline and Fall of the Roman Empire," relates that "below the citadel stood a palace. The statues of all the provinces were arranged in order, each with a small bell suspended from its neck, and such was the contrivance of art or magic, that if the province rebelled against Rome, the statue turned round to that quarter of the heavens, the bell rang, the prophet of the capitol reported the prodigy, and the Senate was admonished of the impending danger." If this account is not a fanciful exaggeration, no modern city is so well provided with telegraphic apparatus as was the Rome described by Gibbon. It was not, it is true, like our post-office telegraph, available to every one according to tariff; but then the warning signal was of imperial importance, and was at once reported to the proper officer of department. Perhaps our discoveries are but recovered reminiscences of the forgotten past.

THOMAS BUCHANAN.

NEW FORM OF VIOLIN—VIOLA AND VIOLONCELLO COMBINED.

[4201.]—I should be greatly obliged by the frank expression of the opinions of "F.R.A.S.," "Suffolk Amateur," and my friend "Fiddler" (who is not only what his signature imports, but also an experienced amateur constructor of fiddles large and small) on the above design for a fiddle which—unless they think it mere fiddle-de-dee—would, I think, be a very effective instrument for solo performance, especially if extreme rapidity of execution be not attempted.

Its compass extends from CC to E, which includes that of the cello, the tenor, and the ordinary violin. The four shortest strings are of the same lengths as those on the latter instrument; but I would suggest that instead of making the tenor C string the usual length, that it be made—as I have shown it in the drawing—2ft. long, and the string which sounds C C—the lowest open note of the violoncello—the same length, both being covered strings, and the latter loaded pretty heavily, so that its tension may equal that of the same string on the cello. Of course, if preferred, the tenor C string might be the same length as it is on the viola, but if made 2ft. long, the tone will, I think, be found to be more powerful and of finer quality. A further advantage being that when the performer has learned to "stop" in tune one 2ft. string (that of the cello), he has only to "mind his stops" that are alongside on the tenor C string, and he will be correct to a "comma." I mean a musical comma, not a printer's.

Possibly, some fiddler may be inclined to inquire "Cui bono?" and say we are able to produce all the sounds this "funny fiddle" can by playing on the tenor and bass. Quite true; and, let me add, it is not intended to supersede those instruments in the orchestra, but for solo performance, especially of chamber music. No doubt, it is considerably larger than an ordinary fiddle, and therefore less portable, but its case—not necessarily a poor case—would not be nearly so large as that of a bass viol, if the stick on which it rests during performance be taken out of its socket. I think this instrument, whose compass extends from the lowest note in the bass voice to above the highest soprano, would be especially suitable for performing, in the absence of the singer, the vocal parts of any composition, if accompanied by the piano or harpsichord, even when those parts are for two voices, for the stops lie well together. Of course, duets wholly in harmonics *à la* Paganini are not to be thought of on the two long C strings; but—excepting that the four fiddle strings are a trifle farther from the hand, and therefore, somewhat more difficult to reach—there is nothing to prevent the young aspirant from attempting, not to say succeeding in, Paganini's favourite feat.

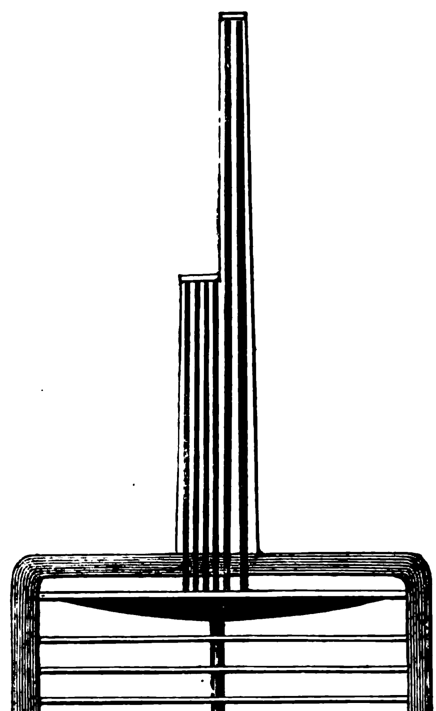
In the ordinary violin its strings are connected with its soundboard or breast only by pressing on its bridge and causing the latter to press on the soundboard with exactly the same force the strings press it. This is, no doubt, very objectionable, but a necessity, so long as no other means for forming their connection can be employed. The down-bearing of the bridge must necessarily impede the vibrations of the soundboard, which can hardly rise so far, while supporting and being held down by that pressure, as it would do were it connected with its strings in a similar manner to that in which the connection of those parts is effected in the pianoforte or harpsichord. Probably no one sees this evil more clearly than the writer does, and this is by no means the first time he has pointed it out; but, bad as it is in the fiddle, it must needs be worse in the harp, whose soundboard has to sustain not merely, perhaps, ten per cent., but the whole tensile force of the strings. Now, admitting these facts, it must seem rather inconsistent that he should propose to make a fiddle whose strings are to be connected with its soundboard exactly like those of a harp; but "circumstances alter cases," yea, even the case of a fiddle.

Had I designed to employ only one soundboard I should have been open to the reproach of choosing the very worst known method of exciting its vibrations; but experience has taught me that a load, intolerable for one, becomes easy when divided into seven parts, and placed on seven backs, or even on seven bellies. On referring to the drawing, it will be seen the said bellies—or rather soundboards (there can be no need to belly them, so we will belay all that)—might say with Mr. Richard Attenborough and the rest of the "Uncles" of that family, "We are Seven;" by the way, somebody said the same thing before that clever taker of pledges uttered it. Now, supposing a string to be strained with a force equal to 21lb., it must, to a considerable extent, mute any soundboard to which one end of it is attached *à la* harp; but when attached to seven such soundboards, it is obvious it can only pull each one of them with a force equal to one-seventh of 21lb. (*i.e.*, with a force equal to only 3lb.), and that it cannot mute any one of them to any very injurious extent; so in practice we may reasonably expect our seven soundboards to be a sort of Ajax' sevenfold shield to defend us from those ugly black melancholy men or things yclept "mutes."

I have assumed it would not be necessary, nor even desirable, to arch the seven soundboards, but if preferred it may be done, in which case it would seem preferable their concave surfaces should be towards the strings, so that the force of tension may tend to flatten them. Arching a soundboard seems only necessary to resist a force which tends to render it concave or convex. Down-bearing has the former tendency, so we make our pianoforte soundboards convex towards their strings; but as the strings in this funny fiddle must, like those of a harp, tend to induce convexity of the surface, which is towards them, I suggest making that surface slightly concave, so that when the strain comes on it, it may become—I fear my friend "Fiddler" will say, like the writer—quite a flat.

I think it will be found needful to glue a piece of hard wood, about ¼in. thick, (say) 4½in. long, by 1in. wide, on the under face of the first soundboard to which the strings are to be attached to prevent it from splitting. I have drawn a series of soundposts or struts, which, in practice, should just fit the spaces between each soundboard, but not be long enough to force them asunder. A screw bolt made of about No. 20 steel wire (screwed and nutted at both ends), passing through all these soundposts, will effectually clamp their ends, and the surfaces of all the soundboards together, so that they must vibrate simultaneously. There is no necessity to take the trouble to bore a hole in each soundpost for the bolt; a groove descending to the centre of each, formed by a saw, is easier to make and preferable, because it affords the means of extracting any one or all the soundposts. I have drawn one bar on the first soundboard. Of course, bars may be glued on every one, if preferred; but this is a mere matter of detail, which I do not think a necessity, although I prefer it to be done.

It would obviously be impossible for any man, whose dimensions did not equal those of Goliath or the Anakim, to "chin" such a fiddle as this, so I have provided a socket to receive a leg on which it can be supported during performance. I should much prefer being able to chin it, but can't, and after all, it may not be necessary for good performance. I have heard



very tolerable violin playing by executants who held their fiddles upright; and that very clever fiddler, Mackney, elicits a really fine quality of tone when he plays on his fiddle behind his back or above his head. Nay, I once saw him take one end of his bow between his teeth, resting its other end on the floor, and rub his fiddle up and down the bow; by no means the easiest method of performance, yet his tone was firm and full. Doubtless it would have been yet better had he held his fiddle properly; and, considering the difficulties of really good violin playing, are, what our Yankee cousins call "pretty considerable," I cannot conscientiously recommend the youthful aspirant to follow Mackney's example, unless, indeed, like him, they are well paid for doing the trick, for that which gets money must be the correct thing; but to shoulder their arms, I mean their fiddles, manfully, and scrape away to their hearts' content. (N.B.—The "content" of the auditors of their industrious practice is not necessarily included in this programme.)

I have not attempted to draw the head or scroll of this fiddle, because those parts are so very familiar that it would be a waste of labour to engrave them; besides, I did not like to trust myself delineate heads either of lions or humans. I fear my attempts at the human face divine might have been mistaken for caricature, in which so serious a person as "The Harmonious Blacksmith," of course, never indulges. I did indeed make the attempt, but instead of the head of Apollo Belvedere, only produced what resembled an ugly specimen of one of those grotesque grinning gargoyles we sometimes see in churches (placed there, no doubt, as aids to *serious* devotion), so I decapitated the original sketch of what was—with the aforesaid gargoyle—a very funny fiddle indeed. I might, indeed, have drawn a simple scroll, but I am not so good at scrolls as at scrawls, as you, Mr. Editor, must well know to your sorrow.

A friend to whom I showed this design said it must fail because you cannot make several soundboards to vibrate synchronously. If I cannot, of course it must fail, but I am very confident I can, having already done it in the piano, nay, it is done daily in the violin itself, for are not the vibrations of its breast and back—connected, as they practically are, to a very great extent, by its soundpost—synchronous? When you want to make things move together, you have only to couple them just as man and wife are, who invariably do "move together," or as a policeman is coupled with the thief by handcuffs, or the carriages of a train on the railway by chains and screws, or the discs of a chain pump by its chain on which they are affixed. Not only do the latter, like the bobby and the man supposed to have "prigged wot isent hisen," and having been "cotched" is being taken to "prisen"—move together, but they move—*i.e.*, lift the inelastic aqueous fluid between each of them together, the seven buckets lifting seven times as much as one can. May I not, therefore, conclude that having succeeded in making my many soundboards move together in both directions, they will move the elastic fluid (air) between them alternately to and fro, and thereby cause those aërial waves we perceive as sound; also that, as the magnitude of those waves must be in proportion to the area of the surfaces which create them, seven soundboards, each having a superficies of 600in., will move seven times as much air as one can do. It is seven air pumps to one, long odds in favour of the brethren who can say, with Mr. Attenborough, "We are seven."

A hint to would-be constructors—possibly the timbre might be finer if the first soundboard be made a trifle thicker than the others—but we must be careful not to make the combination too rigid, or the strings will not move it far enough to produce very loud sounds. As the best degree of rigidity can only be ascertained experimentally, it might be preferable to put one or two light belly-bars on each soundboard, because the depth, and consequent rigidity of each, could be accurately adjusted by a fine rasp until the best effects are obtained. The Harmonious Blacksmith.

ON THE FLY-WHEEL.

[4202.]—The formula $V^2 = 2gh$ gives the velocity of a falling body in terms of the height; hence, if we know the weight of a moving body, we can determine the quantity of work in it by considering the height from which it would have to fall to acquire its present velocity—thus, $h = \frac{V^2}{2g}$; but $g = 32{\cdot}1$ nearly, so we may write $h = \frac{V^2}{64}$. Let V_1 be the greatest velocity of the fly-wheel, and V_2 its velocity in feet per second; on passing the dead-points we have (h_1 and h_2 being the values of h corresponding to these velocities) $h_1 = \frac{V_1^2}{64}$, $h_2 = \frac{V_2^2}{64}$; therefore $h_1 - h_2 = \frac{V_1^2 - V_2^2}{64}$, and if M be the mass of the fly-wheel, and W its weight, $W = Mg$. The work given out towards passing the dead-points is $W(h_1 - h_2) = W\frac{V_1^2 - V^2}{64} = W\frac{(V_1 - V_2)}{64}(V_1 + V_2)$. We see, thus, that for a given weight of fly-wheel (that is, W being constant), if applied to a swiftly-moving engine, $V_1 + V_2$ is large, and therefore $V_1 - V_2$ small—that is, the motion is pretty uniform. In a slowly-moving engine of the same power, the value of $V_1 + V_2$ is smaller, and therefore $V_1 - V_2$ is greater, or the speed is not so uniform, since $W(h_1 - h_2)$ = work given out towards passing the dead-points $= \frac{W}{64}(V_1 + V_2)(V_1 - V_2)$, h_1 and h_2 of course vary in value with V_1 and V_2. It has occurred to me that, if the fly-wheel could be so constructed as to become smaller in diameter at the dead-points, or by weights actuated by springs have its radius of gyration decreased, the motion would be more uniform. In the former case the circumference would require to be in segments, I know the idea is rather crude, but perhaps it might be improved on. Philanthropist.

"E. L. G." AND THE GEOLOGICAL QUESTION.

[4203.]—The following letter appeared in *Nature* this week, singularly apropos of the geological discussion now going on in the English Mechanic. Its bearing on the geological question will, no doubt, soon be confirmed or disproved:—"Geologists state that the volcanoes of Auvergne have not been in action in historic times (see Lyell, Jukes, and Geikie). I find, however, that the Rogation days were appointed by Mamercus, Bishop of Vienne, about A.D., 460, for the purpose of chanting litanies to stay the volcanic eruption which was then devastating his diocese (see Robertson's 'History of Christian Church,' and Proctor on 'Book of Common Prayer.'—(Signed) W. J. Green." I find that it was Mamertus, Archbishop of Vienne, who restored certain fasts, which had fallen into disuse in his diocese: he held a Synod for this purpose in 474. However, I can find no mention of volcanic eruptions; *vide* Gregor. Turon, lib. 2; ado in Chron. Baron. Annal. These references may possibly throw some light on the matter, but I have not the books at hand.

Though not prepared to go with "E. L. G." entirely, I take this opportunity of thanking him for his very suggestive letters. H. C. Key.

GOSSE'S "OMPHALOS."

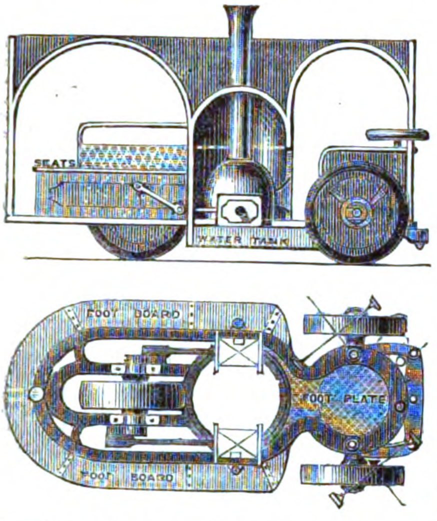
[4204.]—IT is reluctantly that I condescend to notice the gratuitous ungentlemanliness of the last sentence of letter 4134 (p. 223). It requires no abnormal talent or learning to be impertinently saucy, especially under the hiding of a pseudonym; but will "A Fellow of the Royal Astronomical Society" essay to *answer* my "Omphalos"? It assumes to be severely logical. Many have sneered at it (an easy process!); but I have not yet met with a single adversary who, accepting my postulates, has convicted me of a *non sequitur*. If "F. R. A. S." likes to bend himself to the effort, he will find that the work has not "long since been in the hands of the butterman," but is still on sale at Mr. Van Voorst's. P. H. GOSSE.

THIS YEAR'S INTERNATIONAL EXHIBITION.

[4205.]—I FULLY believe that you will favour me with a little corner of your journal, in reference to the present International Exhibition. In the first place, it is a matter of surprise to me how it is that the Exhibition is closed at six o'clock on each evening. Now that the long days have commenced, I think it would be doing the public a good service to allow it to be open until eight o'clock during the height of the summer, if not later even, to give many persons an opportunity of visiting it who are unable to do so in he earlier part of the day. Again, I would recommend that the charge for admission on all Saturdays during the season should be reduced to sixpence—at any rate (say) after two o'clock—thus enabling many of the working classes, to whom a shilling would be an object, to visit the palace of wonders on their Saturday half-holiday. NATHANIEL WATERALL.

YORKSHIRE STEAM TRICYCLE.

[4206.]—IN answer to letter 2900, p. 171, Vol. XIV., I herewith send you drawings of a steam tricycle, for family use, pleasure, or hire; for traction, sawing,



thrashing, grinding, pumping, or forcing water; as a fire engine, for which it is well adapted, for it can be drawn by horses very readily when steam is not up. When wanted to saw, thrash, or pump, the front or steering wheels will only require chocking, and the hind part raising a little from the ground, for the driving belt to be put on the driving-wheel, which is covered with indiarubber tire of a suitable thickness and breadth for weight and power required. The steering wheels have only one-fourth of the radius of those on the old system, when moved from centre of axle; consequently they are much easier to guide or move into or out of lock, and not so liable to upset; the wheels on the old system are one foot further to move back and forward, to be put in the same lock as the others, and the bearings on the ground are 5in., or more, nearer to the centre line of carriage, which is a great disadvantage. There is not that tendency to slip with one driving wheel as there is when two are fixed on each end of crank shaft, with a great deal of unnecessary friction, wear, and tear, when moving out of a direct line. The exhaust steam to be conveyed betwixt the boiler and the jacket that surrounds the whole of the boiler, whereby the steam will be greatly expanded before it comes in contact with the smoke, &c., just above the steam dome. The chimney is in one piece, with the jacket, and I think it will have a tendency to decrease the noise of the exhaust steam, which is a great intimidation to horses on the road. JAMES WADDINGTON.

ORNAMENTAL TURNING.—XI.
