[4437.]—THE recent sufferings and experience of "Irish Mechanic" are nearly identical with my own of ten years since. My recollections of them are as vivid as if they were of yesterday. Like him, I too have a long toe that was always in difficulty. The smell of new leather made me feel faint. The sight of an awl induced pricking sensations in my feet. I longed to administer my shoemaker's wax to his own back. The soles beneath me and the soul within me were worn out. My artist suggested that his "uppers" were soft and pliable. I uttered, half unconsciously, "limp." He tendered (my poor feet) advice, and had even felt for me. It was enough I remarked, "Halt!" My two monosyllables had fully explained the case. He handed me a card of introduction to the last new professor, remarking "Clever man, sir. Studied the foot —fond of anatomy," which latter I found true, as after taking a ground plan and elevation of my foot, he wanted a "section." I left the professor with the fond delusion that there was "Balm in Gilead, for me, even me." The ultimate results did not, however, conduce either to ease or elegance. These two men, sir, if I can call them so, had conspired to place my great toe at the inner corner of what they deemed a boot. But I defeated them, sir, and that through their own base machinations, by doing to the lasts what the professor wanted to do to my foot, making a diagonal section—that is, sawing off the great toe and ball of the foot, and fixing on a piece somewhat wider, which, rasped down to about ⅛in. thick, has left me as the story book says, "happy ever after," and this is a true story, sir.

T. S. USBORNE.

ON THE RIFLING OF GREAT GUNS.

[4438.]—THERE is great difference of opinion on this subject; we may, indeed, call it "the battle of the twists." I, myself, don't like the system of studded shot with increasing twist, but prefer ribbed shot with uniform twist. There is this to be said in favour of the guns with increasing twist: their vents have not been worn so large as those with uniform twist after firing. The increasing twist guns have to all appearances been very unfortunate of late; in fact, it would be a disaster to us of no small magnitude if such "accidents" were to happen to our heavy guns in time of need. I was told by a gentleman connected with the Whitworth Ordnance Company the cost of "tooling" their 12lb. shot; it was very small indeed, I think about three farthings each. I don't think the Woolwich guns with increasing twist could be altered to uniform twist without having new inner tubes, or else being bored out to a larger calibre. I shall be glad to furnish any information in my power for the benefit of such an esteemed correspondent as "The Harmonious Blacksmith" and our readers generally. ARTILLERY CAPTAIN.

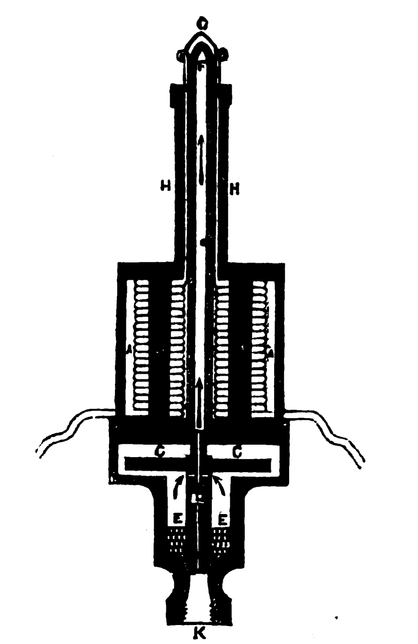
BAROMETERS AT SEA.

[4439.]—SIR J. ALDERSON seems to have fallen into the old error of supposing heavy bodies begin to fall more slowly than light, according to a paper on "Sea Sickness," quoted at p. 323, and Dr. Pollard has followed him with another old and equally false theory. The reason why the mercury does not fall nor rise exactly with the tube is simply because, being a liquid, it is to a certain extent independent of the ship. It is like a passenger in a railway carriage, when the carriage goes on or stops suddenly, the passenger, not being fixed to his seat, suffers in consequence.

M. PARIS.

ELECTRO-MAGNETIC GASLIGHTING APPARATUS.

[4440.]—IN your issue of the 14th inst. I observe a sketch of an electric gaslighting apparatus by Prof. Klinkerfues, University of Göttingen. If you refer to the *Builder*, October 8, 1864, page 743, you will find a description of a similar invention for which I took



"provisional protection" in July of that year—viz.: The invention may be applied to any description of gas-lamp without requiring alteration; the apparatus is about three times the size of a lady's thimble, and very much like an ordinary gas-burner. The principles upon which it is based are stated as follows:—An ordinary telegraph wire communicating with a galvanic battery is connected with the "Electro-magnetic burners" in succession, according to the number of lights required, and the extremity of the wire is conducted back to the battery, when the circuit is complete. Therefore, to light and extinguish the lights it is only requisite to connect or disconnect one of the poles of the battery. Immediately the electric current enters the "electro-magnetic burner" it passes through an insulated wire, which is lapped round two pieces of soft iron, which immediately becomes a powerful magnet, and attracts a soft iron plate, which lifts or opens a kind of valve, and permits the gas to escape through the burner. At the same time that the gas valve is opened, the current passes through a piece of platinum wire close to the burner, which turns red hot, and lights the gas. This effect is produced at every burner at the same instant. This invention was exhibited in Durham eight years ago with success, to the extent of a quarter of a mile of wire and half a dozen lights.

The following is an extract from a letter written upon the subject by Prof. Faraday, dated Aug. 10, 1864:—"No battery having a wire three miles long and at its extreme end a piece of platinum wire affixed would ignite the gas."

I had the experiment tried with a powerful 12-cell battery, using the North-Eastern Railway Company's telegraph wires between Leamside and Durham, and although there was sufficient power to open the gas-valve, it proved Prof. Faraday's statement to be correct.

The cost of the "electro-magnetic gas-burner" (exclusive of battery and wire) was 7s. 6d. each. After the burners are lighted the battery power is reduced to one cell, which keeps the gas valve open during the time required. A, insulated wire; B, soft iron (magnet); C, soft iron plate; D, gas valve; E, mercury; F, gas burner; G, platinum wire; H, brass tube, inclosing insulated wire; K, gas-pipe.

Sunderland, June 17. T. C. EBDY, F.R.I.B.A.

PATRIARCHAL WRITING.

[4441.]—THOUGH it may be bad policy to defend my enemy, "P. Santalinus," against my fellow soldier Mr. Brookwood, I must submit, in answer to the latter, that though the Book of Genesis may not expressly state this or that portion to be copied from journals of the Patriarchs, it certainly implies as much. Chap. v. professes to be "the book of the generations of Adam," and the particulars contained, involving about thirty exact numerical statements, each in hundreds, tens, and units, Mr. Brookwood will hardly suppose could be handed down otherwise than in a book of some sort. It need not be *alphabetical*. Considering the case of the Chinese, who, with the oldest writing known, have not even yet learnt an alphabet, it seems more probable that *they* retain (in principle) Noah's method of writing, and *our* teachers, Hebrew, Sanskrit, and Greek, improved upon it, than that our fathers in the Ark wrote alphabetically, and the Chinese lost the alphabetic principle without losing, like savages, writing altogether. Moreover, if Noah had written alphabetically, I think all his descendants would have retained, though not the same alphabet, the same *direction* of writing, and if in horizontal lines, then most probably, all from left to right, which is certainly more natural and convenient than the Shemite way, at least for right-handed people, and seems suggested by the daily course of the sun, in our hemisphere. Indeed, the undoubtedly greater antiquity of the Shemite way than ours, and the fact of the columns and pages of Chinese going from right to left, would suggest, if it were really Noah's way, a probability that not only might his original country have been south of the equator, but the Antediluvians left-handed, and he or Japhet exceptionally right-handed, as the majority of every tribe descended from them. At any rate, there is good evidence that the Egyptians wrote *alphabetically* (and perhaps on papyri still to be handled and read?) long before Mr. Brookwood's "1500 B.C.," and if he holds the Bible to be anything but forgery, it implies *Books*, we see—they need not be alphabetical—in the lifetime of Adam.

As for Genesis, the Shemite records of Adamite and diluvial times, whence it was compiled, must have come *in writing* either from one who had been in the Ark, or one who *pretended* to have been there. Which does Mr. Brookwood prefer? I think with Halley (p.350, let. 4353, par. 3), "to all that consider the seventh chapter of Genesis impartially, it will pass for the *remains* of a much fuller account," derived in writing from Noah's son, not grandson. And Sir Isaac Newton, in his "Observations upon Prophecies of Holy Writ," the unfinished posthumous fragment that his editors say he had recopied oftener than any other manuscript, and for the latter half of his life had given more time to, than to all his discoveries. Sir Isaac, in the first chapter thereof, shows as well as he ever proved anything, that the man who first translated from these patriarchal writings, the *remains* that we call the Pentateuch, and edited them in the *Canaanite* language (now called or miscalled "Hebrew") could only be the prophet Samuel; and they are probably the document mentioned at 1 Sam. x. 25. They are also rightly called the "Books of Moses"—*i.e.*, Books *about* Moses, and mainly derived from him, but he must have legislated in Egyptian; and Samuel must have compiled from *private* or *family* extracts of the great legislator's works, because the *national* copy had been lost during Samuel's youth, iv. 11; never to be recovered (1 Kings viii. 9), not merely these 5, but the first 7 Hebrew books form plainly one connected work, published by the authority of Samuel, or the college he founded at Ramah, the inferiority of the last two doubtless implying the hands of his pupils, but no ancient work more plainly dates its own appearance. The passage, Gen. xxxvi. 31, fixed the publication of *that* book to be *no earlier* than Saul's coronation, and Judges i. 21, fixes *that* to be *before* the Jebusites lost Jerusalem, which was the eighth year of David (2 Sam. v. 5—10). The whole of this earliest extant Hebrew history limits therefore its publication within those 48 years, and Samuel is the first of now extant Hebrew chroniclers, which *may* be what "P. Santalinus" meant (p. 277) by the funny expression "first of his race." Older Hebrew than his, however, may be extant in Job and some Psalms; for two of the latter (numbered in English 14 and 53) seem plainly two Hebraists' rival translations from one original poem. E. L. G.

ERRATUM.—In p. 352, end of first letter, last line but ten: the parenthetical word beginning this line should be "lunar."—E. L. G.

"J. C." AND DARWIN.

[4442.]—IF "J. C." (let. 4383, p. 356) would look at the letter he is criticising, he would see that no facts of Darwin's are brought forward to assign a particular *date* for the Deluge, but simply as things which the eminent observer, by his own showing, while too honest to deny or obliterate, has been glaringly unable to explain, and does not pretend to have explained; while a fresh-water Deluge, whether at the time all national traditions and old records place it, or at any other time, explains them perfectly. Where is the "implied misrepresentation "? If Darwin has produced a shadow of "explanation" for his great general facts that fresh-water species are *more* distributed than salt-water or land ones, and that sea and land species are *less* freely spread than fresh-water ones, why does not "J. C." produce or quote the explanation, instead of *misrepresenting* Darwin's hypothesis as *explanation*, and "E. L. G.'s" explanation as *hypothesis?*

But his last two sentences are utterly beyond me. I ask why, on Darwin's hypothesis, mammals have not been developed on islands that Darwin insists are "ancient enough," and in his own words have had "time sufficient" for any creation; and "J. C." replies that "a much greater length of time than 'E. L. G.'s' 5,000 years" is needed! What on earth can *my* 5,000 years have to do with it? The question is why Darwin's time has not sufficed, not why *mine* has not!

E. L. G.

CHLORIDE OF LIME.

[4443.]—For the information of "L. T. F." (let. 4281), I beg to state that chlorine in bleaching powder is not fixed. Though commonly called chloride of lime, it is in reality a mixture of hydrate of lime, chloride of lime, and hypochlorite of lime. Mr. Bottone must have adopted an indifferent system of analysis in estimating the available chlorine in this product, or his samples must have been rather long made if he has not found over 20 per cent. in the commercial article. I regularly find up to 30 per cent., but then the sample is quite fresh. After standing aside some days I have found as little as 15 per cent.

Un Irlandais.

GOLAIL OR INDIAN PELLET-BOW.

[4444.]—Letter 4209, p. 255.—If a tube or barrel (breech-loading if you please) were attached to the middle of an ordinary single string archery bow, such tube passing through a ring attached to the bow itself, and having a projection on its end, upto which the bow should be drawn previously to the "loose," it would save the "rap o' the knuckles," and probably increase the accuracy of the projectile, which might be elongated to a bolt.

Suffolk Amateur.

GAMBOGE.

[4445.]—"E. L. G." (let 12050, p. 339) mentions the singular fact that gamboge, slightly transparent when dry, turns opaque when wetted. The fact is singular as being at variance with the general rule that semi-transparent substances become rather more transparent when wetted. May not this opacity result from the motion of the particles of the moistened gamboge breaking up small the reflecting surface? Can "E. L. G." offer any opinion on this subject, and can he or any other contributor say whether this life-like motion of the particles, well known to most microscopists, has been satisfactorily accounted for?

Bobo.

To Mask the Taste of Castor Oil.—According to a correspondent of the Boston *Medical and Surgical Journal*, the following formula affords a method of completely disguising castor oil:—Of glycerine and ol. ricini, two fluid ounces each; ol. cinnam, four minimms. The essential oil should be rubbed up with the glycerine, the castor oil added, and the mixture well shaken before using. This is said to be the very best method of hiding the taste of the castor oil.

Regulating the Hatching of Silkworm Eggs:—M. Duclaux, after a careful observation of the external conditions which favour and influence the hatching of the eggs of silkworms, has prepared the following rules, by attention to which it is said that the development of the eggs can be regulated at will. First, to prevent an egg from being hatched at the usual time, it must be kept, from the period of being laid, at a temperature between 59° and 66° Fahr., and then exposed fourteen days to cold, three months before the time at which the hatching is desired, being subsequently treated in the usual manner. To cause an egg to hatch before the usual time, it must be exposed to cold twenty days after being laid, and kept in that condition for two months, and then removed. Six weeks later it will be in the same condition as ordinary eggs, and can be treated in the same manner. In this way it is possible to have silkworms ready for hatching at any season of the year.

Ozone.—From the address of M. Blanchard, at the re-union of Delegates from the Learned Societies, recently held at the Sorbonne, we learn that M. Houzeau, of Rouen, has considerably extended our knowledge of ozone. By a simple apparatus, he has obtained in about a quart of common oxygen from sixty to 120 milligrammes of the odorous oxygen, or ozone. In this concentrated state it is dangerous for respiration, it burns organic tissues rapidly, attacks gold and silver, and has bleaching properties superior to chlorine itself. In the *Journal* of the Scottish Meteorological Society for January and April 1872, in addition to the usual records of temperature, pressure, rain, &c., is a report on ozone observations, which appears to be of considerable value. The following conclusions are new and interesting:—"When the air had a pleasant sharpness to the feelings, exercising, as it were, a stimulating influence on the spirits, the largest quantities of ozone were obtained. On the other hand, when the air was close, and seemed to exercise a slightly depressing influence, little, if any, ozone was detected."

REPLIES TO QUERIES.

*** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[11275.]—**Darkening Walnut (U. Q.).**—Try chromate of potash solution.—Suffolk Amateur.

[11564.]—**Blackberry and Strawberry.**—The raspberry is undoubtedly what is called indigenous in England, as it is in Switzerland, Germany, and like temperate climates. It may be found, according to a farming friend, growing wild in the woods in Kent; but, of course, birds may have carried the seeds from gardens. All "indigenous" plants, however, may have been thus propagated. Some of the finest wild fruit I have found during a number of pedestrian tours occurred in the woods clothing the volcanic cones of the Eifel. On the Grimsel pass in Switzerland they are very fine, and not only as "plenty as blackberries," but much nicer. The blackberry seems to require a cross to sharpen its flavour. In South America I have read a very good variety exists.—M. Paris.

[11589.]—**Dry Steam.**—Steam of a given pressure, say 3lb. per inch, in contact with water, is saturated steam or wet steam of that pressure, and can be neither above nor below the corresponding temperature, as given in Regnault's, Rankine's, or other tables. If it cool one degree, a part will condense, and the rest be still wet steam of a lower pressure, and containing less water in a given bulk. If it be subjected to more than 3lb. pressure, a part will also condense, but the temperature of the whole must rise to that corresponding to the higher elasticity—otherwise, with no rise of temperature, the condensation would go on till the whole became water. If the steam have its temperature raised out of contact with water, it immediately becomes "superheated"—*i.e.*, dry or drying steam—steam in which water will evaporate, or wet bodies can be dried. It may be of no higher pressure than when it was wet steam, and in that case it must occupy more space. If confined to the same space as when wet, it will be of higher pressure. Thus, high and low pressure steam, indeed, of any two pressures, may have the very same quantity of water per cubic foot; or the lower pressure *may* have, as "A." supposes, "more water than in the same volume of high pressure," if their temperatures are equal. But when we compare two wet steams, or two of any fixed degree of dryness, the more elastic will always contain the more water, or be the denser, as well as the hotter. I cannot see any "carping at terms" in denying that a hand can possibly be placed *in* high pressure steam. The steam issuing from a high pressure boiler shows its instant resolution into cloud and low pressure steam, by becoming visible cloud at the very lips of the outlet. Not so the steam from the tea-kettle. That remains for some inches invisible, and in the invisible state will scald severely. But visible cloud will not scald, at least, when decidedly white and opaque, whether coming from a high or low pressure source; for it can in no case contain high pressure steam, nor, probably, any of half or a quarter atmospheric pressure.—E. L. G.

[11589.]—**Dry Steam.**—It appears that "E. L. G." deems this a "very easy query;" but it does not appear that he has given a much more satisfactory solution of it than those who have preceded him in the attempt; he assumes premises inconsistent with observed facts, and hazards various assertions and opinions without any evidence to support them. The remarks of "E. L. G." on high pressure steam, whether in accordance with ascertained facts or not matters little, high pressure steam having no relation whatever to the subject of this query, and whether he adopts overheated or subsaturated as improved synonyms for dry steam is immaterial. Atmospheric steam, he says, is dry except in a rain cloud—which is, perhaps, questionable—at all events, steam is rather a new term to apply to the hygrometric state of the atmosphere, and why he introduces the imaginary composition of his imaginary "Comet of the Deluge" into such "an easy query" as this I don't know, and won't attempt to follow him into such distant regions of time, space, and speculation, which is the less necessary having no bearing whatever on the present query. The incondensible steam referred to in the query, "E. L. G." says was no longer steam at all, but decomposed as all steam is when passed over iron, zinc, or coal, or other combustibles; but not into oxygen or hydrogen; if not, what else can it have been decomposed into? He then says that in passing over the iron, zinc, or coal, the oxygen remains; but in that case the hydrogen must surely be set free, and discharged at the open end of the pipe as an inflammable gas. This, however, is found in practice not to be the case. He mentions that in the case of the steam being passed over coal, the oxygen remains with the carbon, forming carbonic acid, which, no doubt, if in sufficient quantity, would tend to prevent the inflammability of the hydrogen. Unfortunately, however, for "E. L. G.," this assumption does not apply to the present query, for in no instance on which the query is founded was the steam brought into contact with carbon at all, with the exception of the 2 or 3 per cent. contained in the inner surface of the cast-iron pipe when that metal was used. Zinc is far too easily fused to be suitable for superheating steam. The late Mr. T. V. Lee, who was a patentee for the application of superheated or dry steam to various economical purposes, and among others to that of baking bread, biscuits, &c., for which purpose he fitted up ovens at Wapping, Plymouth, and other places, in which he used cast-iron pipes for the superheating coil; but in consequence of the frequent fracturing of these pipes by contraction from the alternate heating and cooling, he on a subsequent occasion substituted copper pipes when fitting up a kiln at Dulwich for an extensive joint-stock company for drying and burning bricks; but the copper he found melted with the heat required to superheat the steam, and was abandoned. Now, in none of those cases was any discharge of inflammable gas observed, nor any mixture of hydrogen and carbon detected. From the above it seems pretty evident that "E. L. G." has not yet hit on a true solution of this "very easy query," and if he considers it worth his further notice will have to adopt some other method of solving it more in accordance with the results of practical observation and experience.—Caloric.

[11589.]—**Dry Steam.**—"E. L. G." while accusing all your correspondents on this subject of making ludicrous errors, falls into the queer mistake himself of giving a supposed explanation, but one wholly insufficient, of the fact that steam of high pressure escaping rapidly into the air does not scald. He is quite correct in saying that as soon as high pressure steam escapes it expands, and its temperature is reduced, but utterly mistaken in supposing that that is the reason why it does not scald, for it expands only as much as the pressure of the air will allow, and its reduction of temperature by expansion alone is only to the boiling point, at which temperature it would scald just as other steam does. I do not, however, as "E. L. G." would do, call such a natural mistake of a half informed man a ludicrous error; it would be not only rude but foolish to do so, for such is the explanation very commonly given, but it is quite erroneous nevertheless, as a very little consideration will show. If a cylinder full of steam at the ordinary pressure of the atmosphere be compressed to one quarter of its bulk, its temperature will rise to about 296°, and if high pressure steam at that temperature filling one quarter of a cylinder be allowed to expand so as to fill the whole of the cylinder its temperature will fall to 212° but no lower, from expansion alone to that extent, and the expanded steam will scald just as much as it did before it was compressed, or as if it issued from a boiling kettle. If, however, steam at 296° be allowed to blow off into the air it does not scald, though its temperature by expansion is reduced no more. The reason of the difference is simple and evident. When steam rises quietly from boiling water, it carries little air with it, and retains its scalding heat, but when high pressure steam issues very rapidly from a narrow opening, it carries much air with it, as in the steam blast of a locomotive, and the mixture of air and steam being cool does not scald. It is very easy to test the correctness of this explanation. If high pressure steam escaping from a small hole be made to blow through a tube of larger diameter, held near but not close to the hole, it will act like a steam blast, carrying air with it through the tube, which will get as warm only as the mixture of steam and air, but if the tube be held close to the boiler, so as to allow steam only to enter the tube, it will soon get unbearably hot, though the steam will expand alike in both cases. A similar explanation renders it clear why breath blown strongly against the hand feels cool, which, when breathed against it slowly feels warm. The breath itself, is of course, at the same temperature, but the breath alone is warmer than the skin, while the mixture of breath and air driven against the hand when we blow strongly feels cool because it is cooler than the skin. Dr. Arnott was so good as to explain this to me when I, like others, was puzzled to understand how the mere expansion of steam under atmospheric pressure could reduce its temperature below that of steam formed under the same pressure, and I never met with the true explanation elsewhere, and it is not, I believe, commonly understood, though so simple.—Philo.

[11656.]—**Boiler for Small Steamboat.**—I beg to thank "P. W. H. J." for the trouble, and you, Mr. Editor, for the expense, incurred in answering my query; although, being pretty well up in engineering matters generally, I thought before making the boiler to take advantage of the brotherly advice so freely given in "ours" upon all matters. Upon carefully reading the answer from "P. W. H. J.," I find the information scarcely so reliable as I could have wished. For instance, the space occupied by boiler and engine is given as $2\frac{1}{4}$ cubic feet, which I find, taking his figures, to be nearly 8 cubic feet for the boiler alone; then I find that the united areas of tubes amount to as much only as one tube $2\frac{1}{4}$in. bore, which, with the fire-box, must be sadly too small for a 2 horse-power boiler. The fear of others being misled must be my excuse for the unpardonable offence of looking a gift horse in the mouth.—L. M. F.

[11742.]—**Painting Iron Bedstead (U.Q.).**—Here is a question how to gild without gold leaf! and a recipe for a white paint that will not in the slightest degree turn yellow! The first might be explained, but the second would puzzle Œdipus. All I can say is procure the "genuine" white lead, not the threepenny and twopenny stuff, made without a particle of white lead in it, and mix with varnish, this will give your bedstead the best effect, but I will not warrant its not turning yellow. Try some of the gold paint for the gilding portion. If the querist means the knobs, centres, &c., they must be lacquered, not gilt.—H. B. E.

[11748.]—**Humea Elegans.**—The correspondent who inquired about the culture of this plant will find the following reliable. I cut it from the *Journal of Horticulture*:—Sow the seed at the end of May or early in June in a pot or pan of two parts turfy loam, and one of leafy soil, with one part of sand. Just cover the seed with fine soil. Place the pots in a frame with a gentle heat, and keep them near the glass, and just moist. When the plants are up admit air freely, and as soon as they are large enough to handle prick them out in pans at about an inch apart, and return them to the frame. When they are fit to pot off singly in 3in. pots do so, using the compost before named; place them in a cold frame, and water them overhead daily, but avoid making the soil very wet. When the roots show at the sides of the pots, and before they are very closely matted, shift the plants into 4½in. pots, and so on until autumn, when they will require 7in. pots. They cannot have too much air after they are established in small pots, nor, indeed, at any time, especially in winter, so long as they are secure from frost. The main thing is to keep them slowly growing, and to shift them into larger pots as those they are in fill with roots. They should have good drainage, and a compost of two parts turfy loam, one of leaf soil, one of old manure, and a sixth of sharp sand. They may be put into 9in. pots in February, and have 11in. or 12in. pots at the close of March. Liberal supplies of water are required, but do not give any until the soil is dry.—SAUL RYMEA.

[11754.]—**Polishing Diamond (U.Q.).**—Diamonds were formerly polished by rubbing them against each other, as was the case with the Koh-i-noor. It was not till the middle of the fifteenth century that Van Bergem, a Dutchman, adopted the method of grinding and shaping them with diamond powder, and two centuries elapsed before the best true brilliant shape was discovered.—H. B. E.

[11772.]—**Black Lacquer.**—Simply Brunswick black. Consult back numbers.—H. B. E.

[11773.]—**Cleaning Plain Blue Silk (U.Q.).**—My wife finds benzine collas a very useful fluid for the removal of grease, dirt, and wine and other stains from her silk dresses. "A Mechanic's Wife" had better try it, and report progress. If it does not answer, I will prescribe another remedy, as I am eager, alike with other members of "our" brotherhood, to oblige the "fair sex."—H. B. E.

[11776.]—**Commercial Geography (U.Q.).**—Dr. Cornwall's "Advanced Geography" well discusses the imports and exports.—H. B. E.

[11821.]—**Holly.**—Holly, if left exposed to wet or lying on damp ground after felling, will become black and stained.—SUFFOLK AMATEUR.

[11865.]—**Fish.**—Cholmondeley Pennell says that in his experience, flavourings, whether of sugar, honey, or essential oils, are useless or mischievous additions to paste baits, and I never heard of a "good" fisherman who employed them.—A. T., Staines.

[11867.]—**Separating Tar from Wool.**—Tar will mix with grease or oil, and soap remove the mixture.—SUFFOLK AMATEUR.

[11873.]—**Magic Lanterns.**—"A. B." will find information on japanning in Vol. XIV., No. 350, and an illustration of "Jack of All Trades'" japanner's stove in Vol. XIII., No. 324. The proper japan can be purchased at most varnish shops.—E. M.

[11874.]—**Bryant and May's Matches.**—I think there must be something wrong about this query. Is "Hipparchus" sure that he tried Bryant and May's matches on linoleum? In fact, is he sure that they were not ordinary matches, or that he did not rub them on the prepared phosphorus paper?—SAUL RYMEA.

[11874.]—**Bryant and May's Matches.**—I have tried to ignite Bryant and May's matches upon linoleum, and failed.—L. M. F.

[11875.]—**Spectrum Colours.**—If "H. P. H." (whom I had no intention to criticise) will look again, he will not find anything in my reply about "white light." I was speaking of making a coloured spinner appear a white one. You may easily make it reflect white light, but not the quantity necessary to entitle it to be called "white" as an object. The light from a gray object, light or dark, may be equally white, *i.e.*, equally neutral light, and the dark gray object in sunshine may be brighter than snow in the shade, but that does not entitle it to be called a white object. Of course, with thanks for "H. P. H.'s" invitation, there can be as many kinds of white undistinguishable by the eye, but distinguishable by the prism, as there are hues of colours distinguishable or many more.—E. L. G.

[11898.]—**Tempering Cast Steel Chisels.**—"U. V. U." wants to know how to harden and temper chisels made out of old files. Being an experienced "old file" myself, I can sympathise with my fellow old files, and must protest against their being put to uses for which their material was not designed, and is usually quite unsuitable; so instead of instructions for doing what I believe to be an impossibility to do effectually, I repeat *Punch's* advice to (silly) persons about to marry, "Don't attempt it"—I mean tempering, not that trial of temper, marriage. No doubt many chisels and screw-drivers are made out of my brethren—I mean old files—but our nature is, alas! generally very coarse; and unless of much finer quality than usual, our employment for such tools is but "a delusion and a snare," most of us being composed of very inferior material (especially such of us as are natives of Sheffield) to that which ought to be (and by good makers is) employed for cold chisels and turning tools. Occasionally a tolerable tool may be made out of one of us, especially if a native of Harrington, and rejoicing in the honoured, if not very aristocratic, name of "Stubbs;" but the old file who writes this can aver, from long and costly experience, that it don't pay to make cutting tools of any other material than first-class cast steel. When they were made of ordinary Sheffield files (some of which are very queer files indeed) he almost invariably found their edges crumbled away in use, their material being weak and brittle when hard enough. This defect renders files especially unsuitable for screw-drivers. Although not required to retain a cutting edge like a razor or chisel, a screw-driver is subjected to considerable force when in use, and to resist that force properly it requires to be what the Frenchman termed "a very great toe"—in other words, very tough. I am decidedly of opinion that double shear steel best fulfils this condition; it is, therefore, preferable for ordinary use for screw-drivers, spanners, and other tools which are subjected to sudden and violent strains. I have, however, found the same cast (tool) steel which is ordinarily employed for chisels, &c., makes excellent screw-drivers if carefully forged at a low heat, hardened at the lowest temperature it will harden, and tempered rather low, say to a deep or even a pale blue. No screw-driver should be left so hard that a good second cut file will not operate on it if pressed forcibly and moved slowly. In fact, you cannot finish a screw-driver properly on the grindstone; it should be filed transversely, so as to form shallow grooves on the surfaces which act against the groove in the head of the screw, and thereby greatly diminish the risk of its rising in that groove and slipping out. Now you can't do this if the screw-driver be tempered too hard to be filed.—THE HARMONIOUS BLACKSMITH.

[11916.]—**Octave Coupler.**—See p. 369, Vol. IX., where you will find "Adept's" instructions, with illustration.—K. T. L.

[11917.]—**Organ Construction.**—If you mean books containing detailed instructions how to make an organ, there are not; but you will find what you want in the ENGLISH MECHANIC.—K. T. L.

[11948.]—**A Bad Sleeper.**—"N. K. R." should leave off drinking spirits or smoking before bedtime. Let his last meal be at seven, presuming he retires to bed between ten and eleven; do not take arrowroot or corn-flour, as it leaves a nasty taste. Keep a glass of cold water by the bed to sip.—H. B. E.

[11996.]—**Deafness Arising from Cold.**—This often arises from swollen tonsils. It may be ascertained by looking into the back of the mouth, keeping down the tongue with the handle of a spoon, when, if swollen, the tonsils will be seen looking like two red balls on each side of the throat, sometimes almost closing the passage. The homœopathic remedy is mercurius iod. The allopathic treatment consists of tonics and astringent gargles.—H. C. M.

[11996.]—**Deafness Arising from Cold.**—Let "R. C. Y." drop two or three drops of warm sweet oil into each ear morning and night. (Proved).—B. S.

[11997.]—**Warming Greenhouses with Gas.**—I have deferred replying to the inquiry of "H.B.E." (May 31, p. 288) in the hope that I might have been able to give him the information he asks me for, but regret that at present I can only partially do so. I have it from the brother of the gentleman who owns the greenhouse referred to in my letter of September 29, 1871, that it has fully answered his expectations, and stood the test of last winter, but am not at present in a position to furnish drawings or a fuller description of the plan I alluded to. The cost of gas consumed during the winter he believed was about £5, the size of the greenhouse (as I stated at the time) being about 15ft. by 16ft. I will endeavour, if possible, to obtain for "H. B. E." more complete information on the subject, but the state of my health has for some time back prevented my following up investigations as to the application of mixed gas and air for heating purposes. I find, however, it is now becoming very general.—HOUBLON.

[12000.]—**Insects in Tables and Chairs** of English woods, beech and sycamore, are most liable to worm, oak or walnut only in the sap; but the sap of walnut is easily stained like the heart wood, hence much walnut furniture soon returns to dust. Constant use is the best check, stillness, especially if a little damp and dark, favours the wood-worm. I have seen furniture eaten up through not being used. Similar conditions mightily favour moth. Fair use is the best for furniture. Modern upholstery and modern ways encourage these destroyers. Furnish a room to look at, seldom use it, never brush it (especially parts not seen), put on the covers, keep down the blinds, shut the doors, and you will soon have moth first and then worm, no matter what the stuffing is, if the cover is of woollen material. Fourpence extra upon an ordinary chair would put American birch instead of English beech, and prevent worm, but not moth. Moth is the effect of negligence, or of buying what you do not want. But cheapness is king, and if your chair is eaten up you have the comfort of feeling that you have saved 4d. But of all English woods walnut is most deceptive, for a tree will sometimes be half sap, hence the temptation to use it, being so easily stained like heart wood, and as to worm, it can hardly be sold before they appear. But after all cheapness is king — you produce a present effect, and then both you and your chairs return to dust.—AFTER NOON.

[12013.]—**The First Watch and Clock Made.**—In ancient books there is scarcely any authority to be depended upon by which the date of the invention of clocks may be traced; of course, clocks were invented before watches. Beckman, in an ingenious analysis of various statements made with reference to the inventors and period of the first clocks made to go by weights and wheels, ascribes the earliest of them to the eleventh century, but does not attempt to say by whom they were invented. Many statements have from time to time been made as to the inventor of clocks. Archimedes and Posidonius, before the Christian era; Boethius, in the fifth century, or about the commencement of the sixth; Pacificus, about the middle of the ninth; Gerbert, at the end of the tenth; Wallingford, near the beginning of the fourteenth, have each, in their turn, been asserted to be the inventor of the clock. We have earlier data as to clocks in England than that of Wallingford, for in 1288 we find that a stone clock-tower was erected opposite Westminster Hall with a clock, the cost of which erection was defrayed out of a fine of eight hundred marks upon the then Chief Justice of the Queen's Bench. Many remarkable clocks from this date have been erected in England and in other countries, which serve as landmarks to show us the advance we have made to the present time in the art and science of clock-making. From the above remarks it will be seen that the early history of time-measurers, or horologia, is involved in much obscurity. Richard Harris, an intelligent English workman, is said to have invented the first pendulum clock, in 1642. Peter Hele, of Nuremberg, is said to have invented the first watch. Johannes Cocclaeus, in his commentary on the Cosmographia of Pomphonius Mela, published in Nuremberg, in 1511, makes the following announcement:—"Ingenious things are just now being invented, for Peter Hele, as yet but a young man, hath made works which even the most learned mathematicians admire, for he fabricates small horologes of iron filled with many wheels, which whithersoever they are turned, and without any weights, both show and strike forty hours, whether they be carried in the bosom or the pocket." In the year 1658, Dr. R. Rooke invented the balance spring. In 1695, Tompion invented the cylinder escapement with horizontal wheel. In the year 1700, Nicolas Facio discovered the use of jewels in watches. In the year 1766, Thomas Mudge invented what is now universally known as the "patent detached lever." In the year 1780, the chronometer escapement was invented. The compensation balance was invented by Thomas Earnshaw, of London.—FREDERICK R. ROHU.

[12014.]—**Organ.**—Consult "An Adept's" and "J. D.'s" letters on the subject before sending queries like this.—H. B. E.

[12051.]—**Fire Engines.**—"A., Liverpool," in answering this query (p. 318), has got out of his depth. "Fire engines generally are used with flexible hose pipes" only on the delivery side, the suction pipe being prevented from collapsing by a spiral wire of copper or galvanised iron. Has "A., Liverpool," overlooked the quotation from Montaigne?—L. M. F.

[12060.]—**Glass Blowing.**—I am sorry I am not able to give "Emily Jane" directions how to blow a glass bulb on her tube. I think she will find it much more profitable to buy her bulb tubes ready-made. To bend glass tubing introduce the tube gradually into the flame of the lamp. Move it up and down, so that the neighbouring parts may be somewhat heated, then apply the heat strongly to the part where the bend is to be made, turning the tube round in the flame, and when sufficiently soft apply gentle pressure with the hands until it attains the proper form.—UN IRLANDAIS.

[12061.]—**Chemical.**—Dissolve in water. Add argentic nitrate as long as precipitate falls. If no precipitate be produced chlorine is absent. If chlorine be present filter off the argentic chloride and add to the filtrate sodic carbonate, evaporate to dryness, ignite, treat the residue with water, and add to the solution argentic nitrate; a precipitate proves the presence of a chlorate.—UN IRLANDAIS.

[12072.]—**Magnetic Moment.**—I presume that in his reply to this query "Sigma" refers to the unit of force adopted in the B. A. standard of electrical resistance, which Ferguson defines to be a force "capable of generating in a mass weighing one gramme a velocity of one metre per second," and which is equal to $\frac{1000}{9811}$ of a gramme = 1·573 grains. Will he say how the force of a magnet in these units may be ascertained? I am acquainted with the method of determining the strength of magnets by the oscillations of a magnetic needle; but this gives only relative results. I am rather at a loss to know what unit of length "Sigma" refers to, unless it be the metre, which seems rather too long for small magnets; and, again, as the poles of a magnet are not at its ends, how may their position be determined so as to have the correct length? And now there is another point concerning which I want some information. Ferguson states (p. 192): "Each pole of the induction coil is the seat of two opposite electricities, alternating with each other alike in quantity but differing in [illegible] can understand how, when the points [illegible] these together, both induced currents [illegible] to the hazy spark which is shortly before described: and that when they are further separated the direct induced current having the greatest tension would alone be able to spark across, in which case the sparks would be clearer and more like those of an electric machine; but a few lines lower down I read that a Leyden jar may be charged by an induction coil, and I cannot see how that is to be done, for it seems that each current would exactly neutralise the effect of the preceding one, being alike in quantity. And in turning to Tyndall's "Notes on Electricity," I there find (No. 306), that owing to some action of the extra current, which I confess I do not understand, "in a Rhumkorf's coil we obtain discharges in a single direction only, instead of discharges alternating in direction." Will "Sigma" kindly say which is right, and he will further oblige—BEACON LOUGH.

[12073.]—**Scarlet Runners.**—The roots may be taken up and preserved through the winter, just like tulip roots, but there is no advantage gained, as just as good plants are grown from new seed, and in the same time.—J. T. B.

[12077.]—**Pyrethrum Parthenium.**—Thanks to "William" for the information kindly given. The flowers which I noticed somewhat early were on old plants that survived through the mild winter. They had an unusual number of bracts, many more than the ordinary flowers, and each *white floret of the ray* had a green calyx inclosing white petals; the yellow florets were unaltered. Since the ordinary flowers have unfolded, these abnormal flowers have disappeared, ordinary flowers appearing on the same plants.—W. R. BIRT.

[12081.]—**Chemistry.**—There is no really simple method of detecting arsenic in the presence of several metals. If "Molecule" had given a list of the metals likely to be present in the acid solution, one might perhaps be suggested. The following, from Galloway's "Analysis," may answer. Pass H_2S through the acid solution, previously reduced by sodic sulphite. Filter and well wash the precipitate, then treat with a solution of NH_4HCO_3 (1 in 12) for a few seconds only, quickly filter and add to filtrate HCl in excess. If a yellow colour or precipitate be produced, arsenic is present. To find whether it exists as As_2O_3 or as H_3AsO_4 add to portion of the original solution KHO in excess, and a few drops dilute solution of cupric sulphate, and boil; if a red precipitate falls As_2O_3 or an arsenite is present. To another portion of the solution add ammonio-nitrate of silver, a reddish brown precipitate will be formed in presence of H_3AsO_4.—UN IRLANDAIS.

[12090.]—**Strawberries.**—My experience (p. 314) proves the value of this "wrinkle," which I learn from a neighbour whose strawberries were as remarkable as his mania for taking his constitutional among them seemed to me. I do not believe in liquid manure of a strong nature. A dressing of horse dung from the roads thrown, not on, but amongst the plants just as they are coming into flower is far better. The advantages of treading down are the cleanliness from vermin, from splashing of grit, dryness, and, consequently, less chance of mould, keeping in the moisture of the ground underneath the upper crust, and the speedy ripening of the fruit. I earnestly advise "Derf Errac" to make a bed of wild strawberries—he will find it pay the trouble.—M. PARIS.

[12090.]—**Strawberries.**—"Derf Errac" cannot trample his strawberry beds too much.—H. B. E.

[12097.]—**Venetian Blinds.**—This query has been given and answered over and over again in "ours." Will not querists search indices before occupying space to repeat questions?—H. B. E.

[12097.] — **Venetian Blinds.** — The principal peculiarities in painting these are, to put the paint on thin, and to let one coat thoroughly dry before putting on the next.—B. S.

[12097.] — **Venetian Blinds.** — The laths are generally painted on a trough in the shape of a letter V, with wires across to rest the laths. There is a small stick cut somewhat the shape of the holes, to pick them up when painted, and hanging them on old stair rods driven into a wall until dry. Plain paint, turpentine the principal vehicle, being used; afterwards varnished, or finished off with colour ground in varnish to fancy.—JOSEPH WILLIAM FENNELL.

[12097.]—**Venetian Blinds.** — The laths must first be sized. When dry they are ready for the first coat of paint. The best paint to use is called enamel green, made for the job, to be had at any paint and varnish warehouse, price about 1s. 8d. per lb. If too thick thin with turps; it is better to have the first coat rather thin, and be careful that the edges are not left with a mass of paint on them. You must first make a trough, by nailing two ½in. pieces of wood together, so as to form a right angle about the length of the laths. Then nail two square pieces on the ends so as to form a trough exactly like a rabbit trough. Mind that it is large enough to receive the laths. Put twenty or thirty laths together and paint all the edges. This done (no need to wait until dry), place them flat in the trough so that the edges only touch the sides of trough, then paint away. When done both sides, hang on wires through cord hole to dry.—B. R. B.

[12098.]—**Dandelion Roots.**—Collect the plants that have not flowered, roots and leaves. Bruise the roots and cut up small, and put into a wide mouthed bottle equal weight of bruised plant and pure spirits of wine (not methylated spirits), digest for a month, shaking daily. If once or twice during the time you could pour off the spirit and put the plant under pressure to fully extract the virtues it would make the tincture stronger. When complete strain through muslin, and you have tincture *Leontodon taraxacum*. Dose, ten to twenty drops, in water, fasting twice a day. Sluggish liver is rubbish. Read "Ourselves, Our Food, and Our Physic," by Benjamin Ridge, price 1s. 6d., Chapman and Hall, on this point.—WATTS.

[12099.]—**To Advanced Chemists.**—In cases of calculus of the bladder *Cannabis sativa* (hemp plant) or *Arbutus uva ursi* (bear's berry) have been found curative. In calculus of kidneys, *Lycopodium clavatum* (club moss) or sarsaparilla have proved curative. "Cireb" might consult Drs. Carlier or Gandry, Brussels. In chronic cases very small doses should be taken, and the treatment extend over a period. "Cireb" seems an Anglo-Indian; perhaps he has not investigated the Hindu remedies for calculus. They use *Parigdta, Baiʼainti, Nimba, Chitraka, Tamarinds, Durba, Catechu*, and many others. See Wise's "Hindu System of Medicine." 1845. Smith, Elder, and Co., or Thacker and Co.—WATTS, Chotahukeene.

[12101.]—**The Watch.**—"S. H. L.," virtually asks to be taught the trade through the medium of the ENGLISH MECHANIC. This will be asking too much, I think, besides I have little faith in amateur watchmaking. It is a business of which it may be said that you have but begun to learn after having served an apprenticeship of seven years, and in which the proportion of workmen who are thoroughly competent, both theoretically and practically, is astonishingly small; how then can an amateur expect to succeed in it?—WEST CORNWALL.

[12106.]—**Organ Building.**—The same question has been asked, and the answer given to this effect: it has been tried, but proved far from satisfactory.—JOSEPH WILLIAM FENNELL.

[12106.]—**Organ Building.**—1. Nicholson, the organ-builder of Worcester, has given instances of making an open pedal pipe serve for several tones; but as I have only heard, but not seen them, I cannot explain their mechanism. 2. In the Great Exhibition of 1851 there was a noteworthy invention by Brothers A. and M. Ducci, of Florence. They exhibited two chamber organs of good tone, and many other merits, but especially remarkable for the amount of sound from extremely limited space. Rossini had been surprised on finding in one of their organs 9 stops, or, deducting the halvings of the principale (our diapason) and the trompette into treble and bass, 7 complete registers (exclusive, it is presumed, of the pedal contrabass) comprised in a space of "1 mètre, 50 cent. cubes." The platform upon which the music-stool stood measured, he says, 130 cent. in length by 30 in breadth, and that that was the pipe which gave contrabass C of 16ft., and successive chromatic sounds. If my memory serves, in one instrument the music-stool itself was such a pipe. Accompanying them was a detached instrument, called a barystate, of the same construction as the aforesaid pedal contrabass, designed to supply in a portable form those undertones for an orchestra. The chromatic scale of two octaves was given by four pipes. The dimensions, of the lowest, giving the tones from FFFF 24ft., was nearly 5ft. 6in. × 2ft. 2in. × 10in. The next pipe was 3ft. 9in. × —(?) × 7in. The valves or pallets for each note were ranged along the front of the pipe, opened inwards, each in their depression from outside acting on arms and an iron spindle inside, which passing into the air chamber at the block of the pipe simultaneously opened a valve there to give ingress to the current of air. The chief features of their pedal pipes were, first, the production of 32ft. tone from an 8ft. pipe, and so on in proportion. Secondly, the utilising of each pipe for six semitones. Thirdly, the eliciting from pipes of that construction two qualities of tone, the bourdon "timbre," or the rasping quality of the contrabass or violin. These instruments came furnished with the testimonials of Rossini, De Mayer, &c. "Certes," says Rossini, "MM. Ducci ont mérité de grandes louanges par cette inventions qui, en honorant leur génie, recule les limites de l'art; par cette découverte en genre de contrabasse dans un seul tuyau, on peut s'attendre à une suite d'inventions mécaniques qui fourniront au monde de nouveaux effets de phénomènes acoustiques." They stood the test of examination, and in conjunction with an ingenious machine for cutting wood obtained either a silver medal or "honourable mention" from the jurors, and yet, in England at least, they have remained unnoticed—like Barker's pneumatic lever—for twenty years! 3. The pyramidon, invented by Sir F. A. G. Ouseley, an inverted pyramidal pipe, giving the purest bourdon quality of tone, is very economical in height, and the pipes can be conveyanced off to odd places or packed dovetail-wise. The dimensions of C C C 16ft. tone are—the base 2ft. 7in. square and 3ft. perpendicular from base to apex, mouth 8in. × 2½in. But the pipes are difficult to make. 4. Another kind of economy, which I have myself carried out, is by attaching to the usual pedal keyboard of 2 or 2½ octaves any lesser number of pipes from a septave of 12 upwards. The duplicate action is obtained simply by extra arms and trackers from the rollers. In churches and chapels where an organ is wanted almost entirely for choral accompaniment and where, to say the least, the fugues, solos, and concerted pieces of the concert-room are not necessaries, there is economy and acoustical gain in having two pedal stops of the sub-vocal or sub-manual tones only, instead of the usual one stop of 30 pipes or 2½ octaves, the upper portion of which is practically useless for church choral purposes. Some will call this heresy!—H. E. H.

[12108.]—**Confusion in the Head.**—No tobacco; little drink, and that little not too near meal times; no tea; no heavy meals; no food at all near bed or getting up time. This system of negatives proved to be good.—HENRY NEWMAN.

[12108.]—**Confusion in the Head.**—See my reply to query 10720 ("Singing in the Head"). The recommendation proved beneficial. I have no doubt it will do so in "Agent's" case.—WATTS.

[12109.]—**Old Locomotive Tubes.**—Plug one end and fill the tube with melted resin. When cold, bend as required. The resin must be melted out when the tube is bent.—T. G.

[12109.]—**Old Locomotive Tubes.**—The best plan would be to fill the tubes up with soft solder or fusible metal, bending the tube and then melting it out. Fusible metal is composed (one recipe) of 1 tin to 1½ lead. As for soft solder, it can be purchased from the tinman's cheap enough.—P. W. H. J.

[12109.]—**Old Locomotive Tubes.**—I have seen iron pipes bent by making them red hot in a forge, and gradually bent to the required curve by several heatings. I have no doubt such could be done with care in locomotive tubes.—JOSEPH WILLIAM FENNELL.

[12109.]—**Old Locomotive Tubes.** — Anneal your tubes well in coke fire, fill them with lead. You will then be able to bend them, by means of pressure or levers, don't hammer them to bend them; then melt out lead.—A. R.

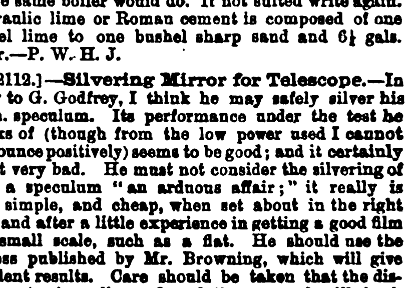
[12110.]—**Silver Plating.**—I thank "Electric" for reply; I have tried the porous cell process, it is too slow, the gold also works through the porous cell. I am sorry after your kind offer that I do not live nearer you. I am in London: Perhaps you can assist through our MECHANIC.—ELECTRO.

[12111.]—**Hothouse Boiler.**—No form of boiler can make much difference in the height that it is to be placed; if the present form cannot be raised, I would advise "W. F." to call in a practical greenhouse engineer to see whether there could not be some alteration in the arrangement of the pipes so as to admit of them being placed higher up, as without a drawing of the arrangements of the pipes, I could not judge upon that point. If no other way would do, a sure plan would be to line the ash pit with bricks backed with 2in. thick of clay, and set in hydraulic lime. I think that upon the whole this would be the best plan, as the same boiler would do. If not suited write again. Hydraulic lime or Roman cement is composed of one bushel lime to one bushel sharp sand and 6½ gals. water.—P. W. H. J.

[12112.]—**Silvering Mirror for Telescope.**—In reply to G. Godfrey, I think he may safely silver his 10½in. speculum. Its performance under the test he speaks of (though from the low power used I cannot pronounce positively) seems to be good; and it certainly is not very bad. He must not consider the silvering of such a speculum "an arduous affair;" it really is easy, simple, and cheap, when set about in the right way, and after a little experience in getting a good film on a small scale, such as a flat. He should use the process published by Mr. Browning, which will give excellent results. Care should be taken that the distilled water is really good, and the sugar of milk fresh and good also.—H. C. KEY.

[12113.]—**Gold Quartz.**—The specific gravity of the substance is 3·25, and that of gold is 19·34. Therefore there is $\frac{3\cdot25}{19\cdot34}$ gold in the substance, and, as it weighs 306 grains, ∵ there is $306 \times \frac{3\cdot25}{19\cdot34}$ grains of gold = 51·42024 grains.—P. W. H. J.

[12118.]—**Organ Construction.** — "Hautboy" asks if reeds can be fixed to make an organ bass. I should expect to find an organ channel too confined to give a round mellow tone; even if the mechanism to sound them could be adjusted. I have fixed reeds of deep tone (C C, and two or three notes above) in pipes no bigger than principal C, modifying the tone by means of a movable perforated tompion, such as is used for stopped diapason, only with a hole drilled through it; and the tone was fair. But we must



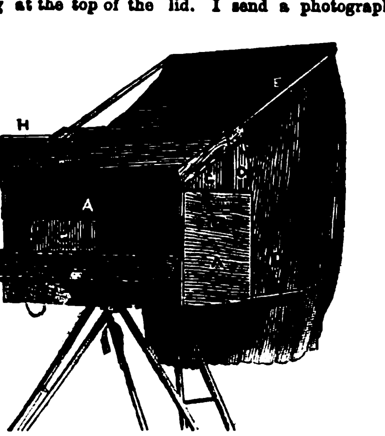
remember reeds speak in a harmonium on a wider area. I should, therefore, recommend the following plan:—Make a wind-chest long enough to contain the six notes on the bass side of tenor C, and another for the six transferred to the treble side, the depth to be three or four inches, according to the room you have on the organ soundboard; the height may exceed the width of an ordinary harmonium. There should be a block running along the bottom of this wind chest, and holes pierced to correspond with the holes on the organ soundboard. These are to take the pipe feet. Cut a slot through the face of the wind-chest down to the pipe-hole. Just above the upper edge of the block fix the note by counter-sinking, and cut another slot below its reed. Then fix a hollowed cap over the note and the slot in the block. Holes must be drilled in the top of the wind-chest to communicate with the outer air. If possible, procure the American notes. I subjoin a diagram: the second note is covered with the cap, and has the foot inserted.—T. S. G.

[12124.]—**Voice Weakness.**—Thanks to Henry Newman for his answer. I have no ailment with my lungs, but have always had (naturally) a weak voice ever since I can remember. I can rise rather high in singing, but have not the power to carry the sound far. Could "H. N." offer any other suggestion than the one already offered. If so, I shall feel deeply indebted.—JACQUES ERICK.

[12127.]—**Herbs.**—Robinson's "Family Herbal." W. Nicholson and Sons, Halifax.—S. COOK.

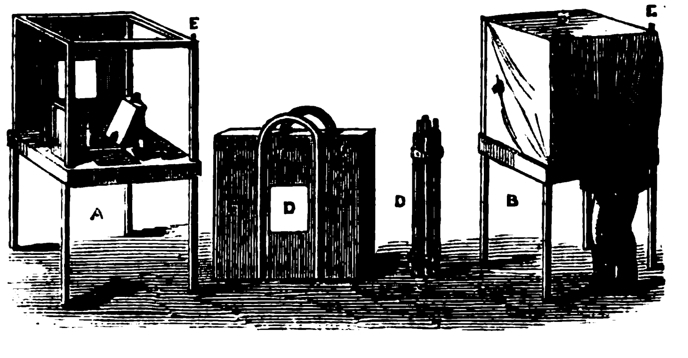
[12127.]—**Herbs.**—Culpepper's "Herbal," Newton's "Herbal," and Paxton's "Botanical Dictionary," either of which may be had cheap at a second-hand bookshop.—ZETA.

[12128.]—**Portable Dark Tent.**—In reply to this query I am able to give the result of a dozen years of photographic work, and not a few experiences in these contrivances. There are three varieties of dark tent:—1. Those in which all the materials for work are arranged *in situ* ready for operation, and thus transported from place to place. The great objection here is the inconvenient bulk and additional weight. 2. Those in which nothing is carried but the belongings to the tent itself (of which kind Rouch's stands as a good example). 3. Those capable of containing all the impediments for a journey, which are removed prior to commencing operations. The last is the kind to be preferred, as it obviates the necessity for a separate receptacle for the camera, chemicals, &c., and thus lessens the weight of the outfit. The tent I use was constructed for me by a country carpenter in the south of Ireland, during a visit in 1868, under my directions. It is simply an ordinary trunk, or box, having a hole for a screw and nut at the bottom, by which it is attached to the head of a strong tripod. The lid being lifted there are two angular pieces hinged inside, that fold down against and close the end apertures, and rest upon ledges an inch below the edge of the box proper. The front (a lock part) of the box is hinged and opens down in a line with the bottom. The upper surface has ledges nailed round, forming a dish or trough to catch the washings, and a small piece of metal tubing through at one corner, to which an indiarubber pipe is attached. This trough and the real bottom of the box form the operating table. In each upper corner of the raised lid a square groove is cut, and covered with a piece of sheet iron. These take a couple of iron bars (just long enough to pack diagonally inside the lid), having eyes at the end to take a transverse rod carrying the calico. There should be three thicknesses of this—two black and one orange. It is nailed round the ledges that form the trough, and to two upright movable bars at the side, which in taking down fold into the trough. Light is obtained from a yellow window in front, and a small triangular one in one of the folding angle pieces at the side; a lid closes in the glass from breakage in travelling. A water-can is hung at one side, having a flexible tube passing into the interior, the end of which, when not in use, is kept above the water level through a ring at the top of the lid. I send a photograph



which may illustrate the foregoing description, and may say in conclusion that, taken "all in all," I have never used or seen anything superior to this arrangement. I may add that the cloth hangs loosely and very full round the operator, and is easily tucked under the waistcoat when light has to be excluded. A, tent box; B, lid; C, angle piece hinged on the under side of B; D, small iron cramp, this shape [———] to hold up the lid, and fitting in brass tubing let into the wood; E, iron rod to support the calico; F, lid to protect the glass G; H, water-can.—CORNUBIENSIS.

[12128.]—**Portable Dark Tent.**—"Occasional Photo" may find the accompanying rough sketch answer his purpose. A is a box made out of ½in. deal, 2ft. square (or thereabouts) by 4½in. deep; the lid is cross-headed, and has fillets round the three unhinged sides for tacking the light proof covering to; a space is cut out in centre 6in. or 8in. square, and filled in with yellow calico. D, the bottom of box has a small sink about 8in. by 10in., by 1in. deep, with a hole for escape of water; the hole is fitted with a cork, which should not be withdrawn until the plate is fixed, and the operator is standing clear of the spray. A frame for top hinged to lid folding down on underside when not in use; two uprights working on pins at front, and fastened when in use to top frame by two iron pins which also answer the purpose of keeping the cloth in its place (see E E); four blocks are strongly fastened at corners for either plain or screwed pins on top of portable legs being let in to them. Four portable legs about



3ft. long, B shows the frame with black waterproof covering, tacked on three fillets on lid, and three insides of box. The cloth is made with a hem and cord passed through it for tying round waist of operator; the cord must be long enough to allow expansion of cloth to full extent, and not disappear at either end. Before packing be careful to dry the inside thoroughly. C shows the box with straps and handles; inside is the black cloth packed along with bottles, dipping bath, water jug, developing dish, &c. D shows the portable legs. F F are holes for ventilation. —A. C.

[12129.]—**Firebars.**—Cast-iron firebars last longer in fire-box with great heat. Cast bars will sooner melt than wrought iron ones, but wrought iron will bend before cast iron will melt. Cast iron is also cheaper. —PLOUGH.

[12130.]—**Electricity.**—This difference is usually illustrated by stating that the electricity developed by the electric machine has greater intensity, but is smaller in quantity, than that obtained by the galvanic battery. Considering facts, it gives a stronger shock than a battery of a few cells would do, but it has much less effect as measured by electro-chemical decomposition, such as decomposing water into its components, oxygen and hydrogen, for example.—PHILANTHROPIST.

[12131.]—**Electricity Applied to Engraving.** —There is a patent process for copying writing, &c., from a plate prepared in precisely the same way as "Philanthropist" proposes, but chemicals are used, which instead of giving a copper deposit adhering to the plate, give blue copies on a prepared paper laid on the plate. A kind of copying press is used. If (as I infer) "Philanthropist's" idea is to bring the engraved parts into relief for printing in the ordinary way, I believe the field is quite open to him, and to insure success only two things are necessary. 1. That the engraving be sufficiently raised above the level of the plate. 2. That there be no irregularity in the surface of the raised parts. I hope it will not be asking too much of a "Philanthropist" to let me know if he succeeds.—COUNTRY PRINTER.

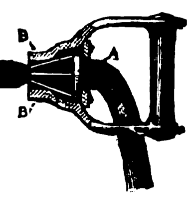
[12131.]—**Electricity Applied to Engraving.** —I think the principle of the pantelegraph, with which no doubt "Philanthropist" is perfectly acquainted, could be still further improved and applied as this contributor suggests, to the engraving of metallic plates by electricity. The apparatus, which has of late years not received as much attention as its ingenuity deserves, should come into general use, and many valuable improvements in its application would soon appear. "Philanthropist" says, "suppose a metallic plate, thinly coated with wax, to be subjected to the action of a galvanic battery, &c., is the plate to be entirely immersed in a boiling solution of wax or rubber, so as to be coated all round? Assuming in such a case that the coating remains intact, except where the steel point has penetrated, while under the action of the battery, which is very doubtful, the deposit of copper would be very slight, and scarcely of sufficient depth to be printed from. I think, however, that "Philanthropist" could easily suggest a process whereby impressions might be taken from metallic plates, something similar to the preparation of lithographic stones.—RAT-TAT.

[12131.]—**Electricity Applied to Engraving.** —For the benefit of "Philanthropist," I send the following extract from the "Year Book of Facts for 1840," which shows the process was gone into many years since. Mr. Thomas Spencer, of Liverpool, stated in the *Athenæum* that he had not only succeeded in doing all that M. Jacobi had done (producing copies of copper-plate engravings—in other words, electrotyping), but had successfully overcome those difficulties which arrested the progress of the latter. The objects which Mr. Spencer says he proposed to effect were the following: "To engrave in relief upon a plate of copper; to deposit a voltaic copper-plate, having the lines in relief; to obtain a *fac-simile* of a medal, reverse or obverse, or a bronze cast; to obtain a voltaic impression from plaster or clay, and to multiply the number of already engraved copper-plates." The results which he has obtained are very beautiful, and some copies of medals are remarkably sharp and distinct, particularly the letters, which have all the appearance of having been struck by a die. For the details of Mr. Spencer's process, see the *Athenæum*, No. 625, p. 811. My opinion is that the deposit would not be fine or even enough to give a clean impression when printed from; it might do for rough common outline work, but for fine shaded engraving I do not think it would answer. If "Philanthropist" tries the process, I for one should like to know the result.—ZOO ANDRA.

[12133.]—**Hard Water.**—Mr. Pearce would do well to construct a cistern of sufficient size, wherein the water might gain a quiescent state after some time, and deposit some of the hard silicious particles. A layer of carbon at the bottom will hasten the precipitation. An excellent ale-filtering tap, suggested by an electrician in a back number of the ENGLISH MECHANIC, might also be tried with success in the manner recommended.—RAT-TAT.

[12134.]—**Restoring Brass Wire.**—All "Keighley" can do with the brass wire, which has become corroded by exposure, is to sell it to a brass-founder, or remove the rust to the sound core, and either tin or paint it.—RAT-TAT.

[12135.]—**Chest Expander.**—I enclose a sketch of a handle of a chest expander, arranged so as to be adjusted to any part of the indiarubber. It will be seen that A is a ring having four short arms each working on a hinge at one end. This ring, with the arms, is to slide a short distance in the circular part of the handle, which requires to be of the same shape as engraving. It will be seen that when the handle is pulled, the parts B press against the arms, and cause them to grip hold of the rubber—more you pull tighter it holds. The part A is kept in its place by a ring or washer screwed on the inside.—ZOO ANDRA.



[12137.]—**Liquid and Solid.**—Maunder defines solid as "not fluid, firm, true, compact"—and liquid as "not solid, fluid, dissolved." Mercury should be defined as a solid which is fluid at ordinary temperatures. Tomlinson says: "Mercury becomes solid at – 40°, in which state it is malleable, flattens readily under the hammer, and can even be struck into medals. At a lower temperature it becomes brittle," &c.—QUERCUS.

[12137.]—**Liquid and Solid.**—No well-marked boundary exists in Nature. If the writer of the book lived at the North Pole, mercury, he might consider, as much a solid as we do butter, which, I suppose, under the line would be a liquid. Ganot, I presume, wrote for temperate latitudes. Ice is a solid, yet, under certain conditions, flows like a viscous fluid. "E. L. G." is, however, the man to tackle this question.—M. PARIS.

[12142.]—**Leaky Tubes.**—Wind round the ends inside with soft wire as close to the end plate as possible; the wire to be of the thinnest kind.—RAT-TAT.

[12143.]—**Cayenne.**—Try covering the face with fine gauze or muslin.—DERFLA.

[12143.]—**Cayenne.**—Plug nostrils with cotton wool, or use wool respirator.—PLOUGH.

[12144.]—**Timber Houses.**—Build the walls without the cavity. Plaster inside and out. That the plaster may hold to the outside, first drive the nails used up to the heads. Then apply the laths and drive the nails into the boards, but be careful to keep all the laths about one-eighth of an inch from the walls. They should not sit closer than this, and be nailed about two inches apart, and may or may not be covered with the cement. The inside may be treated in the same way, or the laths to be nailed on the upright beams forming the framework, so that the plastering stands out a few inches from the walls. By this means a layer of dead air can be inclosed all round the building, and an air-tight and damp-proof building will be [illegible] RAT-TAT.

[12144.]—**Timber** [illegible] shown is not to be [illegible] timber out. If "Bee" is wealthy he should consult an architect, but if he cannot afford to do so, if he will publish an address I will forward him some hints that might, if sent to the Editor, take up too much of "our" space, but on which I believe he might rely, as I have assisted in the construction of many of the better class of the homes of England.—OLD PLOUGHMAN.

[12146.]—**How to Procure a Patent.**—Buy "Law of Patents," Weale's series, 2s.; call at Patent Office, Southampton-buildings, and ask any questions. —DERFLA.

[12150.]—**Photography.**—"Tripod" had better adhere to the old and reliable collodion process than adopt the new collodio-bromide method. With the latter there is a good deal of nicety of manipulation required, and a greater purity of chemicals necessary; and my experience of it is that it is not so reliable as the former. I would advise an amateur especially to be satisfied with the old process.—E. B. F.

[12152.]—**Dyeing Raw Cotton.**—Try a solution of logwood and proto-sulphate of iron (copperas).—C. J. B.

[12154.]—**Varnish for Printing Inks.**—The varnish used in the manufacture of printing inks is made from linseed oil, boiled in a peculiar manner. The process I don't know, but I fancy it can be bought cheaper than you can make it yourself. Ask for printers' ink varnish of any of the ink manufacturers, and you will be supplied with what you want.—ZOO ANDRA.

[12155.]—**The Suspended Shilling.—Another Reason Wanted.**—The oscillations of the shilling are, I think, produced by the action of the pulse, but the latter part, I believe, is entirely a matter of belief—that is, if the experimentalist believes that the shilling will strike the glass the required number of times he will find that it does so. I myself have never succeeded in this part of the experiment but once, when, having seen some one else do it, I was confident of success. It is the same with mesmerists; if the person operated upon believes that he is going to be mesmerised, it succeeds, but if he is so strong minded as to disbelieve the powers of the mesmerist, he cannot be mesmerised. So it may be in this experiment, that it is not purely mechanical, but partly the will of the experimentalist.—EXCELSIOR.

[12155.]—**The Suspended Shilling.—Another Reason Wanted.**—The suspended shilling striking the hour is simply caused by involuntary muscular action, the holder knowing or guessing rightly, or nearly so. Let "H. G. W." wake in the night and try it, he will find his shilling sadly at fault.—PLOUGH.

[12156.]—**Mice Eating Peas.**—To protect peas or beans from mice, take common furze, cut it into inch lengths, and put it over the seeds before covering with earth.—PLOUGH.

[12156.]—**Mice Eating Peas.**—I have found soaking the peas in a very strong infusion of tobacco a preventative. Perhaps the sparrows did the mischief; if so, netting, wire or string, or perhaps soot sifted over them, will protect them.—M. PARIS.

[12156.]—**Mice Eating Peas.**—More likely the sparrow, and I have kept them off this year's peas by pieces of red cloth tied on a piece of string a foot apart, suspended from two stakes in the ground. To protect any kind of fruit or vegetable from the "pests of the garden," I recommend all growers to read part 8 of Beeton's "Book of Garden Management," to be had through any bookseller.—ZETA.

[12156.]—**Mice Eating Peas.**—For some years I have been troubled with mice eating small crops, and even sparrows get so familiar with a "scarecrow" that what was not destroyed at night had a poor chance next day. This year "poor pussy" belonging to an adjoining farm took up her quarters under my garden seat, and, not being disturbed in her occupation, she has proved herself a very useful tenant. I have not had any scarecrow contrivance nor lost any crops by mice or birds.—THOS. A. BRADLEY.

[12157.]—**Smell of Paint.**—"Seagoe" should try a good handful of damp hay in each room, or a pan of water, both of which I have found successful.—THOS. A. BRADLEY.

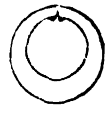
[12157.]—**Smell of Paint.**—1. Place a vessel full of lighted charcoal in the middle of the room or place painted, and throw on it two or three handfuls of juniper berries; shut the windows, the door, and the chimney close. Twenty-four hours afterwards the room may be opened, when it will be found that the sickly, unwholesome smell will be entirely gone. Another and a simpler method is to plunge a handful of hay into a pailful of water, and let it stand in the newly-painted room.—H. T. C.

[12157.]—**Smell of Paint.**—I have heard that standing open vessels of water in the room, &c., will draw the smell. The water will be covered with a film.—DERFLA.

[12157.]—**Smell of Paint.**—To remove the smell of new paint close the rooms at night, cut a large Spanish or some English onions into slices, put them into a plate, and place it on the floor; well ventilate next day.—ELECTRO.

[12157.]—**Smell of Paint.**—Place a vessel full of lighted charcoal in the middle of the room newly painted, and throw on it two or three handfuls of juniper berries, shut windows, chimney, and door. Four and twenty hours afterwards the room may be opened, when the smell will have been extinguished. The smoke of the juniper berry will not spoil anything. Another plan is to plunge a handful of hay into a pail of water, and let it stand in the room newly painted.—H. B. E.

[12158.]—**Packing Rings of Piston.**—I have constructed pistons up to 6in. diameter, which answered well, in the following manner. Let the two rings be cast shape of sketch. If cylinder is made of brass, rings to be of cast iron, or *vice versa*. First, chuck up and turn inside to fit on a mandril very slightly taper. Having placed on mandril, turn both sides with slide-rest, take off, and true up by testing up on a surface plate, and scraping the prominences; eschew any grinding whatever (I am opposed to any grinding of surfaces intended to move afterwards). Now, having got ready the piston-head and cap, place the rings in position, place a sheet of writing-paper between rings and cap, and screw up tightly; place in lathe, and turn them a trifle larger than bore of cylinder; take out, and saw through with a tenon saw in thinnest part, and the ring will open slightly larger than when turned. Take a piece of thin sheet brass and fasten at one side of the saw-cut nicely, with one rivet or little screw, and file down to thickness of ring, and when putting piston together place thin side of one ring opposite thick side of the other; the object of these valve-like pieces is to allow the rings to expand or contract freely, according to the inequalities of the bore and the wear. Thus, if to the steam forces its way through the one, it shuts the other tightly.—A., Liverpool.



[12161.]—**Mangle.**—American birch stands very well; rollers to be 4½ or 5in. diameter; the length is very common, 2ft. 4in. long. If the Editor is agreeable I will send sketch of a new system for giving pressure.—DEVONSHIRE.—[Send.—ED.]

[12162.]—**Machine Punches.**—Some machine punches are actuated like steam hammers. "Try Again" may make a simple punch by forming a screw on the end of a rod, attached to the crank of a fly-wheel to fit any kind of punch.—RAT-TAT.

[12163.]—**Meerschaum Pipes.**—It is possible for an amateur to re-wax his meerschaum, first by taking off the old wax by rubbing with sand-paper marked OO, plugging the bowl and stem with cork (the latter to hold by) and dipping in liquid white wax. When perfectly dry it is polished and finished off with shave grass or crape. The wax will cost six shillings a pound. He can also remove the colouring matter from his meerschaum by boiling it a few minutes in water—but I would recommend him first to remove the amber carefully; then oil the pipe well all over, except that part of the rim he wishes to remain white, then dip the oiled part only in very hot water. Examine after a few seconds, and dip until all the colour required is visible, let the pipe cool and wipe off and polish with a rag. Many pipes are finely restored in this way, but care and practice is necessary in handling and experimenting on manufactured meerschaum.—ZETA.

[12164.]—**Temperature of the Planets.**—There is, as far as I know, no scientific reason why Mars should not be inhabited by some animals of a different kind from those which inhabit the earth. For if animals, or rather animalcula, live in sulphuric acid, a liquid destructive to almost all life, why should they not inhabit Mars, the heat of which, to ordinary animals, would be destruction?—E. JOHNSON.

[12168.]—**Limelight or Electric Light for Magic Lantern.**—I am pleased to give "Hon. Sec." the best information in my power, and having for many years been a practitioner (though an amateur one) in optical science, and more particularly in lantern work, I trust it may prove of some value to him. First, then, a reliable pair of lanterns with achromatic lenses and three and a half compound condensers, will cost about £6; let him not think of a single lantern unless to part with it for a pair after a little practice. Next comes the question of illumination, and if the limelight is fixed upon he will require two burners, a dissolving tap, and one or two gas-bags, as he may determine to employ the mixed gas-jet, or the blow-through; this will cost £8 with two bags, £5 10s. with one. He will find most opticians advise the blow-through system for a novice, as it is devoid of danger. I should advise him, however, to obtain a lesson or two from a practical hand, and go in for the best system if at all. I come now to the electric light: he will require sustaining lamps, and a powerful battery; the latter for real practical work should not be less than a combination of forty Groves or fifty Bunsens, and costs from £12 to £15; the sustaining lamps are expensive affairs, the Duboscque and Highley Malden being to my mind the best and cheapest. I cannot, having due regard to the very wise rule laid down in "ours," advertise these gentlemen by quoting their prices, but these may be obtained through any optician. Having now told "Hon. Sec." what is required, and given him an idea as to the cost, I will give him my opinion as to the value of the two systems; if the apparatus is required simply for purposes of illustration, with paintings, photographs, or prepared objects, let him not for a single moment think of the electric light, as, in addition to larger primary cost, it is more expensive to work, a filthy job to manipulate. The light in the best hands is liable to get out of focus, and even when burning well a certain amount of flicker on the screen is produced, which more than counterbalances the extra brilliancy obtained. If, on the other hand, it is desired to illustrate the phenomena of solar light, spectrum analysis, &c., the limelight is comparatively useless. I can, however, hardly imagine that any one asking for the information that "Hon. Sec." does, could have it in contemplation to go into illustrations, which, even in the hands of Professor Tyndall, are properly designated experiments. The working cost of limelight as generally employed comes to something like four shillings for an entertainment of two hours. In conclusion, I will give "Hon. Sec." one or two words of advice: Have nothing to do with fan dissolvers, almost sure to be offered wherever he goes; and let him get a practical lesson or two before he begins.—M. G. C.

[12168.]—**Limelight or Electric Light for Magic Lantern.**—Let me give "Hon. Sec." the benefit of my experience, and for this purpose I will reply to his questions *seriatim*. 1. The first cost of a single lantern with 4in. condensers and achromatic object-glass would be about £8. An electric lamp to be used with the lantern would cost about £10; and forty cells of Grove's battery would cost about 14s. per cell. It would be useless to attempt to produce satisfactory results with a battery having a less number of cells than forty. A double lantern is never used with the electric light. The first cost of a single lantern for the lime light, with 4in. condensers and achromatic object-glass, would be about £5. Two gas-bags of the best make would cost about 50s. each, the pressure boards about £1 the pair, and the oxyhydrogen jet would also cost about £1. The price of a pair of lanterns varies very much according to the quality and style, but a pair of the best make could probably be purchased for £20. This should include gas jets, gas bags, and all accessories. 2. The cost of working the limelight for an exhibition that would last two hours would not exceed 5s. For the same time the cost of the electric light would not be less than a guinea. 3 and 4. The limelight is incomparably more simple, clean, and easy to work than is the electric light. The former is speedily prepared, and can readily be worked by a handy person after a little instruction and practical experience. Not so the electric light. It requires some hours to amalgamate the plates, mix the acids, and fill the cells; and long practice, amounting almost to an apprenticeship, is needed to produce good results with the battery. Even at the best, the electric light is uncertain, and never can be relied on to produce a continuous effect, as does the limelight. It would be impossible to carry out a two hours' entertainment relying only on the electric light; whilst with the limelight there would be no difficulty in this. 5. In England Grove's battery is generally used for the production of the electric light, whilst on the Continent Bunsen's battery is preferred. Not less than forty cells of either form of battery could be advantageously employed. The first cost of Grove's battery is greater than that of Bunsen's, but it is cheaper in use. 6. The electric light can be used for the purpose of exhibiting experiments in spectrum analysis, for which the limelight is unsuited. "Hon. Sec." will probably have no difficulty now in arriving at a decision. The electric light is altogether unsuited for the purpose that he appears to have in view.—AN AMATEUR LECTURER.

[12172.]—**Constipation.**—I have been unsuccessful in my attempt to obtain answers to two queries ("Rust in Iron Vats" and "A Cement for Cracks in Stourbridge Clay Fire-grate Backs"), but am most happy to give "H. S. A." such information as I have derived from others, or from my own personal experience. I have found the greatest benefit from a tumbler of cold water (filtered soft water), taken before breakfast. Friction of the body by horse-hair gloves, or, if the skin is too tender, with the Persian gloves (goat's hair) —may be got at Savory and Moore, Regent-street. The tepid or cold shower bath (with feet in warm water), or the sponge bath every morning. Before drying the skin let "H. S. A." try friction with the gloves. The skin is but the external continuation of the inner mucous lining, and there is the greatest sympathy between them. Friction of the spinal column by the hand of another person until much redness is produced is most useful. Constipation is much aggravated if the mind is allowed to dwell upon it. Homœopathy is much vaunted for this affliction, but after repeated trials I found it useless for me. To live upon cathartic medicine is useless—indeed, an aggravation of the complaint; but the secretions are usually deficient or defective, and here occasional small quantities of physic are useful. I prefer the best rhubarb to anything else (not the compound rhubarb pill). There is a balance to be preserved in the body, and if any one secretion is greatly increased it will diminish other secretions, to the injury of the health. Moderation in eating—slow eating, and drinking after eating rather than with the solid food are all useful, for the digestion is usually defective in these cases. Are "H. S. A.'s" grinders in good working condition?—R. T.

[12172.]—**Constipation.**—Having been a great sufferer from constipation, I may, perhaps, be allowed to offer a few remarks. However little is thought of it by the large number who are constitutionally troubled with that disorder, I am confident that sooner or later the effect of neglected constipation is sure to be felt; I believe that a large number of diseases are the result of that neglect, or from wrong treatment in endeavouring to regulate the bowels. The use of aperients or a diet suitable to act as an aperient appear to be the usual remedies; the former is a bad remedy, and the latter a very uncertain one, as, however careful some may be of their food, the bowels will be obstinate. If "H. S. A." will try eating figs, prunes, apples, bread and milk, and other light articles of diet, avoiding all indigestible substances, he will receive benefit; but I doubt (if in his case the constipation is hereditary) whether a regular action of the bowels would then take place. If medical skill could have effected a cure, your humble servant would have benefited by it, as money and years were wasted in the vain attempt. Chronic piles was the result, and six months after a successful operation my old friend re-appeared, only to be pronounced incurable. The usual remedies only laid me in bed; whilst lying there I thought of the method used to relieve the bowels in the hospital by means of the enema. In a short time I lost headache and heartache, and other followers of constipations, and my last dose of medicine dates back to the commencement of plain water used with the enema three years back. I now eat anything, and am in perfect health; it is a good thing for the medical profession that so much false delicacy and prejudice exists. I think, with Dr. Lankester, that it would be a good thing if a little physiology were learnt in the schools. There is one thing certain, the ENGLISH MECHANIC supplies the wants of all classes, no matter on what subject.—J. W.

[12172.]—Constipation.—Use bread made of flour from which only the very coarsest portion of the bran has been extracted. Get it direct from the mill, as the bakers will "cook" it by mixing the bran with flour, which is not so good. This bread is more wholesome than bread made entirely from fine flour. Drink half a glassful of cold water at night and a whole glassful in the morning. Avoid medicines. — COUNTRY PRINTER.

[12172.]—Constipation.—A friend of mine who had suffered for two or three years, and at one time narrowly escaped with his life, found at length a remedy in the following simple prescription: Eat an apple (juicy, if possible) and drink a tumbler of water immediately after rising in the morning. If one apple fails, try two, or even three. He was advised to try this by the last physician (a homœopath, by the bye) out of the many to whom he had applied, and having persevered with it is now seldom troubled. Exercise, change of diet, and plenty of vegetables and good fruit should, however, soon render "H. S. A." independent of medicine and medicine men.—TRY THEM.

[12172.]—Constipation.—After having suffered for more than two years from the same complaint, trying everything I could think of, but only obtaining temporary relief, the following advice was given me about six years ago by a medical gentleman, which, after having adopted and faithfully practised since then, I am happy to say has given me complete relief: "After having cleared the bowels by means of any opening medicine, commence and drink one or two tumblers of cold water every morning, say half an hour or so before breakfast. Then, in the course of the day, take a good sharp half-hour's walk, setting the heel firmly to the ground. Make these two simple rules a matter of conscience," said my adviser, "and you will find relief." Six years' trial has proved successful in my case.—G.

[12172.] — Constipation.—As a fellow-sufferer with "H. S. A.," I advise him to use, as I have done for years with complete success, a pint of oatmeal porridge with cream of milk, either as first or last meal daily. A "user of porridge needs no pills."—M. N.

[12172.]—Constipation.—If "H. S. A." has not already tried it, I think the following remedy will be of use:—Take half a tumbler of Friedrickshall water as hot as possible, immediately on waking in the morning. This, if persevered in, will certainly do good.—S. J. H.

[12172.]—Constipation.—To remedy, I got my baker to make me a brown loaf now and then, but finding grit in it occasionally, I suspected the sweepings of the board were put in it. I then ordered a steel mill, like a large coffee-mill, costing, I think, £6; it grinds very fine, and has been in use six years without repairing. We make the bread half ordinary white flour which we buy, and half meal as it comes from the mill.—BRAVIA.

[12172.]—Constipation.—1. Sip cold water when dressing in the morning; not take a draught, but keep on sipping every two or three minutes. This was a London physician's recipe, and cured a friend of mine when every other remedy had failed. If necessary, also drink a little water just before going to bed. 2. A couple of figs cut open and fried, or well soaked in olive oil, will open the bowels without injuring the mucous membrane (as medicine does), and without purging. 3. Eat brown bread. The first remedy I have long used myself.—K.

[12172.]—Constipation.—If "H. S. A." will habituate himself to breakfasting off pure oatmeal porridge for some time to come, and a plentiful use of spinach at dinner, using brown bread, and abstain from the use of malt and spirituous liquors and the weed, I believe, from personal experience, that he may safely do without any purgatives, which but aggravate the symptoms named.—A NOVICE.

[12172.]—Constipation.—Constipation is easily cured without medicine if the sufferer try a cold-water injection—a common enema can be bought for four or five shillings—regularly everyday at a certain hour. Regular habits, plain food, and out-of-door exercise should be followed, and an occasional dose of castor oil is never injurious; but the great thing to be borne in mind is "regularity."—PLOUGH.

[12173.]—Coloured Ink.—If "E. B. F." adds a little lump sugar to his ink it will make it shine, or a little gum will do as well.—ZOO ANDRA.

[12173.]—Coloured Ink.—Add a small quantity of gum Arabic.—QUERCUS.

[12174.]—Agriculture.—The difference between red clover and cow grass is that one has a hollow and the other a solid stem. In case of cattle's stomach becoming distended with clover or green food, give linseed oil at once.—PLOUGH.

[12175.]—Soundboard.—In confirmation of what "The Harmonious Blacksmith" has said about increasing the loudness of tone by placing a musical box on a soundboard. I have placed a small one on top of a large drum, and was astonished at the loudness of tone thus produced. Two or three instruments appeared to be playing in most pleasing unison while the music lasted. "E. B. F." might try a soundboard on the same plan.—RAT-TAT.

[12176.]—Hydrogen Flame.—The cause of failure may be that the cork is not air-tight. To test this, stop the mouth of the funnel by the hand, and apply suction to the tube—before putting the acid and water in, of course.—JAS. C. HARKER.

[12176.]—Hydrogen Flame.—"Whitaker" is not the only amateur who has failed at this experiment by using too large a pipe—one disproportioned to the quantity of zinc and sulphuric acid used, and the amount of gas generated; but if he will put a nozzle with a small orifice on his pipe, he will find the hydrogen to issue from it in a steady jet, with sufficient pressure to expel the atmospheric air, and prevent it from entering the generator.—E. B. F.

[12177.]—Algebra.—ERRATUM.—The first answer to this query, line five, should read *minus* 1, instead of 1.—CERVUS.

[12177.]—Algebra.—$\frac{x}{y} = -\frac{x}{-y}$. The two minus signs neutralise each other. Similarly $\frac{a}{(a-b)(a-c)(x-a)} = -\frac{a}{(a-b)(c-a)(x-a)}$, for $(c-a)$ is the same as $-(a-c)$, and corresponds to the $-y$ in the first expression.—PHILANTHROPIST.

[12178.] — French Magazine. —The *Magazin Pittoresque* is an excellent illustrated publication, cheap, and widely circulated. Published in Paris.—C. J. R.

[12179.]—Vitality and Electricity. — There seems something doubtful about this set of questions. Are they from the real "Rat-Tat" or some one else? However, assuming them to be *bonâ fide*, I will answer as well as I can. 1. Hair is a bad conductor, and there is not the least probability that it conveys any ethereal fluid to the brain, unless it be some barber's concoction so named. A liquid electrically charged has a tendency to force its way through capillary openings, but there is no electric tension high enough in animals to produce this effect to any extent, or to affect the circulation of the blood, though it is possible that the blood in the veins and arteries may be in different electric conditions, and so be attracted through the infinitesimal vessels which connect the two great sanguineous systems. 2. Not the least likely that any true life action, however temporary, could be developed; possibly in many cases death is really not complete, but that which is deemed so is absolute exhaustion of nervous and vital power, and in such cases, artificial respiration, fresh blood and electricity might revive the powers of those who are otherwise practically dead, but in whom the organic system is not destroyed, but its motive power gone; also in such cases mesmerism might recall to life those thus apparently dead. 3. The death of one of a number through whom a current was passing would, no doubt, involve a great shock to the rest, but nothing else. Nor is there reason to suppose that an infectious disease would be carried on by the current, but the general conditions would be such as to greatly facilitate its communication irrespective of any action of the electricity itself.—SIGMA.

[12189.]—Battery Coil.—Mr. Tonkes being silent (I hope not for much longer) I reply: Smee's always diminish in force; the liquid not being cold should be of little consequence. These matters will be explained in a week or two in "Electro-Metallurgy." 2. With twelve cells the platinum is sure to be quickly burnt off, but I expect there is solder run up it also. 3. Halse's coils have no secondary, but a great length, or rather several lengths, of primary, and the shock from them is the "extra current" of the primary itself.—SIGMA.

[12194.]—Enamelling.—The basis of all kinds of enamel is a perfectly transparent and fusible glass, which is subsequently rendered either semi-transparent or opaque by the admixture of metallic oxides. White enamels are composed by melting oxide of tin with the glass, and adding a small quantity of manganese to increase the brilliancy of the colour. The addition of oxide of lead or antimony produces a yellow enamel. Reds are formed by an admixture of the oxides of gold and iron. Greens, violets, and blues are prepared by the mixture of the oxides of copper, cobalt, and iron, and these when intermixed in different proportions afford a variety of intermediate colours. The proportions in which the ingredients are used, as well as the degree and continuance of the heat necessary to their perfection, constitute the secrets of the art. The best enamel was formerly imported from Venice; but during the restrictions imposed on commerce at the beginning of this century the importation almost wholly ceased. The high price of the article therefore induced British artisans to attempt its manufacture, and they succeeded in producing a hard white enamel, superior to the best Venetian in whiteness, and much more valuable to the dial-plate makers. Several years back, Mr Wynn communicated to the Society of Arts a series of recipes for the preparation of enamel colours, and for which the society awarded him a premium. The following is a list:—No. 1. Red lead, 8 parts; calcined borax, 1½; flint powder, 2; flint glass, 6. No. 2. Nitre, 1; white arsenic, 1; flint glass, 10. No. 3. Red lead, 1; flint glass, 3. No. 4. Red lead, 9½, borax, not calcined, 5½; flint glass, 8. No. 5. Flint glass, 6; flux No. 2, 4; red lead, 8. After the fluxes have been melted they should be poured on a wetted flagstone, or into a large pan of clean water, then dried, and finely powdered in a biscuit-ware mortar, for use. To make yellow enamel: Take red lead, 8 parts; oxide of antimony, 1; and white oxide of tin, 1. Mix the ingredients well in a mortar, and having put them on a piece of Dutch tile in the muffle, make it gradually red hot, and suffer it to cool. Take of this mixture 1 part, and flux No. 4, 1½; and grind them in water for use. By varying the proportions of red lead and antimony, different shades of colour can be obtained. To make orange enamel: take red lead, 12 parts; sulphate of iron, 1; oxide of antimony, 4; and flint powder, 3. After calcining these without melting, fuse 1 part of the compound with 2½ of flux No. 1. To make dark red enamel, take sulphate of iron, calcined dark, 1 part, flux No. 4, 6 parts, and colcother 1 part; of the two latter, mixed, add 3 parts. To make light red enamel, take sulphate of iron 1 part, flux No. 1, 3 parts, and white lead 1½ parts. To make brown enamel, take manganese 2½ parts, red lead 8½ parts, flint powder 4 parts. For enamelling watch dials, the enamel generally comes from the makers in small cakes, from 4 to 6 inches in diameter. These are first broken with a hammer and ground in a mortar with a small quantity of water, after which the copper dials to be enamelled are cleansed in the pickle, rinsed in water, and laid face downwards on a smooth napkin, and a thin layer of hard enamel called "backing" is spread over the side with a quill or bone spatula. The coppers are next slightly pressed with another soft napkin, which leaves the enamel dry enough to be spread more evenly with a steel spatula. Next is spread a layer of glass enamel over the side of the coppers called the "first coat." The surface ought to be dusted with a camel's-hair pencil to remove any dust, otherwise the work would be spoilt. The next process is firing, which consists in melting it, till it becomes one uniform mass on the surface of the copper. The firing is executed between a muffle in a small charcoal or coke furnace. The plates must not be over fired, nor must the heat be suffered to melt the enamel too rapidly, but a kind of rotary motion, called coddling, must be given to the work, by holding the loaded planche lightly with the tongs, and gently drawing the edge of it towards the mouth of the muffle, and then returning it to its former place till the fusion is complete. The work is now ready for polishing, technically termed using off. This is performed by rubbing the surface of the plate on a grit stone with fine sand and water, until all the glazed appearance is completely obliterated, and one uniform and equally rough surface is produced. The intention of this process is to remove the mottled appearance on the surface and give a more equal convexity to the plate. The method of painting in enamel is performed on plates of gold, silver, and copper, enamelled with the white enamel; on which are painted with colours which are melted in the fire by which they acquire a brightness and lustre like that of glass. This painting is the most prized of all for its peculiar brightness and vivacity, which is very permanent, the force of its colours not being effaced or sullied by time as in other painting, and continuing always as fresh as when it left the workman's hand.—WILLIAM H. HEY.

[12197.]—Roses.—The great London Horticultural Rose Show takes place on the 3rd July, the great Birmingham Show, 25th to 29th June. Turner and Bragg, of Slough, and Messrs. Veitch, Surrey, are considered the top growers of the day.—ZETA.

[12207.]—Light.—1. A beam of common light would not be entirely intercepted by one plate of tourmaline. A beam of plane polarised light would be sensibly wholly intercepted by such a plate, when its vibratory plane was at right angles to the plane of vibration of the light. 2. Yes. 3. Tourmaline or Nicol prism. Read Sir John Herschell's Familiar Lectures on Scientific Subjects, "Light."—H. P. H.

[12217.]—Violin Tuning.—"Just as you please, my dear, you pays for your fiddle (or ought to do so) and you takes your choice" how you may please to tune it. The big fiddle yclept contrabass is ordinarily tuned so that the pitch of its middle string is a fourth above that of its third string, and its first string a fourth above the former, thus A, D, and G. The strings of the violoncello, viola, and violin are usually tuned each a fifth above the next string below it, and the fifths are, or should be, tuned perfect. As all fiddlers are supposed to put their fingers in their proper places—*i.e.*, to stop in time (by the way, very few do)—the fact that the fifths are perfect with open strings don't matter, for, of course, it would be quite beneath any fiddler's dignity to acknowledge the existence of so vile a thing as temperament; in a word, his harmony is supposed to be perfect, which, considering he is human, and therefore imperfect, is more than could be expected, seeing we don't ordinarily gather sweet figs from prickly thistles. I have been told Paganini occasionally altered the pitch relations of his strings, probably to facilitate stopping in some of his intricate passages, but I am hardly "fiddler" enough fully to appreciate this; probably my friend "Fiddler" could let the light in on this matter, and enable us to see the "guts" of it. I don't understand the question, "How they tune them in each key;" indeed, I hardly know what the expression "tuning in a key" means. The piano is commonly said to be tuned in C; but this signifies no more than that its white keys, or rather the strings sounded by them, are tuned to that scale. Its temperament being equal, it might be said to be tuned in any key or scale from B to G below C, or from C♯ to F♯ above C, provided transposition to the extent proposed in Mr. Ryley's patent (No. 2562, A.D. 1801, price, with drawings, 6d.) be carried out, for its white keys may then be employed for performance in any scale, major or minor.—THE HARMONIOUS BLACKSMITH.

[12223.]—**Wheelbarrow.**—I have the pleasure of informing "C. T." that he can see many wheelbarrows constructed so that their wheels run in the centre instead of the end in daily use if he will just take the trouble to "step over" to the flowery land, alias China. They are not used by laundresses in that country like the two-wheeled ones are in this, both by them and costermongers, for the very sufficient reason that John Chinaman is very "conservative" and extremely sceptical on the advantages of clean linen, so he—being determined to err on the economical, if not the safe side—prefers wearing his cotton inexpressibles and whatever it may be which does duty for a shirt among "celestials" until they become, like unto human righteousness, unclean, not to say "filthy rags," and to ride on what, were he an "ablutionary animal," would doubtless be his laundress's barrow, which resembles the celebrated one-wheeled velocipede excepting that, being rather more under human control, it don't turn over and eject the rider—a thing which some unreasonable persons of a dissatisfied order of mind might object to. As "it's a lang call to Locheil" (I mean to the flowery land), it has occurred to me that "C. T." possibly might prefer looking at this one-wheel affair nearer home. If I am not mistaken, it was exhibited by a London firm, then existing (Messrs. Deane, Dray, and Co.) in one of the cattle shows at the Agricultural Hall, Islington, some few years ago, but *cui bono*. Is this another cropping up of the old idea that it is easier to roll a weight along when supported on one wheel than when supported by two? Certainly, one wheel is likely to encounter only half those obstructions yclept broken, but yet large, stones which are placed on our roads under the fallacious pretence of mending our ways; but to suppose the friction is any less with only one wheel than it is with two is about equivalent to the hypothesis that a man could "walk" with less friction and fatigue on one leg than on two. I fear this would not facilitate "human progress" much. Of this supposed unipedal man it would seem that it might be said, as it was in the case of "our Mary Hann's" epistolary correspondence, "this cums hopping," &c.—THE HARMONIOUS BLACKSMITH.

[12225.]—**Lead in Sulphuric Acid.**—The dark brown substance in the acid named by "Tony White" is not lead, but some organic substance, probably a piece of cork or straw. It is of small consequence, except in delicate cases of quantitative analysis. If required pure, add to a small portion a fourth, by measure, of water, and filter through paper, then evaporate the water out again in a beaker. If lead is present in sulphuric acid it will settle as a thick white sediment to the bottom of the bottle, and by careful decanting the clear acid may be teemed off.—PRIAM.

[12255.]—**Hair.**—Put one ounce of flowers of sulphur into one quart of cold water, allow it to stand twenty-four hours and decant. Wash the beard every night with the sulphur water, taking plenty of time. This recipe, taken from the American *Journal of Pharmacy*, will be worth the attention of our fair friends as a tolerably certain cure for dandruff and other minor (?) evils.—H. P. H.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "Suffolk Amateur" has answered 11275; "H. B. E." 11742, 11754, 11773, 11776.

11858 Nickel Spoons, p. 236
11859 Dyeing Raw Cotton, 236

11926 Malleable Iron Castings, 237

QUERIES.

[12256.]—**Preserving Garden Produce.**—I am an Englishman living on the prairie of America, where the winters are long and very severe, frost penetrating the earth over 3ft., and cutting off nearly every one of our cultivated vegetables and flowers which are exposed to it—parsnips alone of mine withstood its severity. It would oblige me if some of your able correspondents will give me suggestions on the best modes of keeping the various garden products for the table, for use during the long winter, and plants of others, and flowers to put out in the spring, which is six weeks later than in England. Frame-houses are out of the question, as fuel, glass, and labour, are very costly articles. The English here would like to gladden our eyes with familiar perennials and hardy annuals and green vegetables, before or later than midsummer.—EMIGRANT.

[12257.]—**Milking Machines.**—Will any of your numerous readers kindly give me an illustration of the best and simplest milking machines for milking hard milch cows?—FARMER.

[12258.]—**Old Violin.**—Can one of "our" readers inform me whether a violin bearing the label, "Chetianus Amates, Camonensis, 1640," is valuable? The instrument appears to be of the age indicated, and has a full and clear tone.—A. J. L.

[12259.]—**Faulty Acetate of Soda Bath.**—Will any correspondent let me in to the secret why my acetate of soda toning bath has taken a fancy to turn my prints a beautiful pink, just the colour of pink blotting paper?—PINKY TONE.

[12260.]—**Cleaning Back of Teeth.**—The toothbrush only cleans the front of the teeth. Would it not be well to provide also for cleaning the back of them, or are they less liable to decay at the back than in front?—BEAUTY.

[12261.]—**Spirometer.**—Will any reader of the MECHANIC be kind enough to give me what information they can as to the best method of making a spirometer? If with illustrations I should be very glad.—WONDERING WILLIE.

[12262.]—**Press for Cutting Paper, Card, &c.**—I want to construct a cheap and effective press for cutting paper, cardboard, &c. The ordinary press and plough is of no use, as it is required for cutting up and not for trimming. It is important it should cut the paper perfectly square, so as to fold nicely. Will some one kindly assist a—COUNTRY PRINTER?

[12263.]—**Circular Saw Driving.**—I should feel obliged by the following information:—I want to drive a circular saw by an intermediate shaft. The main shaft runs 40 revolutions per minute. My saw should run 650 to 700 revolutions. What size pulley should I have on the main, which I should not like to be above 3ft. 6in.? Also, state size of the pulley and drum on the intermediate shaft. The size of pulleys on the saw bench is 9in.—JAMES DAVIES.

[12264.]—**Freemasonry.**—Will some one kindly inform me how I may become a member? What are the fees and periodical payments? I live at a distance from any lodge, and have no opportunity of consulting any one who can supply me with the information I require. Some information about the objects of freemasonry, &c., would oblige—EDGAR.

[12265.]—**Pig Feeding.**—I should be much obliged if some reader who has had experience in stock feeding would inform me whether it is better to feed pigs with barleymeal, or whether the best Indian meal and bran, in about equal quantities, would not be better than barleymeal?—C. R.

[12266.]—**Photographic.**—Having followed the instructions given in the MECHANIC, under the heading of "Photography for the Uninitiated," I find that my negatives are not so bold as some that I have seen. The details are, however, well out. After they have stood for a few hours they fade almost entirely away. I shall be obliged if some correspondent will state the cause.—KING COTTON.

[12267.]—**Cabinet for Birds' Eggs.**—Would any reader kindly inform me of the best form of cabinet for keeping birds' eggs in?—C. T. B.

[12268.]—**Strength of Shafts.**—What number of horse-power (indicated) is a shaft of the following dimensions capable of turning with safety, when running at the rate of 170 revolutions per minute:—150ft. long, 2½in. diameter half the length, 2¼in. and 2in. equally the other half. Would some kind reader please answer this, and insert the calculation in "ours," for future guidance of Self and Co?—IXION.

[12269.]—**Staining Leather.**—Can any of the readers of the ENGLISH MECHANIC inform me of a good permanent dark brown stain, to stain a plaited leather watch guard (glossy, if possible)?—B. S.

[12270.]—**Charcoal Furnace for Model Boiler.**—Could any reader give me the sizes and description of a charcoal fire suitable for a model boiler 8in. diameter and 14in. long? I have got a spirit lamp 8in. by 3in., by 1½in. deep, with three jets ½in. diameter. Ought it to raise steam enough?—S. O. LEES.

[12271.]—**Double Flageolet.**—Will some one give me a scale for this instrument?—T. CRANE.

[12272.]—**Electrotyping.**—Can any reader of the MECHANIC give a description of electrotyping for printers? I understand all the battery arrangement. What I want to know is, the substance used to make the mould. Is it wax or guttapercha? How is the plate separated from the mould? and what is the process of filling up at the back? Any information will oblige—ZOO ANDRA.

[12273.]—**Water Power.**—I have a stream of water from a ½in. tap; it has a fall of at least 80ft. Will any of your numerous readers tell me how I can utilise it so that by a turbine I may turn a coffee-mill?—BŒTIS.

[12274.]—**Telescopic.**—Will "F. R. A. S." be kind enough to consider the following, and express his views upon it:—Is it impossible, as yet, to so accurately figure a Foucault speculum that the image will bear magnification? Suppose one of the finest reflectors by With or other competent maker, had attached to it, in lieu of a common eyepiece, a complete full-sized Powell and Lealand microscope, with a properly formed low angled objective (say of 25th or 50th inch); if this instrument be now turned on the moon or other object, affording sufficient light, would not some additional details of crater formation become obvious? I have tried this, with indifferent results, with a ¼in. microscopic power, but I consider my mirror altogether inferior, and think the door for further advancement in this direction may be found by trying again with a fine and complete instrument. If the mirror casts a perfect image, the microscope will unquestionably magnify correctly that image; if those mirrors do not cast correct forms, I cannot but place some doubt on all investigations conducted with them.—BETSY SUMMERCITY.

[12275.]—**Test for Arsenic.**—What is Bettendorf's test for arsenic?—W. H. HEY.

[12276.]—**Boiling under Pressure.**—I have about two gallons of a liquid which requires to be boiled under pressure for about eight or nine hours. Could any correspondent inform me the best and easiest way of accomplishing this?—W. W.

[12277.]—**Aniline Black.**—Would Mr. George Davis or any other of your chemical correspondents give me a good process for making aniline black; if possible, one without acid? Also tell me if there are any other books upon aniline dyes that are better and more recent than Dr. Reiman's?—W. W.

[12278.]—**Mercury.**—I have lately been experimenting with mercury, and I am afraid I have unavoidably inhaled the poisonous fumes given off when mercury is undergoing dissolution in nitric acid. I have lately had a very peculiar feeling in the throat, and a heaviness on the chest. Can any one say if this is due to my inhaling poisonous fumes, and what is the best thing to be done in the event of poisoning by mercurial vapours?—QUERCUS.

[12279.]—**Diminished Action of Battery.**—When a Grove's battery has been in action some time its power decreases. Is this owing to a change taking place in the sulphuric or the nitric acids? If so, how may the acids be purified?—SEMAJ.

[12280.]—**Winter's Machine.**—How is it that the ring of a Winter's machine increases the length of spark? Is it necessary that the wire passing through the wooden ring should be of iron? Would not brass do?—SEMAJ.

[12281.]—**Length of Electric Spark.**—What arrangement of an ordinary 18in. plate machine would produce the greatest length of spark?—SEMAJ.

[12282.]—**Holes in Valve-board of Harmonium.**—Will any reader inform me why the holes for admitting the wind through the valve-board of a harmonium are made so long? I cannot get them wind tight on that account. I should like to know if I might make them round.—VANDALK.

[12283.]—**Food Analysis.**—Will some one kindly inform me the best book on food analysis, and how to detect the adulterations? I have Normandy's "Commercial Analysis" (Weale's series), but some of the processes—those for testing flour, for example—are not trustworthy.—JAMES C. HARKER.

[12284.]—**Essence of Phosphorus.**—Can any reader inform me how to make essence of phosphorus, and also say the dose of the same for an adult?—S. COOK.

[12285.]—**Logarithms.**—In the table of logarithms I have before me, the logs. are given of numbers (not exceeding four digits) to only five places of decimals. Thus I find log. 6·102 = ·78547. How can I from this work out log. 6102·5 and log. 6102·57? The table shows at this part an increase in the logs. of ·00007.—C. P. E.

[12286.]—**Moresque Style.**—Would any reader kindly inform me where I could procure picturesque designs of the above style? Is there not something published in England or elsewhere that contains, among others, designs of the kind?—A MASTER SUBSCRIBER.

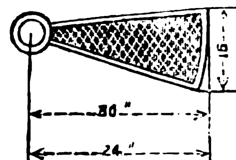
[12287.]—**Telescopic.**—Being desirous of obtaining an astronomical telescope, similar in power to the 3·7in. object-glass of 5½ft. focus, by the younger Gulley, which is often mentioned in "Celestial Objects," "F.R.A.S." or any other subscriber would greatly oblige by stating whether Mr. Browning's 4½in. reflector (the Educational), of 5ft. focus, would be likely to suit my purpose; or whether his smaller instrument of the same aperture and 3ft. focal length would suffice? Is the latter theoretically superior to an achromatic, which has an object-glass of 3in. aperture, and 4ft. focus? My "respondent" would further oblige by mentioning the publishers of the "Mem. R. A. S.," and by saying whether odd volumes of the "Memoirs" can now be obtained.—B.

[12288.]—**Radius of Object-glass.**—I have lately obtained from Chances two discs of optical glass, 4in. diameter flint and crown. The specific gravity of flint is 3·652; crown, 2·5. Will Mr. Oldfield kindly give me (in inches) the radius for grinding the glasses, the focus of the combination to be about 5ft., and convex on both sides? I have some tools by me of the following radius: 34in., 17in., and 84in.—AMATEUR.

[12289.]—**Electric Bell.**—Will some of "our" electrical friends kindly explain and show the mechanism of the above, as worked in connection with Tyer's new block instruments? I am given to understand that there are no magnets, but cannot see as they are inclosed in a box, only the hammer and bell being visible. A drawing would greatly oblige. Will a battery such as are used with the speaking instruments do for the above? I am told that there is no porous partition between the cells. Is there or not? They are charged with bluestone and water each cell. Would not a series of common preserve pots do as well as an oblong wooden box, usually seen at telegraph offices? Would they not be as cheap?—J. W. T.

[12290.]—**Hydrogen Lamp.**—To "ANALYST."—Many thanks to "Analyst," but what "combustion" does he refer to? Is the action of spongy platinum on hydrogen understood? Can "Analyst" tell me why it loses its power after a time? Washing it in nitric acid and heating in spirit flame revivifies it, but only for a few hours. Can "Analyst" tell me how to make it as active as when first bought? The loudness of the explosion is hardly to be accounted for by "Analyst's" explanation. I fancy the hydrogen gets "occluded" to a great extent in the platinum and then goes off.—H. H. G.

[12291.]—**Nature Printed Leaves.**—I have read the article on p. 298, and should like to know the process of carbon printing. Will some kind reader of "ours" give it. Is gum or glue best to use with bichromate of potash in printing?—ROBO.



[12292.] — **Breadth of Stair Steps.**—Is there any rule for making the breadth of spiral stair steps—*e.g.*, if the length be 30in. and breadth 18in., what breadth should one at 24in. long be?—J. G. W.

[12293.] — **Watch Springs.**—Will some reader be kind enough to give instructions to put a mainspring in a lever watch? I have been attempting to put one in, but I have not yet succeeded. —J. L. B.

[12294.]—**Larkin's Iron and Brass Founder.**—Will S. Bottone please give the price of Larkin's "Iron and Brass Founder," as mentioned by him in No. 367, p. 79, query 11857?—A. H.

[12295.]—**Engraving by Graphotype, &c.**—What progress is the graphotype making? I should like some details of the process, and in what respects it is superior to wood engraving—I presume in cheapness. Would Mr. Bottone kindly inform me if he thinks such an idea as the following possible:—To take some hard chemical salt which is not deliquescent but dissolves in water, vinegar, &c., and write on it with a fluid which would make the part written on insoluble in the fluid used, such as water or vinegar, so that the written parts would stand out in relief to be engraved on.—PHILANTHROPIST.

[12296.]—**The Nightingale.**—In answer to "Heders" (let. 4334), we have a saying in the Midland Eastern Counties that "the nightingale is not heard north of Peterborough." Can any of your readers inform us of its being heard by themselves so far north as the East Riding, and in what locality?—PLOUGH.

[12297.]—**The Tremolo in the Violin.**—Will "Fiddler" or any other violinist kindly inform me if there is any way of acquiring the tremolo on the violin? I mean the trembling of the finger on a note, which in slow expressive music is such an ornament. I have tried numbers of times but cannot manage it, and yet a friend of mine says that it came to him naturally, without effort. If any one can give me any information on the subject, I shall be very much obliged.—CORELLI.

[12298.]—**Lighthouses.**—Will any of "ours" kindly answer the above query (p. 107, No. 11591)?—W. H. HEY.

[12299.]—**Tar Pavement.**—Will some kind reader of the MECHANIC inform me how the material is prepared for making the foot walks at the various railway stations near London? It seems to me to be a preparation of coal tar and gravel, but of this I am not certain. It would suit my purpose admirably, as I wish to lay a floor of the same kind to thrash and clean seeds upon. Any reader acquainted with the subject would confer a favour by giving the information as to materials, and the method of doing the work.—HORTI.

[12300.]—**Direction of the Terrestrial Meridian.**—Will any reader of "ours" inform me how to find the direction of the terrestrial meridian—that is, the direction of a line passing through any given place, and joining the two poles of the earth?—YOUNGSTER.

[12301.]—**Unequal Sizes of Cone Pulleys.**—Required, a rule for finding the diameters of one cone, the diameter of the other being given, and the distance of their respective centres given also. In one of the early volumes of the ENGLISH MECHANIC, a formula is given by "J. K. P.," but it is necessary to have a knowledge of trigonometry to work it out, and I am convinced, speaking from experience, that many correspondents and readers know little if any thing of it, hence the necessity of a rule that will not be merely a curiosity, but a boon to many as well as—JONATHAN.

[12302.]—**Stains in Oak Plank.**—I am using some oak plank that has a quantity of brown streaky stains in it. They only occur in some of the planks, others, though cut from the same tree, are the natural colour. Can any reader inform me how I may remove the stains without injury to the planks; or shall I have to stain the light parts to match the dark? This I wish to avoid if possible.—J. C. S.

[12303.]—**Small Castings.**—I do a good deal of electrotype and small castings, and want to know the dodge how the same mould is made to give both right and left. I mean, suppose a medallion with head facing the left, how I can get its fellow with head facing the right.—ROBO.

[12304.]—**Phrenology.**—Will any of "our" readers who are well up in this subject (*i.e.*, what is usually understood by the term) kindly inform me at what period of the individual's life the characteristic bumps are developed? It appears to me if the brain exercises any influence on the shape of the cranium it must be before the latter has assumed its osseous nature; hence if phrenology is anything worth calling a science it is placed on the horns of a dilemma; for either the brain must have received its peculiar developments before Education steps in, or the bones of the head are distorted by the soft mass of the brain? I can't believe the latter, and am very doubtful about the former.—SAUL RYMEA.

[12305.] — **Locomotives.** — The longest barrelled locomotives in this country are, I believe, to be found on the Great Eastern line. What are the advantages gained by a long boiler, and are there not accompanying disadvantages which might outweigh the advantages? —E. M.

[12306.] — **Botanical Names.** — Will any correspondent oblige me with the botanical name of a plant known as the French willow—a sort of bush about 8ft. high, with abundant spikes of pink-coloured bloom; and also of one known as the Rose pea—a name which sufficiently describes its habit, being like a rose bush with a pea-like blossom?—HORTUS SICCUS.

[12307.]—**Kerosene.**—Will "Sigma" explain to me the nature of kerosene and its uses, and what it is produced from?—A. H.

CHESS.

ALL communications intended for this department to be addressed to J. W. ABBOTT, 7, Claremont-place, Loughborough-road, Brixton, S.W.

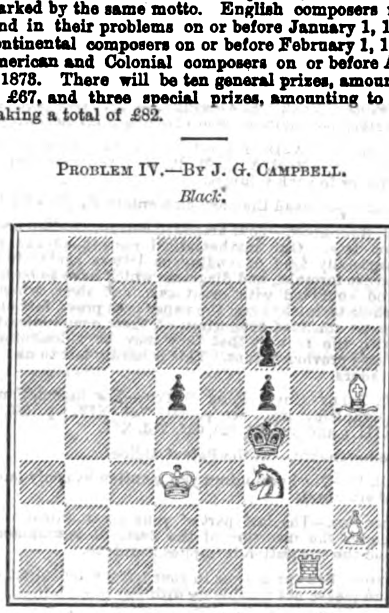
The Managing Committee of the "British Chess Association" announced that play would commence on Monday, June the 24th, at the St. George's, Westminster, and City of London Clubs, and be continued every day, Sundays excepted, until the termination of the matches.

The celebrated Prussian player, Zuckertort, has entered as a competitor in the "Grand Tourney." The foreigner will prove himself no mean antagonist, and he has recently added to his reputation by defeating the formidable Anderssen in two set matches. Our players must look well to their laurels, or most assuredly an important prize will be carried to Berlin.

The Problem Tourney in connection with the British Chess Association is open to the world without entrance fee. Each competitor will contribute five original problems; one in two, two in three, and the remaining two in not less than three nor more than five moves. The problems to be free from conditions, to be written on diagrams, and to be accompanied by their solutions. Each competitor to send in two sealed inclosures; one will contain his problems, and must be marked by a distinguishing motto, the other will contain the name and address of the competitor, and must be marked by the same motto. English composers must send in their problems on or before January 1, 1873; Continental composers on or before February 1, 1873; American and Colonial composers on or before April 1, 1873. There will be ten general prizes, amounting to £67, and three special prizes, amounting to £15, making a total of £82.

PROBLEM IV.—BY J. G. CAMPBELL.

Black.



White.

White to play and mate in three moves.

SOLUTION TO PROBLEM III.

White.	*Black.*
1. Kt to K 7	1. K takes P
2. R to K 2	2. K takes Kt
3. B to Kt 5 dis. ch. and mate	

TO CORRESPONDENTS.

W. H. J. (Lincoln).—A subscription of five shillings constitutes the contributor a member of the Association for the current year, and entitles him to admission to all the proceedings of the Congress.

S. J. H. (Liverpool).—Any friend acquainted with the game would teach you the notation of the board in ten minutes. Hoyle is no authority on chess. Your solution to No. 2 is wrong.

T. W. J. M. (Brighton).—The variation in problem No. 2, which you fail to see through, is clear enough—*e.g.*, (1) $\frac{\text{R to Q B 3}}{\text{K to Kt sq.}}$ (2) $\frac{\text{B to K 6 (ch.)}}{\text{K to R 2}}$ (3) R to R 3 mate.

C. H. YEO (Paignton).—You have evidently overlooked the use of the B P on B 2.

ARGO (Yarmouth).—Your problem shall be reported on next week.

ADDITIONAL solutions to No. 2 have been received from Wiseaf (Dulwich); W. Doery (Glasgow); J. E. and S. H. W. (York).

CORRECT solutions to Problem III. have been received from R. A. P.; W. N. P.; C. R. Howson (Birkenhead); Wiseaf (Dulwich); A. R. Molison (Swansea); C. J. L. (Portsmouth); W. Doery (Glasgow); W. H. Whitfield (Ashford); J. E.; J. Beresford (Vauxhall); Argo (Yarmouth). All others are wrong.

"JACK OF ALL TRADES."

WE have not heard from "Jack of All Trades" since we last went to press. We hope to hear good news before we appear again. We have transmitted him £21, and the following is a list of the contributors:—

USEFUL AND SCIENTIFIC NOTES.

Pre-historic Trees.—An interesting statement was made by Mr. Fallows at the monthly meeting of the Tees Conservancy. The dredging operations in the Tees had been very much impeded during 1870 and 1871, from the bed of the river, between the 9th Buoy and Jack-in-the-Box, twenty-seven oak trees, of sizes varying from 5ft. to 14ft. in circumference, and from 20ft. to 45ft. in length, had been taken out. Those trees were on the south side of mid-channel, on a clay bottom, with about 2ft. of sand around them. The largest tree weighed 11 tons. Mr. Fowler, the engineer, believed the trees had grown in pre-historic times, and had drifted down to some place in the upper reaches of the river.

The Correct Weight of Milk.—Mr. Gail Borden, of White Plains, N. Y., who conducts an establishment for preparing condensed milk, has been making some experiments for the purpose of determining the correct weight of crude milk. He took the milk of several cows, and, mingling it together and then thoroughly cooling it, he had it accurately weighed. The result was that a quart of milk, so measured and weighed on delicate scales, was equal to 2lb. 2¼oz. The tests were made with differrnt samples of milk at different times, but without materially altering the weight. Mr. Borden has adopted the above as a true weight of a quart of milk of fair average quality. Hence, any person who buys milk may determine by weight, with satisfactory accuracy, whether he receives a quart when he is required to pay for that quantity.

Labour and Health.—He that is industrious in his calling shall stand before kings; he shall not stand before mean men," is a maxim conceived in the spirit of true wisdom, if expressed in the language of Oriental poetry; is confirmed by the highest intelligences of ancient Greece, which animated its youth to exertion by exhorting them always to strive after excellence and for the first place; is indorsed by the great and eloquent apostle of the Gentiles, in the well-known words, "Be not slothful in business; fervent in spirit; serving the Lord." Our great workers furnish a living commentary upon these texts. How many complain of their mishaps, misfortunes, and want of success in life, which is in reality all their own fault in the majority of instances! Misfortune is often only another name for mismanagement. They use no arduous exertion, they use no proper endeavour, as if all the good things of nature were to be had without toil or labour, and the world itself were to be no theatre of probation. Kind Providence giveth all things to labour; every reasonable desire is within reach of the industrious. Viewed strictly within the limits of the subject, the importance of a constant occupation of the time in the pursuit of good ends by good means will be acknowledged by all who have ever felt the miseries of inaction and have roused themselves from this torpor. Whether the work is of the brain, or the hand, or both, in whatever proportions existing, the pursuit should be engrossing, and a lively interest taken in the work; not maundering in the clouds, or in the waters under the earth, or the mind occupied with something else whilst seeming to be employed at its real business. It is this half-mindedness which is the bane of labour, and can never advance its performer.

Hints as to the Employment of Blasting Powder.—"Powder is a good servant, but a bad master," and too much care cannot be taken in handling it, says an Australian paper. Strict attention to the following rules would prevent many an accident:—First, only the best powder and safety fuse should be used; the stuff used for tamping to be free from quartz, spar, or flinty matter—clays, slate finely pulverised and dry, will be found to be the best; second, ragged holes to be made smooth by claying, or the safety fuse to be protected by a tube of guttapercha or indiarubber, or by being bound in some hempen substance; third, no powder should be left about the walls of the hole; fourth, the charge should be passed down through a tube having a funnel or bell mouth; fifth, wet or damp holes should be charged with a cartridge, or the powder placed in a bag made of some impervious material—a composition of pitch and coal, or wood tar would answer well. The ramming bar to be copper, or iron tipped or capped with copper. Sixth, a misfired hole, or hole holding fire, should never be bored out, the drill or borer always cutting deeper than the water, reaching the charge first. Holes have been known to hold fire for many hours.

THE "ENGLISH MECHANIC" LIFEBOAT.

No doubt it is a source of grief to many that the English Mechanic Lifeboat should make such slow progress. We, however, have not encouraged it very energetically, for the best of all reasons. Thanks to the National Lifeboat Institution and British philanthropy, there are but few available points on our coasts where a new lifeboat is required. Had we known at the time the fund was suggested that so much had been done, and so comparatively little had been left undone, we should have hesitated before we indorsed Mr. Luff's proposal. Two or three opportunities have since occurred where new boats have been supplied to old stations in the place of old or imperfect boats. But no new station has recently been established. We have preferred, and no doubt the subscribers agree with us, that the boat launched by our aid should be called "The English Mechanic Lifeboat." That, however, could not be easily done if we merely supplied a new boat for an old one, as a new boat generally takes the name of the one it has displaced. We believe in the course of a short time a new lifeboat station will be opened, and we trust it will be supplied with our lifeboat. We therefore venture to call on our friends to complete the fund; at least £400 are required for the boat alone, and we have nearly £336 in hand. We ought not to be long reaching the remaining £64.

Amount already collected .... £335 16s. 7d.

ANSWERS TO CORRESPONDENTS.

*** All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent-Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, June 25, and unacknowledged elsewhere:—

W. Hibbs.—W. G. Owens.—W. Young.—W. H. Willcocks.—P. H. Towler.—Wm. Moor, jun.—Philadelphian.—E. W. R.—Margaret E. Bache.—Screw-driver.—D. M. Thomas.—A Builder.—T. C. Ebdy.—Humanitas.—W. Hewitt.—T. M. Jones.—C. A. Young.—Summer Time.—Glaston.—Avalon.—Fate.—A Swimmer.—E. T. G.—Mason & Co.—Contented.—F. I. R. B. A.

J. E. Reeve, G. W. H., J. M. Martin, and Water Pipe.—See No. 6 "Hints to Correspondents."

T. Parkinson and Co., X. M. S., and a Notts Inquirer, are referred to "Hints to Correspondents," No. 4.

A. P. W., Decimal, Bagshot, and Weatherhead.—Consult last index.

P. Woodhouse, Communicator, and E. A. E.—Really too trifling.

G. W. K. L.—Thanks. Request as to "Saul Rymea" complied with. Your letter on Sewing Machines next week.

Douche-Bath.—The controversy has terminated, and, as Mr. Proctor says, "by consent."

G. L.—What you say about modern "discoveries prove the inspiration of the Bible" is good enough. But if your letter were inserted a dozen correspondents would commence a discussion on the passages you quote, and we should be floated on another Deluge controversy.

Hooslum.—For a method of cleaning felt hats, see reply 12089, p. 840. Carbonate of ammonia is the salt generally employed.

Barmes—Would like to see some instruction on billiard playing in the English Mechanic, written by some one who thoroughly understands the subject.

To Eos.—"H. B. E." says:—"I am sure every subscriber to 'ours' will be glad to see again communications from 'Eos,' when it is convenient for him to write again." Should this reach "Eos" in the depths of his African solitudes, we should like him to know that we thoroughly indorse the desire of "H. B. E."

Mechanical Equivalent.—You make a mistake. We have no desire to come down on you "with a crash" because you persist in believing in perpetual motion, after many weary years of experimentalising. We are only sorry to hear of the expenditure of so much unproductive labour. Only imagine what a number of cabbages you might have cultivated during the time, and so have contributed to the wealth of the world. Try and understand the meaning of the words you write under—"Mechanical Equivalent."

Betsy Summercity.—The discussion on the "Cometary Deluge" is closed, or we should try to find room for your very funny letter. If, however, you would like to start some of the points mentioned by you, such as the world being once red hot, as many rock districts prove, or the age, use, and productions of rainbows, space is at your disposal. But then the comic side of your nature must be kept under due discipline. "E. L. G." is pre-eminently serious, and so, in fact, are most of the other correspondents who have taken part in the discussion. Don't imagine we can't enjoy a good joke because we caution you about being too funny. The reason why we hate bad jokes is because we intensely like good ones.

A Three Years' Subscriber.—Try Gay and Co.'s waterproof solution. See advertisement on front page.

J. Marsden, A. D., A Leeds Subscriber, Bron, J. Pearson, Never Rust, A. Z., W. P., W. K. B., are referred to indices to back volumes.

Inventus.—Read the most elementary English History.

C. J. Recordon.—Your amended communication arrived too late. Our mathematical correspondents seem especially fond of sending us letters containing abstruse formulæ, and diagrams which have to be set up and engraved with great care, and then, when the whole is finished and the paper is at press, forwarding to us amended renderings of their communications, with the request that they may be substituted for those previously sent. This is hardly fair to us or our readers.

T. P. Lilly and A Poor Smith.—For instructions on galvanising iron, see p. 441, Vol. XIV.; p. 546, Vol. XIII.; and pp. 478, 523, 622, Vol. XII.

Phonocamptic.—At the Patent Office.

E. B. F.—The harmonium you mention has only one row of vibrators.

Vent Peg.—The last part of your communication precludes the insertion of the first. It is unmannerly, and the suggestion it implies is untrue.

Horos.—See our answer to your letter a fortnight since and please not trouble us with any more letters.

E. L. G.—Your able letter on the Negro in answer to "Fiddler" next week. It is a most interesting question, and we hope it will be temperately discussed.

The Harmonious Blacksmith.—Yours on the Piano in Canada next week.

J. D., who has sent us so many useful contributions on organ building, says:—"I am happy to say I am recovering nicely from the frightful accident I sustained in March last—viz., a broken thigh, dislocated hip, and injury to the spine—and hope in a week or two to resume my articles on the Organ Built. The Mechanic has been a great source of pleasure to me during my long confinement to bed."

Everard Calthrop.—We know of nothing better suited to your requirements than Leroy's non-conducting composition. See advertisement.

C. E. and Three Bridges.—Your queries are advertisements.

Rev. H. C. Key.—The controversy was stopped not because it was exhausted, but because it occupied more space than we could devote to it, and also because it got unnecessarily warm.

E. L. D.—Fear not for the Truth, but fear rather your own fears for it.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING JUNE 18, 1872.

1752 C. F. Hengst, Fulham, and J. B. Muschamp, Kensington, for improvements in the manufacture of gas, and in the apparatus employed therein.

1753 E. Gilbert, Edinburgh, for improvements in signalling on railway trains, and in the mechanism and appliances therefor.

1754 J. Ducomet, Paris, for improvements in steam gauges.

1755 J. Pollock, Walbrook, City, for improvements in the manufacture of envelopes and postal wrappers.

1756 W. Cotter, Gloucester-street, Bloomsbury, for improvements in bow saws.

1757 S. Cropper, Cheapside, for improvements in ink fountains for printing presses. A communication.

1758 J. H. Johnson, Lincoln's Inn-fields, for improvements in locomotive engines and carriages. A communication.

1759 W. Eacott, Featherstone-buildings, Holborn, for a new or improved advertising apparatus. A communication.

1760 W. O. Palmer, Clapham-road, for a new or improved signal lamp.

1761 J. Farmer, Salford, for improvements in machinery for stretching, drying, and "ageing" woven fabrics.

1762 J. Bloomfield, Colchester, for improvements in sewing machines.

1763 S. Pelle, Carlisle, for an improved mowing and reaping machine.

1764 P. King, Liverpool, for improvements in ships and appliances for raising sunken vessels.

1765 T. White, Birmingham, for improvements in nut-crackers and lobster crackers.

1766 W. Firth, Bradford, and P. Smith, jun., Keighley, for improvements in machinery for spinning and doubling worsted, silk, cotton, and other fibre.

1767 R. W. Kenyon, Accrington, Lancaster, for an improved machinery to be employed in the manufacture of healds for looms for weaving.

1768 G. Anderson and J. Buchanan, Linlithgow, for improvements in apparatus for drawing the charge from retorts employed in making gas or oil.

1769 J. Dupont, Liverpool, for the application and treatment of certain plants not hitherto used for the production of filaments and fibres.

1770 J. Birch, Newton-heath, Lancashire, for improvements in the manufacture of iron and steel, and in apparatus to be used in such manufacture.

1771 H. Shanks, Linlithgow, N.B., for improvements in drawing retorts and in the means employed therefor.

1772 J. Picken, Stewarton, Ayrshire, for improvements in the manufacture of Scotch bonnets or caps.

1773 G. Weir, Glasgow, and J. Weir, Liverpool, for improvements in safety and other outlet valves for steam boilers.

1774 D. Ballardie, Glasgow, for an improved appliance for holding railway carriage and other window sashes.

1775 L. Crévisier and L. Lecamp, Rheims, France, for an improved apparatus for cambering leather, leather cloth, and other fabrics.

1776 T. A. Weston, Ridgewood, New Jersey, U.S., for improvements in differential pulleys, portions of which are applicable to other chain wheels.

1777 W. Stuart, Wolverhampton, for improvements in window-sash fasteners.

1778 R. Searle, Manor-gardens, Hackney, for improvements in the use and application of fluids for obtaining motive power and in apparatus for the same.

1779 R. McFarlane, Rickmansworth, Herts, for improvements in treating wood for the production of paper pulp and in apparatus employed therefor, parts of which improvements are applicable to the making of steam-tight joints for various purposes.

1780 W. E. Newton, Chancery-lane, for improvements in self-cancelling stamps, labels, and other analogous articles. A communication.

1781 A. McNeile, John-street, Pentonville-road, for improved machinery for cutting or shaping wood.

1782 J. M. Zamoyski and W. Jackson, Great George-street, Westminster, for a novel mode of constructing (with reference to independent axles and crank shafts) railway locomotives, traction engines, and other engines, railway carriages, vans, and trucks, as well as tramway carriages.

1783 W. R. Lake, Southampton-buildings, for improvements in rotary pumps and engines, and in means for effecting the transmission of power thereby, parts of which improvements are applicable to the construction of rotary blowers and ventilators. A communication.

1784 J. Heald, jun., Lancashire, for improved door fasteners for railway waggons, carriages, or any other kinds of doors.

1785 H. A. Bonneville, Piccadilly, for a new and improved apparatus for securing corks in bottles. A communication.

1786 J. G. Rolls, Clapton, for a new material adapted for use as an electric insulator for telegraphic and other purposes, and also in a hardened state adapted for use as a vulcanite.

1787 G. A. Tate, West Hartlepool, for improvements in millstones or grinders and in the manufacture thereof.

1788 J. Milroy, Edinburgh, for improvements in constructing foundations, piers, quays, and similar structures.

1789 J. Browning, Strand, for improvements in photometers.

1790 J. Stubbs, Manchester, for improvements in machines commonly called "reels for winding yarns or threads into banks."

1791 J. H. Johnson, Lincoln's Inn-fields, for improvement in the separation and utilisation of volatile and condensible gases, and in the machinery or apparatus employed therein. A communication.

1792 J. W. Bretherick, Over Darwen, Lancashire, for improvements in machinery or apparatus for sizing and varnishing healds for weaving.

1793 G. White, Queen-street, City, for an improved material and its application for the manufacture of hats, bonnets, caps, or other similar coverings for the head. A communication.

1794 G. Hulme, Macclesfield, for a treatment of felted cloth in the production of a washable covering for floors, with patterns not on surface only, but also passing partially or entirely through the cloth.

1795 J. Imray, Southampton-buildings, for improvements in the manufacture of iron and steel, and apparatus therefor. A communication.

1796 E. Korting, Hanover, Germany, for improvements in condensers.

1797 H. Marrian, Birmingham, for improvements in machinery or apparatus for manufacturing lozenges, medals, and other similar articles of confectionery.

1798 W. P. Maddison, Dewsbury, Yorkshire, for improvements in the means of and apparatus for raising water from mines and other low levels.

1799 J. H. Johnson, Lincoln's Inn-fields, for improvements in the manufacture of iron. A communication.

1800 J. H. Johnson, Lincoln's Inn-fields, for improvements in seasoning wood. A communication.

1801 G. Haseltine, Southampton-buildings, for improvements in the manufacture of iron and steel and in apparatus employed therefor. A communication.

1802 C. W. Smith, Highfield, Gloucestershire, for improvements in the extraction of indigo and other similar substances from plants containing such substances.

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

FRIDAY, JULY 5, 1872.

ARTICLES.

ELECTRO-METALLURGY.—II.

By J. T. Sprague.

EQUIVOLT.—A unit devised by me to connect together tension and quantity. It is the force engaged in effecting 1 equivalent of chemical action in a circuit of 1 Ohm resistance, and under the Volt electro-motive force. It is described in No. 351, Vol. XIV., p. 318. Its mechanical equivalent is 4,673 foot pounds. This unit, when thoroughly comprehended, will greatly aid in understanding electricity, and the doctrine of the correlation of forces.

Galvanometer.—An instrument for measuring "current" by its magnetic effects in deflecting a magnetic needle. They are not comparable among themselves unless graduated for the purpose. The tangent and sine galvanometers are proportional, so that knowing the value of any one deflection that of all others may be calculated. Any galvanometer may be graduated to give exact measures, by inserting a voltameter in the circuit with various batteries and resistances, and noting the time in seconds, during which a given measure of gas is produced. The tangent galvanometer was described in No. 283, Vol. X., p. 530; the sine in No. 285, Vol. XI., p. 579; my universal instrument in No. 287, Vol. XII., p. 1, and one specially adapted for use in electro-metallurgy will be described hereafter.

Insulators.—Bodies possessing high resistance; all, however, allow some current to escape or rather "charge," to be lost as current. They are called "electrics," because friction develops electric excitement in them. Ebonite is the highest "non-conductor," paraffin, sulphur, and glass follow. A full list was given in No. 245, Vol. X., p. 272. Telegraphic insulators are the porcelain cups, &c., to which the wires are secured, and which prevent electric communication being formed between the wires and the earth through the posts.

Ions.—Faraday's term for the two parts into which an electrolyte breaks up; they may be regarded as "radicals," and may be either single atoms of elements, doubled atoms which still act as one chemically, or they may be compound radicals, like cyanogen, ammonium, and the radicals of acids. They are of two classes, named from the electrode at which they appear, but it must be remembered that the same radical may be an anion at one time and a cation at another, according as it is united with a radical more or less high in the order of affinity. See anions and cations.

Intensity.—The old term for the properties now described as electro-motive force and tension: Batteries were said to be arranged for *intensity* when the cells are coupled together in series. The term leads to such confusion that it is best abandoned altogether.

Intensity of Current.—A term adopted from the French *intensite de courant.* It means "quantity," and the best writers now use the simple word "current" to avoid the confusion of these conflicting terms.

Measurement.—See Units.

Molecule.—The ultimate particles of free or complete substances. Modern chemistry draws a strong distinction between atoms, equivalents, and molecules, terms as to which there was formerly much confusion. Conceiving the atom of any element, as the ultimate particle possessed of an attractive force (in a degree more or less great) which is part of its nature, the molecule is formed by the union of two or more atoms by means of these attractions. In gases and most vapours a single measure being regarded as the atom, 2 such united form a molecule or molecular volume; it is found that (with a few exceptions), no matter how many elementary atoms may be required to form the complete body, yet (when formed) it only occupies 2 vols., condensing more and more as each atom is added. Of course the measure of volume is to be taken at the same temperature and pressure. Thus, taking the measure of hydrogen as the unit of *atomic* volume, we get as molecules—

Free hydrogen	H_2 =	2 vols.	2 atoms.
„ oxygen	O_2 =	2 „	2 „
Water	H_2O =	2 „	3 „
Ammonia	NH_3 =	2 „	4 „

$$\text{Ozone } O_2 + \begin{matrix} O_2 \\ O_2 \end{matrix} = \begin{cases} O_3 = 2 \text{ „ } 3 \text{ „} \\ O_3 = 2 \text{ „ } 3 \text{ „} \end{cases}$$

The last instance illustrates the action of substances in the "nascent state" as well as the nature of molecules, for while the normal molecule of oxygen is 2 atoms, if one such molecule can be broken up, its constituent atoms can force themselves into 2 other molecules, and then 3 volumes condense into 2; but owing to the tendency to lapse into true normal molecules, this union of 3 atoms is unstable, and the third atom is held by a feeble bond; hence the chemical energy of ozone and its many curious properties.

Nascent.—It is found that substances have a much greater chemical force at the instant in which they are being set free from combination than when they are free bodies. They are then called "nascent." Most of the processes of electro-metallurgy are considered to be effected by secondary electrolysis, through this action of nascent hydrogen. This special energy is supposed to be owing to the substances (or radicals) being then in the atomic instead of the molecular condition, and therefore having all their chemical energy or attractions engaged in seeking a combination. It is commonly the case, also, that a radical cannot be set free at all, unless in the presence of some other bodies with which it is capable of uniting. (See Molecule.)

Negative.—In the battery, the copper, carbon, or platinum plate.

Negative Pole.—Cathode, platinode.

Negative Ions.—Oxygen and acid or chlorous radicals.

Notation.—The mode of expressing chemical substances and reactions by their symbols. (See Equivalent.) There are many modes of expressing the same things in different formulæ according to the special theory of constitution adopted, or the particular view of the matter intended to be described; and there are two distinct systems in use.

= *the Equivalent.* — This system, used in all the old books, is based really on oxygen (which was called 100), and the weight of hydrogen which combined with oxygen being called 1, the equivalents of other substances were afterwards reckoned from this. Hence water is in this system called $\frac{HO}{1\ 8} = 9$. This system will, for some reasons of practical convenience, be used in these papers.

= *the Atomic.* — This, which is called the "New Notation," is generally adopted in all modern chemical books. It is based on the fact that water contains 2 *measures* of hydrogen to one of oxygen, and this being conceived to show the atomic relations, water becomes H_2O, and H being called 1 as to weight, it becomes necessary to call O = 16, and in consequence most of the metals have their weights similarly doubled as compared with the equivalent notation, while the number of atoms of those which are unchanged (the monovalent elements) have to be doubled. The following example of the action of sulphuric acid upon nitrate of soda exhibits the two systems:—

Equivalent.

Salt.		Acid.		Salt.		Acid.
Na,NO_6	+	H, SO_4	=	Na, SO_4	+	H,NO_6
23 62		1 48		23 48		1 62

Atomic.

$$\overline{2Na,NO_3} + H_2,SO_4 = Na_2,SO_4 + \overline{2H,NO_3}$$

23 62	2 96	46 96	1 62

This means that nitrate of soda on being mixed with sulphuric acid is decomposed into a fresh acid and salt, sulphate of soda, and nitric acid.

Ohm.—The unit of resistance, called the British Association unit. (See Units.)

Ohm's Laws.—These formulæ, devised by Ohm, enable us to calculate from certain data all the information we require. The symbols should represent fixed units (see Units) to obtain definite results. Otherwise they are merely comparative.

E stands for electro-motive force, R for resistance, C for current. Any two of these being known we can calculate the third; thus knowing the force of the batteries to be used and the resistance of a circuit, which mainly depends in electro-metallurgy on the size of the plate, we can tell how much metal will be deposited in a given time, and therefore regulate the rate of deposit by adding to or diminishing the cells of the battery, &c.

Current ....$C = \frac{E}{R}$

Resistance ....$R = \frac{E}{C}$

Electro-motive Force...$E = C \times R.$

In these formulæ the symbols represent the total forces and resistances of the circuit, which are ascertained from their several component parts.

For the details of these laws, see No. 330, Vol. XIII., p. 423.

Ozone.—See Molecule.

Platinode.—Daniell's term for the cathode, or that plate in any cell which does not dissolve.

Polarisation.—The act of arranging the substances which form an electric circuit in a polar order or chain of + and − radicals, presented towards and reacting on each other. It resembles the arrangement which takes place in a number of magnetic needles which arrange themselves in an order of NS, NS.

Polarisation of Plates.—This very confusing and absurd term is applied to an action which occurs whenever the current passes from liquid to solid conductors: there forms on the surface of the latter a film different from the liquid. In the voltameter a coating of oxygen and hydrogen gases condenses on the plates; in the Smee and other single acid cells a coating of hydrogen forms on the negative metal; in a decomposition cell, say of sulphate of copper, the cathode is soon surrounded with an acid liquid, while the anode is apt to be coated with crystals of sulphate, owing to the concentrated state of the surrounding liquid. In all these cases not only is a greater resistance introduced, but an electro-motive force is generated, opposing that of the current, so that if suddenly connected to a galvanometer, and the main circuit broken, a reverse current will be maintained for some time. On this principle are constructed, for some purposes, what are called "Secondary Batteries."

Poles.—The wires, plates, &c., leading from the battery; their name is the opposite of that of the plate they lead from, thus the zinc is the positive metal, plate, or element of the battery, but the wire leading from the zinc is the negative pole.

Positive. In the battery, the zinc plate, in a decomposition cell, the anode.

Positive Pole; + the anode, the zincode, by which the current enters.

Positive Ions; hydrogen, metals, and basic radicals.

Quantity.—A term based on the idea that electricity is an actually existing element having quantitative relations to chemical actions similar to the atomic weights of the material elements. The definition applicable to existing ideas of the nature of electricity will be found under "Current."

Radicals.—Either elementary atoms, or compound bodies which act like atoms, retaining their completeness and individuality through a series of chemical changes. It is considered that the acids are formed of such radicals, whose attractions are satisfied by hydrogen, while salts are the same radicals satisfied by metals or compound basylous radicals. These radicals are the *ions* of the theory of electrolysis. Many radicals, indeed most of the acid radicals, are incapable of existence as separate bodies, and the same is the case (at least, in ordinary conditions) with the most important compound basylous radical—viz., ammonium, NH_4, which possesses the reactions of a metal analogous to potassium, but whenever set free breaks up into ammonia and hydrogen $NH_3 + H$.

Basylous	Chlorous
Electro-positives	Electro-negatives
Cations	Anions
Hydrogen	Oxygen
Metals	Chlorine
	Acid Radicals

Resistance.—The opposi[illegible] the circuit to the development [illegible] an inherent [illegible] in degr[illegible] conduc[illegible] called non-conductors. Whatever the special substance however, its actual resistance may be expressed in any common unit; thus we may describe the resistance of a decomposition cell as equal to so many feet of a given wire. The unit of resistance now generally employed is the ohm.

Resistance requires to be considered in the various sections of the circuit as "internal," that of the battery itself, and "external," that of the work to be done, the conductors leading to it, and any measuring apparatus employed.

Resistance, when it is not work in some form, always converts the energy of the current into heat.

See Ohm's Laws and Units.

TENSION.—The strain put upon the circuit by the electro-motive force; it may be regarded as a single amount, or as + and − equal in opposite directions from the source. At the source it is equal to the electro-motive force; calling this 100, it falls throughout the circuit in exact proportion to the resistance; it is, in fact, used up in passing the current against the resistance; the effect of tension will be explained hereafter.

UNITS.—Any fixed measures may be used, but I shall only refer to those employed in these papers; for discussion and comparison with other units see No. 293, Vol. XII., p. 147, and No. 299, p. 280, Vol. XII.

— *the Absolute* are based upon the units of mass, length, and time, 1 gramme, 1 metre, and 1 second; and the fundamental unit is that force which can generate a velocity of one metre per second; gravity being a force of 9·811 such units (or 32·2ft. per second). For practical use larger units have been devised by the British Association, viz:—

— *Electro-motive Force and Tension.* — The Volt = 10^5 or 100,000 absolute units. The Daniell's cell, that is the chemical affinity of zinc displacing copper from its union with sulphuric radical, is 1.079 Volts; and, therefore, for rough purposes may be taken as a Volt.

— *Resistance*, the Ohm = 10^7 or 10,000,000 absolute units; Ohm measures made of German-silver wire can be obtained of scientific instrument makers, and from them instruments for measuring resistances can be made as described in No. 305, Vol. XII., p. 435.

— *Current.*—The Veber, $\frac{10^5}{10^7} = 10_2$ or ·01 absolute unit per second. 1 Veber decomposes ·00142 grains of water.

— *the Chemic.*—The unit of current is much more conveniently based upon an equivalent of chemical action, or quantitative result, and the unit I shall use in these papers will be a current effecting one equivalent of chemical action (in grains) per ten hours. (See Equivalent.) A current of 1 Veber per second is equal to 5·68 of these units, therefore in any calculations (see Ohm's laws) the unit of electro-motive force (the Volt) would have to be multiplied by 5·68 to give the result in chemical units, and a force calculated from these units would be divided by 5·68 to express it in Volts. This unit I will for convenience call a "Chemic." A *chemic*, therefore, is a rate of current which in a second is equal to ·17606 of a Veber, and would in ten hours deposit or set free 1 equivalent in grains of any element or ion.

— *Current and Energy.*—See Equivolt.

VEBER.—See Units of Current.

VOLT.—The unit of Electro-motive Force and Tension. (See Units.)

VOLTAMETER.—An apparatus for measuring the current by its chemical action; the term is usually limited to a vessel provided with two platinum poles for the decomposition of dilute acid and with tubes for collecting and measuring the gases given off. It is of little practical use, as it gives great resistance and no more information than a properly graduated galvanometer which has little resistance. It is, however, useful theoretically, and also for graduating galvanometers to show really quantitative measures instead of mere angles of deflection. (See Galvanometer.)

The voltameter and its principles are described in No. 290, Vol. XII., p. 76.

WIRE.—For gauges and properties of copper wire; the resistances and weights of various sizes, see No. 317, Vol. XIII., p. 97.

ZINCODE.—Daniell's term for the anode.

LESSONS ON CHEMISTRY.*

BY SELIMO R. BOTTONE.

(Late of the Istituto Bellino, Novara, Italy.)

(Continued from p. 243.)

D. DITHIONOUS ANHYDRIDE. *Synonym: Hyposulphurous anhydride.*[1] *Symbol:* $S_2''O_2''$. *Molecular and combining weight:* 96.

181.—This body is as yet unknown in the separate state. Combined with the elements of water it forms:—

D2. DITHIONOUS ACID. *Synonym: Hyposulphurous acid.*[2] *Symbol:* $H_2{}'S_2''O_3''$. *Molecular and combining weight:* 114.

182.—PROPERTIES.—This body is scarcely known in the free state, owing to its tendency to decomposition. When a sulphite (see 163) is boiled with sulphur, or when sulphurous acid is added in excess to a mixture of sulphur and a soluble base (see 169), sulphur is taken up, and a salt containing this acid is the result. Thus:—

$$\overbrace{2Na_2{}'S''O_3''}^{\text{Sodium Sulphite.}} + \overbrace{S_2''}^{\text{Sulphur.}} = \overbrace{2Na_2{}'S_2''O_3''}^{\text{Sodium Dithionite.}}.$$

If an aqueous solution of any dithionite be acted on by acetic acid (or, indeed, any acid which does not produce much heat on admixture with water) it acquires a full golden yellow colour, owing to the liberation of hyposulphurous or dithionous acid. If the mixture be maintained at a very low temperature the hyposulphurous acid produced remains unchanged for a considerable lapse of time, consequently the yellow liquid remains clear and transparent. If the temperature be allowed to rise above 32° Fahr., the acid is rapidly decomposed, sulphur being deposited and sulphurous acid eliminated, thus:—

$$H_2S_2O_3 = S + H_2SO_3.$$

Owing to its instability dithionous acid is of no practical use, *as such*, but combined with sodium, as sodium dithionite or hyposulphite, it is largely employed by photographers to dissolve away the unaltered silver salts used in the various photographic processes. Large quantities of sodium hyposulphite are prepared at Newcastle-on-Tyne by the following process:—8 parts of crystallised sodium carbonate, Na_2CO_3, are well mixed with 1 part of sublimed sulphur, and the resulting mixture is thrown into a vessel containing 16 parts of rain water. Sulphurous anhydride is now passed through this mixture until it acquires a distinctly acid reaction. The mixture is then boiled for a short time, filtered, and after concentration set aside to crystallise. The reactions which take place may be easily understood on examination of the annexed equation:—

$$Na_2CO_3 + S + H_2SO_3 = H_2CO_3 + Na_2S_2O_3$$

183.—Our knowledge of the hyposulphites is due to Gay-Lussac, who first made them known under the name of *sulphuretted sulphites.*

E. DITHIONIC ANHYDRIDE. *Synonym: Hyposulphuric anhydride.*[3] *Symbol:* $S_2''O_5''$. *Combining weight:* 144.

184.—Unknown in the separate state.

E2. DITHIONIC ACID. *Synonym: Hyposulphuric acid.*[4] *Symbol:* $H_2{}'S_2''O_6''$. *Combining weight:* 162.

185.—PROPERTIES.—Dithionic acid is a colourless inodorous fluid, having a specific gravity of 1·347. It possesses a strong sour taste, and has all the properties of an acid. By exposure to heat it is decomposed, splitting up into sulphurous anhydride and sulphuric acid, thus:—

$$H_2S_2O_6 = H_2SO_4 + SO_2.$$

Neither the acid itself nor its salts have found any application in the arts.

186.—PREPARATION.—When a stream of sulphur dioxide is caused to pass through ice-cold water, in which is suspended manganese dioxide, this latter gives up half its oxygen to the sulphur dioxide, being thereby reduced to the state of monoxide, while the sulphur dioxide is transformed into dithionic acid. The following equation will render this clear:—

$$2SO_2 + MnO_2 + H_2O = MnO + H_2S_2O_6.$$

The resulting dithionic acid immediately combines with the manganese monoxide to form manganese dithionate, MnS_2O_6. From the manganese dithionate the acid may easily be obtained by treating the solution with an equivalent of sulphuric acid, evaporating to separate the manganese sulphate formed, and concentrating the fluid until it acquires a specific gravity of 1·347.

F. TRITHIONIC ANHYDRIDE.[5] *Symbol:* $S_3''O_5''$. *Combining weight:* 176.

187.—Not known except in combination.

F2. TRITHIONIC ACID. *Synonym: Sulphuretted hyposulphuric acid.*[6] *Symbol:* $H_2{}'S_3''O_6''$. *Combining weight:* 194.

188.—This body is very similar to dithionous acid. It differs from it in being much more stable. On boiling the concentrated solution, it is resolved into sulphur, sulphur dioxide, and sulphuric acid. Thus:

$$H_2S_3O_6 = H_2SO_4 + SO_2 + S.$$

This acid is of no practical importance.

G. TETRATHIONIC ANHYDRIDE.[7] *Symbol:* $S_4''O_5''$. *Combining weight:* 208.

189.—This body has never been isolated.

G2. TETRATHIONIC ACID. *Synonym: Bisulphuretted hyposulphuric acid.*[8] *Symbol:* $H_2{}'S_4''O_6''$. *Combining weight:* 226.

190.—Resembles dithionic acid. Its salts may be obtained by acting on a dithionite with iodine, when an iodide of the base is formed simultaneously with a tetrathionate. In the case of sodium dithionite (hyposulphite of soda), the following equation illustrates the changes which take place:—

$$2Na_2{}'S_2''O_3'' + 2I' = 2Na'I' + Na_2{}'S_4''O_6''.$$

From the tetrathionates, the acid may itself be obtained by the action of a dilute acid. It is very instable. Owing to the ease with which it loses sulphur, it was formerly employed in photography for *sulphur-toning.*

H. PENTATHIONIC ANHYDRIDE.[9] *Symbol:* $S_5''O_5''$. *Combining weight:* 240.

191.—Like the other anhydrides of its class, this body has not been isolated.

H2. PENTATHIONIC ACID. *Synonym: Trisulphuretted hyposulphuric acid.*[10] *Symbol:* $H_2{}'S_5''O_6''$. *Combining weight:* 258.

192.—This body is prepared by passing a current of hydrogen sulphide into a solution of sulphurous acid. It is a colourless, inodorous fluid, of an acid, bitter taste. By the action of heat it is resolved into sulphur, sulphuric acid, hydrogen sulphide, and sulphur dioxide, thus:—

$$2H_2S_5O_6 = H_2S + H_2SO_4 + S_4 + 4SO_2.$$

SECTION 7C.—COMPOUNDS OF SULPHUR WITH CHLORINE.

A. CHLORINE MONOSULPHIDE. *Synonym: Protochloride of sulphur. Symbol:* $Cl_2{}'S''$. *Combining weight:* 103.

193.—PROPERTIES.—This body appears as a thin, brownish red liquid, having a specific gravity of 1·620. It boils at about 147° Fahr., but is decomposed on boiling with evolution of chlorine. It has a disagreeable penetrating odour, fumes strongly in the air, and possesses a hot, bitter, and acid taste.

194. — PREPARATION. — Dry chlorine gas is passed for several days through flowers of sulphur. The resulting liquid is cautiously distilled at a temperature not exceeding 150° Fahr.[11] A variable mixture of this substance, along with the next described, is largely used in the preparation of vulcanised indiarubber.

B. CHLORINE DISULPHIDE. *Synonym: Subchloride of Sulphur. Symbol:* $Cl_2{}'S_2''$. *Combining weight:* 135.

195.—PROPERTIES.—A dark yellow oily liquid, having a specific gravity of 1·686, and a boiling point of 280° Fahr. Its taste and smell are similar to those of the monosulphide. It also fumes on exposure to air.

1 Dithionous acid, hyposulphurous acid.

2 Hydrogen dithionite, hydrogen hyposulphite, hydric dithionite.

3 Dithionic or hyposulphuric acid.

4 Hydrogen dithionate or hyposulphate.

5 Trithionic acid.

6 Hydrogen trithionate.

7 Tetrathionic acid.

8 Hydrogen tetrathionate.

9 Pentathionic acid.

10 Hydrogen pentathionate, hydric pentathionate.

11 This is the process usually followed, but the result is certainly contaminated with free chlorine.

196.—PREPARATION.—By long continued boiling the last described compound gives off chlorine, and is resolved into this body, thus :—

$$2Cl_2S = Cl_2 + Cl_2S_2.$$

SECTION 7D.—COMPOUNDS OF SULPHUR WITH BROMINE.

SECTION 7E.—COMPOUNDS OF SULPHUR WITH IODINE.

197.—Compounds similar to those containing sulphur united to chlorine exist; in which the chlorine is replaced by bromine, or by iodine. They are of no practical use. No compound has yet been described containing sulphur and fluorine.

OUR FOOD SUPPLY AND THE SEWAGE QUESTION.

By HENRY MAC CORMAC, M.D.

I AM not an agricultural man, but I take the utmost interest in agricultural progress. The loss of ammoniacal ingredients and phosphates of transition I have long deplored, and very often have I intended to draw up some observations on the subject. I have now done so, and describe the means by which I would purpose to accomplish the important result of effectively rescuing the now lost azote, lime, and phosphorus of transition. Without further preface, therefore, I shall proceed to read my Essay on "The Economic and Effective Arrest of the Lime, Phosphorus, and Azote of Transition, through the medium of a prepared Humus or Soil, and their application along with that of ordinary excreta to purposes of agriculture." The liquid phosphate of lime now sells for some £20, and ammonia at from £80 to £100 per ton. Vast quantities of these important substances are imported from abroad, and very largely fabricated at home. But whatever be the actual amount made use of, the supply of animal and mineral phosphates and preparations of ammonia falls far short of the requirements of the soil. Everything, speaking of alimentary substances, which the earth is made to yield ought to be returned in some shape to the soil. This plain and indubitable canon is nevertheless violated continually. What the land gives is very insufficiently and sparingly returned to the land. Fluid and solid feculence, instead of being deposited in the soil, is suffered to pollute the earth's surface and the interior of human dwellings as well; or gathered in cesspools or trailing sewers, contaminates the atmosphere, violating self-respect and human dignity, and everywhere promoting discomfort and disease. Agriculture, properly conducted, would enrich the earth, whereas it positively impoverishes it, so that foreign ingredients—apatite from Spain or America, and guano from the Chincha or other islands—are needful to prevent the land from wearing out, a spectacle which Maryland and Virginia, as I have witnessed, furnish on a large scale. As it is, the yield is vastly less than are our requirements, and much, very much, less indeed than what with proper management our forty or fifty millions of acres might be made to afford. The better the soil is treated, the more it will return, and the worse and more grudgingly it is treated the less it will return. Bad treatment involves bad and insufficient returns, whereas good treatment involves copious returns, abundant corn and green crops, plenty of milk and butter and eggs, any amount of legs and shoulders of mutton, ribs and rounds of beef, flocks of poultry, flitches of bacon, and well nourished, instead of half-starved, impoverished men and women. The food supply in these islands, though relatively less both in quantity and quality than what it ought to be, is still absolutely very considerable. Taking the returns made in June last year there were then, fractions omitted, some nine millions of horned cattle on hand, thirty-one millions sheep, and four millions swine, irrespective of imported cattle and preserved meats. And yet of the thirty-one and a half millions constituting the population of the United Kingdom, very considerably more than one-half almost never taste butchers' meat at all, and of those who do, the meat supply might often be most advantageously increased. With spade labour, or machine labour the equivalent of spade labour, and house feeding, the corn yield and the meat yield of our acres might be doubled, possibly trebled, at once. Of course, stalled animals would be the better of a little daily outing, with strict attention to stall ventilation and stall cleanliness as well. As at present conducted, the feeding of stock, horn cattle, and horses alike is conducted with the greatest possible waste; the land is not adequately utilised, and the manure supplies or possible manure supplies, are in a great measure dissipated and lost. Now, as manure is of quite as much moment as the soil itself, and as manuring ought to be carried to as great an extent as the soil will profitably take it in, it is of the very greatest urgency that no available particle of compost should be wasted. It is quite as important to save manure as to reap grain or to feed stock. One, in fact, is the needful correlative and complement of the other. And yet the collection of manure is most imperfect, and what is actually stored past is exposed to almost every element of waste and decay at once overhead and under foot. In addition to the proper storage and preservation of manure, in respect of which the practice of the Chinese colonists in Java seems to me deserving of special attention and consideration, I propose that the solid and fluid excreta of man and brutes should be commingled with a prepared humus or soil, consisting of the following ingredients, as well calculated to insure the desired results :—

Prepared Humus.	lb. or parts.
Perfectly dry humus or soil	100
Calcined gypsum powder, from ...	10 to 20
Common alum, from	1 to 5
Copperas (green), from	1 to 5
Sulphuric acid, from	1 to 5

These ingredients and the proportions hold equally good for a thousand or ten thousand tons as for a single hundredweight, duly comminuted and commingled, constitute a very effective disinfectant and deodoriser and vehicle. The cost of a thousand tons of earth or soil I need not specify, but I may mention that common gypsum may be had at some £1 10s. per ton, sulphuric acid and sulphate of iron at 7s. 6d., and alum at 10s. per hundredweight. The humus or soil has its own great especial merits, while the three sulphates, along with the sulphuric acid, combine their several utilities and constitute an admixture well adapted to the objects in view—namely, the effective and inoffensive conservation of the products of animal waste and decay until they can be returned to the soil. This admixture will grasp the ammonia compounds, whether *in esse* or *in posse*, firm and fast, and as for the phosphates, they will likewise be laid hold of and retained. Every farmsteading, according to its dimensions and requirements, ought, at the outset of every year, to be provided with hundreds or thousands of tons of this prepared humus, properly stored, and at hand in order to be effectively utilised. The ordinary summer soil, dried and levigated, answers every purpose as a main ingredient; clays, however, calcined and levigated might be resorted to. The waste refuse of brick and limekilns, road dust, turf, and coal ashes, charred seaweed and charred peat, so far as the supply sufficed, might also be had recourse to. The foregoing effective and economic compound might further be advantageously employed wherever animal waste was liable to be deposited, as in provision stores, slaughter-houses, sheep-pens, fowl-houses, catgut factories, knackers'-yards, pigstyes, stables and stable-yards, pork and fish-curing establishments, and the like. The water now employed in the closet system, leading as it does to extended cesspools beneath the level of the streets, fouling the rivers and foreshores of the sea, ought to be entirely superseded by sanitary humus instead. The importance of common soil as a deodoriser and disinfectant, as we find from Roman and Israelitish records, was not unknown to the ancients. By the moderns its utilities have been strangely neglected. The inhabited surfaces of India are dense with trodden-down ordures. The towns and villages of Europe are in little better case. And yet feculence of whatever description ought to be consigned to the soil, and never for a moment suffered to pollute our dwelling-places, or those of the creatures whom we associate with us. In my treatise entitled "Moral Sanitary Economy," published some twenty years ago, the subject was dwelt upon in the strongest terms. The resultant admixture of sanitary humus and feculence, fluid and solid, might be preserved until needed in suitable receptacles, slate or brick lined, or dried as in the sample now exhibited, by a moderate temperature in kilns or otherwise. The sooner, however, the procedure here described could be resorted to, the better would it prove, at least, if we are to realise the great objects to be accomplished. The recent bones of a horse or ox weigh, let us say, from 80lb. to 100lb., of a man from 11lb. to 15lb., of a sheep or swine from 10lb. to 15lb. per cent. of its living weight. Now, all the phosphorus, or, if we prefer the expression, all the phosphates of the bones, brain, and nerve structures generally, along with all the azotised excreta, or possible ammonia which, guided by the laws of tissue metamorphosis, I calculate at one-half the amount of the phosphates, that is to say, all the bones and all the flesh of any given animal find complete transit from within to without, in about ten weeks or so, mainly through the kidneys and allied structures, and, owing to our present treatment of them, are almost utterly lost and dissipated. The proportions and the time as above stated, though not absolutely, are approximately true, inasmuch as tissue change is much more rapid with some than others, and with young animals and children at least twice as rapid. Otherwise, the calculations are founded on physiological data, and in the main correct. Suppose we take the horse or ox in illustration. During each and every year of its life, then, this animal, and other animals in proportion, sheds or expends, be the same more or less, one thousand pounds avoirdupois of the phosphates, and about five hundred weight of nitrogenous compounds, both of which all-important substances, human wants and the requirements of the soil regarded, are now as effectively lost and dissipated as if that phosphorus and that nitrogen were actually thrown into the great deep, a destination indeed which, for the most part, they positively incur, or as if the annual tens of millions sterling which the lost phosphates and ammonia of transition may be supposed to amount to were squandered similarly. By the judicious application of sanitary humus, the nitrogenous and phosphatic compounds, the amount furnished by the individual multiplied by the grand aggregate of living beings, might, I believe, be effectively saved and utilised, thus supplying a mine of wealth to which all the Potosis and Golcondas in existence were the merest trifles in comparison. In effect, animal waste, both fluid and solid, could be turned to full account, the general health and well-being prodigiously enhanced, and the yield of the soil multiplied to an extent to which I am quite incompetent to fix a limit.

INSTINCT.

THE following is a summary of the Lowell Lectures on this subject delivered by Professor Chadbourne, for which we are indebted to the *Boston Journal of Chemistry* :—

The nature of Instinct is not defined till its manifestations have been carefully investigated in all their diversity of modifications. It is at length defined to be "an impulse to a particular kind of voluntary action which the being needs to perform as an individual or representative of a species; but which he could not possibly learn to perform before he needs to act." It "includes all the original impulses, excepting the appetites;" and also includes "that knowledge and skill with which animals are endowed, which experience may call into exercise, but which it does not give." The appetites are regarded as functional and as proper conditions for the activity of certain instincts. The operations of instinct are simulated in inorganic nature, and on a still higher scale in plant life. The catch-fly pours out a sticky fluid which holds the smaller insects. The Venus's fly-trap puts forth leaves fashioned to act like barbs for holding their prey. The pitcher-plant beguiles insects down into its deep cavern along hairs pointing downward that hinder retreat. The provisions for the fertilisation of plants, for the diffusion of the seeds, and for the securing of them in places favourable to their germination and development, are in many cases exceedingly like instinct. Plants, like some animals, even become protectors to other species of life: as the oak forms a gall or oak-apple which serves as a home and food for the gall-fly. The first connection of Instinct with these instinct-like processes is seen in the provision for the nourishment of the young animal life. The raising of the head and the opening of the bill to receive food by the young robin, to which the act of the parent bird in supplying the food is a corresponding act of instinct, is an example.

Pure instinct needs no experience. It goes before to preserve life until knowledge from experience is possible. It works by a wisdom of which its possessor has no apprehension. The theory of transmitted skill involves an ancestry certainly of marvellous ingenuity. How did they come by it? How did the species survive till these geniuses appeared? The theory of natural selection accounts for the survival of the fittest; but how does it account for that characteristic in the animal by which it preserves itself? Hibernating animals feed voraciously in the autumn, when food is abundant, and accumulate fat to an unwonted degree; instinct then leads them to their winter's retreat, when the whole vital activity is so reduced that life is maintained for months without food. How were the species preserved till the changes in structure and function corresponding to these hibernating habits were effected? Then we find some species of animals dependent for their preservation on other species. The caw-bird lays its eggs in the nests of other birds. The owner of the nest hatches the eggs and nourishes the young as its own. When mature, the foundling forsakes its home and all the birds it has ever known, to seek its own species, hatched in scattered nests, and mates and lives henceforth with them. Darwin tries to account for the hexagonal cell of the bee on the principle of economy. The bee wishes to save as much as possible of honey from going into wax. But the question is, how came the bee to be a builder at all? Nor does the existence of the instinct to build such cells turn on the continuance of bee-life through the winter, as Darwin would have it. For some wasps, that perish every fall, leaving only eggs to perpetuate the species, build mathematical cells like honey bees.

The Pianoforte.—There are in a good pianoforte of seven and a half octaves, when completed, 214 strings, making a total length of 787ft. of steel wire, and 500ft. of white (covered) wire. The total number of strings, when properly stretched to produce the right tone, exert a pull of over ten tons; this represents the force with which one end of the piano is drawn towards the other end, and it explains the reason why good pianos are built so strongly and so heavily. Such a piano will weigh from 900lb. to 1,000lb., and will last, with constant use, not abuse, twenty to twenty-five years.

THE HOLTZ ELECTRICAL MACHINE.

THIS machine, invented by Herr Holtz, of Berlin, in 1865, an illustration and description of one form of which we gave on p. 90, seems to be gradually rising into favour, and obtaining an increased share of the patronage of experimenters and lecturers on electricity. It is one of that class of machines the type of which is seen in the well-known electrophorus, in which the electricity is "generated" or developed by the continuous inductive action of a body already charged, as contradistinguished from that class in which the effects are produced by friction. It consists of two thin glass plates, one a trifle larger than the other, the smaller being made to revolve in close proximity (about an eighth of an inch) to the larger, which is fixed, and has at opposite ends of a diameter two windows or apertures. Along one of the edges of each of these windows, and partly covering the aperture, a strip of paper is glued, having a point, or tongue, projecting into the opening and pointing in the opposite direction to that in which the smaller glass plate is revolving. Opposite the windows, but separated from them by the revolving plate, are brass conductors with points, generally denominated "combs," which, being connected with other rods and insulated, convey the electricity to the discharging knobs. To put the machine in action it is essential that the atmosphere should be dry, and this desideratum being secured it is only necessary to electrify one of the armatures and put the revolving plate in motion to obtain sparks varying in length from 2in. to 8in., according to the size of the machine, and according to the degree of electrification of the armatures, the latter condition being limited solely by the completeness of the insulation. Thus, as the motion of the revolving plate is continued, the armatures become more and more strongly electrified, and the conducting rods being affected in a similar manner, the discharging knobs may be *gradually* withdrawn further and further apart, and the length of the spark increased as far as the capabilities of the machine will allow. But the prime necessity is a dry atmosphere—moisture or dampness in the air being an effectual bar to the successful operation of the machine. The armature is generally charged, and the electricity induced, by striking a piece of ebonite or vulcanite, as it is indifferently termed, with flannel, or preferably catskin, but a glass cylinder, tube, or plate, excited by friction with a silk handkerchief, will be found to give almost equally good results. The electrified ebonite or glass being brought near to one of the armatures, and the machine put into motion for a few seconds, the discharging knobs having been put into contact previously, electricity is speedily developed, which may be known by the strong smell of ozone, the hissing noise, and the increased resistance experienced by the hand in turning the crank, and in the dark by the fringes of light which appear on the points of the conductors and the paper tongues. If the discharging knobs are now gradually withdrawn a continuous stream of sparks will pass so long as the machine is continued in motion; but care must be taken not to separate the knobs by too great a distance, or the action of the machine will cease, and it will be necessary to begin de novo, as will also be the case if the movable plate is allowed to stand still for a few minutes.

The Holtz machine of the original design is *cæteris paribus* more powerful than the ordinary machines; but it is said to be impossible to obtain sparks of greater length than four or five inches, unless accessories, such as the two condensers, H H[1], shown in the illustration at p. 90, are employed. These condensers are, in fact, small Leyden jars, and are coated with tinfoil inside and out for about a fifth of their height. With their assistance sparks of 8in. or more may be obtained.

It is obvious that the handiest method of arranging the plates is that shown in the figure referred to, but within recent years Holtz has introduced a modified form of his machine, in which the plates are arranged horizontally, both being made to revolve, but in opposite directions. In this design the "windows" and armatures are dispensed with, but four "combs" are employed, two above the upper plate at the opposite extremities of a diameter, and two below the lower plate at the ends of a diameter crossing the other at right angles. Each of the two upper combs is connected through the conductors by means of a brass rod with one of the lower combs, and the electricity is induced by holding an electrified sector of ebonite over the upper plate opposite to one of the lower combs. The action of this modification is exactly similar to that of the original machine, and it is, of course, governed by the same difficulties as to the duration of its action. These difficulties, have, however, been overcome to a considerable extent by Poggendorff, who increases the size of the armatures and adds a second pair of combs, connected together somewhat in the fashion of the modification by Herr Holtz, mentioned above. We have no practical acquaintance with Poggendorff's modification, but we have reason to believe that a machine which formerly could be induced to yield a spark of only 3in. or 4in., by this simple means can be made to develop sufficient electricity to give a spark of 8in. or 9in.; while, best of all, the machine remains in action if the knobs are separated to the extreme distance, or the movable plate allowed to remain still not merely for minutes but for hours.* A Mr. Ritchie, a philosophical instrument maker of Boston, Mass., has also improved the Holtz machine, by constructing the fixed plate as shown in the annexed engraving, which gives the ordinary design (Fig. 1) with windows, and the improved form or Ritchie

FIG. 1

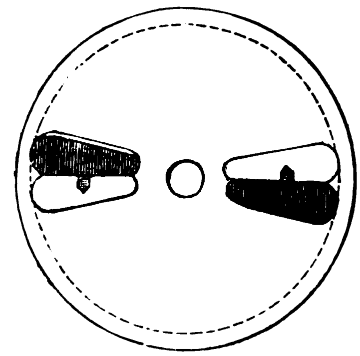

FIG. 2

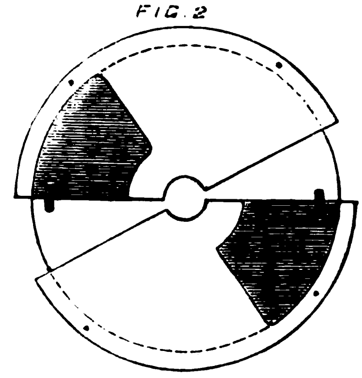

FIG. 3

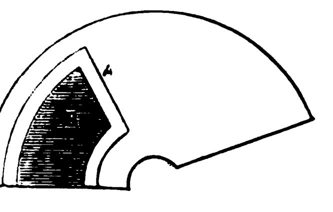


sector (Fig. 2). We understand that small instruments on this plan exhibit greater effects than machines double the size of the ordinary construction. Professor Henry Morton, however, has communicated to the *Journal of the Franklin Institute* a further modification, which is claimed to be a great improvement on the Ritchie design. This has been invented by Mr. C. Van Brunt, who describes his amended Ritchie Holtz as being "evidently near perfection." An inspection of Fig. 2 will show that instead of a plate with windows Ritchie employs two sectors, and considerably increases the size of the armatures. In the experiments made by Mr. Van Brunt he discovered that a series of paper points instead of the one tongue considerably improved the action of the machine; that short points are as effective as long ones; that the increased size of the armature was not only a decided gain, but that an armature of a good conducting material was better than an ordinary paper one. Under these circumstances he was led to arrange a machine with an armature of tin-foil and paper, the latter, however, being used as an insulator. The modification is shown in Fig. 3, where A is the paper and B the tin-foil. The paper A, which may be the ordinary paper supplied with the machine, should be about the width of the collecting points; the outer edge being opposite to and level with the edge of the revolving plate indicated by the dotted line. According to Mr. Van Brunt, the paper should not hang over the edge of the sector; and in place of the paper tongues he uses a row of common half-inch pins, cutting off the required number from the strip of paper on which they are sold, and pasting them down just as they are. The superfluous paper he turns underneath, and places a wedge of cardboard beneath the heads, so as to cause the points to "cant" over the edge of the sector towards the revolving plate. After gumming all securely a piece of tin-foil is pasted down on the paper, leaving a margin on three sides of half an inch, the other side being brought into connection with the heads of the pins. A strip of paper about an inch wide is then to be pasted round the foil, and covering it for half an inch. The surface of the strip and the outside edge should be well covered with shellac, but none is needed under the foil or anywhere else. By this means the foil is placed in an insulated pocket, as it were, "the paper tapering off the tension as when used around the inside top of a Leyden jar." The machine arranged in this way will, it is said, yield sparks of a length certainly equal to the radius of the revolving plate: it is easily put into action, and produces a "torrent of electric discharge," while, if the edge of the paper is well protected with shellac, the machine will not reverse or lose its tension. A large Leyden jar attached to the negative side in place of the small condenser shown on p. 90, "will increase the length, brightness, and sound of the spark, and the machine will retain its charge twenty-four hours, and perhaps longer, in ordinary winter atmosphere [U.S. weather]. This acts as a large and small ball for passage of sparks on an ordinary electrical machine. There is no danger of breaking the large jar, for the small phial acts as a unity jar, the strain is thrown on the phial; this should be protected by a cork the size of the phial, covered with tin-foil pushed down to the inner coating for the conducting-rod to rest upon: the strain is thus distributed. The upper edge of the coatings of the phial should be covered with strips of paper and shellac, to prevent spontaneous discharge." Mr. Van Brunt also says that his machine runs with little friction or noise and makes much less ozone; but he thinks that an entire modification of the parts will still further improve it. He discovered, too, that the form of the windows is of no consequence whatever, a few holes, a mere slit, or large holes answering the same purpose. In fact, Poggendorff had already constructed a machine in which the paper tongues were passed through small holes, and Töpler, of Riga, had made an arrangement in which the inductive action was exerted on tin-foil mounted on revolving glass plates, but it does not seem to have been successful or to have received much attention.

* We believe that several of these Holtz machines are in use in the colleges of the United States, and it is probable that some of our correspondents there can give us reliable information on the subject.

IMPROVEMENTS IN GLASS-MAKING.

FROM the *American Manufacturer* we gather the following particulars of the experiments made by Dr. Benrath, director of the glass-works at Dorpat, Russia, to produce a glass which has the good qualities of flint glass without its defects:—The good qualities of ordinary flint glass are: that it is as clear as crystal; that it has a high specific gravity; a low fusing point, so that it melts easily; and strong power of refraction and dispersing light. It is, therefore, invaluable for chemical and optical purposes. Its defects, however, are that it is easily acted on by chemical and mechanical influences—that means its surface cannot stand rain and sunshine, much less acids or boiling water, and it is so soft that it is most easily scratched. The chemical difference between ordinary and flint glass is that the former consists of silex, lime, and soda or potash, while oxide of lead is added to make flint glass out of it. Chemically speaking, common glass is a silicate of lime and potash, while flint glass contains also silicate of lead. Döbereiner was the first who, in 1829, substituted baryta for lime, making a glass which, in chemical terms, was a silicate of baryta, of soda, and of potash; but his glass was too soft, as it contained too much of the latter two ingredients—55 per cent. of silica, 21 of baryta, and 22 of the alkalies. During the last few years Benrath took the matter up, and attempted to produce a glass with less alkaline matter and more silica and baryta. He made one of sand 1,000 parts, heavy spar (sulphate of baryta) 785 parts, Glauber salts (sulphate of soda) 435 parts; the glass obtained was found by analysis to contain 58 per cent. silicic acid, 30 per cent. baryta, and 12 soda. But the glass had a slight blueish or brownish shade, probably from the sulphur reduced from the sulphates, and like ordinary glass, had usually a greenish tint from the iron contained in the sand or other ingredients. Splitgerber proved, in 1855, that three-tenths of 1 per cent. sulphur is enough to give to glass a very intense yellowish brown colour, but Benrath succeeded in overcoming this difficulty by using different forms of baryta, as the carbonate, and now declares that by the substitution of the heavy and cheap baryta compounds, in place of the more expensive lead, a very clear, hard, heavy, and cheap glass can be made, which in many instances may supersede the more expensive flint or so-called crystal-glass, and will be preferred for some purposes, as it is uninfluenced by the weather, as is the case with the softer flint.

THE CULTIVATION OF GRAPES UNDER GLASS.

THE following method of growing grapes in an economical manner was contributed to the *Farmer* by Mr. James Dougall, and will doubtless supply many amateur gardeners amongst our readers with useful hints:—

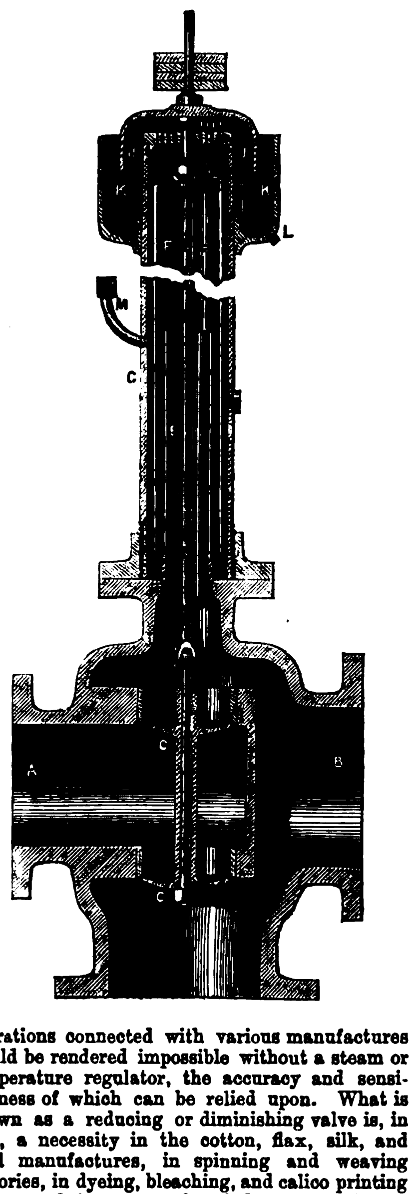
Many persons would be induced to erect a small vinery for the culture of the finer varieties of grapes, were it not for the great trouble attending their culture under glass in the ordinary manner, in watering, syringing, ventilating, &c., requiring the services of a professional gardener, or occupying more time and attention than the generality of persons can spare. By adopting the following plan in erecting the vinery, they will be relieved of the greater part of this trouble, and have a fine supply of delicious grapes, with no more trouble or attention than is required to grow the natural vine out of doors. The sashes are made stationary, but so that they can be unscrewed and taken off for repairs at any time. They extend from the front wall to within 1ft. or 10in. of the back wall at the top, leaving an opening of 10in. wide along the top, to be closed by sheet-iron ventilators in the winter, or when requisite, but which is kept constantly open from the time the vines are uncovered in the spring till they are laid down and covered in the autumn. The principal peculiarity is in the glazing. The glass is laid end to end without lapping or putty, and merely kept in its place by small pieces of tin, and a space of ¼in. is left open between every third or fourth pane, so that all the rain that falls on the house is distributed pretty equally over the entire house, very little running off the roof except in very heavy thunderstorms. There is no ventilation whatever below, as a draught I have found injurious to the vines. Any air that comes in is by these openings in the glazing, and the heated air finds vent at the top. Last year was a very dry one; but the vines never suffered from the drought, though they were never watered or syringed from the time they were uncovered in spring, when it was done copiously, till again uncovered this spring. Nor were they the least affected either last year or this with mildew or red spider; though previous to adopting this plan I was annually troubled with both, in spite of syringing copiously morning and evening.

My present vinery was not erected for that purpose, but for a small conservatory, and the floor was sunk about 2½ft. or 3ft., with a brick wall all round. About twelve years ago I filled it up level with good compost, and planted the vines all inside, there being no opening for their roots to extend to the border outside. It was intended principally for proving the newer seedling vines and varieties, then out, with a few of the best old varieties, and in a space of 24ft. by 14ft. contained for several years thirty-six vines, which were thinned out as they were proved worthless, till it now contains twenty-four; this is still too many, about sixteen being all that could be properly grown in that space. Last year it got a liberal supply of liquid manure in spring; this year it got nothing but clear water at first and rain as it falls, and is doing as well as last year, and vigorous enough for a house containing so many vines. The ends of my present vinery are not glazed, having only a small window and door on each end. Were I to erect a new one, I would have the ends glazed to within 3ft. of the ground, and would have openings in the front wall to allow the roots of the front row of vines to extend into a prepared border outside. For those who may wish to try this plan, I would recommend the following varieties as being the most successful with me, and of the finest quality:—Black Hamburg, Muscat Hamburg, Champion Hamburg, Lady Downes, Golden Hamburg, Bowood Muscat, Buckland Sweet-water, General de la Marmora; the first four are black or purple grapes, and the last four white grapes.

Black Hamburg is by far the most profitable and best of the blacks, and Bowood Muscat and Buckland Sweet-water of the whites. Lady Downes and Bowood Muscat are the better for artificial impregnation, as they do not set the fruit very well. The principal trouble in following this plan, more than is required in out-door culture of the vine, is the necessity of thinning the grapes on the bunches to about one-half when about a quarter grown, to give room to the rest of the berries to swell.

SELF-ACTING REDUCING VALVE.

THE annexed engraving is a sectional illustration of what is believed to be the best form of reducing-valve hitherto designed. It has been patented by Messrs. Crossley and Hanson, of the firm of John Crossley and Sons, Halifax, and is another instance of the truth of the old adage that "Necessity is the Mother of Invention." There are many manufacturing processes which require at some stage or other steam of a low but steadily maintained pressure, or at all events the temperature which corresponds with the specified pressure. In many cases, indeed, the value of the process entirely depends on the success with which this result is obtained, and sundry delicate



operations connected with various manufactures would be rendered impossible without a steam or temperature regulator, the accuracy and sensitiveness of which can be relied upon. What is known as a reducing or diminishing valve is, in fact, a necessity in the cotton, flax, silk, and wool manufactures, in spinning and weaving factories, in dyeing, bleaching, and calico printing works, and in many other industries carried on in the United Kingdom; for it is simply impossible to obtain a constant and unvarying pressure in the steam boiler, which shall be also suited to the requirements of the processes in operation. For this reason, and owing to the defects of other appliances for securing similar results, the reducing-valve which forms the subject of this article was designed by Messrs. Crossley and Hanson, and is made by Messrs. Whitley, partners, of Leeds, who are sole European manufacturers for the patentees. The vertical section annexed will, with the following description, serve to explain its action. Steam from the boiler enters at A, passes the equilibrium valve C C, and acts with equal force at the outlet B, within the tube E, and on the float F, which latter works in mercury between the inner casing E and outer casing G, and is weighted to yield the required pressure. When the pressure of the steam in the tube E and at outlet B is not sufficient to support the weight on the spindle D, the valve C C opens, thus permitting the passage of more steam, and in conjunction with a contrary action when the steam pressure is in excess of what is required, insuring an unvarying pressure or corresponding degree of temperature. If the valve, through any casualty to boiler or pipes, or through scale or sediment resting on its seat (a contingency of rare occurrence) is prevented from closing properly, excess of pressure forces the mercury up through the holes I in the cover, where impinging against the dome J, it is thrown back to the receiver K, whence it is easily drawn off by the plug L and returned to its proper place through the capped elbow M. By this means any loss of mercury is prevented, and the apparatus to which the valve is attached is preserved from the injurious action of the excess of pressure. In the engraving the valve is shown in the act of closing, the steam pressure acting on the mercury in the tubes. It only remains to say that a large number of these valves are in use, yielding results which have not hitherto been attained with other forms of diminishing valves. Dial gauges are supplied to indicate the pressure at the outlet B, and by decreasing or increasing the weight on the spindle, the pressure or temperature can be varied as desired.

PRESERVING PHOTOGRAPHIC PRINTS.

A METHOD of preserving photographic prints so as to retain permanently the beautiful tone they exhibit when in the washing water, is mentioned by Mr. Sutton, the French Correspondent of the *British Journal of Photography*:—

Every photographer, he says, must have observed how beautiful prints sometimes look in the washing water, and how much they lose of their vigour and beauty on drying. This is especially true of fully-toned prints, which, although they show a warm tint of black in the water, dry sometimes of a cold inky tint, besides becoming mealy. It seems important, therefore, that prints which are intended to be framed for an exhibition, or which the artist desires to keep for himself as choice specimens and the best which the negatives will yield, should be so printed as to lose none of the beauty which they exhibit in the water—none of the rich warm tint, the transparency in the shadows, the clearness of the details, the perfection of surface produced by the water acting as the varnish. But the only way to preserve all these excellences is to substitute glass for water, and so to mount the print against the back of a glass plate as that when viewed through the glass it may appear exactly as it does under water—that is to say, exactly as it would if removed from the water and pressed whilst still wet against the glass plate. The problem, then, is to substitute for the water some kind of varnish which, when perfectly dry, will not produce any change in the appearance of the print. Imagine for an instant the problem solved and the thing done, what would be easier than to mount all such prints as we intended to be framed and glazed against the glass of the frame instead of upon a cardboard which is placed more or less loosely behind it? or to mount all such choice prints as an artist might desire to keep for his own use upon plate glasses, to be pressed in a plate-box like negatives or glass transparencies?

The problem is a very old one, and it has been already solved by means of collodion and gelatine. M. Davanne has recently described the process at a meeting of the French Photographic Society. It is as follows:—Coat the glass plate to which the face of the print is to be applied with plain collodion, and immerse it immediately in a bath of cold water in order to wash out the ether and alcohol, as in the common wet process with the nitrate bath. Then pour over the film a solution of white gelatine, strength about eighty grains to the ounce of water. It must be sufficiently hot to flow freely, and care must be taken to avoid dust and air-bubbles. Tilt the plate so as to let the excess of gelatine run off into another vessel, and then place it upon a horizontal support. The film of gelatine will thus be very thin. Before waiting until it is quite dry, lay the face of the print down upon it just as it comes wet from the washing water, and press it into close contact with the glass. When viewed through the glass it will, of course, look just as it does in the water, and this beautiful appearance it will not lose on becoming dry.

With respect to the white background, ... of any other colour, ... may consist of ... paper applied t... the gl... the print. Or ... m... paper for a ... print will b... be trimme... will, of co...

the print has become dry against the glass it may be put into a frame with a thin board behind it. Several prints may be mounted together upon the same glass. The only objection to the plan is that if the glass should be broken the print would be destroyed; but this objection is greatly outweighed by the increased beauty of the result. I strongly recommend the plan to persons intending to send framed prints to an exhibition. By using a rather thick plate glass the risk of breakage would become very small indeed. The perfect optical contact between the surface of a print and that of so splendid and smooth a varnish as a sheet of glass is an advantage not to be underrated or despised. There is no loss of detail, no change of colour, none of the mealiness produced by drying, and none of the vulgarity of albumen. The result is not only technically but artistically finer than when any other method of enamelling and mounting is employed. If, when the print is dry, it be brushed over on the back with plain collodion, the pores of the paper would be so filled with air and water proof material that greater permanency would, no doubt, be secured.

WOODS USED IN SHIPBUILDING: THEIR CHARACTERISTICS AND SPECIAL APPLICATIONS.*

In this article it is intended to consider briefly the kinds of trees used in ships at the present time, and to notice their characteristics and the purposes to which they are applied. All *timber* trees belong to the *exogenous* tribe of plants, which increase in bulk by additions to the external surface. They are divided into two classes—viz., leaf and cone bearing, which may likewise be distinguished as non-resinous and resinous respectively. The latter includes all kinds of firs and pines; the former all other varieties of the above-mentioned tribe. Of the former class, the following trees are those chiefly used in shipbuilding—viz., oak, teak, elm, mahogany, greenheart, sabicu, mora, ash, and lignum-vitæ. Of the latter class, red or Dantzic pine, yellow pine, cedar, cowdie, Oregon pine, spruce fir, and larch. An examination of the longitudinal and cross sections of the trunk of a tree shows two distinct kinds of tubes, or grain, as it is termed, formed by the fibre of the wood. These are a longitudinal or vertical series of tubes, grouped so as to form concentric rings, and a series of tubes radiating from the pith at the heart of the tree. The former are termed *vascular tissue*, and the latter *medullary rays*. Besides these, in the former section a great number of small pores or cells are discovered. These are termed *cellular tissue*. The concentric rings of vascular and cellular tissue are divided into groups by the intersection of the medullary rays, which are in planes about normal to the surfaces of the tissues. We have remarked that the medullary rays radiate from the pith; this last is a soft substance, composed of cellular tissue, and inclosed in the *medullary sheath*. Under the bark the wood is young and soft, and is termed *sap wood*. This is rarely used, as, except in a few cases, it is very liable to decay. Without entering into the interesting subject of the manner in which wood grows—a question which belongs rather to the province of botany than to that of naval architecture—we may simply say that the growth takes place under the bark, and that the oldest wood is, therefore, nearest the centre of the tree. The concentric rings already referred to are generally considered to be the growth of a year in a temperate climate; but in the tropics they denote the number of wet and dry seasons during which the timber has been growing. It is asserted by some that the pith is always nearer the north side than the other sides of the tree as it grows, the reason given being that the sap flows more readily under the direct influence of the sun's rays than when shaded. Generally speaking, trees which have these rings close together yield superior timber to those in which they are wider apart.

Leaf-bearing Trees.

A careful examination of the sections of leaf-bearing trees will at once suggest two principal divisions of this tribe:—

1. Trees with *distinct* medullary rays. 2. Trees with *indistinct* medullary rays. Of the former, the chief instances are oak, beech, &c. Of the latter, elm, teak, greenheart, mahogany, ash, &c. These are again sub-divided into those in which the rings are distinct and those in which they are not:—

First division. Medullary rays distinct.	First sub-division. Rings distinct.	Oak, &c.
	Second sub-division. Rings indistinct.	Beech, &c.
Second division. Medullary rays indistinct.	First sub-division. Rings distinct.	Elm, ash, &c.
	Second sub-division. Rings indistinct.	Mahogany, teak, greenheart, lignum-vitæ, &c.

Oak.—The oak is found in all European countries, but chiefly in Great Britain, Italy, Sicily, Spain, and Prussia. It is also indigenous to North America. The two chief varieties of oak found in the British Isles are superior for general shipbuilding purposes to all the others. These two varieties are principally distinguished by the manner in which the acorn grows upon them, and are termed the stalk-fruited oak (*Quercus robur*) and the cluster-fruited species, or *Quercus sessiliflora*, respectively. The latter is sometimes known as the Durmast oak, and the former as the true English species. The stalk-fruited oak is by far the better of the two for shipbuilding purposes, although the Durmast oak is very commonly used. The Sicilian and Sardinian oaks are valued chiefly for their great curvature, and are, therefore, very suitable for the frames, especially the floor timbers. As, however, the timber cracks, or "shakes," in drying, it is not suited for other purposes. Prussian and Polish oaks (known in the market as Dantzic oak) grow very straight and tall, and the timber is tough, and dries without shaking; it is therefore specially adapted for deck plank, to which purpose it is applied. It arrives in this country chopped or sawn into planks of various thicknesses. When the tree is curved, the curvature is cut in the plank, which is bent straight when laid as deck. A considerable quantity of American oak is now consumed in shipbuilding. The best variety, termed *live* oak, is very hard, and is used for frame timbers, pillars, &c. The American white oak grows to a very large size, and is generally straight. It has sometimes been used for stern-posts on account of its size; but it is neither so strong nor so durable as English oak. Among the defects to which oak is liable, the following are the most common:—*Cup shakes*, caused by the sap freezing under the bark, and separating two of the ring layers, which remain thus separated throughout the future growth of the tree. *Rind galls*, produced by damaging the inner bark, or by improperly lopping the branches; the wounded part decaying, and the future growth covering it up. Extensive rottenness from this cause is sometimes found in the interior of a piece of timber whose surface is perfectly sound. *Foxy stains* occur in timber grown on marshy soils. These are indications of its being in a state of decay. Oaks from damp or sandy soils are very liable to this defect, and are generally much softer and lighter than those grown in more suitable situations. Mountain oak is by far the hardest and most durable of all. The introduction of iron for shipbuilding purposes, besides lessening the amount of oak timber required for the frames and side planking, has also precluded its use in places where wood is still required, from the fact of its containing gallic acid, which dissolves the iron with which it comes in contact. The principal application of oak in wooden ships is as frame timbers, plank both of side and deck, stems, stern-posts, pillars, topside chocks, and sometimes as beams. In iron ships, for the reason stated, it is rarely used, except as deck plank and towing-chocks.

Beech.—Beech is very little, if at all, used in the Royal Navy; in merchant ships it is sometimes employed as bottom plank under water. It is very liable to dry rot.

Elm.—This tree is indigenous to, and attains its highest state of perfection in, this country. It is valuable chiefly on account of its lateral toughness, the fibre being intertwined; it is, however, very subject to shrinkage, warping, and alteration of form: besides which it cannot be used with advantage in situations where it is liable to become alternately wet and dry, as under these circumstances it speedily rots. When constantly under water it is very durable, and even seems to be improved by a lengthened period of immersion in salt water. It is, therefore, specially adapted and generally used for keels, garboards, and planking of bottom under water. Elm is the chief timber used in boatbuilding, although for the diagonal-built large boats of H.M. Navy mahogany has superseded it. A kind of timber termed Canada rock-elm is now in very common use. It is a light-coloured, straight, close-grained, and very flexible wood; it grows to a great length, and of nearly uniform dimensions throughout. It is much used for boats, ladders, gratings, planking, and in some cases even for beams.

Ash.—Ash is a wood but little used in shipbuilding. It is a native of Great Britain, and is often found of very large dimensions. It is light-coloured, and very elastic and tough, and is chiefly worked into capstan-bars, handspikes, and other similar appliances.

Mahogany.—This timber, which but a few years since was used only by the cabinet-maker, now enters largely into the construction of ships. It is of two kinds, distinguished as Spanish, or Cuba, and Honduras mahogany. The former is obtained from the West India Islands, and the latter from the countries of Central America. Spanish mahogany is chiefly used for ornamental purposes on account of its greater hardness and its superior appearance. Honduras mahogany has a coarser grain, grows in larger logs, is tougher, and generally far better adapted to structural purposes than the former. Great care is required in its selection, as some kinds, owing to their growing in swampy soils, are very light, spongy, and liable to decay. In fact, the heavier Honduras mahogany is, the better it is found to be. Cuba mahogany may be easily distinguished from Honduras by its having the pores or cellular tissue filled with a chalky substance, those of Honduras mahogany being empty. Cuba mahogany is used for cabin furniture, steering-wheels, binnacles, and other work which is made ornamental as well as useful. Honduras mahogany is usually employed for inner and outer side-plank, beams, waterways, shelves, the plainer portions of cabin furniture, &c.

Teak.—Teak is now the most useful wood employed in shipbuilding, both from its great strength, toughness, and durability, as well as from its not injuriously affecting iron with which it may be in contact. It is also very free from shakes or shrinkage when drying. The best teak is procured from Malabar, although a great deal of inferior wood is imported from Ceylon, Java, and the Malayan Peninsula. The chief defects in this timber are worm-holes, which are frequently found to traverse the interior of the log in all directions, the surface appearing sound. Great waste therefore occurs in converting it, and much judgment is required in selecting it for purchase. Good teak when freshly cut is usually of a greenish-brown colour, changing to reddish brown after a few minutes. It contains a great quantity of an oily substance, and is, therefore, very inflammable. At the heart of teak a peculiar deposit is often found, which dulls the edge of carpenters' tools when working it. It has a chalky appearance, and at first sight one would be led to suppose that it came there by artificial means; but upon careful inspection it is found that the cellular tissues in the neighbourhood of the heart, or pith, are charged with the substance. Mr. J. Davidson, the teacher of chemistry to the Royal School of Naval Architecture, has analysed some specimens, and found them to consist of phosphate of lime, which had presumably been abstracted from the soil, and secreted at the centre of the tree, similar to camphor and other resins. Teak is chiefly used for backing behind armour-plates, deck-flats, beams, inner and outer side plank, sometimes for frame timbers, also for bulkheads, companions, skylights, coamings, &c. It is also frequently chosen in preference to mahogany for cabin furniture, as when polished it has an appearance very like walnut, from which wood knotty specimens of teak can hardly be distinguished. The shrinkage of teak when drying is inconsiderable; hence it is very useful for the engine and boiler bearers of wooden ships and for other such purposes.

Greenheart.—This wood is obtained from British Guiana, where it attains a great height. It grows very straight, but is very liable to split. Its colour is generally a greenish yellow, but in the most valued varieties it is black. It is highly esteemed for its durability under water, and its freedom from the attacks of marine insects. It is used for waterways, shelves, plank of bottom, &c.

African Oak.—This timber is procured from Western Africa. It grows very straight and long, and is somewhat similar in appearance to teak, but heavier, harder, and usually in smaller logs. It is not suited for work under water, as it is very liable to attack from marine insects. The chief application of African oak is for keelsons, pillars, beams, waterways, and frequently for sheerstrakes and wales. It is very liable to destructive shakes at the heart when drying, and to perforation by insects.

Sabicu.—This is a very hard kind of timber, somewhat similar to coarse-grained, deep-coloured mahogany in appearance, but considerably harder and heavier. Its grain is very short, and the fibres are usually very much twisted and interlaced. From its great hardness and toughness it is very much used for such parts of a ship as need these qualities, and at the same time do not require longer pieces than can be obtained with tolerably straight grain—for instance, bitts, bollards, cleats, &c. It is a very durable wood, but is frequently found shaken at the heart, while the outside is perfectly sound.

Mora.—This wood has but recently been introduced into shipbuilding, and as yet has not been used to a sufficient extent to enable us to judge exactly of its qualities. It seems, however, to be durable and tough, and very difficult to split. Its chief application, as yet, has been for side plank. It is procured from British Guiana, where it is found in great abundance.

Lignum-vitæ.—This is procured from the West India Islands, and is a very useful wood, both to the rigger and the marine engineer. It is remarkably tough, dense, and heavy, and has the property of resisting crushing forces with nearly equal strength along and across the grain. Hence, being excessively hard, it is very useful for dead-eyes, sheaves, and rollers. The sap wood is very much lighter in colour than the heart, the latter being a dark green, while the former is nearly yellow. In cutting a log for sheaves the direction of the grain should be parallel to the axis of the sheave, and in making the latter it is usual to leave a ring of sap wood around the heart wood, in order to prevent it from splitting by too rapid drying. The marine engineer uses it for shaft-bearings when in contact with sea-water.

* By Samuel Thearle, Fellow of the Royal School of Naval Architecture and Marine Engineering. From the *Annual* of the School.

Cone-bearing Trees.

The coniferous trees are divided into two classes—pines and firs. The former have needle-like leaves, growing in clusters from the same stalk; the latter have them straight and separate, but many growing on the same leaf-stalk, like the teeth of a comb. In shipbuilding the pines are far more useful than the firs, for besides attaining a larger size, they are generally more durable and stronger. All the coniferous trees are characterised by a straightness of growth, which, combined with their lightness and flexibility, render them specially suitable for masts and spars. They have, however, many other important applications, as will be seen presently.

Red or Riga and Dantzic Pine.—The most useful of all the pines used in shipbuilding is the *Pinus sylvestris*, commonly known either as Red, Dantzic, or Riga Pine. That obtained from Riga is the best on account of its size, strength, and flexibility, making it suitable for the larger spars of ships, such as the lower masts and topmasts. It is a reddish-coloured wood, the depth of tint varying with the amount of resin contained. It is also very much used for the deck plank of ships, the outer cuts, free of heart, being termed Dantzic Crown Deals; those at the heart are inferior, and sold at a lower price.

Yellow Pine.—This is the largest kind of pine now commonly obtained, and is imported from Canada. It is very much used for large masts and yards, for neither of which purposes, however, is it so well adapted as Riga pine, being considerably lighter, and not so elastic, strong, or durable. Large spars of the latter wood are, however, getting very scarce, and hence yellow pine is superseding it. The decks of passenger ships and yachts are sometimes made of this wood on account of its light colour and freedom from knots. It is very much used for cabin bulkheads and other light fittings. It is now grown in Great Britain, being known as the Weymouth Pine.

Oregon Pine.—A species of red pine obtained from Oregon and the adjacent island of Vancouver's, is now becoming very generally used for lower and topmasts, and as it grows to a large size, at the same time being very straight, tough, flexible, and durable, it is a very good substitute for Riga pine, which, as has been already remarked, is now rarely obtained of large proportions. Spars of this pine 130ft. in length have been brought to this country, and one of gigantic dimensions was presented to the Queen about four years since by the Colonial Government. The mast, when planed, shows a pretty waved grain, which is much esteemed by seamen. The trees brought from the mainland are superior to those from the island, being generally freer from knots. The chief disadvantage its use has at present is its high price, due chiefly to the heavy charges for freightage.

Cowdie Pine.—This is a species of pine recently imported in large quantities from New Zealand. It grows to a very great size, and has been used for some of the largest spars in a ship. It, however, lacks elasticity, and is very liable to warping and shaking. Being very free from knots it is sometimes used for the decks of pleasure vessels, as, when planed or cleaned, it has a most agreeable light yellow colour.

Spruce Fir.—The chief variety of the fir tribe as regards its use in shipbuilding is the spruce, *Pinus abies*, which grows in Norway, Scotland, and other northern countries. It is used for the small spars of ships and for boats' masts. The wood is tough, close-grained, and elastic, and also whiter than the pines. As it is very full of large knots, great care is required in the selection. Spruce deals are used for some of the lighter fittings of ships, but not generally to the same extent as yellow pine.

Larch. — The larch is common to Northern Europe, although it has been grown in this country only during the past century. The Duke of Athole was the first to plant it in Scotland on his estate at Blair Athole, about the year 1738, since which time it has become very common. It is a timber of great strength, and remarkable for its durability when exposed to the weather, but it is much harder to work and more liable to warp than Riga pine. The larch has not yet been extensively used in shipbuilding.

Cedar.—This is a species of fir more frequently used for ornamental than for useful work, as it is very weak. It is, however, almost indestructible from time, and no insect will attack it. It is chiefly used for cabin furniture, and in such parts of the ship's hull where durability and no great strength may be required.

MECHANISM.*

(*Continued from p.* 376.)

M. AMPERE appears to have been the first to direct public attention to the importance of kinematics as a special study. Plato speaks of astronomy as "the doctrine of the motions of solids;" and to come to recent times—very recent indeed—there is a still valuable work by Emerson, which we have here, and which contains some very good illustrations. Here is one of the mechanism of a rat-trap, and very well it is done. The reason why the book is produced is this. It was probably first published about 1750; this copy, which is the second edition, corrected and very much enlarged, with 43 copper plates, was published in 1758. The title-page is well worthy of our consideration in connection with the present course of lectures. It is—"The Principles of Mechanics," explaining and demonstrating the General Laws of Motion, the Laws of Gravity, Motion of Descending Bodies, Projectiles, Mechanic Powers, Pendulums, Centres of Gravity, Strength and Stress of Timber, Hydrostatics, Construction of Machines: A work very necessary to be known by all gentlemen and others that desire to have an insight into the works of nature and art; and extremely useful to all sorts of artificers, particularly to Architects, Engineers, Shipwrights, Millwrights, Watchmakers, &c., or any that work in a mechanical way. The Second Edition, with 43 Copper Plates. 1758.

The order of Emerson's subjects is remarkable. They begin with motion, lead on to equilibrium, and end with structures. In our days the habit seems to be to begin with structures, descending through equilibrium, and very seldom proceeding so far as motion is understood in mechanism. In the preface he lays great stress upon motion, and not, as in modern books, equilibrium. On that he lays no stress. He writes:—"What else is there in the visible world but matter and motion? Mechanism is a science of such importance as without it we could hardly eat our bread, or lie dry in our beds, and by it we come to understand the motions of the parts of an animal body—the motions of the celestial bodies. Without mechanics a general cannot go to war, and the meanest artificer must work mechanically, or not work at all, so that all persons are indebted to this art, from the king down to the cobbler."

Although pure mechanism or kinematics has thus been recognised as an important study in and by itself, yet no work appeared in the English language, as far as I know, until the year 1841, one year after Dr. Whewell's book, which was six years after M. Ampere had drawn attention to this subject. Then Professor Willis, the Jacksonian Professor of Natural and Experimental Philosophy in the University of Cambridge, published a volume on "The Principles of Mechanism, designed for the use of students in the University, and for engineering students generally." To this work all who have alluded to mechanism acknowledge great obligations. In it the subject is treated as a mathematical one, and although in the present course of lectures the purely mathematical aspect of the problem must be ignored, there is no reason whatever why the young mechanicians should not study the subject with the only key that can unlock for them its treasures.

Whilst allowing the "open sesame" character of this mathematical key in the question of mechanism, it is well to avow that purely mathematical minds have claimed for their favourite science far too much of the power of a magician's wand over terrestrial mechanics and mechanism. Mathematicians boast that they hold the key of the gate; it is a reflection upon their good taste that they seldom walk in the pleasant pastures of which they have the key. If mathematicians would but become as familiar with the technicalities and wants of machinists and mechanists as they are with the omnipotence of x and y, they would often receive the right hand of brotherhood, where now men are provoked to say, "Stand back; we do not want you." There will be no solid progress in the refinements and precision of mechanism, either constructive or kinematical, until there is less dissociation between mathematics, physics, kinetics, and practice. The youth of England are led in the dynamical relations of x and y to calculate the path of the earth in its orbit, and they can do it to a second in a year. The same x and y enable them to tell the periods of the revolution and rotation of the earth; to find the velocity of light, and to measure the length of its waves to the millionth of an inch; to calculate the exact curve of the spectroscopic diagrams in the solar corona, and this with an accuracy that even decimals fail to represent to the mind. Such is considered a triumph of mathematical dynamics. But ask a mathematician to determine the quantity of irregularity produced by an unbalanced fly-wheel; to say how a small weight on a large fly-wheel may produce back-lash through a mill, and destroy the teeth of some of the largest wheels in that mill, or to state in what motions or how to utilise the heat that passes away, or to what influences a ship is subject by the rotation of heavy machinery within, or to calculate in any given case what is called negative slip; and how is that slip in a screw propeller to be avoided. Ask the mathematicians to take a given problem, with given numbers, under any of these heads, and they will turn from it and think it beneath their notice—probably it is beyond their skill.

Mechanism, then, is the alphabet; machinery is the written expression, and that machinery is a combination of parts. These elementary parts are furnished by the mechanician. Hence the study of mechanism should precede the study of machinery; but it has failed, and still fails to do so.

Apart entirely from the mathematical and scientific reasons why mechanism does not hold its own as a branch of well-defined and intellectual study, there are one or two obvious social ones. Mechanism is not directly allied to utilitarianism; it bears a relation to utilitarianism of a character similar to that which art bears to it. The necessities of life must first be met, and then may be entertained improved means for meeting them. Houses, boats, bridges, clothing, and food must first be procured, and then, and not until then, need be considered the best way for accomplishing these, or for rendering them more attractive when they are procured. Hence art and mechanism first succeed, and then precede, utility. Again, our very bodies, and the contrivances which nature has so profusely scattered around, have given man what may be called an intuitive knowledge of mechanistic combinations. Men avail themselves of these as they do of books in a library, and rarely give a thought to anything but the branch that they are themselves at the time wanting.

Mechanicians are only a numerous class of those who do this. To the extensive storehouse of nature's contrivances perhaps every branch of art and science resorts more than it is willing to allow. When the Government, about 100 years ago, referred the question of a lighthouse to Smeaton for the Eddystone rock, Smeaton, who was experienced both as a kinetical and constructive mechanician (he was the first to intoduce the use of cast-iron teeth in large wheels), did not contrive a lighthouse, or even consider he was called upon to design one. What he did was to look about through nature's storehouse, and to consider where and how resistances were met similar to the resistances he was called upon to meet. Hence, when he published a report, in folio, of the designing and executing of the present Eddystone lighthouse (three or four previous ones having been either burnt down or washed away), he printed, side by side with a drawing of the structure he proposed, the trunk and the branches of an oak tree, which he took as his model. On the wall is a diagram taken from Smeaton's own account of the Eddystone lighthouse, and showing the peculiar mode in which he dovetailed the stones one into the other. The question of the Eddystone lighthouse is quite foreign to our present purpose, but the diagram there shows the mode in which the oak branch enters into the stem of the tree; and in the text Smeaton points out how beautifully the obtuse angle of the branch is fitted in with more material than the acute angle, and how it strengthens the acute angle; he also shows how the stem of the tree is fixed into the ground, and to this natural contrivance he owed his ideas, for from them he writes:—"I could make a figure not ungraceful; and at the same time carrying the idea of great firmness and solidity" (p. 42). That is sensible constructive mechanism. There may be many in this room who remember the year 1851, when the country was very much perplexed to know what to do with the Exhibition it had summoned, and did not know how to put it under cover. Architects, engineers, and others, were completely baffled. They felt that if they raised a building, either of brick or stone, damp in the walls would spoil the treasures of art to be deposited there. No available suggestion originated with them. In the crisis a gardener came forward, and to him is due the credit of having suggested the design for the building. Sir Joseph Paxton, who owns he was no engineer, writes of the Exhibition of 1851:—"Nature was the engineer in this case," and he requests those who choose to do so to compare the leaf of the water lily (the "Victoria Regia") with the building erected in Hyde Park, for he says, "from this I obtained all my ideas" of what should be comprehended in the first iron and glass building that was ever seen. Let us look—the inquiry shall be as brief as possible—at a few more of similar illustrations. A spider's web across a garden path suggested the Menai Bridge to Telford before 1818. The structure of bones suggested the tubular one which carries the railway across the Menai Straits. The little worm which perforates the wood of ships suggested the Thames Tunnel to Brunel; the telescope, the microscope, and the camera obscura are all clearly set forth in the eye; it was a lobster shell which gave the idea of curving wrought-iron tubes to Watt; wasps make paper, and there are other wasps that make paste-board. Spiders form nets; hail and shot are formed exactly alike. Birds' feathers suggested the slates to our houses, and birds' nests are lessons to this day in basket weaving. England, as an island, is warmed as this room is warmed. In the torrid zone there is a boiler and furnace, and the Gulf Stream is the enlarged pipe of a huge heating apparatus. In the hand we have a vice, and looking at that vice which we all possess from a mechanical point of view, it is evidently one more perfect than the most ingenious vice the accumulated skill of engineers could possibly produce. There are eight or nine different vices in one, that is to say, it is a vice of varying

* By the Rev. ARTHUR RIGG, M.A., being the Cantor Lectures delivered before the Society of Arts.

size and form; it needs no clams; there is no chance of damaging the work put in it by the serrated edge, as is the case in an ordinary vice, for, as you know, clams of wood, lead, cloth, and other materials are used to save the work. Look at it from any point of view, it is unapproachable. If you want to hold a circular piece of metal, how much more beautifully do you do it than can be done by any contrivance of engineers. You hold it between two fingers and a thumb. Although this is a question of statics, it is worthy of a few moments' consideration. You observe, many people put things upon four legs; theodolites*, instruments, tables, &c., are generally put upon four legs, but Nature tells us we should put them upon three. When this pencil is held on three sides by two fingers and one thumb, you cannot press it any direction without its meeting with resistance, but once put it between four fingers and there are four places in which it may escape. Another peculiarity of this vice (viz., the hand) is, that you may hold a chisel in it so as to be quite steady, and yet it will slide along, and there is no vice known to me which will do this. This vice, then, is not only a very curious one, but, in respects which would draw us very far aside, it is one possessed by no animal except man. Look, again, at the wrist joint. We have vices with balls and sockets, and universal joints, but none equal to this universal joint at the wrist. There is a fortune for anybody who can make a vice to equal it, so simple and so universal. Then, again, the stomach is a perfect laboratory. The lungs are a bellows; the skull is an arched vault, beautifully put together; and the teeth! what a complication we have of knives, saws, wedges, and mill stones; and in the jaws there is an arrangement which has often been tried, but which has never yet been successfully attained, called a draw-cutting action, the nearest attempt to which is in bread, hay, and paper-cutting machinery. Not only is the eye a telescope and a microscope, but there is in its apparatus (viz., in the "iris") a specimen of what engineers have been attempting for a long time—an expanding pulley. No expanding pulley has yet been successful. To adapt such suggestions as these supply, and to combine them with the structural schemes which ingenuity or necessity furnished, seemed to satisfy all the wants of men until the steam-engine enlarged its usefulness by giving a rotary motion in addition to a reciprocating rectilineal one. Watt did this in 1770, and from that time we began to date our mechanical progress. Then it was that men who saw a high scientific and intellectual study in mechanics were gradually turned from such considerations as the mathematical demonstration of the parallelogram of forces, or the abstract beauties of algebraic analysis, to the more important considerations which these engines producing rotary motion led them to entertain.

When we note how slowly, even in these days, the direction of men's thoughts change, we must not be surprised that comparatively few minds have left the beaten track, and entered on studies of pure mechanism. It is, both in its abstract and practical character, a very fascinating study, and those who promote it render the art of the mechanic less empirical and far more scientific than it is at present. As an architect should study engineering, so a mechanic should study mechanism. A mechanic, as the term is applied, means one who makes machinery. This view is just as narow as that which would restrict the term engineer to one who drives an engine. If there is one occupation more than another which should win respect from the required combination of mental knowledge and handicraft skill, it is that of the mechanic; and of mechanics none need these qualifications more than the smith—

> A mighty man is he,
> With large and sinewy hands,
> And the muscles of his brawny arms
> Are strong as iron bands.

For that man can take an uncouth, shapeless mass of cold iron and so correctly judge of the volume of that uncouth mass, as to select the required quantity, and no more, for a form to which it bears no resemblance, and to which form he shapes it, although he is never able to touch it with his fingers. Before you is one of the recent triumphs of skill in wrought iron, and if there is any one present who has taste for work of that kind, it is well worth study. It has been lent by Messrs. Peard, Son, and Peard, and is a pure piece of wrought iron. It is most artistic and graceful in form, and is put together without brazing in any part. How far it has been screwed together, or how far it has been simply welded, there are, no doubt, those in the room fully competent to judge. No one, however, can leave it without admiration, and recognising the truth of the statement, that of mechanics there are none who more deserve the thanks of the community than the class called smiths.

(*To be continued next week.*)

* The adjusting-screws of theodolites, are, as a rule, four in number—the three-legged stand is the support of a four-legged instrument.

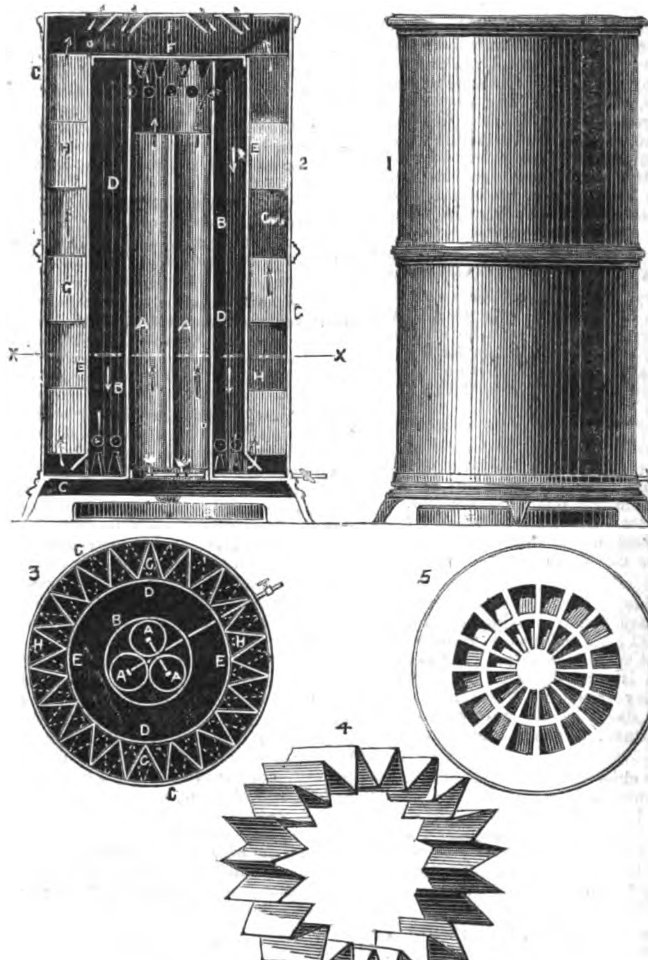
EBDY'S PATENT GAS-STOVE.

THIS invention is for warming, ventilating, and disinfecting buildings, heated by gas, coke, mineral oils, or other fuels: the stove is so constructed that a current of warm air is continually circulating therein. Each light or burner is inclosed, or burns within a long tube or chimney, by which means all or nearly all the offensive products of combustion are burned, and by the use of the radiating heaters or gills the air within the stove is thoroughly warmed before making its exit at the top of the stove. Fig. 1 represents the exterior of the stove, Fig. 2 vertical section, Fig. 3 shows a section on line X X; Fig. 4 shows the circular radiating gills or heaters H; Fig. 5 represents the top of stove I. A A, Fig. 2, chimneys, B B another tube inclosing chimneys, C outer casing of stove, D D chambers which are formed by placing an inverted cylinder E, having an air-tight cover F, over the tube B; G is another chamber; H shows the radiating gills or heaters. It will thus be seen that each light or burner is inclosed or burns within a long tube or chimney, these tubes or chimneys being inclosed within another tube, which is attached to the bottom of the outer case. This tube has air-vents cut at the top to allow the air to pass into the chamber D. This chamber is formed by means of an inverted cylinder E, which has an air-tight cover F, over the tube B, and chimneys, by which means an air space is left between the top of the cylinder and cover of the stove; air-vents are also cut at the bottom of the cylinder to allow the descending current to pass into the chamber G, which is formed by the outer casing of the stove. The spaces thus formed between the outer casing of the stove and the cylinder are filled with radiating heaters or gills of zig-zag form. The stove is raised above the floor upon a stand, so that the atmospheric air may pass up the chimneys and between the air spaces and thence down the downcast chamber, and from thence into the outcast or gill chamber. As the air circulates in the stove in ascending and descending currents it becomes well heated, and is deprived of those noxious qualities which generally accompany the use of gas. The gills warm the air which circulates within the chambers and maintain an even temperature.

When it is intended that coal should be burnt in the stove, the chamber is made larger, a grate is placed at the bottom and a fire-door in the side, and the top of the cylinder is inclosed and carried through the top of stove, and a small tube or chimney connected. The stove may be placed either in another apartment, or may be sunk beneath the floor of the building with down-cast and up-cast shaft.

The stove is well adapted for disinfecting rooms and buildings: when so used, the disinfecting fluid is to be placed underneath the stove in a vessel, as shown at Fig. 2. The fluid evaporates, is taken up by the air which passes into the stove, and is given off together with the heated air at the top of the stove. Any number of lights may be employed, the size of the stove being regulated accordingly.

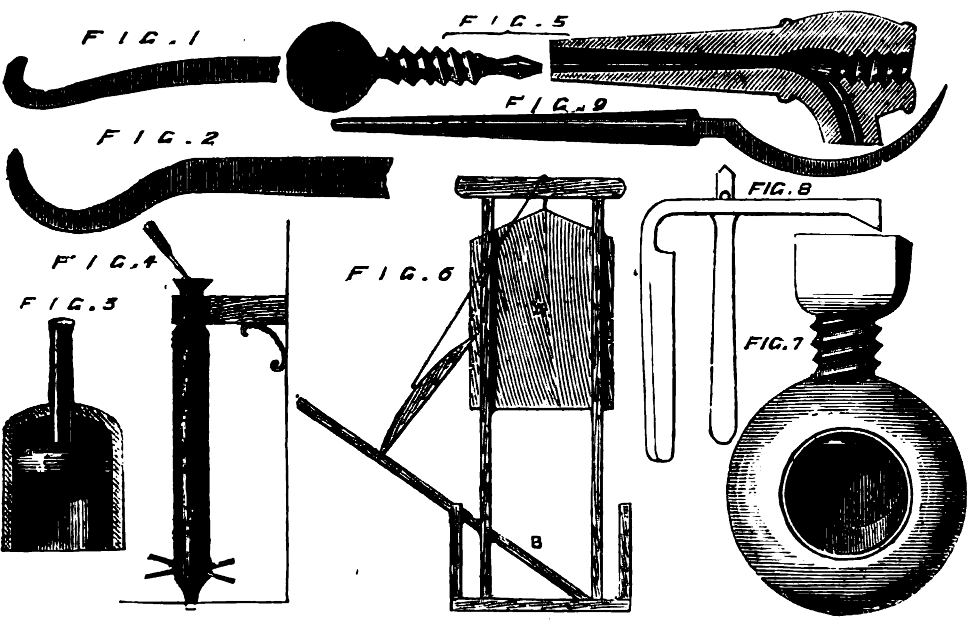
Mr. T. C. Ebdy, architect, of Sunderland, is the inventor and patentee.



THE TURNERS AND TURNERY OF KING'S CLIFFE, NORTHAMPTONSHIRE.

WE extract the following interesting information from the *Quarterly Journal of the Amateur Mechanical Society*, to which it was contributed by Mr. J. H. Holdich. For very many years the small town or rather village of King's Cliffe, about eight miles from Oundle, has been remarkable for the manufacture of various useful articles in soft wood, chiefly by means of the lathe. I cannot, says Mr. Holdich, tell much in the way of history. On making inquiry at Cliffe itself, all I have been able to learn yet is from a man who told me that his grandfather died in 1818, at the age of eighty-eight, that he was brought up a turner, and practised it all his days. This takes us back about 140 years; but probably the trade had been carried on many years previously. There are at this time no fewer than forty men constantly employed in the trade, so that it has not decreased since the days of Morton. The woods most in request by the turners of King's Cliffe are maple, sycamore, alder, birch, lime, chestnut, beech, ash, and whitethorn. Lime, sycamore, and beech are often cut into boards for trenchers, when of sufficient size, but the woods in most request are poles from two to six inches in diameter.

It is usually sold in parcels, each parcel containing a rood, or half rood, the buyer to cut it down and convey it home. So much of the country having been disforested, there is a comparative scarcity of this material, and it has to be sought at greater distances than formerly, while the workmen complain somewhat of the "Leicester folk," who come to them to buy poles for "bobbins" to wind cotton on, for which they commonly give about £1 5s. a ton, delivered at the nearest station. When the poles are brought home they are stacked out of doors for twelve months, then put under cover for another twelve months, before they are fit for use. Sometimes green wood is boiled to extract the sap, and is thus used in a very short time after being cut down, but an experienced turner told me he did not consider this to answer; the wood under such circumstances being very liable to split; e.g. salt-cellars and egg-cups are turned out roughly and left some time before finishing; but if the wood is boiled, as above, a large proportion of them crack and are useless. The tools employed are simple enough; the lathes—at any rate, by the side of a Holtzapffel—are generally clumsy, heavy-looking, with wooden wheels, and wooden chucks ringed with iron. I find the lathe-heads usually come from Birmingham, and cost about £1 5s. to £1 15s. each, the frames being home made. Common chisels and gouges, with hook tools, are used with great dexterity, the result of practice in one particular line. The "hooks" are commonly made by the village blacksmith, under the turner's direction, for different turners seem to me to have different twists, and each prefers his own. I have had a set of six made for me at 1s. 6d. each. They are more substantial than some I have, of Holtzapffel's, and of a different shape.



The Holtzapffel's pattern, Fig. 1, has a shank of 5in. and a handle of 9in.; the King's Cliffe pattern, Fig. 2, has a shank of 8in. and a handle of 12in.

It is really very interesting to see how cleverly these tools are managed. There is here, as in other places, a division of labour, for though most of the turners can do many things, each one has his own speciality at which he is most expert. Thus, at one shop are made spice boxes, salt-cellars, &c., at another pump buckets, at another water and beer taps, at another spoons, and so on.

The articles made are, however, very numerous. I have before me the price list of a man who, with his son, carries on a fair business; it comprises about sixty different articles; and these again divided into different sizes, though, it must be observed, he does not himself make all the articles mentioned, but supplies them. However, he and his son make a great many of them. It would be needless to name them all—let me rather select a few. First on the list we have "butter prints" of four kinds; 1, in cases (Fig. 3); 2, single prints; 3, oval prints; and 4, mould prints. Those in cases are divided into six sizes, viz.—1lb., ½lb., ¼lb., ⅛lb., 2oz., and common size. The simple prints are divided in like manner, and with the others there are different sizes and prices. The turner will readily understand how the ordinary prints and cases are turned, but there is an ingenious device (Fig. 3) in connection with the carving which calls for notice. They are, of course, carved with chisels, gouges, &c., the contrivance in question is for holding them, and very handy it is for the purpose. It consists of an upright post, the bottom formed as a pivot, turning in a hole in the floor usually, the upper part in a wooden collar carried by a bracket projecting from the wall. Near the lower extremity are two bars of iron, running through the post at right angles, on which the workman keeps his feet and so steadies the work or turns it as may suit his purpose. The butter print is fixed by a thumbscrew in a socket in the upper part of the post; napkin rings are first fixed in a holder fitting into the socket. There is no turning about the butter moulds—they consist of two pieces of wood, three or four inches square and about an inch thick, on each of which one half of the device is carved (a wheat-sheaf, swan, &c.), the butter being pressed between them.

The spice box is another article of which many are made. These are divided into small, middle, large, and large with five lifts, each lift being, in fact, a separate box, the bottom of which forms the top of the one immediately beneath it. There is a screw for each division, which is cut with a simple V-tool by hand, without any guide. The lathe head is turned with the left hand and the tool held in the right, and it is curious to see with what facility and accuracy this is done. The insides of the divisions, like the insides of all other boxes, are cut out very quickly with the hook tool (Fig. 2), and the bottoms squared with a similar tool of rectangular shape.

Taps are made of various sizes—large ones for water-butts and smaller ones for beer and other purposes. Fig. 5 represents a tap in section. The screw is cut by hand with the V-tool. To cut the female screw the tap is chucked on a taper iron mandril which holds it sufficiently firm for the purpose. The outside is turned as far as the projection for the spout, which is shaped with the paring knife.

The mouse-trap (Fig. 6) is also made in considerable quantities and is very effectual for its purpose. It will be seen that there are seven pieces besides the string, five of these being turned, and all put together for one shilling—less if sold wholesale. The principle is very simple; the wooden block A falls on the mouse when, to secure the bait, he ventures his foot on the treadle B.

The turned nutcracker (Fig. 7) may be seen on many stalls at fairs where nuts are sold. It is simple enough, consisting of two pieces only, a wooden box and a screw. The figure will sufficiently show what it is and, I should suppose, the manner of its use.

Salt-cellars and egg-cups are made in large quantities; the wood is cut into proper lengths and roughly pared with the knife. A taper screw, or worm chuck, is fixed on the mandril and the piece of wood screwed on with a few turns and cut out most expeditiously with the hook tool and gouge.

The words "puzzle boxes" and "Chartist whistles," which occur in the list, may excite curiosity; they are, however, very simple articles. The puzzle box is in the form of a ball, ornamented with sets of concentric circles, two of which, on opposite sides, serve to conceal the ends of a cylindrical box which is fitted in diametrically and capable of being pushed out with the finger, when the proper place is found. We have no Chartists about here that I am aware of, and why the whistle, which, by the bye, is not a whistle, should be named after them, I cannot tell. It is a small box with a perforated top, standing on a foot, something like a pepper box in shape, with a cylindrical piece projecting from the top, made to represent a whistle, but whoever attempts to sound it receives a puff of flour in the face, through the holes, to the discomfiture of the performer and amusement of the lookers-on.

And now let me turn to the manufacture of spoons, which is peculiar and has peculiar appropriate tools. They are made of poplar, alder, and, it may be other woods—of poplar by preference. The first process is to cut them into lengths and give them the rough shape of the article with the saw and paring knife. The bowl is then cut out with a curious instrument called a "fixel" (Fig. 8), if that be the right word, for I have not yet been able to find it. The blade is in the form of a gouge, about six inches long. The spoon is held by the left hand on a block and the fixel in the right when the bowl is chopped out with ease and considerable precision. It is then finished with the "smeething" (Fig. 9), the bowl being held in the left hand, with a bit of rag to guard the hand, and the tool in the right, the long handle going under the arm to steady it and give power. The spoon is then put into the lathe (commonly the simplest form of pole or spring-lathe) where, in a few turns, the handle is completed with a gouge. The whole is then finished off on the block with a knife of peculiar shape, with a long handle like the smeething, and used in the same fashion. All these tools are made by the village blacksmith.

Some few toys are also made here, as humming tops, small churns, rattles, &c. The humming tops are made of four pieces, painted, varnished, and sold at 6d. and 4d. each, which seems but little money. Some rather ornamental watch-stands, cotton-stands, pin-cushions, and spill-cups, also deserve a passing notice, but probably I have already become sufficiently tedious, so will pass on to a few words about the demand for, and the price of, the various articles of which I have spoken. Bearing in mind that not less than forty men are constantly employed in these works, it will be seen at once that the demand is considerable. Wooden spoons are not yet out of fashion, and notwithstanding the great increase of metal spoons and dishes, and the cheap and cleanly crockeryware, there are places where wooden ware is still preferred, and where it holds its head aloft. Large quantities are sent to Liverpool for exportation, mostly, I am told, to America; and the manufacturing districts of England, Yorkshire, Lancashire, &c., are ready markets. I was in a shop the other day where a man was turning tobacco boxes, in the form of little barrels, He had an order for a gross from Lancashire; these are sold at 4s. the dozen (wholesale). An order was once given for fifty pounds' worth of butter prints alone for America.

Touching the price at which the Cliffe ware is sold it seems marvellously small, and yet an industrious workman will make a very fair living out of it. It is not very easy work, but a man will turn six dozen salt-cellars in a day, which being sold (wholesale) at 1s. 6d. per dozen will produce 9s.; but then something must be allowed for wood, wear of tools, &c., so that probably he will not earn more than 7s. 6d. Egg-cups again are sold at 10d. a dozen, and I was somewhat surprised when a boy about seventeen told me, perhaps a year ago, that he had, by way of trial, turned 16 dozen in a day, no less than 192, but that it was a very hard day's work, lasting from 3 a.m. till dark. He has, however, now outdone himself; I was in his shop a week or two ago, and he told me he had turned 19 dozen in a day, from 7 a.m. to 7 p.m., allowing one hour only for meals, and that he intended the day after my visit to turn 21 dozen, for he had an order for 2 gross, of which he had turned 3 dozen only, and he wanted to complete the order next day. Probably he did it, but it seems to me a marvellous quantity—252 separate articles! The wood, I should observe, was cut into lengths of about two inches, and roughly pared, and each piece had to be screwed on to a taper screw and turned, the inside with a hook tool, the outside with a gouge. Another man told me he had once begun and finished 13 dozen spoons in a day, which, if sold at 10d. a dozen, would produce 10s. 10d., but these are unusual quantities, and could not be produced for any length of time in like proportion. Butter prints are variously priced according to the size. Those in cases for 1lb. are sold at 14s. per dozen, for ½lb. at 10s., and so on. Spice boxes with five lifts are sold at 18s. per dozen, with four lifts at 15s., &c., which, taking the many pieces into account, seems very little. Nutcrackers are sold at 8s. per gross. Puzzle boxes at 1s. each, retail; considerably less, probably 8s. per dozen, wholesale, and so on. Croquet sets are also made here, but not many of them. at from £1 to £3 the set, and very well made too. The balls are of crab tree, which is getting somewhat scarce.

There is a pretty method of ornamenting small boxes and other ware by transferring small pictures from paper to the wood, which are then varnished over. A word about the varnish. It is usually home-made. A very useful one is composed of—6 ounces of gum sandarach; 1 pint of methylated spirit of wine; 4 ounces of black resin. Perhaps a quart is made at a time, mixed in a tin can, and set near the fire to melt. The can should be large, as it is liable to boil over if care be not taken, and care must be taken in this matter. When [illegible] ly mixed it is strained into bottles [illegible] simply laid on with a camel's-hair [illegible] room. Another kind, somewh[illegible] with shellac.

Origin of Volcanic Energy.

AT the last meeting of this Society for the Session just concluded Mr. R. Mallet, F.R.S., read a paper on "Volcanic Energy;" being an attempt to develop its true origin and cosmical relations. He discovers the true cause of volcanic heat to be derived from a crumbling process going on in the interior of the earth. It is necessary to presume a hotter nucleus than crust, so that the rate of contraction is greater for the former than the latter. Thus, if there was no crushing and dislocation going on, a cavity would be formed between the nucleus and the crust. The author, however, imagines that the solid crust sinks together after the shrinking nucleus, and the work thus expended is transformed into heat, by which, at places where the crushing takes place sufficiently, the material of the rock so crushed and of that adjacent to it are heated, even to fusion. A volcano is formed by the access of water to such places, for without water no volcano. It would thus appear that the volcano is our safety-valve. We get steam up inside by the crushing of our crust and the influx of water, and have bursting prevented by the outlets and channels in communication with the interior. Applying the theorem of Lagrange—

$$T = P\left(\frac{1}{\zeta} + \frac{1}{\zeta}\right)$$

the author shows that the earth's solid crust, however great its thickness, and even if of materials far more cohesive and rigid than those of which we must suppose it to consist, must, if even to a very small extent left unsupported by the shrinking away of the nucleus, crush up in places by its own gravity and by the attraction of the nucleus. In order to test the validity of this view by comparison with known facts, the author gives in detail two series of experiments completed by him, the one on the actual amount of heat capable of being developed by the crushing of sixteen different species of rocks, chosen so as to be representative of the whole series of known rock formations from öolites down to porphyry; the other, on the co-efficients of total contraction between fusion and solidification at existing mean temperature of the atmosphere of basic and acid slags, analogous to melted rocks. The views are further tested by the data of total annual vulcanity of all sorts of our globe, by known facts of vulcanology and seismology, and by reference to other planets and our own satellite. The author submits that if his view will account for all the known facts, leaving none inexplicable, and presenting no irreconcileable conditions or necessary deductions, it should be accepted as a true picture of nature.

A Voltaic Standard of Electro-motive Force.

Mr. Latimer Clark stated that in the year 1861 a committee was appointed by the British Association for the Advancement of Science to report on standards of electrical resistance, and subsequently on other standards of electrical measurements. The reports handed in recommended the adoption of a system of electro-magnetic units based on the metre and the gramme, the relations of the units being such that the unit of electro-motive force acting through the unit resistance should give the unit current, and that the unit current flowing for the unit time should give the unit quantity. They issued standards of resistance and standards of electro-static capacity, but no material standard of electro-motive force had hitherto been issued. This want the author supplies in the discovery of a battery of pure mercury and pure zinc separated by a paste made by boiling mercury sulphate in a thoroughly saturated solution of zinc sulphate. This battery is sensibly constant and uniform in its electro-motive force, and the measurements are readily made by the potentiameter. Mr. Clark says that the standard of electric potential is second only in importance to that of the standard of electric resistance, and the use of such a standard, combined with an auxiliary battery in the manner above described, admits a of variety of applications, which it is believed will be found of great value in electrical research.

CHEMICAL SOCIETY.

Preparation of Chlorine.

AT a recent meeting of this Society, Mr. Henry Deacon read a paper on his process for the production of chlorine. He said that about two years ago, at Liverpool, he gave an account of his process for the preparation of chlorine from a heated current of hydrochloric acid mixed with air, which since then had been the subject of a great amount of research, with the object of ascertaining how this could be effected continuously, readily, and at the smallest cost. This problem may be resolved into the following:—1. As to the most suitable active or catalytic substances. 2. Whether the mass or the surface of the substance was the active agent. 3. As to the effect of temperature. 4. As to the best arrangement of the substance. 5. As to the effects produced by variation in the velocity of the current of gas. 6. As to the effect of various proportions of air or oxygen and HCl. He had observed that the heated mixture of hydrochloric acid and oxygen or air does not yield chlorine unless it is in the presence of some substance capable of being attacked by the hydrochloric acid, amongst which the copper compounds were eminently active. Sulphate of copper was fixed upon for economic reasons, and almost all the experiments mentioned in his lecture had been made either with the pure sulphate or with pumice-stone, or fragments of clay saturated with it. In experimenting, two clay tubes were generally employed of different bores, glazed externally, and coated internally with sulphate of copper, placed side by side, and passing through the cork of a glass tube sealed at the other end. The mixed gases on entering first traversed the glass tube, and then passed out by the clay tubes. In the more recent experiments this apparatus was placed in a thick, massive iron tube, heated externally by a furnace, so as to maintain a uniform temperature. This was measured by the change in electrical resistance of a fine platinum wire, and also by a mechanical pyrometer. The mixed gases were contained in gasholders worked with strong sulphuric acid, both the amount of hydrochloric acid passed and the amount of chlorine produced being ascertained by passing the gases into a solution of caustic soda. The lecturer then explained the numerous diagrams and tabulated results of experiments with which his discourse was illustrated, from which it would appear that there is a certain comparatively small range of temperature between the critical limits of which the percentage of hydrochloric acid decomposed varies greatly, and that this is not the same for the chloride as for the sulphate of copper, being higher for the latter, although it is the same whether solid sulphate of copper be used, or merely pieces of brick saturated with it. This shows that the action is essentially a surface action. It is, however, remarkable that in experiments on a large scale this temperature is invariably lower than in the laboratory experiments—usually 100° or 150°; also, that when the mixed gases are passed through a series of parallel tubes an increased velocity in the flow of the gas yields only about one-third the increase of the amount of chlorine produced, that an irregular surface does under like circumstances.

From the results of all the experiments contained in the tables he inferred:—(1) That with the same mixture of gases at the same temperature, the amount of hydrochloric acid decomposed by the aid of a molecule of the copper salt in a given time depends upon the number of times the molecules of the mixed gases are passed through the sphere of action of the copper salt. (2) That in long tubes of the same diameter the number of opportunities of action in the same time are nearly the same at all velocities. (3) That in long tubes of different diameters the number is the same when the velocities of the currents of gas are in inverse proportion to the square of the diameters. (4) That in porous masses the opportunities of action increase with increased velocities in nearly direct proportion. (5) That other conditions remaining the same, the percentage of hydrochloric acid decomposed varies with the square root of the proportionate volume of oxygen to hydrochloric acid. (6) That the $CuCl_2$ formed bears no definite proportion to the amount of chlorine produced. (7) That as the sphere of action includes molecules not in contact with the copper salt, therefore hydrochloric acid must be decomposed under circumstances where the union of either element with the copper salt is impossible.

The President (Dr. Frankland) said that the process for preparing chlorine at present used was essentially clumsy and unscientific; the hydrochloric acid given off from the salt cake was first dissolved in water, and then treated with manganic peroxide in order to liberate the chlorine, giving rise at the same time to a large amount of waste products which were thrown into our streams and polluted them. As especially interested in our rivers, he sincerely hoped the process would prove a commercial success.

Dr. Williamson said he would like to ask a question or two for his own information. He understood that the mixture of air and hydrochloric acid was heated before being passed into the decomposing chamber; was it cooled again before it went into the chamber containing lime for the preparation of chloride of lime, and was the undecomposed hydrochloric acid previously removed by washing?

Dr. Debus would like to know whether the sulphate of copper was found to be unaltered after having been exposed to the action of the mixed gases for a considerable time, and also whether, when Mr. Deacon used straight tubes with the mixed gas passing through at different velocities, the gases in both instances had attained the same temperature when it came in contact with the sulphate of copper?

Dr. Gladstone observed that many interesting points started up in one's mind in connection with this subject, and he should like to know more fully why the lecturer believed the sphere of action to include molecules not in contact, and that the decomposition was not due to direct chemical action. It appeared to him that it was unnecessary to suppose the cause to be the mechanical striking of the molecules of the gas against the sulphate of copper surface in their passage through the apparatus, and therefore depending on the flow, for it must be remembered that when a gas was mechanically in a state of rest the molecules composing the gas are in a state of motion, and that when we heat that gas this rate of motion of the molecules amongst themselves varies, although the gas is still mechanically at rest.

Mr. Deacon replied that he thought it would save the time of the Fellows present, and avoid getting over old ground, if they would permit him to put aside all technical questions, and reply only to those which had a scientific interest. In the first place, there is a definite range of temperature where chlorine is freely formed, but no chloride of copper, although at a higher temperature the sulphate of copper is partly converted into chloride. This only applies to pure sulphate of copper, which, even after the action had been continued for six months, contained but mere traces of chlorine. In the presence of clay, however, the sulphate of copper is decomposed, and chloride formed, probably owing to its containing some base which combines with the sulphuric acid. In the case where the exterior glass tube contained two clay tubes of different diameter, the gas coming in contact with the copper salt, certainly had the same temperature, although moving with different velocities. With regard to his allusion to chromium he had expected from the well-known oxidising power of chromic acid that it would have been very active, but, on the contrary, he had found that it was reduced to oxide of chromium, which is one of the most inactive substances. With respect to the theory he had laid before them, without vouching for its correctness, he could say that it was the only way he knew of accounting for the results he had obtained.

USEFUL AND SCIENTIFIC NOTES.

Society of Arts' Music Examinations.—The newly-issued results of this year's examinations in musical theory and composition under Messrs. Hullah and G. A. Macfarren, show that of the 87 certificates and three prizes awarded by Mr. Hullah, tonic sol-fa pupils have taken the first prize, and 68 (more than three-fourths) of the certificates. Mr. Macfarren has awarded two prizes and 86 certificates, and sol-faists have taken both the prizes and 81 of the certificates. The Society has now relinquished its musical examinations, in which, during the last six years, 594 certificates have been issued, more than three-quarters (449) having been obtained by tonic sol-fa pupils. In Mr Hullah's examination the ordinary notation and nomenclature of music is strictly used; in Mr. Macfarren's the exercises may be worked in either new or old notation at the candidate's option. The Council of the Tonic-Solfa College, having tried in vain to induce the Science and Art Department and the University of London to carry on these examinations, has determined, as a provisional measure, to undertake the work for three years at least.

Incubator.—A Mr. Hunt has patented an improved incubator or apparatus of simple and inexpensive construction for hatching eggs, and also for rearing the young when hatched. The incubator is composed of two boxes placed one within another, a clear space being left at every part between them (say of about 1in.), which is filled with a non-conductor of heat. The inner box contains a metal vessel, which is filled with heated liquid (say) every twelve hours, and above this is placed a tray to contain the eggs for incubation. The heat is graduated and air is admitted by a perforated lid at the top of the outer box. That part of the invention relating to rearing the young when hatched, which the inventor calls "the mother," is constructed as above described, save that the vessel for the heated liquid is placed at the upper part of the box, so as to leave a sufficient space to admit the young to warmth. The liquid is admitted to and drawn from the apparatus by pipes and cocks suitably arranged for such purposes.

Gas Purification.—The report on gas purification by the gas referees, which some time since was sent by them to the Corporation and Metropolitan Board of Works, has been published. It announces that the gas referees have devised a new method of purification, by which the gas can be almost entirely freed from the sulphur-impurity at every gas-work (as at Bow-common and Beckton) where lime can be used. But, although the report is dated in January, and the referees state that they had informed the engineers of the Chartered Gas Company of their new method of using lime-purifiers, the official testings for the quarter ending with March show no improvement whatever in the purity of the gas supplied to the City, either from Beckton or from Bow-common. The monthly averages of sulphur in the Beckton gas since the year began have been as follows:—January, 45 grains per 100ft.; February, 44; March, 38; while in those months respectively the impurity has been as high as 58, 51, and 53. In the gas supplied from Bow Common, the average of sulphur in January was 23, grains per 100ft.; February, 22; March, 21; while in those months respectively the sulphur has been as high as 35, 30, and 30 grains.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

A GIANT PLANET.

[4446.]—"HYRAB SCEN" (letter 4429, p. 384) is a pleasing critic. It appears there is "so much loose reasoning" in my article (I may as well admit the authorship) that "it is not amiss to call the attention of your readers to it." This, however, "Hyrab Scen" only talks of doing; for he proceeds to attack part of a sentence which does not belong to my reasoning. Let me give the whole sentence. It runs: "And after all, let us remember that the theory that Jupiter is an intensely heated globe—*a theory to which we have been led by the consideration of many observed facts, and which, in its turn, suggests very satisfactory explanations of other observed facts*—would merely show that [as Jupiter and Saturn hold an intermediate position between the sun and the minor planets in respect of size, so these giant orbs hold a corresponding position in respect of inherent heat]." The part in brackets is the only part quoted by "Hyrab Scen." All my reasoning had been already given, and I was merely describing the general character of my inferences, in that half sentence which "Hyrab Scen" chooses to present as part of my reasoning. Then comes his startling discovery that 82,000 is not the arithmetic mean between 8,000 and 840,000. Has "Hyrab Scen" never heard of a geometric mean? and would he denounce a mathematician who said that "2 is a mean between 1 and 4," because 2 is not the arithmetic mean? Is not 82,000 pretty near the true geometric mean between 8,000 and 840,000; and do I attach the slightest importance to the numerical relation? I do not think any one of my readers (including "Hyrab Scen") for a moment doubted the real meaning of my statement. Then he goes on to the question of "size" as distinguished from "diameter;" and he says. "When we remember that the sun's bulk is more than a thousand times greater than Jupiter's, we shall easily see how little he (Jupiter) is entitled to hold the place the writer assigns to him." Does "Hyrab Scen" need to be told that Jupiter's bulk is more than a thousand times greater than the earth's? or that it was the (rough) correspondence between this relation and the relation between the sun and Jupiter that I had in view? He then similarly maltreats my remark about Jupiter's heat, as compared with the sun's and the earth's. And he very fitly concludes this portion of his argument by saying that "when the writer of the article thinks fit, with insufficient regard to facts, to place Jupiter midway between the sun and earth, in respect of bulk and temperature it looks very much like struggling to find the materials with which to build a theory at any price." He must have known perfectly well (or why garble the extract from the above quoted sentence?) that the materials for the theory had been already found—see the italicised words above; and that the theory would not be in the least affected, even though "Hyrab Scen's" reasoning were correct.

As to the next paragraph of his letter, "Hyrab Scen," if he has read my article, knows perfectly well that I do not regard the cloud envelope as covering the whole of Jupiter. It is the very essence of my reasoning that the red-hot surface of the planet would be discernible—perhaps even through the cloud belts which seem to us the densest. Dr. Tyndall's researches about the "*very material retardation*" (doubtless "Hyrab Scen" means *absorption*) of radiant heat by aqueous vapour relate (in the main) to obscure heat rays, and my theory presents the heat of Jupiter as (in the main) not obscure. "Hyrab Scen" holds that "the clouds of Jupiter *must* be as dense as a Newfoundland fog bank," and also that "they *must* partake more of the nature of semi-condensed steam than of terrestrial clouds." When he has selected between these utterly discordant "must be's" it will be time to discuss his inferences, which at present seem based on a convenient mixture of the two. It further appears that granting Jupiter to have such and such a temperature, the amount by which his satellites' temperature will be augmented, "admits of strict calculation." Unfortunately "Hyrab Scen" does not give us any illustrative calculation. He only tells us that if Jupiter's heat be 1,200° F., the outermost satellite must receive less than 2° from such a source. I should very much like to see the calculation by which this result has been achieved. I fancy "Hyrab Scen" counts degrees Fahrenheit much as a schoolboy counts marbles.

Amazing, also, is the assertion that if not illumined by the sun and shining only as a red-hot planet, Jupiter would be invisible to any dwellers in his most distant satellite. This is almost as bad as Mr Lockyer's mistake about Huggins's ingenious experiment for testing the luminosity of certain nebulæ! "Hyrab Scen" may take it for granted that under his supposed conditions Jupiter, as seen from its most distant planet, would appear as a red-hot orb showing a disc 65 times as large as our moon's. This disc would appear just as *bright* as red-hot iron. I conceive that on a dark night a globe of red-hot iron subtending to the eye an angle of $4\frac{1}{2}$ degrees would be discernible without "any optical power greater than our unassisted vision." But "Hyrab Scen" shares the common error that distance *per se* has an effect in diminishing the apparent *brightness* of a luminous object.

In the third paragraph of his letter "Hyrab Scen" makes me say that "Jupiter shines three or four times as brightly as a globe of his size should if reflecting the sun's light only." He omits the somewhat important words, "*if* constituted like Mars or the moon." To remove all misapprehension, I actually added the words, "Jupiter shines, in fact, very nearly as brightly as though he were constituted like one of our terrestrial clouds." This would, however, have ruined "Hyrab Scen's" ingenious argument, and is accordingly not admitted.

Of course, the argument though ingenious (in a bad sense) is sheer nonsense. What does "Hyrab Scen" mean, for instance, by saying that "sunshine here is hundreds of times brighter than the light emitted by a body heated to redness"? He can hardly mean that a body illuminated by sunshine is hundreds of times brighter than red-hot iron. If he does, I would ask, "What sort of body?" Does a piece of black cloth, for example, illuminated by full sunlight, shine hundreds of times brighter than red-hot iron? If he means that the sun's disc as we see it is hundreds of times brighter than red-hot iron, then what does he mean by the sun's light at Jupiter being one twenty-seventh part of what it is on the earth? The sun's disc as seen from Jupiter is just as bright as the solar disc *we* see. It is its apparent size, not its brightness, which is reduced to one twenty-seventh by the increase of distance.

But "Hyrab Scen" knows perfectly well that in my article on Jupiter I only weigh actual evidence, and deduce certain probable inferences as to Jupiter's condition. I do not attach the slightest *weight* to the questions whether his satellites are inhabited, whether he warms them, and so on. I only touch on these matters in the concluding paragraph of the article. I expressly indicate my belief that such considerations afford no valid testimony for the theory embodied in the essay, adding "that theory must stand or fall according to the evidence in its favour or against it." Nor even do I describe the evidence I have gathered together, in the body of the article *and elsewhere*, as in any sense conclusive.

I hoped, when I read the first sentence of "Hyrab Scen's" letter, that I was coming upon honest criticism, from which I might learn something. To such criticism I am always glad to listen, and not unfrequently I have found in it good reasons for modifying or abandoning opinions of my own. Nor do I in the least mind how strongly it may be seasoned. But "Hyrab Scen's" criticism is not of this sort. He garbles extracts too cleverly for me to suppose that he is either so simple or so ignorant as he represents himself.

To a critic of another sort, who asked recently whether there may not after all be living creatures in such a world as I take Jupiter to be, I would submit that life on a red-hot globe, if possible at all, must be of a kind too far removed from our experience to be a fit subject for reasoning or discussion.

RICHARD A. PROCTOR.

[4447.]—"HYRAB SCEN" is sadly wrong in his criticism of the remark (let. 4429, p. 384) that a diameter of 82,000 is "midway" between 8,000 and 840,000. It could hardly be more accurately so. The nearest whole number to the mean is 81,975; and if these are taken for the earth, Jupiter, and the sun, the latter will be in diameter just as many times Jupiter as Jupiter is diameters of the earth; in surface also, as many Jovian surfaces as Jupiter would display terrestrial ones; and in bulk, the sun would divide into as many Jupiters as Jupiter would into earths. What other intermediate dimension would "Hyrab Scen" suggest as "midway"? He remarks rightly, however, that a mere red heat would by no means account for the fact (if it be a fact) of Jupiter and Saturn each emitting a sensibly greater amount of light than can fall on them from the sun. It would require a decidedly white heat, as high as that of melted cast iron, to rival the brightness of a white object reflecting even Jovian sunshine (a twenty-seventh part of ours), or perhaps even Saturnian, which is about a hundredth of the intensity of ours. This admits of easy proof, even in London, this fine weather; for if we let a sunbeam pass through any concave lens, it will so diverge that an object placed in the shadow of the lens, and at 4·2 times its focal length, will be just as much sunned as Jupiter, and one at 9 times the focal length will be in the condition of Saturn. We may thus exactly represent the sunshine of any exterior planet, and with a convex lens that of Venus and Mercury. By putting your hand at three-tenths or at six-tenths of the way from the burning-glass to its focus, you can judge, in the former case of Venereal, and in the latter of Mercurial sunshine; and the appearance of these planets, as well as of Mars, very well agrees with theory, supposing all about as reflective as the moon, or a lightish gray slate. But not so with the two giant planets. Years ago the sight of their occultations by the moon impressed me with the idea that they far too nearly resembled her deeper-tinted portions, and Jupiter even her bright edge, to be emitting only a twenty-seventh and a hundredth of her average light respectively. Their total lights might be very exactly compared, without much difficulty, by their images in convex mirrors, removed to different distances from the eye, till they are equalised, by night; and by day the moon's reflectiveness might similarly be compared with that of white lead, frosted silver, soot, lamp-black, or other standard materials. This is, I suppose, the way Dr. Zöllner arrived at the result of Jupiter shining "three or four times" as much as he could by sunlight, though the "three or four" seems to me very vague for a serious experiment.

But surely such a result would be conclusively tested whenever a satellite and its shadow are both seen on the disc and near its centre at once, which is not a rare event. If the planet's total light be "*three* or *four* times" his possible reflection, his independent light must be at least *two* or *three* times the reflected, supposing him as reflective as snow or white lead, and in a greater ratio if he is only as reflective as the inferior planets. On the probable assumption of the satellites having no native luminosity, then the spot shadowed by one would be *twice* or *thrice* as bright as the sunned satellite itself, so that whenever the two are seen well within the disc, say in the central half of its area, the body must be decidedly the darker of the two spots. Is this so *always*; or rather, has it *ever* been observed? A late correspondent described a transit in which, when the shadow entered the disc, he was surprised how little darker than the satellite it was. But this must have been at the border, where, by hypothesis, Jupiter's non-luminous but reflective envelope is alone visible. His brightness does certainly decline towards every border, like the sun's, and contrary in this respect to that of Venus, and notably of the moon. But on the self-luminous hypothesis there must be a majority of the disc whereon shadows, far from being *any* darker, must be never, *in any case*, so dark as the satellite casting them, if visible at all. On the other hand, the common theory of solar light alone requires them to be *always* darker, and, indeed, absolutely black, unless the satellite casting them have a very great atmosphere, for nothing else can reflect or refract solar light to them in sensible amount. The other satellites are either absent or in their horned phase.

Again, the question of Jupiter's temperature is surely now far more within experimental reach than that of stars. If Mr. Huggins has detected *any* star's heat rays with his refractor, how much more might be expected of the 6ft. Rosse mirror, with some 30 times the grasp, and no passage of the rays through any medium but air! Would, indeed, it were Teneriffe air instead of Irish, and reflection from a silver film on glass instead of bronze, and capable of being turned to receive rays of the interior planets or horned moon by night, instead of only by day; but still, this thermometry would seem the special work for a giant mirror, and considering that its image of Jupiter must cover a good-sized pea, so that a thermo-battery need not have more surface than to be nearly covered by it; surely the temperature of either the giant planet, or of nebulæ, or comets (all, I believe, yet untried) must be more accessible (as well as more desirable to know) than that of stars, which few have ever doubted to be hot—

Doubt that the stars are fire,
Doubt that the sun doth move!

No, Hamlet, we have quite returned to Mediævalism from both these doubts, but we remain in much doubt about nebulæ and comets (the only bodies really interesting us, as possible and not improbable intruders on our home), and even of our neighbour the moon, what heat she really absorbs and re-radiates is a question as yet strangely ill-approached. The important distinction of her merely reflected heat rays from those warming her has not been made, as it might easily have been, by comparisons of radiation from her illumined and dark parts, and specially at her two quadratures, and between those that have just left their fortnight's day and those about to enter it. All these are experiments that it seems wasteful to grope after with instrumental powers so very far below the highest as all those on which the duty has been hitherto thrown.

E. L. G.

[4448.]—REFERRING to the article with the above title, reprinted on p. 244, and to the reply (let. 4429) of "Hyrab Scen," I may be permitted to supplement the latter's objections to the idea of Jupiter being a sort of midway sun, by calling attention to the planet's appearance at quadrature. If he were a light-giving body, there would be no approach to a gibbous form. I am aware that Arago says there is no phase, but with all due deference to the French philosopher, we must not forget that his assertion has been contradicted by our eminently exact observers, De La Rue and Webb. This fact alone seems to me to tend greatly to nullify the theory that Jupiter gives out unreflected light—unless, indeed, the writer of the article in question considers the inherent light to be so faint, from the heat being of a dull red, as to cause a portion of the planet to be invisible at quadrature by contrast with the reflected light. If this be so, the gain to the satellites must, indeed, be slight.

I may also remark that though Mr. Browning did not see the orange belt till 1870, he having, I ...

previously observed with a smaller aperture, it had been constantly observed at Greenwich.

For my own part I see no reason why we should not allow that planets have atmospheres, differing from our own in such a way that the heat and light rays of our sun are so mollified or intensified as to make Mercury and Venus as habitable as Uranus and Neptune for beings adapted to their respective situations.

L.

AXES OF THE PLANETS.

[4449.]—THERE is a slight inaccuracy in the statement made by "F. R. A. S." (letter 4404, p. 380) on this subject, where he says that the equator of Jupiter is inclined less than 2° to the plane of its orbit. The inclination exceeds 3°. The *positions* of this planet and of Mars are pictured in my charts of the planetary orbits. Recent researches by Dr. Oudemann set the inclination of Mars at about 1½° less than Herschel's estimate. I conceive that De Vico's observations of Venus, even if their accuracy be not admitted, are scarcely spoken of quite justly when "F. R. A. S." says De Vico *imagined* the inclination of Venus to be so and so. Webb speaks of De Vico's work with some degree of confidence. Admiral Smyth adopts Bianchini's estimate of the inclination—viz., 75° (between equator, plane, and ecliptic). So does Prof. Grant.

As to Mercury's inclination, can any reader of the ENGLISH MECHANIC give Schröter's estimate? Webb gives it as 70° for inclination of axis to orbit; but I am uncertain whether he means this angle or its complement, for he speaks of the *axis* of Venus as greatly inclined. Grant says that "the axis of Mercury is greatly inclined to the ecliptic, according to Schröter." Hind omits all reference to Bessel, saying that only Schröter has seen any signs of rotation. I have always supposed that Schröter found the inclination between Mercury's *equator* and orbit to be 70°; but this may be wrong. If the complement of this angle is in question, and Bessel's observations are independent, there would seem to be better evidence respecting Mercury's axial pose than is commonly imagined.

I wonder why Mr. Johnson (answer 12164, p. 390) thinks *Mars* so very warm that its heat "to ordinary animals would be destruction!"

RICHD. A. PROCTOR.

GASSENDI.

[4450.]—REFERRING to Mr. Birmingham's letter (4241), I think difference of illumination, though occasioning some difference in the aspect of lunar objects, cannot fully account for the differences found in our respective sketches. The principal cause I believe to be our difference of purpose. Mr. Birmingham has tried to give a general view of the aspect of the north portion of the floor of this crater, while I almost entirely disregarded appearances, my aim being to note down the place and describe the nature of every distinct object seen at the time. Doubtless, it would be far more pleasing to the eye, and in no way diminish the usefulness of sketches, if they were always neatly shaded, as desired by your correspondent "E. B. F." (letter 4381). Only, in that case, details would have often to be sacrificed. Now details are certainly what we need the most. "To understand how celestial objects appear when viewed through large telescopes," is not, certainly, an unreasonable desire; but this is not the ultimate object one ought to have in view when looking at celestial objects. The telescope is not merely an instrument to introduce us into magnificent shows, but it is a means of study. Mr. Birmingham shows ridge 21 (see letter 4076) as extending eastward of crater 18. I never saw it thus. On the other hand, the position of crater 16 given by him is better than in my sketch, as this crater ought to be nearer cleft 20 than cleft 17.

Jumet-Hainaut. C. GAUDIBERT.

P.S.—Though late, allow me to tender my thanks to Mr. Knott for his prompt answer to my query about ζ Cancri, and also to the Rev. H. C. Key, who so willingly gave such interesting and very uncommon details about this double. It would seem that the companion was about this time at its nearest approach to the primary, as I find (p. 381, Vol. X. of the ENGLISH MECHANIC) in a letter of "F.R.A.S." that according to the latest measures in 1869 it was 0·40". In May, 1868, Mr. Key found it just separated with his 18in., or about 0·25", or 0·30", and since then the distance has continually increased. This date, May, 1868, is of importance as the starting point to ascertain the time of the revolution of this star, which time is not yet satisfactorily determined. Mr. Webb, in "Celestial Objects," p. 199, quoting Jacobi gives not much less than 100 years, while Mr. Hind (see ENGLISH MECHANIC, No. 318, p. 128) gives 58·23 years.

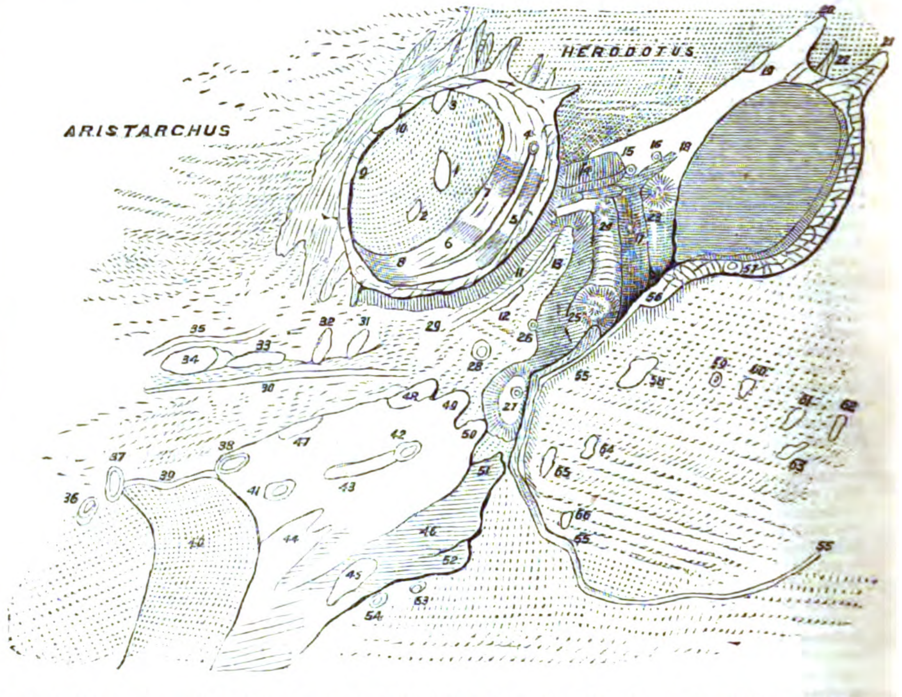
MILK.

[4451.]—THE paragraph, p. 393, quoted from American sources, may mislead many, as it is utterly erroneous. All the world over "a pint of water is a pound and a quarter"—*ergo*, a quart should be 2lb. 8oz. Now, the specific gravity of cow's milk ranges from 1·03 to 1·04, and, therefore, the lowest weight of a quart of milk, if pure, must be 2lb. 9·6oz., instead of 2lb. 2½oz. I fear Mr. Gail Borden, of White Plains, N.Y., must be a 'cute Yankee, who employs measures which would make even a London dairyman turn green with envy, though the latter fully adopts the maxim once calmly enunciated to me by a Chinese to whose charges for milk I objected, "You want milk more cheap, I can,—can put more water." SIGMA.

ARISTARCHUS AND HERODOTUS.

[4452.]—ON May 12, 1872, you kindly published one of my sketches of this lunar group. Unfortunately, I did not then follow the excellent advice given by Mr. Birt, of numbering each object seen, so that when new objects are discovered, their position can easily be determined by referring them to other objects in their immediate neighbourhood. This, and also some other objects not seen by me before, whose positions I could not very well give by referring to that sketch, without a long and doubtless confusing description, is my excuse for soliciting the engraving of another sketch containing the observations of two consecutive evenings, the 17th and 18th of June, 1872.

1 is the central peak on the floor of Aristarchus; it was neatly seen on the 18th, very bright, elongated in a south-west and north-east direction. I think those observers who have large apertures, might successfully look for another small peak on its north-east end. 2 is Browning's peak, which was dull compared to 1. 3 is the peak I saw for the first time on May 30, 1871. It was also dull, but rather easier to see than 2. 4, a shallow craterlet along the eastern interior slope, nearer to the top. 5 is an interior ridge, running from crater 4 parallel with the eastern ridge of Aristarchus, which I saw for the first time on May 1, 1871, but which, I believe, had been seen before by Mr. J. Birmingham. 6, 7, and 8, are dark portions of this slope quite in contrast with the rest. The darkness of 6 is narrower from the floor of the crater to ridge 5, than above. 9 and 10 are two elongated bright peaks on the south-west wall of Aristarchus, but they are not high, I believe, for I scarcely could distinguish their shadows on the 17th. Just north-east of Aristarchus the surface is very much depressed if compared to the portions marked 14, 24,



and 25, but is very much on the same level as the large flat valley running north-west of Aristarchus, where 30 stands. I have tried to show this depression, as it gives a better idea of this whole locality. In this depression 11 is a cleft, and 12 and 13 are two elongated ridges along its north-east border. Here, also, are two other craters which will be described below; 14 is a mass of darkish rocks which with cleft 18 penetrate into the streak of light forming the south-west border of Herodotus, and divides it into two branches. No drawing made with the hand while the eye is at the telescope, will give an adequate idea of this object. 15 and 16 are two very small craterlets on the south border of the eastern portion of cleft 18. These craterlets were seen on the 17th, when the streak of light was on the terminator. The next evening not the slightest trace was visible either to the eye or imagination, though I knew where they are, and I carefully looked for them. 17 is the large valley cutting the plateau which stands between Herodotus and the depression east of Aristarchus. It runs in a somewhat south-west and north-east direction. Its south-west end opens in the middle of cleft 18; its north-east extremity rapidly descends from the towering height where it runs, but it is not cut perpendicular as one would think, when some shadow remains there. It reaches a small cleft, 56, described below. Just south of 17 in the valley there is a small hill seen only on the 17th. 18 is a cleft extending from the east side of Aristarchus into the streak of light. It runs at the foot of rocks 14, but far above the depression on the north, and before it reaches valley 17 it is stopped in two places as if it had been made of an elongated double crater whose walls were still standing. Its eastern extremity clearly stopped in the streak of light and the rim of Herodotus showed no cutting, and yet I have seen at other times this portion of the border of Herodotus quite dark, as if cut. Does cleft 18 cut through this border, or is the darkness caused by the shadow of the towering hill 23? 19 on the south border of Herodotus is a mound on the streak of light seen only on the 17th. 20 and 21 seem to be the remains of an old crater whose south portion has disappeared; 22 a low ridge inside; 23 is a very prominent hill between Herodotus on the east, part of cleft 18 on the south, and valley 17 on the west. On the 17th its shadow was crossing the east rampart of Herodotus, when it came into light. 24 is another hill, but smaller on the opposite side of valley 17. 25 is a very high hill on the north extremity of the west side of valley 17. At the west foot of this mountain, in the depression, there is a craterlet 26, seen for the first time on the 17th; no trace of it next evening. 27 is another mountain not so high as 25, and connected with it by a lower range still along the west border of serpentine valley. On the top of 27 I found a craterlet on the 17th, not seen before by me. 28 is Browning's mountain, but I see it still as a crater with the east and west sides higher than the north and south. 29 is a mound at the opening of the large valley where 30 stands. 30 is a cleft running almost diagonally through this valley. 31 to 34 are mounds forming the south border of the large valley. South of these mounds there are others whose positions I had no time to take. South of mounds 33 and 34 there is a cleft following their contours to some extent. 36 a crater, 37 and 38 are two craters, one situated just on the border of the table-land west of valley 40, and the other on the border of the table-land east of 40, and connected with each other by a cleft 39, bulging north nearly in the middle; 40, a large flat valley; 41, a crater; 42, another crater, west of which is a low ridge 43, running in the direction of crater 41; 44, a low large mound forked on the south-east; 45, a low mound brighter than its immediate neighbourhood; 46, portion of this table-land lower than the rest; 47, an elongated mound along the south border of this table-land; 48, a mound which as well as 49 and 50 project into the depression east of them; 51 and 52 are two other projections of the same kind in the lower portion of this table-land; 53 and 54 at the north foot of the table-land are two craters; 55 is the great serpentine valley. This curious object takes its origin at the north foot of mountain 25; it is enlarged at once more than in any other portion of its course, and encroaches upon the slope of the mountain. It follows the eastern slope of the mountain range 25 and 27, and continues its zig-zag course very much as shown in the sketch; 56 is an opening in the north border of Herodotus, which has been pushed outwards. Within this opening runs a small cleft which connects the great serpentine valley 55 with the interior of Herodotus, and along its course, passes across valley 17, but on a lower level, and seems to cut it much in the same way as cleft 18 cuts the opposite end; 57 on the north border of Herodotus is Schmidt's crater; 58 is a mound; 59 is, I believe, a crater; 60 to 66, mounds. On the south-west of Aristarchus are ridges somewhat as shown, but time failed me to examine them with sufficient attention to describe them.

Jumet-Hainaut. C. GAUDIBERT.

SUN SPOTS.

[4453.]—POSSIBLY Mr. Hart's letter (4398) may serve to explain the nature of sun-spots. May they not be incrustations on the molten substance of the sun? It is singular that Sir John Herschel says that he once saw a sun-spot break across in the middle—or, at least, saw a band of light suddenly appear across one; which would be a phenomenon precisely like that mentioned by Mr. Hart, where he says that the hardened lava at Hawaii suddenly splits up. A.

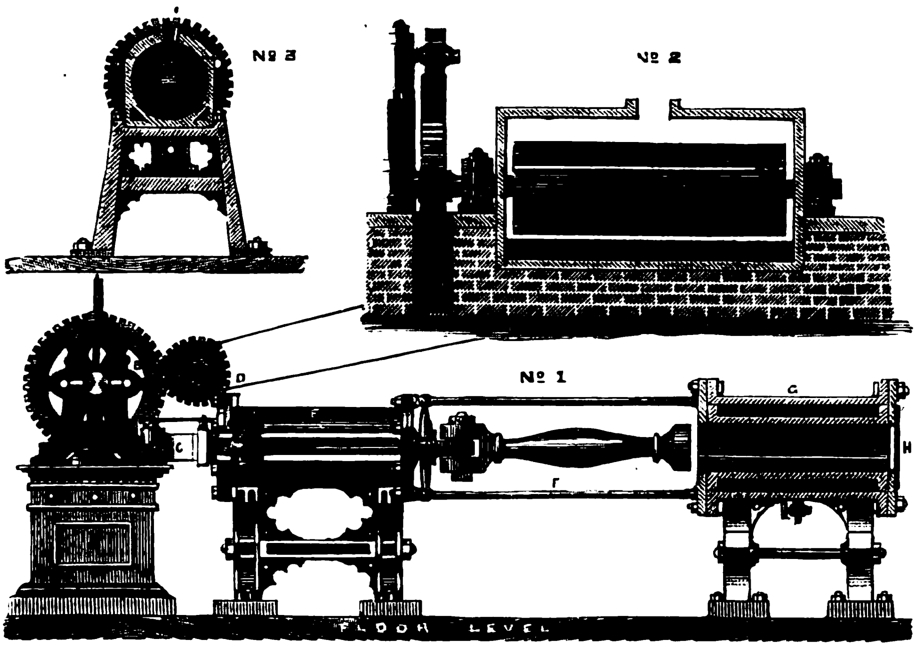
NOVEL METHOD OF SAWING TIMBER.

[4454.]—AN extremely original method of sawing timber has been recently patented in the United States by Dr. G. Robinson. It consists in applying a method hitherto employed in removing tumours from the human subject to the felling of trees and cutting up of wood. Most of your readers are aware that when a current from a galvanic battery is passed through a platinum wire the latter becomes red or even white hot. This red-hot wire is made to burn through a tumour or other excrescence which it is desired to remove, and the idea suggested itself to Dr. Robinson that wood might be divided in a similar manner. On trial it is said that this proved to be the case; for on pressing pieces of wood against a red-hot platinum wire through which a current of electricity was passing, and imparting to them or the wire a movement imitatory in a way of the action of a saw, they were divided in any required direction. By fitting the wire with handles so as to guide it in any and every direction the most intricate fretwork can be done. Some of your readers, who have the requisite appliances, will probably experiment and let us know the result, especially as to the cost of the process. G. J. H.

WIRE-COVERING MACHINES.—II.

[4455.]—IN reference to diagrams last sent (let. 4410, p. 381) of the wire-covering machines, I did not mention that the wire has to pass through the machines twice, and sometimes three times; if more than one wire is required two operations are needed to cover one wire. Sometimes three or four wires are made to pass through the same die, consequently there are as many separate currents of electricity; each wire has a separate covering first before it is made to pass through the same die. In order to prepare the material for covering the wire it is necessary to employ strong and powerful machinery. The tenacity of the material can only be understood by those who have had the working of the same. The writer has not only supplied these drawings, but worked the machines and worked and cut up tons of the material. Gutta-percha must first be cut up with a machine, by some called a "devil," next it is heated in a tank, the water kept boiling by steam; when sufficiently heated it is taken out and transferred to the masticator, whence it is thoroughly wrought into a mass resembling more the appearance of common putty, only of another colour, and more tenacious. It is then taken out from each masticator in masses of about 160lb., and transferred to the hydraulic strainer from which it has to pass through a fine wire gauze, backed by a strong perforated steel plate, after passing through this all impurities are removed. After undergoing several hours' more mastication it is again carried to the machine-room to be cut up in 80lb. pieces for small pickles or masticators, and after that to 40lb. pickles. When a wire machine is to be charged one of the 40lb. pickles is taken out and passed through hot steam rollers; as it passes through it is rolled up in a long roll and then cut in charges the size of the cylinders, and the screw plunger set to work. The second cylinder is charged in the like manner; as soon as the first cylinder is nearly exhausted indication is given by the plunger ringing a bell to summon attendance, the stop cocks are turned in turning off the exhaust; the charged one is turned on, the empty plunger is run out, and the cylinder recharged to be also in readiness at the next sound of the bell. No. 1 is the principle of the hydraulic strainer; A, water-tank, cog-wheels working four eccentric pumps; D, stop cocks for forcing piston and plunger, or withdrawing the same; E, cylinder; F, plunger; G, cylinder with vacuum for steam; C, safety-valves. No. 2, the 160lb. masticator. No. 3, end section of 80lb. and 40lb. pickle.

JOSEPH WILLIAM FENNELL.



THE NEGRO.

[4456.]—"FIDDLER'S" difficulty (let. 4365), which superficial would-be critics in every age continue to make, about deriving negroes and other varieties of man from one ancestor, Noah, overlooks the fact that no history, Biblical or other, has ever implied the existence of more than a quarter of Noachian or Adamite blood in any modern race. Our common father, Noah, is represented as the last Adamite, or member of that peculiar, last-formed, and noblest human race who lived commonly 900 years, had children at the end of five centuries, and in no case under the age (according to the most trustworthy copies) of 162. Such a race must have been, as Professor Owen has lately pointed out, different enough from any now existing, to merit, according to any extant zoological ideas, being classed as another *species*, rather than mere *variety*. Perhaps the rare but well-attested phenomenon, in all historic times, especially the most civilised, of very old persons occasionally cutting new teeth (as old elephants, &c., regularly do) may be a case of *atavism*, or casual reappearance of an Adamite peculiarity, inherited through our single Adamite ancestor, Noah. But did Noah, like his nine paternal ancestors, marry an Adamitess? The suddenly shortened life of his son, barely three-fifths of his own, and still more shortened in all that son's posterity, surely implies that Shem was only a half-blooded Adamite, and his mother one of the "daughters of men" mentioned in Gen. vi. 1, 2—*i.e.*, of the Nephilim or inferior and shorter-lived races, wherewith the higher caste of Adam, who had long been "called by the name of the Lord" (iv. 26, marg.), or had been a sort of Israel, or sacred, teaching and ruling Brahminical caste among antediluvian man, began first in Noah's time to intermarry. There is not a word to imply this new custom of "the Sons of God" had been forbidden, or was generally wrong, or inconsistent with Noah's character as "a just man and perfect in his generations." The latter phrase may mean no more than a monogamist, or may not refer to morals at all, but imply a man of perfect or pure race, he being the last on earth who was so. Now, if his youngest son, Shem—born after the first prediction of the Deluge, indeed above twenty years after (vi. 3, viii. 13, xi. 10)—was, as we see the story implies, a half-caste, there can be no reason for supposing his elder brothers higher born. But they were the sons of two, and probably three, mothers; of two at least, because Gen. ix. 21, corroborated by the Pagan proverb "as old as Japetus," implies Japhet to have been old when his brethren were not so; and decidedly older than Shem, even centuries older, would his *eldest* brother naturally be, if his father married, as all his forefathers had done, in their second century. But then the mother of Japhet cannot be supposed to have not borne her third son till two or three centuries later. The obviously greatest probability is that she died; and not only she but a second Mrs. Noah, the mother of Ham, some time later. This is implied by Shem being called (after Ham's posterity has been described) Shem, "the brother of Japhet the elder"—a brother of old Japhet in some sense wherein the intermediate Ham was *not* so. It may mean brother in character, or in maternal pedigree, their two mothers being of one race or nation, and in either case implies Ham to have had a different mother from both. But if, as is thus plainly implied, our three fathers were each a half Adamite only, and maternally descended of two, if not three, distinct non-Adamite varieties or species, each would be most likely to choose a wife of his own mother's race (if not of his father, Noah's, which may have been providentially prevented, or even forbidden); and hence their children, the first three born after the Flood, would be only quadroon or quarter Noachites; three of the grandparents of each being of one race, we know not how distinct from Noah, but if no further than present Malays, Mongols, and Negroes are from Caucasians, these first-born postdiluvians would be as different as a Sambo (or three-quarter Negro), a three-quarter Malay, and a Mestizo (or three-quarter Carib and one quarter European). And such dilution of the long-lived Adamite element is plainly implied, in Gen. xi., by the longevity in Shem's line falling *not gradually*, but first to about *half* the old standard, and then, after three nearly uniform generations, as suddenly to about *half* again. Doubtless the mass of antediluvians, the "flint-folk," and other kinds of Nephilim, had been shorter lived than ourselves, not having the quarter of Adamite blood that, as a whole, we moderns inherit one with another.

"Fiddler" must surely allow, then, that our common descent from Noah does not prevent our supposing the differences seen between human varieties to be far older in origin than his time, or even his ancestor Adam's. Not only does his story, when examined, make such differences probable, but I maintain it makes for one race being as specially marked off from other four or five as he says the Negroes are. It plainly represents Ham as more different from his brothers than they from each other. Now every son of these three must have married either a cousin or sister, and as we read of no law against the latter, though it would be naturally the rarer case, there would arise in the next generation six varieties, the purely Semitic, Hametic, and Japhetic, and the three sorts of half castes, more in number than the three former. Ham's and his wife's peculiarities in their full intensity could only descend in the family of such of his sons as married a sister. Now, of his four sons (Gen. x. 6) there is but one, Phut or Put, to whom Negroes, or central and south Africans appears traceable (see Nahum iii., 9, spoken of the city of Thebes, or No-Ammon). The other three, Cush, Mizraim, and Canaan, are well identified, as fathers of the dark but not black nations, they having doubtless married cousins, and only Phut a sister.

If Negroes were not Noachides, they would have no traditions or ceremonies alluding to the Flood, the Ark, the Dove, Noah's Sacrifice, &c. But such they have, as well as all other races. The *Jonkanoo* dance was a memorial of the great deliverance, which they still preserve in the West Indies, or did during slavery, though their masters, by making them repeat it for their amusement, at any season indifferently, eradicated its religious and chronological character. In Cynric R. Williams's "Tour in Jamaica," 1826, it is noticed. The chief dancer, though chosen for activity, wears an aged mask and white beard worthy of Noah, and the Ark is always represented by a model of a roofed vessel. The real marvel, in the varieties the traditions have taken among such separated tribes as Mexican, Chinese, Polynesian, is that so many should be recognisable and unmistakeable, when we consider how the priests of civilised ancient Egypt, for instance, had disguised the whole subject, to feed the national vanity with ideas of their fabulous antiquity. None, probably, could guess that in their story, as preserved by Plutarch, the killing of Osiris by his brother Typhon, floating of his divided body to sea in an ark, &c., was the killing of humanity, or the antediluvian civilisation, personified as Osiris, by the Flood, also personified as Typhon, &c., were it not for the chronological note that "all these things were said to be done on the 17th day of that month wherein the sun" (in Plutarch's time) "enters Scorpio."

If the most separated nations had not a common ancestor, it would be quite inexplicable how their theogonies came to agree in the attributes, relationships, and alliances of all their principal and secondary gods and goddesses. When Greeks or Romans learnt the mythology of any newly found distant barbarians, they had no difficulty in recognising their own deities. One nation could always tell which of another's gods was their Saturn, or Vulcan, or Pan, or Silenus, either by the characters or kinship and marriages; for marriages of every nation, however numerous, are all related, and married to brothers, sisters, or cousins. But this would not have been, unless the myths related to the same real persons, the children and grandchildren of Noah. They are seen through a multiplying glass, but rarely are two confounded. One man, by the different sides of his character, became various gods. Noah, being father and ruler of the golden age, but being also inventor of tippling, and these characters being too incongruous to adhere long to one subject, he necessarily becomes, as the great Saturn, one deity, but as Bacchus, quite another, among the secondary Olympians. So, again, he was in one view the father of gods and men, but yet was rather the past father, old Cronos, superseded, and his dominions taken by his three sons, of whom all nations knew, and how the youngest and yet mightiest ruled earth in a special sense, the most continental and dry regions, another the sea and "isles of the Gentiles," and a third the hottest lands and swarthy races. And all knew of the "war of the giants," the first rebellion of Cushites against Shem's authority, soon after succeeding to his father's peaceful rule of 350 years; agreeing not indeed with the corrupted and absurd numbers of the modern Jews' version and English of Gen. xi., but perfectly with it genuine readings, the Samaritan, and copies used by Josephus and all ancients; which make Peleg's birth, when "the earth was divided," 50 years after Noah's death.

Another coincidence between all the oldest nations' traditions, inexplicable if it were not a fact, is the identical change in the length all give to their reig[illegible] or generations about that Peleg's time. It is no va[illegible] memory, observe, that a long while ago our anc[illegible] were longer-lived than we. This is totally mi[illegible] senting the phenomenon, which is an extremely and precise one—namely, that whatsoever people have kept records of dated time professedly reaching above 24 or 25 centuries B.C. have all written the reigns, throughout these 43 centuries at least, of no greater average length than modern reigns, but all agree just as uniformly in making the preceding two, three, or four reigns, whichever number they record before that date, reigns approaching or exceeding a century. The Chinese do this; the Hindoos do it; the Persians do it; the ancient Chaldeans, Phœnicians, Egyptians, each did it, as testified by Berosus, Sanchoniatho, Manetho, &c. Now the length of reigns nowise depends, observe, on length of life, but only on the time elapsing between a father's birth and his son's birth. The last ten lords of any manor would have had no longer average tenure if they had all enjoyed the longevity of Noah. The coincidence of histories on this point, then, is totally distinct from that of patriarchal longevity, in which they equally agree. Thus, apart from length of life, the reigns attributed to the first four Chinese emperors from Fo-Hi (the father of the Ark) average the very same length as the contemporary four generations of Shem's line in Gen. xi., as preserved by the Greek and Samaritan copies (not, of course, as they appear in the Jewish and English, which have for these sixteen centuries been well known to have suffered intentional sacrilege in the shortening these numbers). E. L. G.

[4457.]—I am unable to give "Fiddler" any information as to the origin of the Negro (letter 4365, p. 358), but I write this simply to correct an anatomical error into which he appears to have fallen. The cause of the negro's black skin is not, as he imagines, a distinct "membrane consisting of minute vessels charged with fluids of the deepest hues." In order to make the matter clear, I will briefly explain the structure of the skin, which is essentially composed of two layers, the deeper being chiefly formed of fibrous tissue, the surface of which is raised into a series of minute elevations; in these the blood-vessels and nerves ramify; this is called the cutis; the other layer covers over the last superficially, filling all the depressions and serving to protect it; it is called the epidermis or scarf skin: it is entirely composed of cells, which being spherical next the cutis, become more flattened as they approach the outer surface. These deeper cells are called the rete mucosum; in the Negro they are filled with a black pigment, but excepting in the greater or less development of this colouring matter they are alike, as far as I know, in all races of man. To show that climate alone does not cause the black colour of the skin in Negroes, it is only necessary to mention the Esquimaux, who, living in the Arctic regions, are, nevertheless, very dark; moreover, they differ in colour from the red Indians, their next door neighbours in America. This fact sufficiently demonstrates the necessity of seeking for some cause, other than climate, for the variations in the tints of the human race. P. Santalinus.

[4458.]—When in Bombay a good many years ago, I remember hearing of (and seeing some of) a tribe which lived in some of the neighbouring districts. They were Jews, bearing the national stamp unmistakeable on their countenances, and therefore not mere proselytes. They retained many of the Israelitish customs, and kept themselves distinct from the other inhabitants. All this is nothing uncommon, but what is so, and is the reason I now mention them, is that they are the same colour as the Hindoos among whom they live, though other Jews of the same district are white. If I am not mistaken in my memory, various circumstances tend to show that these are descendants, not from the last scattering of the Jews, but of some very much older colony, possibly from the first captivity.

I mention this with the hope that some one who has had better opportunities of observing these people, and more full and accurate memory of them than myself, may furnish particulars. Such circumstances as this, and also the observation that the Americans born tend towards the type of the Red Indian, give support to the opinion that climate, food, and habits are the causes of all the varieties of the human race, though there is much to be said, also, in favour of their distinct origin, and that more particularly as regards the negro race. Sigma.

STONE COAL.

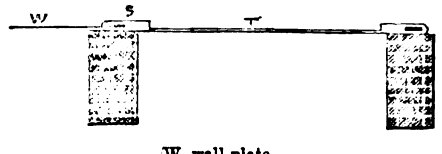
[4459.]—(4414, p. 381.)—Stone coal is so named from its hardness. It can be thrown about like a stone without breaking. It is a general name for the best varieties of smokeless Welsh coal used for malting purposes. Amateur.

METEOR.

[4460.]—On the evening of Saturday, 29th June, at about half-past ten, I observed a large meteor in the western sky. The night was clear, and there were scarcely any clouds. The meteor seemed to come from the neighbourhood of ζ and ι Ursæ Majoris, and described a longe curve westwards, sinking below Leo. Its colour was an orange red, and was of a dull light. It was much brighter than any star above the horizon; but might, perhaps, be compared to Regulus, only it was of much greater brilliancy. A long train of sparks followed, but were instantly extinguished. The duration of its visibility was not more than eight seconds. Antares.

BRANNAN'S SYSTEM OF MONOLITHIC BUILDING.

[4461.]—I accept the invitation of our "Harmonious" friend to give my views on the subject asked. It is my firm belief that doors, window-sashes, chimney-pieces, and even cart and carriage wheels might all be made in moulds from papier-mâché or some other agglutinative material, and be made as strong as, if not stronger than, wood or even iron. I believe many years ago that a very ingenious gentleman, by name Haddan, did take a patent out for the construction of railway wheels in a solid disc of papier-mâché; whether this has been adopted I cannot say. What has been done by Bielefield for full twenty years in the way of house decoration, where the great strength of the material is virtually thrown away, may, I think, be done equally well in articles of every-day use, such as tables, chairs, buckets, water-pans, &c. Considerable tact will, however, be required in the making of the moulds in such a form and in such a number of pieces as to insure perfect casting, and afford facility in detaching the moulds from the castings. I shall certainly try and see what Mr. Brannan has been doing in the way of concrete floors, and see if I can get a wrinkle. I may, however, state that in the house, or rather wing of a house that I have put up, I have availed myself of concrete floors turned on iron girders 10ft. apart, versed sine of arch 13in. I had intended to have placed wooden floors on sleepers let into the concrete, and bought the prepared boarding for the purpose; one room alone, however, has been boarded, that is the drawing-room, where, possibly, the grandchildren may want to have a dance. In the other rooms I have let into the concrete under the skirting a strip of wood 2½in. × 1in., to which the carpets can be nailed level with the floor, and to secure the wood I have nailed every two or three feet pieces of iron hoop about 15in. in length, and carried them under the concrete; nothing can exceed the strength of my floors. The house is, in fact, *one* solid mass. The shell of the arch is at the haunches about 6in., and at the centre about 3½in. I fill up the spandrils of the arches with dry sand, and over all I put about 1in. to 1½in. of *fine cement plaster*. I never leave the centres up longer than a week; on the eighth day I strike them. My stables and farm buildings are also built of concrete; in them both floors and roofs are of concrete without any iron beams. These I build all to one width—namely, 18ft., and carry my arch from wall to wall. I avail myself of the tensile force of iron inside to retain the arch in the place of a buttress outside. I place a piece of bar iron 5in. by ⅜in. or ½in., the whole length in the centre of either wall; at distances of 5ft. apart I have tie rods of ⅞in. or ¾in. iron, these are attached to the wall plate by means of a strap with two eyes, to which I bolt my tie rod.



W, wall-plate.
S, strap.
T, tie-rod.

In these buildings my versed sine is 1½in. to each foot of span, or 30in. for an 18ft. span. The most of these buildings are two storied. My work has cost me about 6½d. per cube foot for walling, and 8½d. for roofing and flooring. I find I can put my roofs on at a cost of about 57s. per square, not of roof, but of ground covered; this includes the blacksmith's bill. I have lately been constructing dairy and larder tables. These I have built on the principle of railway dry arches with flat surface on the top—versed sine of arch about ⅜in. to foot span contained by ½in. tie rods. Nothing can be more beautiful. One of the dairy tables has been made about six weeks, and is fully as hard as slate. The only objection I have to concrete is that it makes me a prisoner; I dare not leave it. I feel sure that some accident would occur. The so-called skilled labour of the English mechanic is so careless and self-conceited that it is not enough to show how a thing is to be done, but one is compelled to sit over the work and actually see it done. I have had two narrow escapes: in one case owing to bad workmanship of the blacksmith, in the other to the conceited ignorance of the carpenter. If concrete be properly done I do not hesitate to say that it can be done at 30 to even 40 per cent. cheaper than brick-work, and four times stronger. The material must be not only of the best and cleanest sort, but must be thoroughly mixed, not too moist, and well rammed. Railroad speed in putting filling over filling must be avoided; at the very utmost the frame should not be filled more than five times in a fortnight, better if only three times. This, of course, involves a considerable outlay in framing. I have, or rather had, about 500 running feet at work at a time. One learns, however, as one goes on, and were I to start again I should go a much cheaper and more expeditious way to work than I have done. The corners have always been the great difficulty, and a great deal of ingenuity has been spent to little purpose in all sorts of patented corner frames, all of which can be avoided by a little arrangement of the frames. In concrete arching it is best not to nail the ligans to the ribs; it is also as well to bear in mind that if they are kept a little apart it is much easier to take them down; the small irregularities in the soffit of the arch form an excellent key for the plasterer. With reference to the flat floor made by Mr. Brannan with the aid of a network of wire, I think the same thing can be done equally well and conveniently with good hoop iron, provided time be allowed for it to dry. The elder Brunel, I believe, made a floor 15ft. square with nothing but three tiers of 1ft. flat tiles laid in cement on a wooden platform, breaking joints in each tier. I believe there is a raised terrace to a public-house, somewhere near Notting Hill, on which our London friends may be seen enjoying their beer and 'baccy pretty thick on the ground, of larger dimensions than the above, but made in the same way. For my part, I believe a monolithic slab of floor might be made of any size self-supporting, provided the materials were good, and time given to let it harden thoroughly. In Bengal, the floors and roofs of houses are all flat, and made of large sâl beams, 3ft. or 4ft. apart, across which are placed 3½in. × 1½in. battens, a foot apart; on these battens are placed two tiers of tiles, 12in. square, 1in. thick, and on the tiles a mixture of broken brick, brick-dust (called soorkiug), and lime, to the thickness of 5in. or 9in., which is beaten down to about 4½in., and plastered with a preparation of jaggery (coarse sugar) and lime. This forms an excellent roof. I mention this in connection with a monolithic floor for the reason that in one of the old abandoned factories of the East India Company in Beerbhoom the natives had cut away all the beams of a room 23ft. by 35ft. or thereabouts, and the floor made of the materials above mentioned remained like a vast flagstone for years. Our "Harmonious" friend alludes to the desirability of building at a cheap rate dwellings for the labouring classes, in which the young, male and female, may have separate dormitories, and the heads of families be somewhat better lodged than they are at present. There is a pretty strong fever on that subject just now, and a number of architects are planning and contriving all sorts of cottages, and publishing their devices in all sorts of magazines, journals, and pamphlets. Many of their designs are no doubt clever, but I have not seen a single plan that accords with my notions of the requirements of the case. Great taste has been shown in the architecture, great consideration for the intended inmates, but at what cost? I have never seen any of these improved dwellings for the labouring classes that are in reality within the reach of the wages of the labouring classes at a proper rental. A dilettanti landowner, newly made, with an enthusiastic wife and daughters given to Dorcas and good deeds, may stud their acres with model cottages, and let them at rentals of two shillings a week, realising a percentage of 3 or 3½, but this is not the sort of building that will do for the masses, who are left as badly off as ever. What is wanted is a class of dwelling, with no external ornamentation, but as much internal accommodation as can be given at a rental of 1s. 6d. to 2s. a week, and to pay a return of not less than 5 or 6 per cent. to the builder. I can see no other way of doing this than by building lower roomed cottages entirely of concrete, including floor and roof, not a bit of wood in the construction save and except in the doors and window frames. At this present moment I am just finishing a cottage for my gardener, in which I give a living room 10ft. × 15ft.; parents' bedroom, 10ft. × 12ft.; girls' room, 10ft. × 8ft. 6in.; boys' room, 10ft. × 8ft. 6in.; and scullery, 10ft. × 8in., making altogether a floor surface of 520 superficial feet. All the bedrooms have fireplaces, not simply for fire, but for ventilation. This cottage, when completed, glazed, painted, fitted with fire apparatus, and a porch at the entrance, and necessary outbuildings, I shall be able to do at a cost not exceeding £85. This would let readily in the neighbourhood for 2s. 6d. a week. I have put no fireplace in the scullery, simply a ten gallon boiler. My reason for this is, that if the back kitchen or scullery is too good, the occupants dwell in it like pigs, keeping the main living room as a show place. A friend of mine has built a pair of model cottages where he has a fireplace in his back kitchen, consequently the main room is never used, but kept shut up and always smells mouldy, and redolent of turpentine and beeswax, laid pretty thick on an eight-day clock, and a highly varnished chest of drawers. My work has been done hitherto with concrete made with Portland cement. Within the last fortnight I have been trying concrete made with General Scott's selenitic lime and selenitic clay. It would be premature to draw conclusions; I may state, however, that the three or four hundred cubic feet of concrete wall which I have made in that way promises well, and if it should answer expectations, I shall be able by the use of the selenitic clay and lime to save not less than twopence per foot cube, notwithstanding that for its proper manipulation it requires 25 per cent. more labour. Before I conclude I may state that I am plastering the inside of my house with this selenitic mortar, and that at less than half the cost of plaster made with ordinary lias lime, I am getting a beautiful face for either paint or plaster, without a vestige of a crack to be seen anywhere. So good is it that a well known architect who came to visit my place was after a long conversation with, and numerous queries put to my plasterer so well satisfied with it as to tell me he should insert its use in the construction of a row of houses about to be built under his plans and inspection. And now for a word for our English Mechanic. I shall be always happy to give to its readers the results of my experiments, although gout in the hand makes writing a task, as the hand cannot keep pace with the idea. An article that would a few years ago have taken forty-five minutes, now takes three or four hours. I have for the weekly twopence picked up so many ideas from the writings of "Sigma

"Jack of All Trades," "The Harmonious Blacksmith," "Philo," and others, that I feel it almost a duty, if not a pleasure, to contribute something on matters in which on experiment I have either failed or succeeded.

KHODA BUX.

MONOLITHIC BUILDING.

[4462.]—THE letter of "our" esteemed fellow-worker, "The Harmonious Blacksmith", on this subject is of great interest as adding one more blow to that assault of truth on the barriers of prejudice, ignorance, and self-interest, to which they must inevitably succumb sooner or later. That this style of building should meet with much adverse criticism and abuse from members of the building trade is only what might fairly be expected, seeing that its employment tends materially to diminish prices; and certain of the arguments employed have, as it is only reasonable to suppose they would have, certain right and truth in them as, for instance, the very favourite one that the work being mixed and constructed in courses it is practically impossible to give each course the same consistency, and hence weak places result. Now, just for argument's sake, grant the objection to be well founded, and let us see what results. We have to compare the strength of joint between a mass of stone and the like in concrete; the stone is smooth-tooled and bedded together with a thin layer of cement or mortar. The concrete is left with a surface more or less rough, according to the size to which the staple material has been broken, and into every crevice of this surface the cement of the next course must run. Now, I venture to suggest that no great effort of mind is required to see that such a joint must be by far the stronger, and granting that the material is not in itself of equal tenacity with stone still the superiority of joint renders a wall of concrete superior in point of tenacity to one of stone; as the weakest link in a chain constitutes the measure of its strength, so must the value of the wall be measured by the strength of its weakest joints. With respect to floors, again, I have no hesitation in saying that the plan of open joist floors as generally used in this country is a palpable absurdity, which, combined with lathe and plaster partitions, renders an English house the nearest akin to a tinder-box possible to imagine, in addition to which all this soundboarding, tends to give to the interior of our dwellings such a drumlike character that peace in any corner when the children are at play is as a rule altogether out of the question. Now, with a truly monolithic structure fire would be next to impossible. The system pursued in France of making all floors and partitions of plaster concrete with iron joists for the floors and oak quartering for the partitions is sufficient to render the buildings almost fire-proof, and as for sound in a well-constructed house a dancing party overhead does not materially interfere with one's comfort. What, then, may we not expect from a truly monolithic structure, ribbed together and braced where requisite with iron? I do not hesitate for one moment in saying that such a structure is as much superior to an ordinary brick and mortar one as that is to a weather-board shanty. Ventilation of the question cannot but tend to good, and I trust that the subject having been taken up we may have from the army of readers of "ours" many valuable suggestions.

W. G. C.

THE HARP.

[4463.]—THE extreme grace and beauty of the harp, the simplicity of its construction, its cheapness, and permanence, lastly its effectiveness as a musical instrument, justly combine, the writer conceives, to commend it to the favourable consideration of every one. Of great antiquity, its image has been found sculptured or otherwise depicted on the Egyptian tombs. It was on the harp that the old Irish performers played, and it was on and for the same instrument as well as for the voice that they composed those glorious airs which render Irish and Scotch music the delight and solace of the world; strains, the love of which Edward Bunting tells us ("Prospectus of a General Collection of the Ancient Music of Ireland," p. 3) neither the experience of the best music of other countries, the perverted public taste, nor the influence of advancing years, has been able to control or diminish. Therefore it is that I wish to see both instrument and music introduced into our dwellings, and brought within the reach of every one. Bunting, indeed, is never tired of enlarging on the merits of his favourite instrument. The Welsh, who appear to have derived it from the Irish, have carefully preserved its use. It is heard in the concerts of London. It is played upon in Italy, France, and Germany. It is the national instrument of Ireland. It may be produced in a cheap and yet efficient form. It possesses merits which the piano, with every improvement, does not share. I would not put down the piano if I could, but let us have the harp also. And let it gladden abodes in which there is no room for the piano, an instrument which the purse does not always suffice to reach, even if there were room.

The piano, however admirable in many respects, is a costly and somewhat perishable instrument, and under existing circumstances is certainly not fitted for every man's dwelling. Begun with one string to each note, it then included two, and finally three strings. Difficult enough to bring into tune, or to keep in it, the piano in many ways is less desirable as a popular instrument than the harp. The harp, if simply constructed, is a very much cheaper instrument. It lasts longer, it is tuned by the player; and, finally, the string of gut or metal is manipulated by the finger of the performer instead of being separated from it by a series of complicated wooden levers which, in some measure, impair the expression, and render the instrument more perishable. The pianoforte is a harp in a box. But if we keep the harp out of the box, we can obtain a vastly cheaper, more enduring, as well as in some respects more expressive instrument. For as many shillings as the piano numbers pounds, we may obtain a cheap, portable, and reasonably efficient instrument that, without impeachment to the real merits of the pianoforte, would suffice to realise most of the satisfactions realisable by music which could be taken into the garden or brought down to the sea-shore, and further prove an excellent accompaniment for violin or voice.

I am desirous, then, of turning the attention of the general public to the importance of musical culture in general, and of the harp in particular. I do not think that musical culture should be confined to musical dilettante, thinly scattered here and there, but extend to the youth of the whole community; in fine, that it should constitute an integral part of general education. Every one should learn to sing, every one to play on two instruments, of which I would have the harp one. I dare say that there might always be some whom accident or disinclination should disqualify, but, in other respects, I would have musical culture as much the rule as the absence of it is now found to be. I shall not enlarge on the excellence of music. Every one who peruses these lines is, I dare say, as much persuaded of it as I am myself. Music, in truth, is one of the stepping-stones to a very great enjoyment, and, if not the only, is at any rate among the most stainless that earth affords.

The harp has been in use in England itself from a very early period. It was under the disguise of a performer on this instrument that King Alfred obtained admission into the Danish camp. In Scotland it was also well known, and we learn from Mr. Gunn, in his history of the instrument, that Queen Mary's harp is still preserved in a noble Scottish mansion. The writer of these remarks has had constructed a facsimile of King Brian's harp, as preserved in Trinity College, Dublin. This beautiful instrument he would wish to send to Kensington, but, beautiful as it is, one of much simpler construction would suffice for all ordinary requirements.

The common Irish harp, of some six-and-thirty strings, or five octaves, is strung with wire, the eight lowest strings of wire No. 18, the next six of No. 20, the next seven of 22, the next seven of 24, and all the rest of 25, or five numbers in all. The wires below the middle G on the harp now beside the writer, and on which many performers have in succession discoursed, are of brass, but the upper register consists of ordinary steel pianoforte wire. But wrapped wire would, doubtless, admirably answer for the lower registers. This, however, is a matter of detail which, should the harp come into vogue, could be settled at any time. The French harp, so named, is strung with gut, and, as recently constructed, is provided with an apparatus for altering the key. The Irish harp was and/is played in but the two major keys of G, one sharp and C natural; but the F and C strings could be raised or lowered at discretion. I have heard the most admirable performers, Italian, French, English, Welsh, on the gut harp, a harp perhaps costing a hundred guineas or more; but, speaking for myself, I found the execution of some poor blind Irish player on the wire harp—that could, I dare say, have been constructed for some 30s. or 40s.—go far more directly to the heart. The wire harp—on which Irish harpers, going on traditions of more than a thousand years, always play the treble with the left hand—I earnestly commend, as a sweet, cheap, and most effective instrument, to the attention of the readers of the ENGLISH MECHANIC and the English community generally. The instrument, if made of a simple bow and sounding-box, would cost the merest trifle. A strong angle-piece of brass or iron would do away with the necessity of an upright pillar; wires, brass and steel, are very cheaply to be obtained. The wires at their upper portion are secured and tuned—*i.e.*, tuned precisely as are the strings of the pianoforte. The lower portion of the string passes through a hole in the sounding-board and is secured to a loose peg or bit of wood behind. Apertures sufficiently large are made in the back of the sounding-box to yield admission to the hand when adjusting and securing the string. The holes through which the strings pass in front are fortified by little triangular bits of metal, or a perforated metal plate, properly fastened, can be substituted. All difficulties in regard of tuning may be got rid of by having recourse to one of Debain's tuned, I believe, metal reed octaves, for I am not quite sure, which he has arranged for the use of pianoforte tuners, and the name of which I now forget. I believe the universal introduction of the harp, gut or wire, and without prejudice to other instruments, would prove the greatest boon to the lovers of the divine art of music that can possibly be imagined, and in this light I most earnestly urge its universal adoption.

IXION.

FIDDLES.

[4464.]—PRACTICE is the only way to decide a theory. Thick strings sound louder, as a contra bass will drown a kit, or, perhaps, a violin—although in the latter case I doubt it. Some may remark, because the tones of each are different, one bass, the other treble. Very good. But I mean both playing the same tone, say upper C, or any of the higher notes; the contra bass would stand a poor chance. You may use the force necessary to produce the tone on the bass, and apply it to the violin, and (cruel treatment it would be!) the result would be a shriek. Now, it is apparent that if we bow too hard, which we must do if the string is too thick, we stop the vibrations as though we put a weight on the string. The bow remains on the string, also the pressure, not so the hammer of a piano; there the string is released. In the contra bass we have large strings, which, when played on in the upper region, become useless as representing violin tones, and Bottesini or any other man could not play solos with effect without the use of harmonics, or by having the instrument strung with thinner strings, which would be a mistake, as far as tone is concerned, but excellent for manipulation. Then the reason why a gut string will not move more than one soundboard is, that it cannot bear the pressure or weight sufficient for that purpose. If thicker gut is used it becomes a bass instrument, for it will not tune up to the desired pitch. I do not mean to say that the pressure of the bow would break the gut, but it would stop the vibration. With respect to a fiddle-string being tuned higher than it is usually, the manipulation would be difficult both as to insuring a clear tone, and fingering. Of course, it could be done if the strings did not break, which they certainly would. That "tubby" tone noticed by "The Harmonious Blacksmith" is the rigidity caused by over straining the string with the weight of tuning, or so many more pounds pressure put on it by means of the peg. Now, Paganini used thin strings tuned high, and produced a tone equal to a piano. I think he was right, but the tuning, fingering, and everything would have to be different; but it is most important to know this, as we take advantage of the present construction without altering it; rather a serious matter to do.

As to the reflectors or soundboards (it matters little—"What's in a name?"), I feel pretty confident they will come in use when known. The late M. Jullien would have made use of them, for in an orchestra an entirely new effect can be made. I presume the reason why a violin sounds louder in an empty room is, because the sounds have a larger plane or flat surface to act upon or react without an interposing medium. May not my reflector act in the same way, considering that it presents a tolerably large surface for the tone to act upon?

FIDDLER.

AMATEUR ORGAN BUILDING.

[4465.]—THANKS to Joseph William Fennell (letter 4372). I, however, propose to place a harmonium pan vertically upon the bellows frame, containing twelve rosewood reeds, from CCC to CC (the 16ft. tone), without pipes, but with tuning wires to supersede the stopped 8ft. pipes.

The specification is as follows:—Open diapason, 8ft., metal (12 lowest, Green's stopped metal pipes, tuned by the ears), 56; dulciana, 8ft., tenor C (grooved to base of open diapason), 44; Lieblich Gedact, 8ft., 56; Wald flute, 4ft., 56; oboe, 8ft., 56; principal, 4ft., 56; Bourdon, 16ft. (the 12 rosewood reeds); one row manuals, CC to G; no swell-box; 2 octaves pedals attached to keys; no coupler; Bourdon stop shuts off wind from harmonium-pan.

Is the organ balanced? If Wald flute is only taken to tenor C, will it give more scope for solo playing, or will it be a worse organ, having less base? If a harmonic flute, which is a 4ft. metal pipe overblown, thereby giving a 2ft. tone, be substituted, shall I benefit by the change? How is the harmonic flute made, and what is the scale with reference to the open diapason; does it require a special pressure of wind? Any information as to the softening of the oboe will oblige. Not feeling myself competent to give information on organ building matters, I have endeavoured to suggest in my queries such data as almost all amateurs must require, in order that the space may be rendered common to at least a large section of readers.

DRAUGHTSMAN.

WOOD PULP FOR PAPER-MAKING.

[4466.]—A STEADY and considerable advance in the price of rags, from which unsavoury and unwholesome materials our cream-laid note and other glossy papers are usually manufactured, has coincided with a fall in the price of paper. The apparent anomaly is easily explained. It arises that from time to time very different materials have been pressed into the service of the paper-maker. Straw is well known as the material from which a tolerably good paper is manufactured. Spanish grass (*Spartium spygarem*) has been utilised to a large extent in some of our paper-mills; in fact, so much so that the streams have been dyed and the fish poisoned wholesale by the foul refuse which is left in the process of manufacture. The bark and even the woody fibre of the paper mulberry tree (*Broussonetia papyrifera*) is used exclusively in Japan, the cunning industry of which almost unknown country produces no less than ninety distinct kinds of paper. This I can vouch for, having seen the Japanese at work during my five years' residence at Yokohama. In 1865, 70,000 tons of vegetable fibrous substance were imported by the paper-makers of the United Kingdom. And now, on the Continent, we find that wood is used in large quantities for the same purpose.

Heinrich Voelter, of Heidenheim-on-the-Brenz, in the kingdom of Wurtemberg, is the inventor of a successful method of manufacturing a tolerably clean white paper pulp from wood at a low price. It does not require bleaching. He has, I believe, obtained patents for his process in almost all European countries and America. It is adopted by all the large paper manufacturers of France, Belgium, Germany, Switzerland, Norway, Austria, and Canada. A single paper-mill in Germany consumes yearly 500 tons of wood pulp, and scarcely a newspaper is printed in Germany which does not contain some proportion of this material.

The cost of the paper pulp produced from wood is stated to be nowhere more than half the cost of rag pulp, and considerably less where there is a good supply of wood and water-power to drive the machinery. If of inferior quality as regards what is called the luxury of paper, the article thus produced from wood is tough, but serviceable and well adapted for printing. By mixing wood with rag pulp in various proportions, papers of different sorts may be produced at moderate prices. For printing papers, either white or coloured, from 30 to 70 per cent. of wood pulp is mixed with that produced from rag fibre; 85 per cent. of pine-wood pulp gives a common tinted drawing-paper; from 30 to 50 per cent. of wood pulp serves for writing-papers of various colours, the latter proportion of pine-wood pulp being used for an ordinary blue letter-paper, which takes the ink easily and is pleasant to the touch of the pen. Coloured papers for book-wrappers, tissue-papers, paper-hangings, cardboards, are all produced by similar instances in various proportions. No single article of manufacture can be taken as a more distinct test of the state of civilisation than paper. Besides all those subsidiary purposes of wrapping and packing, the direct use of paper for the spread of intelligence for the communications necessary to commerce and for the service of literature need only to be hinted at. The reduction of cost of this necessary is thus one of the many boons to mankind. H. B. E.

CONDENSATION OF STEAM IN PIPES.

[4467.]—I AM desirous of conveying steam of 294° initial temperature, 45lb. super pressure per square inch, through 2in. wrought-iron gas tubes, in all 850ft, underground:—*i. e.*, in the first instance 300ft. horizontally, then 200ft. vertically downwards, then again 140ft. horizontally, and finally vertically downwards to engine 210ft. The present temperature within the mine averages 60°. I require to know:—1. What amount of total condensation will take place, the steam flowing through the tubes at a velocity corresponding to the requirements of a steam-engine 8in. diameter of piston, and making 250ft. (piston speed) per minute. The tubes to be supposed as non-clothed, but otherwise kept dry. 2. Difference of initial and terminal pressure of the steam, *i.e.*, between boiler and valve chest. 3. The best way to draw off the water resulting from condensation previous to steam entering the cylinder. 4. The waste steam from engine must be carried away by a 3in. tube going up vertically through a shaft direct to surface, a height of 450ft. This shaft has a strong downward air current, so that in winter it often freezes therein to a depth of 70ft. from surface. There would doubtless, therefore, be also a large amount of condensation in the waste steam-pipe as well, which, however, could probably be accommodated by a proportionately open tap at the bottom. 5. If the temperature within the mine is likely to be raised disagreeably high by steam-heated tubes and resulting hot water. 6. The probable difference in point of fuel consumption as compared with a close proximity of engine to boiler, all else being supposed the same. 7. If in consideration of there being no dead material, in the shape of rods, cranks, &c., to move, this system may be regarded for draining purposes as equally cheap in point of fuel consumption with the more usual methods. I should, perhaps, mention that the tubes would be suspended freely in the shafts and levels of the mine. Any information on the foregoing will be gladly received by

Cologne. A. W. E.

DRAINING MINES OF WATER.

[4468.]—I AM given to understand that of late compressed air is being employed for driving pumping machinery fixed down in mines at convenient points for draining purposes. Would some kind contributor to "our" journal, who may have had experience in this way, give me information thereon? I require an effective power of about six horse-power for this purpose, and its application to the pump, 440ft. horizontally and 410ft. vertically away from the point at surface at which the production of the compressed air could take place. I am, however, uninformed as to the question of cost of power thus obtained. The compression would in the first instance have to be effected by a steam-engine, either direct-acting, or air-pump, or otherwise, and the air would have to be compressed, as stated, to a distance of 850ft. The most suitable pressure, with a view to a possibly small engine within the mine, would be 60lb. per square inch above atmosphere, and it would be desirable to use the air expansively for the sake of economy. In order to compare with other pumping arrangements it would be necessary to know what relative power to that given out would be required to compress the air at surface, and the probable duty obtainable from a bushel of coals thus indirectly consumed in the production of power. The absolute work to be done is that of raising 2,000 gallons of water 410ft. vertical height per hour.

Cologne. A. W. E.

TURRET CLOCK LINE.

[4469.]—WILL some of "our" readers kindly give an opinion of the following idea:—In case of turret clock lines breaking, it has been suggested that a stout wooden bucket (just large enough to freely admit the weight upright) fixed to the floor directly under the weight's position, with three springs screwed to the bucket inside, bending to the centre, and a cushion at the bottom, would break the force of the fall, thereby preventing injury to anything beneath the tower floor. The idea, I think, is remarkably good, providing the weight shall fall exactly perpendicular; but to suppose it would in my estimation is positively absurd, as I naturally suppose that any substance whose length is greater than its breadth, or, that is not of spherical shape, is acted on in falling more or less by the force of gravity and air pressure, causing any such substance to turn over and take an indirect course, the same as an ordinary rifle bullet fired from a smooth bore would by no means take a direct line. And as well as the action of gravity and air, a falling clock weight would, in violently snatching the piece of loose line through its pulley, be pulled on one side, and I think the probability is that in a fall of 80ft., a weight of 200lb. would reach the ground at quite an uncertain point, and possibly 2ft. or more out of a perpendicular line. A firm kind of mattress would then be one of the best means of checking the force of such a fall, and buckets for that purpose, I believe, are useless; but for satisfaction I shall be obliged to any one that will give an opinion on the bucket idea. CURIOUS.

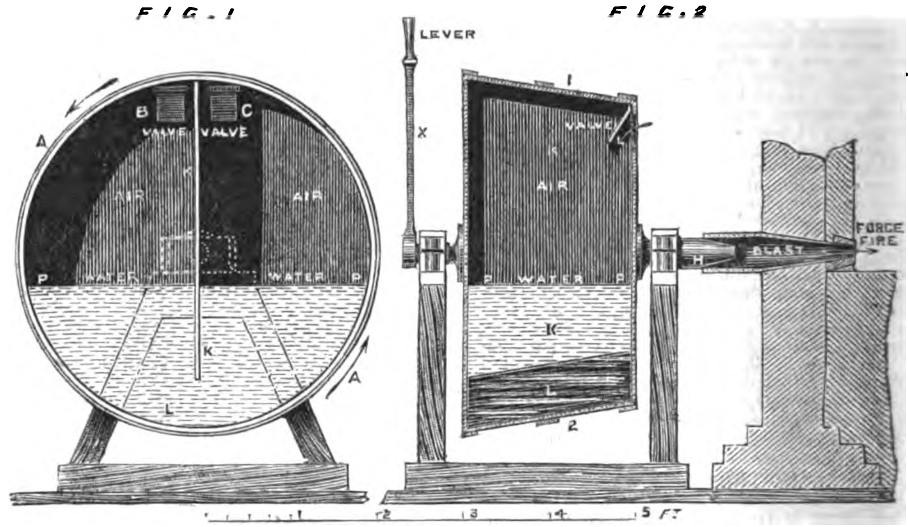
WATER BELLOWS.

[4470.]—HAVING often seen inquiries in your valuable paper about a useful kind of bellows for a smith's forge, I send the accompanying sketch, which I trust will be easily understood. The machine is called a water bellows, and is made of wood—hooped, staved, and headed same as a cask. The taper is to allow hoops to be driven up tight. There is a division in middle K of wood, and a space about 6in. left at bottom L for water to pass through. Two valves B and C of leather are fitted (about 6in. square) one on each side of division K. The lower part of cylinder is filled with water P; a pipe H conveys blast to furnace. When the machine is turned in direction of arrows A, air enters at C, valve B closing. When the machine is reversed in motion, valve C shuts and valve B opens, and *vice versâ*, the air being discharged at pipe H, Fig. 2, which acts same as a trunnion, the water P always keeping its level, but the spaces on each side of division K are lessened and increased as the machine oscillates backwards and forwards by lever X, or any other contrivance to give the required reciprocating motion. The air is constantly being drawn through valves B and C, and discharged through pipe H to fire.

The advantages derived from this machine are cheapness, that there is a very steady blast, and no leather required except for valves B and C, and little power necessary to work it.

The above could be made of metal. I have seen one of these bellows at work for a number of years with good result.

Jamaica, W.I., May 28. HYDRO-VULCAN.



SEWING MACHINES.

[4471.]—IN reference to the Robin Hood sewing-machine described and figured by R. Tansley (letter 4378, page 355), I should like to know whether he has used it, as well as "invented and made" it, as he says, and also what good on earth it can be to have a sewing-machine with ten (or even two) needles set close together in a row. It is self-evident that the work must pass through the machine either at right angles to the row of needles, or in the line of said row. In the former case you will have ten closely-packed lines of sewing—*Cui bono?* and in the second alternative, you will have but one line of sewing, but done ten times over; and a pretty mess it would be. And *cui bono* again? The only way out of the puzzle that I can see, is to suppose the feeder has a monstrous long-stitch motion, and makes the work jump through for the length of ten stitches at each go. What an artful dodge! not very pleasant, though, for the operator; and I cannot suppose that any woman would be induced to use such an alarming apparatus even by the temptation of making 2,000 stitches a minute," or "more stitches in two minutes than she could make by hand in one day." I had all but overlooked the fact that each stitch would also be the length of ten stitches, unless every stitch were separately fastened off before the feed made its next stride. But I am puzzled and give it up. Surely no fellah can understand it. The House calls vehemently upon R. Tansley to "Explain, explain!" He has judiciously omitted to show any trace of the stitching and feeding machinery. Surely the whole thing is a "goak," to which the inventor seeks to add piquancy by the naive inquiry "if there is such a machine at work."

"W. H. T." asks (query No. 12247) after a wheel-brake for the Wheeler and Wilson sewing machine. Mr. Mabson, of Newcastle, some years ago invented a very simple and effective one, which, with his other improvements, is applied to that form of the Wheeler-Wilson called the "Belgravia," but I believe it is patented. It consists of a wedge-like piece of wood suspended on a pivot above and towards the front of the fly-wheel, to which it offers no resistance when travelling in the right direction, but at once wedges it tight if it tries to go wrong. Mr. Mabson's inventions were described in the ENGLISH MECHANIC some two or three years ago, but they have been much improved since. The names applied to them are mostly rather stupid; for instance, this brake is called the "wheel preventer," and sometimes "preventer" simply. The one in plain English means a thing to prevent wheels, and the other, to prevent anything in general. This by way of parenthesis.

Neither the "Belgravia," however, with all its advantages, nor any other form of the Wheeler-Wilson that I have seen, has any means of starting the machine above the table—a most important desideratum, which Singer's, Thomas's, and many other machines possess. Instead of that, the operator has to leave go of the work with the left hand—the very one that is most required in guiding it—in order to give the fly-wheel a shove; or else, very awkwardly, to cross the right hand over the lap and under the table, and all amongst the work. In every other respect the Wheeler-Wilson—and especially in "Belgravia" form—is surely the most effective and uncomplicated of all lock-stitch machines. It has of late had applied to it an improved feed, called the "Archimedian," which works by cams on the spindle, giving positive motions only, and thus dispensing entirely with springs. The only springs in the whole machine, in fact, are those of the tension discs and of the cloth presser. The latter is adjustable to the requirements of different fabrics, by an ingenious contrivance. I hope "A Practical Man" will give a good critical account of this machine and all its parts. If he does not, I should like to send you a drawing and description of the "Archimedian" feed aforesaid.

G. W. K. L.

THE PHENOMENON OF ARGOSTOLI.

[4472.]—IN reply to "Sigma's" questions (let. 4353, p. 352), the phenomenon at Argostoli having been under my observation for about half an hour only, and not at the time being provided with the means of taking the levels asked for, I can only reply from memory and judgment, which, however, will be pretty near the mark. The transverse section of the point of ingress of the sea-water, and also of the channel along which it flows to the point of disappearance, may be represented by the letter U. It will be about 5ft. across and 7ft. in height, with about 3ft. of water along its entire course. (I am speaking of the particular time when I saw it, of course.) The channel is circuitous, and the gradient of its bed will be about 1 in 40. The final level of the surface of the water is precisely what I am desirous of getting at. The water pursues its course through and along an aperture in the rock, which rises abruptly across the channel, and is speedily lost in darkness.

As my guide informed me that the water is always running, and there being a depth of 3ft., while the sea level in the Ionian sea is rarely disturbed to the extent of more than about 2ft., the flow, or rather descent, is, no doubt, continuous.

Boats can approach the sea barrier close to the point of inrush, but the channel is too winding for a boat to traverse. There is no appearance of a reef either close inshore or in the offing; indeed, I can speak positively as to this, for I saw nothing of the kind in reality, nor do I find any indication of one in a plan which I have before me of Port Argostoli. As to a race or strong current, so far as my experience went, there was no evidence of either. I have been riding at anchor in various parts amid the Ionian Islands—once for five months between the Islands of Corfu and Vido—and we always rode "head to wind"—*i.e.*, of course, when there was any.

"E. L. G." mentions five points at which the sea rushes inland; the probability is, therefore, that this description may not apply to the other four; however, the phenomenon is the same. As this matter has had "E. L. G's" attention, perhaps he will give us his theory, for I am sure he has one. "Sigma," too, and several others, might give their opinions on this very interesting question. J. W. RODWELL.

THE ANCIENT CONSTELLATIONS.

[4473.]—I AM quite at a loss to imagine what Mr. Proctor means by any one of the constellations (let. 4408, p. 380) having "got its name from its aspect," but the "very strong evidence" about the four named will perhaps enlighten me. He can hardly mean that the stars scattered over the wide-spreading Argo so connect themselves, apart from others, and into a ship-like or canoe-like form, as to have suggested this form (turned in all manner of positions) to the most separated races of men! As little does it seem conceivable that tribes of both hemispheres, regarding the present winter quarter of the ecliptic, would find its stars divide themselves into three groups, and these suggestive of a centaur archer, a goat-fronted walrus or seal, and either a pourer or pouring vessel of water! Which of the latter (as the same stars make both) does the "aspect" suggest? The grand fact about the zodiacal signs, we must remember, is that not their figures, but only the ideas—only the meanings of their names, are everywhere identical or connected, some or all. The Chinese, most peculiar in this as in most other matters of tradition, seem, indeed, to have but one or two of the twelve identical with ours, and one or two connected in ideas—as dragon for lion, serpent for scorpion, mouse and hare for ram and crab. But, in the second volume of "Asiatic Researches," Sir Wm. Jones has an essay to prove the independence and antiquity of the Indian zodiacal signs, whose names he translates, beginning at our Aries, as "Ram, Bull, Pair, Crab, Lion, Virgin, Balance, Scorpion, *Bow*, Sea Monster, Ewer, Fish." The Bow, he further says, consists of "eleven stars, the γ, ϵ, δ, ζ, ϕ, τ, σ, ν, o, ξ, π of the Sagittary." Maurice, in his "History of Hindostan," maintains that the oldest authorities make it only a bow, with neither arrow nor archer; and it was connected with all the neighbouring asterisms, especially the Ship, the Altar (both, admittedly, of immemorial antiquity, and known to all tribes that had constellations), and the Victim and Sacrificer, which classical authors allow to have rightly and originally accompanied the latter, though the Sacrificer has curiously turned into a second "Centaur," and the beast in his hand, which Ptolemy knew only as a "Beast" undefined, has since become our "Lupus." Besides these seven of the most ancient asterisms, those writers claim to identify with Noah's history at least four or five more; without going to the length of Jacob Bryant, whose three great quartos of "Analysis of Mythology" (unhappily without an index), they admit to have brought "an overwhelming body of evidence," for the Noachic origin and meanings of not only most of the myths, but *all* the 48 ancient constellations. We may at least admit the "Corvus," so inexplicably placed, to be best accounted for as one of Noah's birds; and the zodiacal Fishes, which the sun enters next after the Deluge sign, to represent the peculiar condition succeeding to the memorable 40 days' downpour, the two opposed classes of fish, swimming one over the other, in the sea, and its temporary freshwater covering, before their complete mixture.

As for the zodiac of Dendera, supposing it really the very ancient one Mr. Proctor implies—though I believe its Roman date is now regarded as settled, —it would have had no bearing on my remark about us "westerns," which the context must surely have implied to include all west of Ararat. However, I find that it was incorrect to say "*only* we westerns" had (even to this day) enlarged the Bow into Sagittarius, as Hindoos have learnt (probably from Europe) to make a similar addition to the *figure*, though the *name* remains only the Bow. Sir W. Jones, in the above paper, translates a *modern* Indian account of them thus—"The *Ram*, *Bull*, *Crab*, *Lion*, and *Scorpion* have the figures of those five animals respectively; the *Pair* are a damsal playing on a *Vina*, and a youth wielding a mace; the *Virgin* stands on a boat in water, holding in one hand a lamp, in the other an ear of rice corn; the *Balance* is held by a weigher, with a weight in one hand; the *Bow* by an archer, whose hinder parts are like those of a horse; the *Sea-monster* has the face of an antelope; the *Ewer* is borne on the shoulders of a man who empties it; the *Fish* are two, with their heads turned to each other's tails; and all these are supposed to be in such places as suit their several natures." In support of the rainbow origin of the *Bow*, Maurice cites the classic story of the Centaur's birth (who now holds it) from a *cloud*; and as for *Argo*, he quotes from "Hyginus" "that it is "the ship Minerva numbered in the asterisms, as having been built by her directions," (compare Prov. viii. 22-31), "and the first that ever went on the ocean." E. L. G.

PLATO.—JUPITER.

[4474.]—I INCLOSE a copy of a sketch of Plato as seen on June 14, 1872, at 9.19 p.m. with my 3⅝in. The shadows of the original I adjusted by means of a fine wire stretched across the field of a 120 power eyepiece. I noticed some markings (shown in my sketch) on the floor. I also saw several small craters, or crater-like formations, near or on the border. The shadows appeared sharp and well defined. I have also noticed that the radiating streaks which proceed from Tycho, Copernicus, &c., appear to consist of higher ground, such as rills, &c., when near the terminator, and change into streaks at or near the full. Is this supposed to be

so? Also, may I ask "our" obliging "F.R.A.S." for a few star tests for my telescope? It will clearly divide 52 Orionis, ϵ Boötis, and many more. Will Mr. Proctor please tell me if his theory of Jupiter being red hot will agree with the complete invisibility of the satellites when in his shadow, and the intense blackness of their shadows when in transit? J. W. DURRAD.

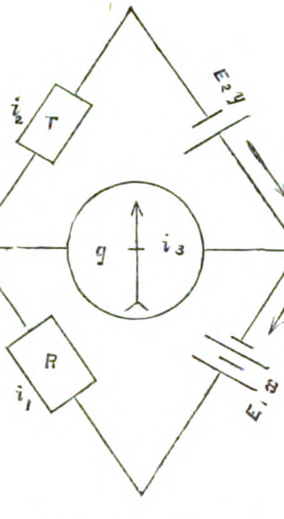
COMPARING ELECTRO-MOTIVE FORCES.

[4475.]—THE following null arrangement for comparing electro-motive forces is, as far as I am aware, original; at least I have never seen it described anywhere:—Join up the two batteries E_1 and E_2 with a galvanometer, as in the diagram, so that their currents go through it in opposite directions. Also insert resistances R and r. Let x and y be the unknown resistances of the batteries, and i_1, i_2, i_3, the intensities in the three branches. Then we have—

$$i_1 - i_2 \pm i_3 = 0,$$
$$(R + x)\, i_1 + g\, i_3 = E_1,$$
$$(r + y)\, i_2 + g\, i_3 = E_2.$$

Now, by altering the resistance R, bring the needle to zero. Then, $i_3 = 0$, and $i_1 = i_2$, therefore—

$$\frac{E_1}{E_2} = \frac{R + x}{r + y}.$$



Here we have the unknown resistances, x and y, in our result; but, by taking another value of R, say R^1, and finding the corresponding value of r, say r^1, we get the simple result—

$$\frac{E_1}{E_2} = \frac{R - R^1}{r - r^1}, \text{ or } \frac{dR}{dr},$$

the ratio of a difference in the value of R to a difference in the value of r. This method, involving no calculation, as only two differences have to be observed, and being perfectly independent of the resistances of the batteries and galvanometer, gives very good results. A further advantage is that, as $i_1 = i_2$, and no current passes through the galvanometer, each battery is being worked to exactly the same degree. Thus they are compared under *similar conditions* which is not the case in Poggendorff's and other methods. I should like the opinions of "S. T. P." and other practical contributors. In the diagram it appears like a Wheatstone's bridge, but it is quite different in principle. O.

OUR COAL STORES AND THE ATMOSPHERE.

[4476.]—MAY I ask Mr. Thompson (let. 4349, p. 334) how it is that the rate of mortality is lower in towns where there is a large number of manufacteries. And in one instance I know of (where the manufacturers threatened to close their works if they were continually prosecuted by the inspector of nuisances for not consuming their smoke) the inhabitants looked to the death rate, and finding they were more healthy with the smoke than other towns were without it, they asked the manufacturers to keep their works going; so that Mr. Thompson's carbonic acid gas must be beneficial in the atmosphere. W. ALLAN.

BALSAMED OBJECT-GLASSES.

[4477.]—"F. R. A. S." in letter 4276, p. 300, was quite right in saying, as a rule, only object-glasses for terrestrial telescopes are balsamed, and then only when the proportion of the flint lens is such as requires the crown lens to be ground to the same curve as the flints on the inside surfaces; then they are balsamed to prevent loss of light, &c., but principally to enable the makers to burnish them fast in the cell to prevent inexperienced owners from getting the object-glass the wrong way in the cell, because in balsamed objects the two outside surfaces only require cleaning, while those that are not require all the surfaces to be cleaned after they have been in use any length of time. Some firms notch the edge of the crown and flint lenses on the two sides which go together, which is a very good plan; and these object-glasses are preferred by the great majority of ships' captains in preference to the balsamed objects, as in using telescopes with balsamed objects they very justly complain of their not being so good when they get out abroad, the balsam slipping with the heat of a tropical climate. The Barlow lens spoken of by "C.B.," I may say, requires the inside surfaces to be ground to the same curve and cemented, which is its principle. But as regards balsamed astronomical object-glasses the least said the better.

WILLIAM OLDFIELD.

[4478.]—I HAVE cemented a large number of achromatic lenses with balsam, and never found it to shorten the focal length. I fancy "C. B." (let. 4366, p. 353) must be mistaken; but if not, then the inner curves of his object-glass do not coincide. Glasses are balsamed together to reduce the number of surfaces, thereby saving light. Large-size object-glasses are not balsamed on account of the risk. RT. THOMAS.

MICROSCOPE CASTINGS.—MOUNTING SMALL OBJECTS IN BALSAM.

[4479.]—IF E. B. Fennessy (let. 4369) will refer to the advertisement columns of the ENGLISH MECHANIC a few numbers back he will find microscope castings advertised for sale. To the possibility of any workman of average ability fitting up a sound, serviceable instrument, I can testify, having just completed one which will bear comparison with any of the instruments sold in the shops at £15. It has English objectives, five powers (½in. to ¼in.), three eyepieces, prism, and analyser, and cost me less than £4, exclusive of my labour.

I have no doubt many microscopists have found the same difficulty as I have in keeping small objects, such as starch grains, diatoms, &c., in the centre of the slide when mounting in balsam—the balsam, if dropped in the centre, or placed at the side, pushing the object before it to the edge of the cell. To prevent this, draw a ring of balsam round the object, and, as it spreads, add as much as will fill the cell, the ring will probably not meet in the centre, but the air-bubble inclosed therein will be driven out by using a clip after the cover has been dropped on. The contraction of the ring of balsam towards the centre drives in the objects, and prevents them being scattered too far to be easily found. MICROS.

MICROSCOPE CASTINGS.

[4480.]—I DESIRE to indorse the wish of the writer in a recent number (let. 4369) "that some one would supply microscope castings at a reasonable price." I have lately had the greatest difficulty in procuring even a stand, and I went to a great number of working opticians, too; they must have had them, but I suppose would not part with them. However, I got an iron one at last, and am now making the models for the stage, &c.; but if I could get these anywhere I would willingly pay a fair price for them in the rough, and I have no doubt that a great many others would also do so.

J. D. H.

ENTOMOLOGICAL.—V.—ON IMAGOS.

[4481.]—WITH regard to killing apparatus, I like an ammonia box used with benzole on wool instead of ammonia for stifling insects; and for large moths I use a solution of oxalic acid, piercing the under side of the thorax of the moth with a pen dipped in it, which dispatches the insect almost immediately. For sugaring, I think the best places are the lee side of wo and the rides and clearings in them, if the wood is not too thick; but almost any locality whatever will, in the season, yield its special variety, and we must remember that where there is one there are generally more, and if a moth is about a certain time after dusk it will be out very probably the same time before daybreak. After catching moths at sugar, I think it a good plan to prick their abdomens, if at all full, to let out the sugar, which may be absorbed by a piece of blotting-paper, or the sugar may appear after the moth is put in the cabinet. The wingless females of moths are hard to distinguish at first from spiders, though practice soon enables us to tell the difference. Virgin females of many sorts will, if put in a gauze-covered box and placed in woods and such places, attract many males. Sallow bloom in the spring and ivy bloom in the autumn are as good, if not better, than any sugar for attracting moths. Street lamps are excellent spots for capturing moths at, and should occasionally be "swarmed." Let it be remembered that few moths come out much before midnight. Yew trees are worth beating at night and day to drive out the moths concealed in them. If insects are not set soon they will become quite rigid, and then they should be put in a zinc box lined with cork and soaked with water, and in a few days they will come out quite soft.

Though these notes are short, and might doubtless have been written by a more able pen than mine, yet I hope that they may be of some use to many of the readers of the English Mechanic, and I conclude by heartily wishing all collectors success in their undertaking.

Ento.

FINDING INTERNAL RESISTANCE OF A BATTERY.

[4482.]—I have tried "S. T. P.'s" plan (let. 4402), and obtained tolerably accurate results. It can be further simplified by making g, the galvanometer resistance, = R; then, to halve the total resistance, we have only to take away R.

If we make the resistance unplugged in the first equal to twice that unplugged in the second part of the test, or say $R = 2r$, then we have $\frac{B}{S} = \frac{r}{r+g}$. Here we cannot neglect g, unless it is very small compared with r, and if so, our deflection will be proportionately small, unless we have a very delicate instrument. Having at our command such a refined instrument as the Thomson reflecting galvanometer, whose index is without weight or friction, of course perfectly accurate results can be obtained by "S. T. P.'s" plan; but if, as will generally be the case, the experimenter has only a common galvanometer at his disposal, neither very delicately pivoted nor graduated, a null method, by which making and breaking a circuit produces no alteration in the deflection is very desirable. This want "S. T. P.'s" method does not supply, because we have two operations to perform—viz., to reduce R to r, and to put on the shunt. In the mean time the needle has moved, therefore this method cannot be accurately called a null method. The nearest approach to perfection, that I am acquainted with, is Mance's method. Even there the needle jerks when the circuit is made and broken, owing, I presume, to the direction of the current being changed in one of the branch circuits.

O.

RADIUS OF SURFACE OF OBJECT-GLASS.

[4483.]—In reply to Mr. Cash (let. 4380, p. 355), if the crown glass is free from veins, and if he will take the density of both the flint and crown lenses themselves, and not the fragments, very correctly, I shall be able to assist him in dismissing the curious phenomena he speaks of. Till now I have thought that his crown lens was made from what is called British plate, and not Messrs. Chance's white crown at all, because I have only seen one or two pieces of the density stated in his letter some time ago; but I think he will find the crown, when he has taken the density of the lens itself, to be 2·55. Their white crown in sheets is oftener that density than any other. Be certain and state the density of both very correctly to the fourth decimal number. Soft iron tools are the best for grinding and smoothing object-glasses, but they must be made in pairs to true each other with. As the object is now, it will never make a good one, because the proportions are not at all good, and to start afresh will be the best way. I advise Mr. Cash not to make the focus of the object-glass less than 72in., he will find it short enough for him to work. For myself I like the following proportions the best:—3¼in. diameter to 50in. focus, 4in. diameter to 60in. focus, 4½in. diameter to 70in. focus, and 5in. diameter to 80in. focus. I consider these good proportions, and have found them work well.

Wm. Oldfield.

RECURRENT VISION.—ELECTRICITY.

[4484.]—The interesting experiment described by Mr. Petrie (p. 282) does not seem to me to contain a satisfactory explanation of "recurrent vision." The latter phenomenon is seen as well with one eye as with two, and is far too rapid to be compared with the other; indeed, on some occasions have seen, *after* the recurrent vision, persistent spectra, much like those which Mr. Petrie describes, floating before the eye, changing colour, appearing and disappearing alternately in the darkened room, for perhaps thirty seconds after the flash—just such images as one may see at any time by looking steadily at the sun when near the horizon, and then closing the eyes and turning towards the shade.

That the phenomenon is not founded on any special peculiarity of my own eye is evident from the fact that I have shown the experiment to at least fifty different persons, and never found any one who failed to see it. At the same time, I wish to say that I do not consider the idea of a reflected nervous impulse which I suggested as at all certain to prove correct. It is difficult to see how it should take so long a time as one-fifth of a second for an impression to travel along the nerve from the brain to the eye and back again.

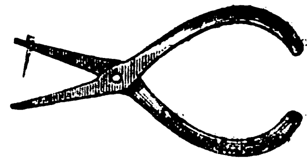
I may add that in my own family I have long been familiar with electrical phenomena similar to those discussed in some recent letters in your paper. In houses heated by a hot-air furnace it is not at all uncommon to obtain sparks of from ½in. to ¾in. in length by simply scuffling briskly over the carpet; and when undressing for the night ladies sometimes receive a rather unpleasant shock by dropping upon their feet the hoop skirt worn between two flannel petticoats during the day. In 1857 I resided in Northern Ohio, and occupied a study heated by one of the abominations called an air-tight stove, the apartment beneath being heated in the same way. In this room the phenomena were more striking than I ever observed elsewhere; and on some favourable occasions, when the temperature of the external air was below zero, I obtained sparks very nearly an inch in length, with which I charged Leyden jars, and performed many other of the ordinary experiments. By a process which I need not explain, but easily enough imagined, I found that the source of the electricity was solely the friction of smooth sole-leather upon the woollen carpet.

C. A. Young, Prof. Nat. Phil. and Astron.

Dartmouth College, Hanover, N.H., U.S.A.

A TOOL FOR PUNCHING THE RIVETS OUT OF BROKEN WATCH-CHAINS.

[4485.]—Most watch jobbers in mending a watch-chain have to split the old link before they can get the old rivet out, so as to get a new joint. The tool that I invented and have used for years (of which I send sketch) is a most decided improvement on the old



system. Any watchmaker can make one out of a pair of strong watch pliers; you may soften the pliers at the ends, drill a hole at one side, tap it, then fit a screw with a fine point, spring temper, and at the other side drill a small hole exactly opposite, so that when the chain is placed under the punch, the rivet pops out without any further trouble.

Ein Uhrmacher.

PERFORMANCE OF TELESCOPE.

[4486.]—In reply to Dr. Blacklock's query (let. 4387, p. 357), I may say that the conditions required for the experiment on dividing power are simply the most favourable; the magnitude of the stars depends on the aperture, the discs increasing in size inversely as the aperture; the power used should be sufficient to show a round disc.

This question, however, is distinct from the test of the telescope's quality. By choosing twilight a close pair may be well divided by an instrument giving much false light, which would fail on the same object on a fine dark night.

The star δ Cygni is an admirable test, owing to the closeness and faintness of the comes, which becomes lost in the light surrounding the large star unless the telescope be good. Reflectors have scarcely any chance with it, as, owing to the intervention of the plane, they exhibit more rings round large stars than do refractors, and these rings, brandishing about as they always will, make it exceedingly difficult to perceive the faint comes.

I have very seldom been able to see it at all, and never well, with my large reflector, as ordinarily used, but with an excentric aperture of 7in. or 8in., which escapes the flat, it is almost always visible and measurable, and as beautiful as in the finest refractor.

H. C. Key.

SPINNING-TOPS AND GYROSCOPES.

[4487.]—As a matter of course Mr. Proctor (letter 4411) has experimented upon and experienced the extraordinary resistance which a swiftly-revolving wheel offers when turned in any direction contrary to the plane of its motion. Now, I would feel much obliged if he will explain for the benefit of all of us, how, as he says, that a body moving at various velocities and admittedly travelling for any period, no matter how short, in a horizontal direction, can fall to the ground in the same time as if dropped from some height and acquiring a constantly-increasing velocity, what becomes of the resistance to change in direction of motion?

I am much obliged to J. M. Taylor (letter 4361, p. 353) for his good temper, as, although unwittingly, I sometimes offend by plain speaking, and must now tell him that having counted so much upon the atmosphere in his former letters, he appears just as anxious now to discard it. But whether in atmosphere or vacuo, I deny *in toto*, until he shows me proof positive, that a cannon ball or any other swiftly-moving body in a horizontal plane is attracted to the earth in the same time as a body left to fall freely from the same height. I am amazed that both "E. H." and himself can hold such an opinion, because if they admit that the ball travels for any portion of its flight in a horizontal direction, then it becomes evident that the ball dropped vertically with constantly-accelerated descent must reach the ground first. *Q. E. D.*

Will "E. H." kindly drop making assertions, and just inform us how he proves that if a cannon ball were fired horizontally in vacuo that it would fall to the ground as soon as if dropped from the same height vertically? Does he deny the force which any moving body exerts against being moved in any direction contrary to a straight line? If so, I would recommend him to proceed to an artillery ground where ball practice is being carried on, and to help gravity by catching one of the passing balls, and endeavouring to drag it to the ground. And, in conclusion not to misrepresent me by attributing to me the statement, "that particles rotating in a plane cannot get out of it." What I did say was that they could not fall to the ground if the velocity were kept up.

A., Liverpool.

SPINNING-TOP.—UPWARD DEFLECTION OF BULLET.

[4488.]—Gravitation acts vertically to the plane of the earth, consequently does not pull the top either to the right hand or to the left, to the north or to the south. Demonstration: Pare carefully just the point of the peg to a level surface. No difficulty will now be experienced in making the top stand, and yet who can say the conditions under which gravity acts have been altered? We have simply extended the base through which the vertical line of gravity acts, and, theoretically, the top would stand without the alteration. Physically it will not do so, because we should require a perfectly-balanced top, even surface, and entire absence of tremor from any and every source, any one of which (and not gravity) would kick the top over; some power (no matter how infinitesimally small) must be applied to turn or remove the centre of gravity.

It is an axiom, and generally received, I believe, that bodies have a tendency to retain any motion imparted to them, in fact, it seems a natural law, and they would retain this motion for ever if none other force interfered. Now, in spinning a top, we impart and convey to it a gyrating or revolving motion, proportioned to the force used in the spinning. Friction, both atmospheric and terrestrial, and possibly, also, electrical, presently extracts the imparted force, and the top ceases to gyrate, and consequently falls, but not through gravitation. As previously stated, in all gyrating bodies, whether vertical or horizontal, the centres of gyration and gravitation must be coincident; if otherwise, "wobbling" ensues, proportioned to the amount of such divergence; when coincident, the top "sleeps." In all heavy, high-speeding machinery this divergence causes immense loss of power and speedy destruction of the machine itself, exampled in an unbalanced fly-wheel or mill-stone.

In the upward deflection of bullet three points require consideration—(1) The difference between the thickness of the barrel at breach and muzzle. (2) The almost utter impossibility of retaining the eye in exact axial position with the two points of sight, to which is added the great annoyance of reflected light from the surface of the barrel. This would, of course, be greatest nearest the eye, serving to depress the breech in order to obtain sight at the further point. (3) The method of igniting charge. To be accurate in results, this should take place exactly in the centre of fore-end of charge, next the bullet. It is, therefore, highly probable an amount of reality does exist in this last question. It can be easily tested by firing the piece at point blank range in inverted positions.

Epsilon.

CO-OPERATIVE STORES.

[4489.]—Mr. R. R. Smith (let. 4389) merely reiterates the perpetual complaint now heard, that we cannot get justice by dealing unjustly; that insane rules and methods bring confusion and absurd results; and he does not gather grapes after sowing thistles? Who makes it necessary for his shopman or he to "realise" this per cent., or that per cent; or in selling one lb. of stuff in one parcel, and another lb. in ten parcels, to be paid for each of these lbs., as for two equal works? Is not selling one parcel doing one thing? Is not selling ten parcels doing ten things? What possible good can he expect for the haphazard injustice of paying the same for one job and for ten?

E. L. G.

THE PIANO-VIOLIN.

[4490.]—I have just seen your issues of the 3rd, 17th, and 31st May (lets. 4074, 4155, and 4282), and am pleased to find that the subject of the piano-violin, or tetrachordion, is being analysed, as in this manner the value of the instrument will be clearly gathered for orchestral and general purposes. I have heard the instrument played, and was much pleased with its sensitiveness and volume of tone, and I should like all persons who have a real taste for music to embrace the opportunity of listening, and, if they choose, playing it also. One of these instruments, of M. Baudet's make, has been publicly performed upon for months past at Theiller's Rooms, Charing-cross Station, to which any person, on presenting his card, can obtain admission. M. Maitre, of Paris, purchased all M.

Baudet's rights and interest in the English, Belgian, and the United States patents some three years back, and he is now about introducing the invention into the English market upon a large scale. I regret that S. Bettone did not better inform himself of this fact before he penned his letter to you, in reply to "The Harmonious Blacksmith," as M. Baudet had no patent to sell to Messrs. Stead and Co., to whom he refers. Baudet did try to dispose of the English patent to Messrs. Stead, but the sale was never completed, and an action is now pending before Vice-Chancellor Wickens' Court to restrain Messrs. Stead from continuing the infringement of Maitre's patent rights, which they have been doing to a large extent.

The instrument I saw and heard was like an ordinary cottage piano, only with two pedals beneath, to which an up-and-down movement was imparted by the feet of the player for rotating a roller, situated above a series of tufts of hair, these being permanently attached to, and standing out from, the strings. The keys, which were acted upon in the same manner as in a piano, had each a rod at the inner end, at the top of which was a strip of rather hard indiarubber; these, being lifted, pushed the tufts into contact with the roller and produced a vibration of the strings, which gave out the musical notes, the tone and volume far exceeding that which can be obtained from a perfect piano. H. GARDNER.

Coloured Suns.—ERRATUM.—In the list of colours on p. 383, from "ash-coloured" to "lurid," ought to have been given in simple order, without the distinctions which are given as headings.—T. H. BUFFHAM.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[10478.]—**Pork Diet.**—Does A. H. Cooke know that pork, as an article of diet, has the following defects among others?—(1) It is less digestible than most other articles of food; (2) it is more difficult to detect disease in this than in other meat; (3) it is the principal refuge for the germ of the tapeworm.—HENRY NEWMAN.

[11531.]—**Water Wheel.**—In reply to "D. S." I regret to say that time will not allow me to take advantage of his proposal, which, I will do him the justice to say, seems perfectly fair to both sides. However, I shall be glad to see any other correspondent taking advantage of it. To find the average efficiency would require a number of trials, extending over a long period of time. Consequently, any one taking the offer, if it was proved in his favour, would have well earned it.—P. W. H. J.

[11531.]—**Water Wheel.**—May I ask "D. S." to give us some idea of the form of his rotary engine? We all know the future value of the rotary principle if physical conditions permitted its construction to "wear tight;" but I have never yet seen one (a rotary) in which I could not at sight see unequal speeds and pressures of contact surfaces bound to produce their one fault (not practical because won't wear tight). We all know the even far better expansion utilising capabilities of certain forms of rotary engines over the reciprocatory pistons. But may we ask him also for the "chap. and verse" of his figures, 9, 10, and 30 per cent. Against what makers of modern engines does he lay this charge?—X. M. S.

[11554.]—**Pedestrian Tour.**—Some little experience in this recreation—its joys and discomforts—made me glad to read "Philo's" suggestion of canvas shoes, with stout, broad soles. They are the very thing required—that is, if they will stand hard work. Calf leather shoes or boots are an abomination, and the more you try to make them waterproof the worse they are. I mean that they become offensive from the confined perspiration, and also from the occasional soakings from rain or wet ground, which are inevitable; and, when "set to dry," they become hard and rigid, and make the feet sore. Further, they look horribly shabby from perpetual attrition and dirt. I mean to try the canvas boots this autumn; but I certainly shall not have elastic sides. They are very bad for walking in a hilly country, because they throw a severe strain and pressure on the tendon of the heel and ankle, which ought to be perfectly free. I have before suffered severely from this cause. No more "elastic" for me, I thank you. I would rather go barefooted, or with rags and sandals, like the *pifferari*, now so frequently seen in our streets. Don't be afraid of getting the feet wet, or the whole body, for that matter. There is not the slightest harm in it, if you don't stand about or sit down in wet clothes or boots. If you get ever so wet, walk yourself dry again, if you can; or if arriving wet at your halting place, strip, have a rub down with rough towel, and put on a change of clothes, or go to bed (between blankets preferable) whilst your wet garments and boots are being dried. I have been wet and dry, wet and dry, several times in course of a day, but kept "continually going ahead," and, though of by no means robust constitution, suffered nought; but, on the contrary, felt awfully jolly at being thus able to defy the elements to do their worst. Another thing, don't invest in a knapsack. A commodious satchel, not too large nor too small, is the best thing for stowing what your pockets will not contain. It must have a light strap by which to sling it over your shoulder. You can then wear it either at your back or under one arm, or carry it in either hand, or sling it to your umbrella "crome" (hooked handle), and carry it pedlar's pack fashion. There is an enormous advantage and comfort in being able thus to change and change again the location of your load (be it ever so light a one), which quite contrasts with the irksomeness of even the best possible knapsack.—G. W. K. L.

[11564.]—**Blackberry and Strawberry.**—In answer to "E. L. G.'s" inquiry on p. 307, I beg to say that the raspberry and blackberry are certainly distinct species; the former is known to botanists under the name of *Rubus idæus*, and the latter as *R. fruticosus*. The raspberry is a native of Britain, and is plentiful in many of our hilly and mountainous districts, as well as in moist situations. Withering gives eight or nine places where it is to be found growing wild, and in Carnarvonshire Anne Pratt informs us you have only to wander out about half a mile to gather a basketful. The black and red currant are distinct species, known as *Ribes nigrum* and *Ribes rubrum*, and are both to be found growing wild in many places in Britain.—AVON.

[11589.]—**Dry Steam.** — I maintain that my original statement is correct that superheated steam is merely a higher pressure steam, which necessarily contains more heat and less water in a given bulk, and "E. L. G.'s" letter (p. 386) fully confirms this—vide, "It may be of no higher pressure than when it was wet steam, and in that case it must occupy more space." Now, is not this one way of evading the fact that it is really higher pressure or more heat and less water in any given volume of less capacity than the boiler? I would ask "Caloric" seriously to answer this question. Does he really suppose that he can apply additional heat to steam without converting it into higher pressure steam? and does he, "E.L.G.," or "Philo" imagine that if a vessel be filled with steam at 1lb. per inch, or that at 100lb. per inch, that when condensed there would not be far more water remaining from that at 1lb.? Also, I would suggest to "Philo" that although only one half educated, I know that if the manhole were left off the boiler that the water would evaporate far quicker than if merely escaping through his small vent, which proves that what I assert is correct—viz., that there is less water escaping from high pressure steam at the same moment, although there may be the same ultimately; and that although Dr. Arnott's theory has something to do with it, it must be taken into conjunction with the lesser quantity of water issuing from the orifice. Thus, take any boiler and see how many times it would fill the cylinder before all the water was exhausted (having no supply pipe) with steam at a high pressure, and see how many times less it would take to exhaust it with low pressure steam. —A., Liverpool.

[11589.]—**Dry Steam.**—"Philo" has doubtless given, from Dr. Arnott (p. 386) the correctest way of explaining the sudden cooling of a steam jet, but he was, and still is, wrong in supposing that high pressure steam escaping into air tends only to expand down to a pressure balancing the air—the tendency is to expand till balancing only the steam atmosphere, as if the oxygen and nitrogen atmospheres were absent. Dalton showed that a gas or vapour thus diffusing in a mixture of them, has its ultimate tension limited simply by that of the fluid similar to itself, quite apart from the dissimilar ones, as if they were non-existent. Steam from a boiler, of 30lb. per inch, released into an atmosphere whose steam presses but half a pound per inch (which is about the maximum of atmospheric steam) will expand almost instantly sixty-fold, and not merely two-fold, as "Philo" imagines. It will be sixty-fold whether the half-pound steam be the only resistance present, or whether there be also oxygen of 3·2lb. and nitrogen of 11·2lb. (as usually happens), or airs of double or triple these tensions, even equalling or exceeding that in the boiler. These other fluids merely retard somewhat the time occupied in expansion, but do not affect its amount, for the three atmospheres are independent. The presence of air, therefore, is not necessary to the sudden cooling, as Arnott's instructive experiment seems to lead "Philo" to think, for doubtless a jet escaping into vacuum (whether forming cloud or not) would be as cool. To produce a scalding cloud the escape must be into warm and wet steam. Two steams of different temperatures, whatever those temperatures be, and both near saturation, become on mixture, supersaturated, and therefore form cloud. It is possible, however, for very dry (*i.e.*, very superheated) steam, escaping into air also of great dryness, to diffuse invisibly, and form no cloud even for a moment. This may be what "Caloric" observed with Mr. Lee's superheated steam, but I doubt if it could have occurred in a moist S.W. wind. I have seen a mere momentary cloud re-dissolving at a yard or two from the funnel, with even engine steam (necessarily wet) in the West Indian dry season. Slightly superheated steam would have spread invisibly, but wet steam, as that of engines, cannot do this, I believe, in any natural degree of drought. Even on the Egyptian and Suez railways it must always form cloud for a moment or two. Though "Caloric" did not see the connection, there was a curiously close one between this opportune query and the "Comet of the Deluge." In fact, "Sigma's" mistake that water from a cold steam comet must reach the ground scalding hot, and that of "Philo," that very hot steam should form a scalding cloud, were mutually illustrative, though not identical. Neither the rain in the first case nor cloud in the second need be scalding; but "Sigma's" was the greener mistake, because wholly ignoring our atmosphere's presence. Doubtless, if the earth had no more air than the moon, he would rightly reason that the diluvial water must have fallen boiling hot (which would make small difference physiologically, seeing that, if in drops at all, they would have about 20 times the velocity and impact of rifle bullets). But our globe's 40 or 50 mile great-coat of air formed at once a cushion and fire-screen, as it does in the case of the 11 or 12 times more rapid (and therefore 1,331 to 1,728 times more heating) impact of the November meteors. The upper 30 or 40 miles of air-coat bore, in either case, the brunt of the encounter and its heat, radiating most of the latter into space, before the small residue could descend by the very slow downward aërial conduction. As for high pressure steam in its escape forming snow instead of water cloud, though I never heard of an instance, it is not an absurd idea, having a close parallel in the escape of compressed carbonic acid, which, from far above its boiling point, cools in this manner below its freezing point, so as to deposit itself in a snowy form, not obtainable, indeed, in any other way.—E. L. G.

[11625.]—**Deaf Dog (U.Q.).**—I would use the cayenne pepper tea as recommended for "Deafness from Cold" (No. 11996).—N.B., whenever a dog has to be dosed, wear thick gloves.—H. O'B.

[11801.]—**Question in Trignometry.**—In reply to my inquiry (p. 309 of No. 376 of ENGLISH MECHANIC), "H. H." (or "W. H.," whichever he may be) says "that both the construction and calculation are adapted to the general problem, whatever be the values of the angles about P." But he does not explain how the intersection of the circles described from the centres of the equilateral triangles described upon the sides of the triangle A B C (see his directions and diagram, p. 260, No. 374, the ENGLISH MECHANIC), will fix the position of the station or point D. It does not appear, from his diagram, that these circles can intersect each other in D at all. In his last letter (p. 361 of No. 378 of ENGLISH MECHANIC) he says "only the triangles must be isosceles," &c., but an equilateral triangle and an isosceles triangle are different things; which statement is correct? It happens in "Numa's" triangle that the angles subtended by the sides from P are equal, and that the sides are nearly so, but this will not occur in actual practice one time in ten millions, perhaps. What we require is a rule by which this question may be answered—Whether station P be near the centre of triangle A B C, or far removed from it, so long as it be within the triangle, and whether the angles subtended by the sides from P be equal or very unequal. If nobody else does it, I will one day send such a rule.—THEODOLITE.

[11837.]—**Organ Bellows (U.Q.).**—The size of a bellows for such an organ should be 4ft. by 3ft. 6in., with a pressure of 2½in. of wind.—J. D.

[11872.]—**Carbonic Acid Gas and the Atmosphere.**—When I made my calculation I included Ireland, and, therefore, took the area at one hundred and twenty thousand square miles. Likewise, the expression one hundred and forty million tons should have been one hundred and forty thousand million tons. I may state that the weight of the whole atmosphere is about five thousand billion tons and not thirty-five billion tons as "Philanthropist" makes it out to be in his reply.—WILLIAM THOMPSON.

[11969.]—**Cochineal.**—I believe this insect has been reared in this country on its food plant and under suitable conditions, but of course only as a curiosity.—E. M.

[11973.]—**Magnetic Engine.**—Does "Glatton" want an electric engine or an electro-magnetic machine? It is doubtful from his query.—L. C.

[11996.]—**Deafness Arising from Cold.**—A pinch of genuine cayenne pepper, with boiling water, say as much as will cover a sixpence to a gill of water, when half cold used as an ear wash, by pouring in a teaspoonful at a time, thrice repeated, that is three spoonfuls one after another as one wash, and used two or three times a day as long as the deafness continues.—OFTEN PROVED.

[12011.]—**Magic Lantern Effects.**—The following is extracted from "The Magic Lantern: How to buy and how to use it." The slide to give the effect of falling snow consists of a light framework of mahogany, between the two sides of which are arranged parallel rollers, one of which, being worked by a winch handle, unwinds a piece of black linen, or silk, pierced by numerous pinholes, through which the light passes when the fan is lowered, and on turning the handle in the proper direction the appearance of falling snow is produced. Care must be taken that the perforated curtain be focused while bringing it down, or the snow will fall invisibly." A moonlight effect is sometimes produced by means of a single slipping slide; the scene is first exhibited in colours representing a day view, and on pulling the glass slip a blue tint painted on it is thrown over the picture, giving a very good effect of night. The moon is represented by a circle scraped out of the blue tint.—C. BROWN.

[12012.]—**Water Power.**—"P. W. H. J." considers that my reply to the above question is of practically although correct in theory; he states that I have calculated the natural effect due to a fall of water, but that I have not gone any further. If he will refer to my letter he will perceive that he is in error; I have made a large allowance by putting the velocity $v = 10$, instead of 19¼, to allow for the effects of fluid friction and the well known phenomenon of the contracted vein. I stated that I did not know the length of the pipe, and I hinted that the data precluded great accuracy as in most physical problems; perhaps if the pipe is a very long one, the allowance I made was not enough; a further deduction should have been made for the modulus of the wheel employed, but it would vary accordingly as a turbine or other motor was used. "P. W. H. J." states that in the rainy season there might be 2 horse-power, but he previously estimates the ordinary power at ¼ horse-power; I made my calculation on the supposition that there was as much water as could run through the 3in. pipe. To suppose otherwise would add another element of uncertainty to the calculation. I think it would be useful if some of our correspondents would give us extracts from tables as to the practically observed effects of fluid friction as depending on the length, diameter, and inclination of the pipe. At the same time I must say that "P. W. H. J." has given practical details which I could not have furnished. I said almost all I had to say on the subject, and I could do no more.—PHILANTHROPIST.

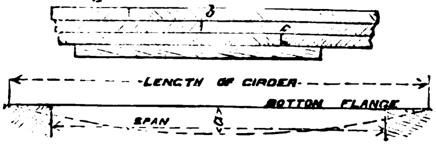
[12013.]—**The Frst Watch and Clock Made.**—In answer to "A Glasgow Highlander," Reid's "Treatise on Clock and Watchmaking" contains a vast amount of useful and interesting information; published by Blackie and Son, Glasgow and Edinburgh; as also E. J. Wood's "Curiosities of Clocks and Watches." There are also a great number of works on watchmaking published in French. Ancient writers differ greatly as to the date at which clocks were first introduced. Claudian states that Archimedes constructed a machine or sphere for the measurement of time 200 years B.C., but the most ancient of which we have any definite record is the one constructed by Henry de Vick or Wick, a German artist, in 1370, of which there is a full description and engraving in Reid's work alluded to above; but there is no doubt that Vick's clock was the invention of no one man in particular, as we may fairly infer that different men at various times made additions and improvements to horological machines, before they attained even that state of perfection.—TEMPUS FUGIT.

[12014.]—**Organ.**—If "E. C." will refer to No. 359 of ours, article "The Organ Built," he will find that I have explained how to do what he asks.—J. D.

[12072.] —**Magnetic Moment.**—I fear that I cannot give "Beacon Lough" the information he seeks without a greater expenditure of time and labour than I can at present spare. It is not contained in any book I know of, unless buried under a mass of mathematical symbols which I only very partially comprehend. I should think the readiest mode of getting at the magnetic moment in absolute units would be by ascertaining in those units the current which produces a given deflection to each magnet in the same galvanometer (tangent being, of course, most convenient), and deducting the force used up in the resistance itself; probably a very careful measurement of the extra resistance produced by the magnet would also furnish it. As to the coil, I do not myself understand the quotation from Tyndall, and have not the book to refer to. There is an alternating discharge of different tensions, and, as "B. L." sees, by careful regulation of distance, one of these discharges can be suspended, in which case the "extra current" will be brought into play: is this what Tyndall refers to. It is by the same means that a jar is charged; it cannot be done if both terminals are connected to the coatings; a discharger must be included and opened to the distance at which the one discharge cannot pass; then sparks pass to the jar and gradually charge it.—SIGMA.

[12106.]—**Organ Building.**—Stopped pipes will not answer well to produce more than one tone, although they can be made to speak two notes by a valve on the top of a "chimney," yet I have always had the idea that a perfect organ of one or two stops is preferable to one with a dozen imperfect stops, and if every alternate semitone is left out what can be done with a number of the little effects which organists often use, but which puzzle the uninitiated so much? An open pipe may be used to produce three notes.—J. D.

[12125.]—**Cover Plates.**—The cover plate of a girder is that piece of metal added to supply the deficiency of the joint of the plates at *a b c*, and the rivet holes in same. If each plate were taken singly, it will be seen that the joint at *a* is only spliced, so to speak, by plate *b*, and the strength is only the strength of *b*, likewise of *b* and *c*. It should be calculated to supply as nearly as possible that deficiency, taking the number of square inches area. Cover plates are necessary on the bottom flange of a girder, because the metal is in tension, say four tons to the square inch. Cover plates are not considered necessary as a matter of calculation at top flange of a girder, because there the metal is in compression, and the edges butt upon one another. But the practice is to place them both at top and bottom of a girder; it makes a good joint, and is something to the good to resist the varied strains that may not have been taken into the general account. Four tons to the square inch in tension and compression is the practice for wrought iron. I generally strike a parabolic curve from end to end of girder, and see that my plates are well beyond the curve (for load distributed). The formulæ will give the depth of metal required at *a*, from which the curve can be calculated. Do not cut the metal too fine.—DRAUGHTSMAN.



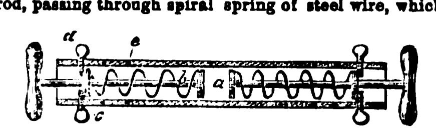
[12125.]—**Cover Plates.**—By cover plates I mean (and I think I have used the correct technical term) the plates which are bolted or riveted on each side of a girder, sometimes one side only, where a joint occurs in the vertical web.—EXCELSIOR.

[12130.]—**Electricity.**—The force which urges the current from a galvanic current or voltaic current, as it may be called, is enormously less than the force with which frictional electricity is urged on. The consequence is that the latter or frictional is able to leap over or pass obstacles that would stop the former; but by linking cells together the voltaic current is caused more and more to approach the nature of the frictional current. It, however, requires 1,000 cell battery to make the current leap over a space of $\frac{1}{1000}$ of an inch in air. But an electric current of moderate power, furnished with a proper conductor, is competent to urge the current across an interval ten thousand times as great; but measured by other standards the frictional electricity is almost incomparably more feeble than the voltaic electricity. For example, it is not without special arrangements for multiplying the effect that frictional electricity can be made to deflect a magnetic needle. The difference may be expressed thus: Voltaic electricity is low in intensity but in great quantity, and frictional electricity the reverse. The deflection of a magnetic needle and other actions of the voltaic current depend upon quantity solely, hence superiority of galvanic battery in producing such deflection.—P. W. H. J.

[12133.]—**Hard Water.**—Try Professor Clarke's plan of adding lime-water. Quantity to be added depends upon degree of hardness. For very hard water you might try proportion of 1 lime-water to 10 water. The way that it has been done at some waterworks is to let the mixture run for some distance at considerable velocity. For water of 10° hardness the process requires sixteen hours to render it good serviceable water. This, I think, will be the cheapest plan. I don't see how Condy's fluid could be profitably employed.—P. W. H. J.

[12133.]—**Hard Water.**—Boil, and allow to get cold, all cooking and drinking water. This will precipitate some, if not all, of the solid matter it contains, and kill any living organisms which may disport themselves therein. To re-aërate it (*i.e.*, to restore its sparkling appearance and destroy insipidity) pour two or three times from one bucket to another from a height of two or three feet.—HENRY NEWMAN.

[12135.]—**Chest Expander.**—"Jack of All Trades" being so unwell I venture to reply for him. In the diagram *a* is a tube, say a foot long; *b* piston and rod, passing through spiral spring of steel wire, which



is fastened at one end to piston, at the other to flat ring *c*, held at different distances within the tube by thumb-screws *d*. Of the three sets of screw-holes, those marked *e* are suited for the greatest strength. All this gear must fit the tube loosely.—HENRY NEWMAN.

[12136.]—**Monkey Nut.**—Botanical name *Arachis hypogea.* Will not live through the winter. Used largely on the Continent for making a first-class oil. Very nice when slightly roasted.—S. BOTTONE.

[12137.]—**Liquid and Solid.**—Mercury is liquid at all temperatures above − 40° Fahr., but solid below that point.—S. BOTTONE.

[12138.]—**Chemicals that Absorb Moisture.**—The principal deliquescent bodies are:—Calcium chloride, zinc chloride, caustic potash, possassium sulphide, potassium carbonate, potassium cyanide, caustic soda, strontium chloride, magnesium chloride, aluminium chloride, iron perchloride, manganese protochloride, chromic acid, copper protochloride, &c.—S. BOTTONE.

[12138.]—**Chemicals that Absorb Moisture.**—Carbonate of potash absorbs so much moisture from the air as to become almost, or quite, liquid in time.—J. C. L.

[12142.]—**Leaky Tubes.**—Wind round the ends inside with soft wire, as close to the end plate as possible, the wire to be of the thinnest kind.—RAT-TAT.

[12142.]—**Leaky Tubes.**—I presume that it is the junction of the tubes with the tube plate that leaks; if so the collars that fit in over the tubes want removing, and fresh ones substituting. A good plan would be to get the waste ends of wrought-iron tubing from the gas-fitter's, and just roughly turn or file the surface. They must be at least 1in. long, and made slightly taper. They must then be gently driven into the place of the old ones, not the whole distance at once, but all be fitted into their places, and then driven home by degrees. If the old collars have been long in their places there will be some difficulty in starting them without damaging the tubes. One plan would be to loosen the collars at smoke-box end, which are always the easiest to loose, and then drive the tubes out. They can be best driven out by getting a tube that will just fit over boiler tubes, and driving that against collar. The greatest caution is requisite, or it will result in the fracture of the tube plate.—P. W. H. J.

[Will "P. W. H. J." please favour us with his address.—ED.]

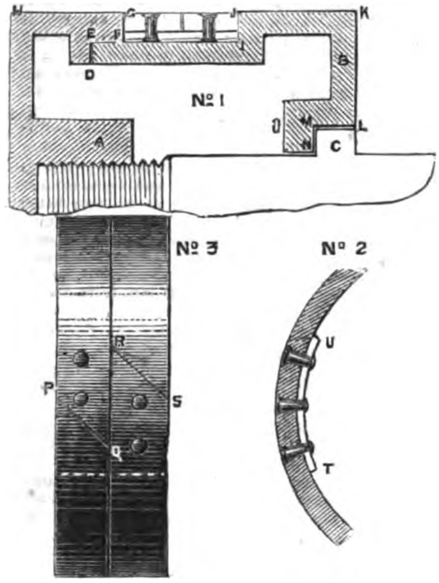
[12145.]—**Small Steam Boiler.**—By the cylinder being 5¼in. depth, I should imagine that it would be 5in. stroke. Probable number of revolutions = 100, and pressure 30lb. (I would here observe that amateurs, in asking questions of this class, seem to make a point of omitting both pressure desired and number of revolutions, making it almost an impossibility to answer them correctly). Then the piston speed is $\frac{200 \times 5}{12} = 83{\cdot}5$ft. per min., and pressure upon piston is 119·28lb. ∴ Units of work performed = 83.5 × 119·28 ∴ H-P = $\frac{83{\cdot}5 \times 119{\cdot}28}{33000}$ = ¼, about, taking friction into account. Then we have to design a ¼ horse boiler. A one-horse boiler requires a square foot fire-grate, and therefore a ¼ horse requires 36 square inches. Thus the boiler is to be 18in. long, 6in. diameter, and grate 6 by 6in. Now this boiler has to stand 30lb. pressure. The thickness that would safely resist this pressure is ·05, or $^1/_{20}$in. thick. This is No. 6 B. W. G. For the boiler, there will be at most 400 square inches. Now, copper of that thickness weighs 9·4lb. per square inch. ∴ Boiler weighs 26lb.; cost of material, at 1s. per pound = 26s.; and of labour = 20s. ∴ Total cost = 46s. Any further information will be given if able. It may be either brazed or riveted, but preferably the former, if a good hand at it.—P. W. H. J.

[12148.]—**Boiler Query.**—From "Molesworth's" I find the following rule:—Let D = diameter of the boiler in inches, P = the pressure in pound per square inch, T = thickness of boiler plate in inches. Then $T = \frac{PD}{6000}$ for ordinary plates, ∴ $\frac{3}{16} = \frac{P \times 22}{6000}$, ∴ P = 51lb. about. The tubes I have not taken into consideration, but by acting as stays they will probably make the boiler able to stand 60lb. safely. The calculation supposes that the rivets are properly distanced and proportioned. In example given, the rivets are too small, for $^3/_{16}$ in. plate requires not less than ⅜in. rivets. On account of the smallness of the rivets, it renders the thickness of the plates useless, as those ¼in. rivets would yield before the plates. A boiler ought always to be so proportioned so that every part would be equally likely to give way at the bursting pressure. The rivets should be 2¼in. distance or pitch. The horse-power I cannot determine without more data. I want to know size of firegrate, whether boiler is vertical or horizontal, height of internal fire-box, and kind of fuel used.—P. W. H. J.

[12155.]—**The Suspended Shilling.—Another Reason Wanted.**—I might almost ask "H. G. W." why mackerel always roost in apple-trees, had it not been gravely asserted in a semi-demi-scientific work some years ago that the shilling would so act, even if the holder were not "up to the time of day." The assertion that an inanimate body will conform to the conventional divisions of time which men use, and spontaneously strike the nearest hour, bears a lie on its face, and another on its back. (Query: Would it be so suave as to strike up to 24 in Italy?) The only solution of the question is that the holder, consciously or unconsciously, brings about the effect he desires, and that a strong wish that it should not overstrike steadies his hand, and stops the vibration of the shilling.—HENRY NEWMAN.

[12158.]—**Packing Rings of Piston.** — The pistons for model engines, and engines of small power, are made in two parts, one fitting on the top of the other, and the ring or other packing goes between. By this plan the ring can be easily turned true. The way it is done is this. Suppose the ring is a brass casting, then fasten a piece of plank to the face-plate and turn in it a recess so that the ring will tightly fit in it. In this turn out the interior to fit recess turned for it in the two halves of the piston, and face truly square both sides. Next place it in position on piston and screw the two halves together, clasping it tightly. Before doing this the piston-rod must be fixed in position on piston. Then the whole must be put between centres in the lathe with carrier on end of piston-rod. The ring must now be turned the merest trifle larger than piston. It is now to be taken off and a saw-cut made at an angle of 45°, with a circular saw. The ring ought now to be ¼in. thick, and ⅛in. to ¼in. broad. If the piston has been turned all in one piece it will be a difficult thing to get a ring on it. One way of doing it would be this: turn a brass ring as before directed, heat it, pass it into recess, and then quench it with cold water. I am afraid that you will hardly make a good job of it. In this case steel would be the best material for the ring, as it would yield more with permanent distortion.—P. W. H. J.

[12158.]—**Packing Rings of Piston.**—Inclosed I send you a rough hand sketch of a piston and packing rings, and herewith append some descriptions:—Surfaces D, E, F, G, H of bottom half A of piston, all turned true to a common centre. As also must be surfaces D, E, I, J, K, L, M, N, O of upper half B. Piston surfaces H, G, and J, K, turned at first a shade larger than cylinder's diameter. The two rings turned at first three-sixteenths of an inch larger than cylinder's diameter, and of a width (together) such as to just jam fast, when surfaces D, E, M, N (by the thread or piston rod) come to contact by the collar C, on the rod being screwed hard. The surfaces O, N, M, L, E, F being moving contact without any shake. The rings are then taken out, and ⅛in. slit out by a saw, as shown (Fig. 3) at P, Q, R, S; while a piece of thin thirty-second part of an inch spring steel is riveted to each ring, as shown (Fig. 2 and 3) permitting their sliding contact on each other through holding them both as one ring. They are now put in their groove in piston, closed the ⅛in. that has been taken out of them, and jammed fast by the thread on the rod. All are now placed in the lathe again (in the previous



centres), and a cut taken from H through G and J to K till just fitting the cylinder "exact." Then release the rings by introducing a sheet of writing-paper between D E and M N, when all is screwed hard again and ready for the cylinder. The amount of paper introduced should not be more than will permit motion to the rings without chatter. The paper must not be omitted, as it not only prevents unscrewing when at work but will be found in years after, by a few hours' soaking in hot water (boiling) to give way curiously when the piston is required again to pieces. Piston rings and cylinder of "cast iron," when if the cross-head guides and stuffing-box on rod be true in a straight line, and a good priming trap be used, this, piston rings and cylinder, will soon become one brilliant burnished surface, friction and wear becoming thereby nearly *nil*. Mr. M. L. Dodsworth, if he takes care to produce this burnishing result, will be astonished at the years his piston will go quite tight.—X. M. S.

[12160.]—**Size of Iron Tool, &c.**—I thought "Optical Bricklayer" (p. 341) would have inferred from my last letter that there could only be one correct size for the polishing tool, the diameter of which should be just so much larger than the diameter of speculum as the sloping margin of the pitch requires. It is obvious that anything larger is superfluous, while anything smaller will not give enough support to the edge facets. The performance of his mirror is certainly very creditable, but if he aims at still greater perfection, he will find that scrupulous attention to the size of tool is not of so much consequence as perfect regularity of pressure between every part of tool and mirror. There is no difficulty in getting this when the two surfaces have rubbed together for an hour or two, but it is in the retouches when parabolising that the difficulty occurs, and each time the mirror is removed from the polisher for the purpose of testing it will be found, on recommencing work, that they do not work so smoothly as before, owing undoubtedly to the fact that the pitch tool has lost its fine figure. To keep this fine figure on the polisher is, then, the point upon which all the operator's skill and patience should be brought to bear. I regret, for the sake of your querist, that what suggestions I can offer I have not yet had the opportunity of trying, as pressing engagements have obliged me to discontinue optical work for some time past, but it appears to me necessary that a duplicate mirror, or else a concave tool that has been ground and polished upon the same tools as the mirror, should be kept for the express purpose of re-figuring the pitch, which should be done with precisely the same stroke and motion as that used for the speculum; and as soon as the concave tool rotates regularly and smoothly upon the pitch, the retouching of the speculum may then, and not till then, be commenced. I may add that it seems equally necessary to figure the pitch tool accurately at the commencement of the spherical polishing, as for those finishing touches that only occupy a few minutes, and on no account should the speculum be made to do the rough work of rubbing up an incorrect polisher until it assumes its own figure. It is advisable, too, to finish the parabolising with rouge of the softest kind. I should be pleased to know the opinion of the Rev. H. C. Key upon this mode of procedure, as a few words from him would be worth more than all I could say to your querist, although I have no doubt that if "Optical Bricklayer" will patiently follow it out, he will in the end find his pains handsomely rewarded.—W. PURKISS.

[12165.]—**Cream Cheese.**—There is a kind of cheese made by the Germans which I hope no Englishmen will imitate. I think that the people who could eat that with relish deserve a prize medal for endurance. I will therefore describe the process of making English cheese as ordinarily carried on. Cream cheese is prepared by mixing an additional quantity of cream with milk previously to coagulating the whole with rennet. Rennet is the membrane of the calf's stomach, prepared in a peculiar manner, which possesses during life the property of coagulating milk, and retains this property to a remarkable extent after death. All the different methods of preparing rennet have the common object in view, to protect it from undergoing putrefaction. This is done either by smoking, salting, or by both at once, or, lastly, one of the three methods combined with the use of spices. When rennet is salted in the dry state it soon produces a salt brine, which also exhibits the power of coagulating milk, and is employed for that purpose. While in many districts it is the practice to remove the milk that has curdled in the stomach, custom has proscribed in others the use of the stomach, together with its contents, as rennet. In the latter case the cheese is less easily preserved, the butter in the coagulated contents of the stomach having a strong tendency to become rancid. It is remarkable how powerful an action is exerted by a very small quantity of rennet. Thus, one square inch of rennet, smoked and salted, is sufficient to coagulate 80 quarts of milk. In Scotland, for instance, where they do not employ the rennet itself, but an infusion of whey or salt and water with rennet, a tablespoonful is enough to coagulate 120 quarts of milk. The infusion employed in the manufacture of the Limburg cheese appears to exert a still more powerful influence. It is obtained by allowing salt and water to trickle through the smoked rennet. According to the statements of the farmers, from four to six drops are sufficient to coagulate 24 quarts of milk. Whether the acid property of rennet is the sole cause of this power has not yet been ascertained, at least I have not seen it mentioned; and it is to be remarked that very often acid parts of vegetables (say, for example, lemons or bramble leaves) are used to assist the rennet, and that that substance, according to all experience, becomes more active by keeping. Berzelius found that 1 part of rennet only lost ·06 parts by weight of its substance in coagulating 1,800 quarts of milk. In Cheshire, a portion of this dried stomach is put into half a pint of lukewarm water, with as much salt as will lie upon a shilling; is allowed to stand over night, and in the morning the infusion is poured over the milk. Dr. Holland said that for a cheese of 60lb. weight a piece about the size of half a crown will often be sufficient, though of some skins as much as 10 sq. in. is often required to produce the same effect. The coagulation of the milk is often assisted by means of large caldrons built over a fire. The best temperature is about 104° Fahr. Soft or hard cheese, with proper attention to these circumstances, can be prepared at will. Season and locality appear to exert great influence in the amount of cheese yielded by milk; 8lb. to 10lb. of good milk and cream should give 1lb. of cream cheese.—P. W. H. J.

[12180.]—**Seasoning Pear Wood.**—A. H. Cooke should cut the trunk of his pear tree into planks, when it would become seasoned much more quickly, and would not be injured by splitting. It will turn well, and is a nice kind of wood for carving into ornaments.—E. B. F.

[12185.]—**Madnip and Wood Laurel.**—Madnip is an old name of the cow parsnip, *Heracleum sphondylium* L., and a figure is given in Gerard's "Herbal," by Johnson, p. 1009. Among the virtues of the plant these are enumerated:—"If a phrenticke or melancholicke man's head be anointed with oil, wherein the leaves and roots have been sodden, it helpeth him very much, and such as be troubled with the headaches, and the lethargie, or sickness, called the forgetful evills." No special medicinal virtue is attributed by modern writers to the cow parsnip. I have somewhere read that in northern Asia the skinned root is a favourite morsel with the natives. Wood laurel is, I conclude, *Daphne laureola* L., spurge laurel, a dwarf shrub, not uncommon in woods, hedges, and thickets. In most catalogues of native plants it is named spurge laurel; but in the excellent "Flora Vectensis," Dr. Bromfield gives it the name of copse or wood laurel, as well as spurge laurel. I remember when in Sussex, the sudden clearance of a wood of every plant of this species by strangers; on inquiry, the cottagers told me that it was taken to market at Chichester and Portsmouth, and sold as a horse medicine, but I could not learn in what class of diseases it was used. The bark is hot and pungent enough. The plant, especially the bark of the roots, has been usefully applied in some skin diseases of bipeds. See *Pharmaceutical Journal*, 1, 397, and Dr. Cullen. I had some reason for believing that the bark of *D. laureola* was sold as a substitute for that of *D. mezereon* in making compound decoction of sarsaparilla. Its qualities, indeed, are similar; as are those of other species, *D. Gnidium*, *Pontica*, &c. See Dr. Lindley on the subject in "Vegetable Kingdom," p. 531, second edition.—GERARD SMITH.

[12186.]—**Cheap Farming.**—Try the Scotch rotation crop system, or stall feed all your cattle. Large portions of land are ruined by turning it into pasture or grazing ground for sheep and cattle. The grass is trodden upon, killed or stunted in growth, and the surface becomes hard and barren for the want of cultivation. A great many things could be said against the grazing system, but as it is an easy, indolent, and aristocratic way of farming, it is generally adopted to the impoverishment of the labouring classes.—RAT-TAT.

[12196.]—**Rendering New Rope Flexible.**—Unlay it and make it up softer, or take the turns out—*i.e.*, twist it partially open, or trust to weather and wear. White manilla is naturally stiff and unmanageable.—HENRY NEWMAN.

[12197.]—**Roses.**—Gloire de Dijon, Maréchal Neil, Souvenir de Malmaison, Louis the XIV., and Sénateur Vaisse. These embrace as many colours, and the three sections, Tea-scented, Hybrid Perpetual, and Bourbon.—IRISH MECHANIC.

[12199.]—**Speeding Pulleys for Gut.**—Has Mr. Williams tried a pair of conical pulleys?—RAT-TAT.

[12199.] — **Speeding Pulleys for Gut.**—If E. Williams will make exactly the same difference in the diameter of his large cone as small one he will find his gut will drive on any speed. Thus, suppose his large wheel is 2ft. 6in., and the smaller speed on his cone 4in., the next on large wheel is 2in. less in diameter; the next on the cone will require to be 2in. in diameter larger, and so on; and *vice versâ*, 2ft. 6in. = 4in. speed; 2ft. 4in. = 6in. speed; 2ft. 2in. = 8in. speed.—E. S. S.

[12199.] — **Speeding Pulleys for Gut.**—The principle is that the sum of the radii of each speed shall be equal. For instance, suppose a driving-wheel of 4 speeds to be 3ft. diameter, or 36in. at smallest groove, then let diameter of largest speed of pulley be (say) 14in. Then 36 + 14 = 50, which is a constant to be abided by. Let diameter of pulley be required to diminish in steps of 2in. Then successive diameter = 14, 12, 10, 8, ∴ diameter of grooves of driving-wheel = (50 − 14), (50 − 12), (50 − 10), (50 − 8), that is 36, 38, 40, 42in. respectively.—P. W. H. J.

[12200.]—**Levelling.**—In reply to "Bricklayer's" question, the figures 50·76 mean 50ft. and 76·100ths of another foot, above a fixed datum level. This may be called 50ft. 9in. without any greater error than the one-hundredth part of a foot, or a little less than an eighth of an inch, the exact height in feet of 50ft. 9in. being 50·75ft. And in all cases of decimals of feet, if they be multiplied twelve times the result will be inches, or inches and parts of an inch. Thus ·76 × 12 = 9·12—that is, 9in. and 12·100ths of another inch. And in the same manner if the decimal ·12 be multiplied eight times the result will be eighths of an inch. Thus, ·12 × 8 = ·96, or very nearly one-eighth of an inch.—C. S.

[12200.]—**Levelling.**—"Bricklayer" is perfectly correct in his assumption; the levelling staff is divided into feet and decimals—thus, 50·76 would stand for 50ft. and 76·100ths of a foot.—SURVEYOR.

[12200.]—**Levelling.**—"Bricklayer's" idea is no doubt correct, though he has not managed to express himself precisely; the 50·76 represents 50ft. and 76·100ths of a foot.—EXCELSIOR.

[12202.]—**Boat Building.**—The best book, in my estimation, on the above subject is "The Book of Boats," by W. H. G. Kingston, price 3s. 6d., to be obtained of any good bookseller in the country. It has very clear and concise directions for making and rigging models of all descriptions; it also contains descriptions of all ships and boats to be found floating in any part of the world.—A. G. H.

[12204.]—**Pansies.**—In answer to "One Anxious to Learn" (No. 378), if not already answered, I find the following an easy method of striking slips of pansies:—Get some good loamy soil (*i.e.*, turfs cut from an old pasture is the best, and turn the grass side down for about a year, until they are thoroughly rotten and incorporated into one mass), ½ part of this to ¼ of dung rotted to mould, and ¼ part sand. Well mix and run through a wire sieve, having prepared a place on a warm border, by taking out the common soil, and replacing with this composition. Get some cuttings of choice sorts, about 1in. or 1½in. long, cut just below a joint, cut the leaves close off half-way up, water the composition, and with a sharp-pointed stick dibble them in up to the lower leaves—that is, put the cutting half way in, sprinkle a little sand round about them, and cover with a hand-glass; shade from the sun for a few days, and in six or eight weeks they will be ready for transplanting; they may be saved during the winter by sticking a few twigs round them or lightly covering with a little straw. I have never succeeded well with the frame, nor yet tried seed; the following are good ones:—D'Israeli, White Sergeant, Ophir, Aurora, Gem, Queen of England, Duke of Norfolk.—PHŒNIX.

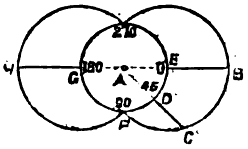
[12205.]—**Double Rockets.**—Best from seed. Sow in the autumn to bloom next year. Perennials, quite hardy.—S. BOTTONE.

[12206.]—**Geraniums and Fuschias.**—The two following are good fuschias:—Bo-peep, and Warrior. The finest scarlet single geranium, Bonfire; double scarlet, Madame Lemoine, and Triompe, generally sold by London florists about 3s. 6d. per dozen.—PHŒNIX.

[12206.]—**Geraniums and Fuschias.**—Geraniums: Excellent and Victor Emmanuel, zonale; Mrs. Pollock and Lady Cullum, tricolor; Crystal Palace Gem and Bijou, bicolor. Fuschias: White Perfection and Marvellous.—S. BOTTONE.

[12206.]—**Geraniums and Fuschias.**—Clipper, Monster, and Richard Headley, among the former; Wave of Life and Cloth of Gold, among the latter.—IRISH MECHANIC.

[12207.]—**Light.**—(1) A beam of polarised light can be readily and completely intercepted by the rotation of the analyser, whether it be a tourmaline, Nichol's prism, or plate of glass, or mica, placed at exactly the right angle. (2) The proportion of polarised to unpolarised light increases very rapidly as the position of complete polarisation is approached. In the accompanying diagram the amount of light which will pass through the analyser in various positions is indicated by the distance which the radius of the smaller circle must be produced before it cuts the circumference of one of the larger circles. Thus, if the analyser be arranged so that it may coincide in position with the polariser, and the amount of transmitted light be represented by the length of the line E B, on revolving the analyser through 45° the light will be reduced to D C, and at 90° complete darkness will occur. On passing this point the light very rapidly increases, attaining its maximum again at 180°



and returning to zero at 270°. On this account in reflecting polariscopes when the angles of the glass plates are not perfectly accurate, a very sensible amount of light is observed when complete darkness is expected. Nichol's prisms, tourmalines, and Herepathite readily give complete darkness.—ALFRED H. ALLEN.

[12207.]—**Light.**—If two similar plates of tourmaline be placed together, so that light polarised in one plane can be transmitted, objects may be seen distinctly through them, but on turning one at right angles to the other, absolute darkness occurs, because the second plate absorbs the light transmitted through the first. A ray of plane polarised light may be very conveniently obtained by allowing common light to be incident on a double refracting crystal, as calcite, when it will be divided into two beams polarised at right angles to each other; by sticking a wafer or a piece of black paper over the point of emergence of one polarised ray, it is possible to obtain the other in a state of isolation. If one of the beams of light obtained by double refraction, either by the above method or by some other, be received upon the lower plate of Birt's polariscope, the light will be completely absorbed, provided that its planes of polarisation be in the same position and angle. When light is reflected from glass at an angle of 56°, 45° consists almost entirely of light polarised in one plane, equal to nearly one half of the incident light, it refuses to be reflected from a second glass plate on which it is incident at the same angle, when the plane of reflection is at right angles to the plane of polarisation of the ray. Hence, as one portion of the incident light only is reflected from the first plate, and that being absorbed when the second plane of incidence is at right angles to the first, it follows that no light ought to be reflected from the second plate if the polarisation of the light is complete. The effects thus observed of extinguishing light, by altering the position of the reflectors, are analogous to those observed by crossing two tourmaline plates. In that part of your question numbered 2, I am not exactly certain, but I have a table of the effects observed by turning the top plate of Birt's polariscope, allowing a candle to shine upon the bottom plate. I should think that from that you could get an approximate.

Inclination of planes of reflection.		Varying brightness of candle.
0°	..	Greatest intensity of light.
0° — 90°	..	Light decreases until it nearly vanishes.
90°	..	Light scarcely visible (with tourmaline probably vanishes).
180° — 270°	..	Same as 0° to 90°.
270°	..	As at 90°, scarcely visible.
270° — 360°	..	Gradually increases as from 90° to 180°.

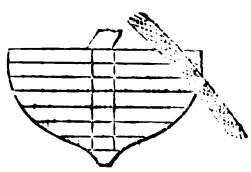
—P. W. H. J.

[12209.]—**First Railway.**—The first railway opened for passenger traffic was the Stockton and Darlington. The Act was passed in 1821 and the opening took place in 1825. The passengers were at first conveyed in a carriage, built by the late George Stephenson, and named by him the "Experiment," it had seats on each side with a table running up the centre, and was drawn by one horse. First, second, and third class passengers were all jammed into this carriage, and in dark winter nights it was lighted with a penny candle. It performed a journey daily each way between Stockton and Darlington. Although locomotive engines were used on this line from the date of the opening in 1825, for the conveyance of minerals and merchandise, yet it was only after the opening of the Liverpool and Manchester Railway, in September, 1830 (the second line opened in England), that they were brought into use for passenger traffic. Mr. Clephan, the editor of one of the local newspapers, describes some very amusing scenes that occurred on the line after it opened.—NORTHUMBRIA.

[12211.]—**Sea Mouse.**—The type of the family *Aphroditidæ.* Its scientific name is *Halithæa* or *Aphrodite* (Goddess of Love and Beauty) *aculeata.* It is well known on our coasts, and probably derives its name of "Sea Mouse" from its abundant covering of silky hairs, which are of a very brilliant metallic lustre, and may bear comparison with the plumage of the humming bird. The back is furnished with two rows of membranous scales which inclose the gills, but these are concealed by the hairy covering of the animal; the lateral setæ or bristles display on their surfaces a beautiful iridescent colouring, which on the movement of the hairs is seen to great advantage. The structure of the bristles or hairs is admirably adapted for weapons of defence; they have rows of barbs on each side, not unlike, when examined through the microscope, the spears used by certain savage nations. All the barbed setæ can be withdrawn into the body of the animal, but to obviate any injury which might arise from that act each bristle is inclosed in a smooth horny double sheath, which closes when retracted into the body and again opens when protruded. Although this animal is endowed with such gorgeous colours, displaying under a full supply of light the changing tints of orange, scarlet, and azure, yet its dwelling-place is in the mud. Even when kept in an aquarium they appear to avoid the light, and hide themselves among the weeds and stones. They are not unfrequently thrown up on our coasts after a gale of wind.—NORTHUMBRIA.

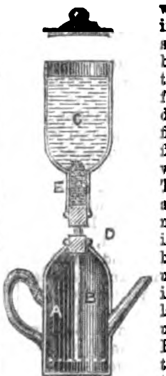
[12211.]—**Sea Mouse.**—The sea mouse belongs to the sub-kingdom *Articulata,* class *Annelida,* it is a sea worm allied to an animal with which "Scrutator," if he is addicted to fishing, is most probably acquainted, the rag-worm. The scientific name of the sea mouse is *Aphrodite aculeata*; it lives in the muddy or sandy bottom of the sea; it is of a long oval shape; its feet or pseudopodia are provided with bundles of long setæ or bristles, which form interesting objects for the microscope; its chief peculiarities are, however, first, the presence of expansions or flaps, one of which is attached to the upper edge of each foot in such a manner that they cover over the back and overlap each other like tiles on the roof of a house. They are capable of being raised and depressed so as to admit and expel the sea water into and from the chamber formed between them and the back, thereby aërating the fluids of the body which are admitted into their interior through an opening; the other peculiarity is that the stomach sends off numerous prolongations with blind ends which pierce the muscular walls of the body and are turned back close under the skin; this structure recals to mind the similar arrangement in some *Arachnidians,* the spiders for instance.—P. SANTALINUS.

[12212.]—**Yacht Building.**—Perhaps the way I adopted in building a similar yacht may be of use to you to know. Make a frame of inch stuff the shape you wish the widest part of the boat to be, and



fasten up in the place where you intend her to be widest; then take several of what are technically termed ribands, thin pieces of wood, say, 1½in. × ½in., and stretch from stem to stern, round frame on one side; then take an instrument, which you can make by riveting pieces of hoop iron, say about 2in. long, capable of taking any bend. This gives the general outline of the timber, and you can easily round off the angular lines produced, by the straight edges of hoop iron.—A., Liverpool.

[12213.]—**Coffee.**—Perhaps the following French machine will suit "Aggrieved Householder." The constituents of coffee and their reactions clearly indicated that to boil it upon the old plan cannot be judicious, but must always cause the loss of the greater part of the aroma. The better mode of preparing it is that of infusion, and it mainly depends upon good manipulation whether, with the same proportions of



water and coffee, an equally strong infusion with the same quantity of soluble matter is obtained as by boiling. The following is the contrivance that has found most satisfaction and is represented in the drawing:—The glass tube B B is fitted tightly into the neck of the flask C, by means of a cork, upon which a pierced drainer is placed. The tube can at any time be made air-tight in the boiling vessel, by means of the cork D D. The water is poured into A, the ground coffee being placed in C, which then lies upon the drainer. When the water is boiled by means of the spirit lamp, the inclosed steam pressing upon it, forces it to rise through B B into C, passing on its way through the ground coffee. When the lower end of B B is thus left open, the air and steam which is evolved from the remainder of the water find their way out through C, and soon bring the contents of this vessel to 212° Fahr., the steam condensing in the first instance, but afterwards passing through unchanged. This actual boiling is allowed to continue for a few minutes, and then removed from the lamp. The steam then condenses in A and produces a vacuum; the atmospheric air consequently forces the water with considerable pressure through the coffee, which, in the mean time, has settled down on the sieve E through B B to A, where it collects as a strong infusion. The coffee forms a narrow and tall column in the neck of C above E, which is consequently extracted rapidly with boiling water under a high pressure. The air rushing through after the infusion has passed forces out what remains in the pores. Attention must be paid with respect to the size of the powder of the coffee; when the strongest possible infusion is desired from a given quantity of the bean, one-fourth more extract is gained from coffee ground to consistency of flour than from the ordinary coarse powder. The filter must, of course, be adapted to this powder in order to keep the liquid clear. This machine will not act so well with heavily adulterated coffee, though it seems to pass chicory best of all the adulterations.—P. W. H. J.

[12216.]—**Transferring Marble Paper on Book Edges.**—Wring your book with the edge perfectly flat in the press, as tightly as possible. Then cut your strips of marble paper about 1in. longer than the edge. Pour on a plate some spirits of salts, and lay the strip on it, marble side upwards. When soaked lay it on the edge, which has previously been damped with a little water, then lay over the strip a piece of old blotting paper, and a pad of old waste paper, ½in. thick. Then take your hammer and rap it smartly and evenly all over, or it will wrinkle the leaves. Remove the pad and see if you have rapped it all over, if not, repeat the operation. Remove all tools out of the way and have your window open. Be careful not to let the spirits touch the glazed side of the paper, which spoils the effect.—PRACTICAL BOOKBINDER.

[12217.]—**Violin Tuning.**—Violins are tuned in fifths from the A string, downwards and upwards, and are thus tuned once for all, alterations in keys being made by different fingering, the open strings speaking natural notes, being, in extreme sharp or flat keys, avoided altogether. Some players, on the violin particularly, do not use the open strings whatever may be the key, the *timbre* thereof being different from that of a stopped note.—HENRY NEWMAN.

[12217.]—**Violin Tuning.**—Tune the 4th to G, the 3rd to D, the 2nd to A, the 1st to C, by a piano or good concert flute. Put your fingers in the right place at the proper time and there is no fear of you.—JOE.

[12217.]—**Violin Tuning.**—Tune your second string to A, and the others from it by fifths. Do not tune for each key; the defects in each key will be best got over by using the fourth finger instead of the open strings—*i.e.,* use the fourth finger on the fourth string; for D, open on the third string, and the fourth finger on the third string; for A, open on the second string, and the fourth finger on the second string; for E, open on the first string.—J. R., Leicester.

[12217.]—**Violin Tuning.**—With thirty years' experience, I never tuned my instrument in any other way but to fifths, and never alter to play in any key whatever.—A., Liverpool.

[12218.]—**Momentum.**—Mr. Jagger may have noticed that horses are inclined to stop when led slowly up a hill with a heavy load. The momentum gained by increasing the pace is very slight, as much is lost by the upward and backward tendency of the load, and can hardly amount to one-quarter of the additional force exerted. Drivers of locomotives, however, say that they get over inclines more easily by "taking a race at it," and the ease of ascent is greatly facilitated by beginning at a good speed.—RAT-TAT.

[12218.]—**Momentum.**—Yes.—XYLOGRAPHER.

[12219.]—**Turning Ivory.**—Ivory turns beautifully and requires no preparation. Use hard wood tools and polish with whiting and water, using flannel.—D.

[12221.]—**Brass Screws.**—"Falstaff" will find some very useful information in No. 335, p. 555, where the number of threads per inch for a bolt or screw 2in. diameter is given as four and a half.—J. C. L.

[12225.]—**Lead in Sulphuric Acid.**—The brown colour is not caused by lead alone, but is some other impurity. Water added to the acid will precipitate the lead as the sulphate, but you will not be able to use it for testing, or any purpose requiring pure acid.—XYLOGRAPHER.

[12225.]—**Lead in Sulphuric Acid.**—The discoloration of the sulphuric acid cannot be owing to lead, but is most probably caused by the contact of some organic matter which has been charred by the action of the acid, and has communicated to it the dark brown colour. If "Tony White" will concentrate the acid to specific gravity 1·845 (the strength of rectified oil of vitriol), with the addition of a little nitrate of soda, he will doubtless obtain a colourless acid.—ANALYST.

[12228.]—**Wood Engraving Tools.**—It would be simply impossible to use the present handles; but you must get some the same shape as shown at p. 298, Vol. X. They can be bought at any shop where they sell engraving tools. Perhaps the tools you have are wood carvers' tools.—XYLOGRAPHER.

[12228.]—**Wood Engraving Tools.**—In reply to "Zoo Andra," the tool handles figured in p. 298, Vol. X (not p. 288, Vol. IX.), are quite correct. The tools with handle should be 4½in. to 5½in.—A. T.

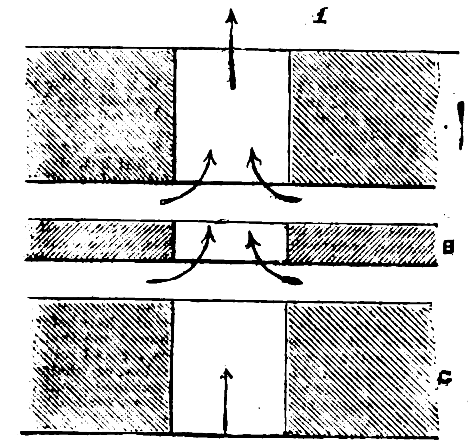
[12232.]—**Secret Spring or Lock.**—The piece of brass or other metal covering the key-hole could be easily furnished with a secret ward inside, which could be removed if discovered.—RAT-TAT.

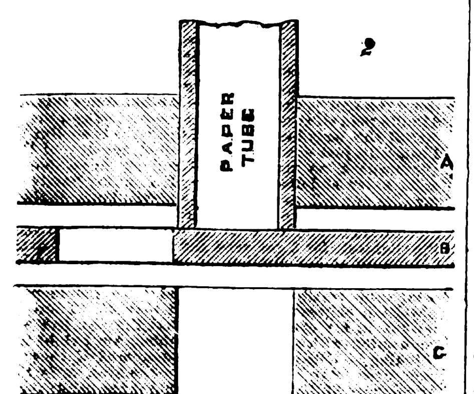
[12233.]—**Red Varnish for Patterns.**—If "England" experiences as much annoyance with red varnish on patterns as I have had, his cry will be, "save me from such stuff again." About twelve months ago I got from London a pattern covered with some sort of red stuff, which I took for red lead mixed with patent drier, probably a little oil. It did not leave a clean mould, the sand stuck to it and made a mess, and it took some three coats of varnish before the pattern was workable. The best varnish I know of to resist damp and an ordinary amount of heat is spirit varnish made of shellac, to be had at any druggists. If it needs be red, add dragon's blood to the desired tint. Give two coats.—W. D. T.

[12238.]—**Red Varnish for Patterns.**—"England" will find the following a very good varnish, resisting damp, and more than an ordinary degree of temperature. The recipe is gum shellac 1lb., methylated finish 1 quart. When the gum is thoroughly dissolved by the aid of gentle heat and frequent shaking, dilute with the finish to the required consistency for use.—C. N. M.

[12237.]—**The Organ.**—The fault appears to be in the chest rather than the bellows. Please answer the following queries:—1. Are the surfaces of the bars to which the pallets bed perfectly true? 2. Are there any chippings, &c., on surface of pallets? 3. Are they sprung or warped? 4. Do guiding-pins grip pallets and prevent their closing? 5. Are their upper surfaces properly leathered? 6. Do they sufficiently overlap the bars and front cheek to exclude wind from grooves, supposing spring, &c., to exercise the requisite force to press and keep them home? 7. Are tail pieces at joint end of pallets omitted, or not fixed sufficiently firm to press pallets home without straining hinge? 8. Are the grooves from tail end of pallets to back of chest properly covered in? 9. Is the joint between wind-bar (back of pallet chest), and under side of bars and pallet grooves, made air-tight? 10. Is the movement attaching pallets to keys put in, and if so, does it draw the pallets down, without the pressure of the finger on the keys? Take off front board of chest, and examine them. The escape of wind "all over the soundboard" is a serious matter, but the first step will be to prevent its unbidden escape from the pallet chest.—J. W., Plymouth.

[12237.]—**The Organ.**—I think I may venture to suggest that as the wind from the bellows reaches the stockboards it must pass the pallets, if I read "Aleph" correctly, and consequently there is fault there. I think that the contact of a well-fitting valve is sufficient, and the mere addition of a stronger spring if the valve is defective will not make it windtight. I subjoin the following as a matter of theory:—Let the diagram 1 represent—A, a portion of the upper board;





B, the slide; C, the table; and let a column of air pass up the hole, not fitting tighter than shown. The hole forms a kind of case or chimney for the air, which I conceive will draw air in from between the slides, and not force it out as generally supposed if the hole is bored true and set vertically as it ought to be. If the holes do not coincide, a great deal of wind must be lost, and, no doubt, this is the cause of the loss of wind in "Aleph's" organ. If I find in my own organ that I lose wind, or that a certain note speaks instead of its neighbour, I shall try the following:—Bore the hole much larger right through, shut in the slide. Make a paper tube to fit the hole and insert it as far as the slide. Cut the tube off level, and insert the foot of pipe. I also suggest another plan where the stockboards are not true. Cut diamonds or washers of leather and glue on to stockboard, one for each pipe. Provide a good straight-edge, and having surfaced the washers at each end, surface all the others to the straight-edge; this will provide a flat board mathematically true, and save the trouble of cutting grooves to prevent runnings. —DRAUGHTSMAN.

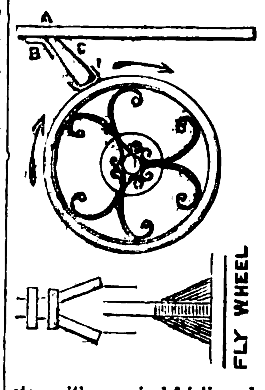
[12237.]—**The Organ.**—"Aleph" has got into a very common difficulty—viz., too hard leather on his pallets and not enough of whiting; no leather will do except the best unstrained and it must be well filled with whiting; the better plan will be to take the windchest to pieces, put another thickness of leather on into which plenty of whiting has been well worked, and try again; success will not be far off.—J. D.

[12239.]—**Hens' Eggs.**—Give plenty of room, change of food, and put a large wheelbarrow full of old lime rubbish or plaster within their reach. They are short of lime and grit.—JOE.

[12239.]—**Hens' Eggs.**—For laying soft eggs give Mrs. Chanticleer chalk, old mortar, pounded oyster shells, &c., strewed about her abiding place; but not egg-shells, as this latter induces her to eat her eggs, for which complaint try cutting her throat.—HENRY NEWMAN.

[12241.]—**Organ Pipes.**—The block wants bevelling off at the top and it will speak correctly.—J. D.

[12247.]—**Sewing Machine.**—"W. H. T." can apply a brake to the Wheeler-Wilson sewing machine in the following manner:—A, table of machine; B, small brass hinge; C, brake, with a piece of leather over the end to keep the wheel from slipping. When the wheel is running it knocks the brake up, soon as the wheel stops the brake falls, and prevents the wheel turning the wrong way. A 2¼in. stroke would drive the machine well with a good supply of steam. The best place would be underneath the machine, and start and stop with a conical friction clutch.—E. S. S.



[12247.]—**Sewing Machine.**—If "W.H.T." has an opportunity of inspecting one of Wilcox and Gibbs' sewing-machines, he will find that that machine has an extremely serviceable and simple brake attached to it, which prevents the machine working backwards. The brake is attached to the large driving wheel. There is an iron guard placed round the near part of this wheel and toward the lower part of the guard is a cup formed in the casting, in which is placed a round rubber ball. Of course the guard should be fixed not so far off as to allow any possibility of the ball falling out, and yet not so close that the ball won't have free play in the forward motion of the machine. "W.H.T." will find that if he can apply one of this kind to his Wheeler and Wilson, it will effectually prevent any backward motion of the machine, as when it is inclined to go that way, the rubber ball having fallen to the bottom of the cup acts as a brake on the wheel and stops the motion entirely, but when the machine moves forward in its proper direction the ball is no impediment whatever. I don't know if this part of the machine has been patented or not.—TOM-TIT.

[12247.]—**Sewing Machine.**—Wheeler and Wilson's machines are now made with a brake by means of a ball which checks the fly-wheel. It can be removed, and I think, except for learners, with advantage.—IRISH MECHANIC.

[12249.]—**High-Pressure Fire-box Boiler.**—By the above title I presume that "495" means a Cornish boiler. There is a little vagueness in his remark that 80lb. steam will be sufficient for warming and dyehouse; the pressure in this case has nothing to do with the quantity of steam required. Besides, for warming, steam is working the most economically when there is only one or two pounds pressure. For a mill of 40 by 80 by 20 yards one horse-power would be more than sufficient. I shall suppose that five horse would do all the warming, dyehouse and all. To move the engine I shall allow thirty horse. Then I shall suppose that thirty-five horse will be large enough. I will now furnish a rough specification:—The boiler is to be of the class known as Fairbairn's boiler; it is to be 30ft. long and 7ft. diameter, double riveted throughout; there are two tubes that contain the fire, and act as flues, each 2ft. 3in. diameter; the tops or crowns of the tubes to be 3in. below centre line of boiler. They are to be ⅜in. thick, best Lowmoor iron, with strengthening ring of 3in. angle iron riveted on to the tube at 10ft. from each end. There are to be three iron rods 1in. diameter for stays, one passing through the centre line and the others 2ft. from it, forming an equilateral triangle. The length of firegrate is to be 7ft. 9in. long, width same as tube; thickness of firebars, ⅞in., distance between them, ½in. For each tube the bars are to be made in three sets, supported by crossbars ⅞in. by 2in. cast iron bolted to the tubes. Each set is to be made 2ft. 7in. long, and 3¼in. deep at middle, diminishing to 2in. at ends. Bridge to be of firebrick, about 20in. high. The fire-doors are to be 16in. by 13in., set in an iron casing bolted to boiler, to be ½in. thick; the door to have ⅝in. burn plate fastened to it, at about 1½in. distant from the door *in principe*, which is to have a 1in. hole in the middle, with a brass slide over it to admit air. The burn plate is to be 17¹⁵⁄₁₆in. by 12¹⁵⁄₁₆in., and to have 20 ⅛in. holes drilled in it at about equal distances. The casing is to stand out 6in. from front plate of boiler, and to be the same for both tubes. The dead plate is to be 10in. long, and the whole width of the tube. The manhole is to be oval, with cast-iron ring riveted to top of hole to be ⅞in. thick and 2in. wide; the hole is to be 18in. by 15in. The door, or lid, is to be 21in. by 17½in.; two ⅞in. bolts are to be riveted into the door, and they must have good screws and nuts. There are to be also two cast-iron D pieces with holes for the bolts to pass through. The weakest section of the D pieces must not be less than ⅞in. by 1in. The nuts are ·9in. square. Next for the mountings. The safety-valve is to be an iron casing bolted over a hole of 5in. diameter. There is to be a gun metal seat in the casing; it is nowhere to be less than ⅜in. thick; the valve opening is to be 6⅜in. diameter. The bearing surface of valve upon seat is to be ⅛in. broad. The valve is to be ½in. thick gun metal, there are to be three guiding ribs cast on it ¼in. thick; total depth of valve and ribs = 6in. The valve spindle is to be 1½in. in diameter. Length of lever to be 3ft., depth = 4in., diminishing to 2in. at weight end, with a small projection ½in. high at that end to prevent weight being thrown off. Weight required to produce 80lb. = 874lb., and diameter of ball or weight = 13in., flattened a little on both sides with screw a side ½in. diameter so as to clamp it in any position. Area of damper = 4ft. by 16in. to be ⅛in. thick sheet iron. Damper counterbalance weight to be 8in. by 10in. by 5in., to be connected with damper over pulleys by chain about ⅜in. thick. The blow-off is to be 3½in. diameter at mouth, and other parts in proportion. There are to be two large glass water gauges, having a range of 10in. The boiler is to be inclined about ¼in. in 10ft. in setting towards blow-off cock, which is to be fixed at the front of boiler, near the side at the bottom. The back pressure valve is to be fixed at front at the bottom between the tubes. These are the principal details, and if "495" is in a further difficulty, if able, I will answer it.—P. W. H. J.

[12250.]—**Chemical.**—Potassium and sodium unite readily. One part of sodium forms with from one-third to ten parts potassium, a compound which remains fluid at 0° Centigrade. When too much sodium is added the alloy becomes brittle and crystalline. In all these alloys the potassium becomes oxidised first. The above is an extract from Gmelin's "Handbook," Vol. III., p. 119. When this alloy is brought into contact with water hydrogen gas is evolved, and the water contains in solution a mixture of sodium and potassium hydrates.—ANALYST.

[12253.]—**Organ Construction.**—The stops I would recommend "Amateur" to use are—Great organ, open diapason, stopped diapason, bass, claribel treble, principal, fifteenth; swell Lieblich Gedact (metal) gemshorn, hautboy; pedal, Bourdon. In "ours" of September 8 last "Amateur" will get full directions respecting couplers.—J. D.

[12255.]—**Hair.**—Shave for a couple of months, and avoid hair lotions as you would avoid poison.—D.

[12277.]—**Aniline Black.**—Leaving Mr. Geo. Davis to give a recipe for the preparation of this colour, without acid, I beg to recommend "Couleurs a l'Aniline," one of the manuals in Roret's "Enciclopedie" as being a most exhaustive work on the subject. —S. BOTTONE.

[12279.]—**Diminished Action of Battery.**—Due to exhaustion of acids, which can only be remedied by replacing with fresh. Great care ought to be given, and very seldom is, to the balancing of the strength of the nitric acid and the sizes of the inner and the outer cells so as to secure efficient working and economy.—SIGMA.

[12292.]—**Breadth of Stair Steps.**—The breadth of step is not proportioned to the length but to the rise, and in such a narrow example as that given, should be calculated at the middle of the step. It is found thus: Breadth $= x - 2h$, in which $x =$ the length of a step in ordinary walking on level ground, generally taken as 24in. Thus, if the rise be 6in., breadth $= 24 - 2 \times 6 = 12$. But account must also be taken of the position of the top step in relation to the bottom one. If it be vertically over, the higher it is the greater will be the rise and the tread less of each step.—C. E.

[12294.]—**Larkin's Iron and Brass Founder.** —I bought my copy at Batsford's, High Holborn, for 6s. 6d.—S. BOTTONE.

[12295.]—**Engraving by Graphotype.**—Though the mode of etching on a salt, as proposed by "Philanthropist," is theoretically possible, I am afraid that in practice it would be found extremely difficult of execution. Few salts which would admit of being produced as smooth blocks would possess sufficient hardness to give a number of impressions, besides, there would be the difficulty of limiting the sphere of action of the hardening fluid so as to obtain sharp lines. Again, the action of the hardening fluid, if it were possible so to limit it, would be so superficial as to render the resulting block of very little service.—S. BOTTONE.

[12297.]—**The Tremolo.**—The art of playing on the violin is so difficult to acquire that the learner has to attack each obstacle with great perseverance, remembering that when he is about to give it up as a bad job, then it is the proper time to begin over again. Young ladies and gentlemen require a great deal of pressing before they will sing a song; but the violin is very much in want of pressure before it will even squeak out "God Save the Queen." Our great Dr. Johnson, who hated music, said, "Give a man a pig of leather and he might cobble a shoe, or some of and he might make clothes, or try him in anything and he would manage to make a somehow, but put a fiddle in his hands and he can do nothing." If the Doctor had only learnt to play on the fiddle, we should have had the gruffest sentimental compositions in the world, and John Bull would have been first again. With respect to playing tremulously, or in a trembling manner, it is wrong for a beginner; rather learn to play tremendously, that is, with determination; hold your fiddle tight round the neck with your thumb, press your fingers down on the strings as hard as you like; then, after an hour's practice, begin the trill, or shake very slow at first, never too quick, and I think by the time you can shake one note after, or into another, without changing the position of the hand, you will have learnt a great many curious things (as the spider said to the fly) you never saw before.—FIDDLER.

[12304.]—**Phrenology.**—Without going fully into this I may say that the brain forms its case, and the brain is derived primarily from the parents and under causes acting during gestation. That brain, education can only very partially modify, and no greater mistake was ever made than to suppose, as some of our great writers do, that a child's mind is a blank sheet of paper on which we can write what we please. Even this partial effect of education is limited to the period of life when the brain and the bones are in process of development, and thus "Saul Rymea's" difficulty vanishes. I have known one person at least who watched this matter upon himself and declared to me that he found a very distinct alteration in form of his head after some months of earnest study.—SIGMA.

[12306.]—**Botanical Names.**—The plant described as "French Willow" is in all probability one of the willow-herbs; Latin, *Epilobium*. Of the *Epilobiums* there are nine British species — viz., *E. augustifolium*, *E. hirsutum*, *E. parviflorum*, *E. montanum*, *E. roseum*, *E. tetragonum*, *E. palustre*, *E. alsinifolium*, and *E. Alpinum*. The individual possessed by by "Hortus Siccus" is probably *E. hirsutum*, well known in the country as "Codlings and Cream." The plant which my inquirer calls "Rose Pea," I do not know under that name. It is certainly one of the *Leguminosæ*, and most likely *Ononis arvensis*; Anglice, "Rest Harrow."—S. BOTTONE.

[12307.]—**Kerosene.**—This is the American name for the illuminating oil (so-called) derived from petroleum. It is, of course, a very variable article as to its constituents and quality, and its only extensive use is for lamps, though it is occasionally stated to have various medical properties.—SIGMA.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "H. O'B." has answered 11625; "J. D." 11837.

QUERIES.

[12308.]—**Iron Vats Leaking with One Liquid and not with Another.**—Will Mr. Davis or Mr. Bottone, or any other chemist, kindly inform me why the above do not leak with a boiling solution of Bengal nitrate of potash, but do leak with a boiling solution of muriate of potash and nitrate of soda (the artificial mode of making nitrate of potash)? My notion is that there is often an excess of nitrate of soda in the solution (caused by the analysts abroad giving an erroneous analysis of the muriate of potash—*i. e.*, it is not so pure as estimated). I presume that nitrate of soda with common salt is a more penetrating solution than nitrate of potash, but, perhaps the chemists can suggest cause and cure. The vats are cast in five pieces with angles or flanges, which are screwed together with nuts, a thin piece of wood being placed between some, but in others they are caulked with iron cement. I have formerly refined nitrate of soda by itself, and the solution did not leak from the vats.—R. J.

[12309.]—**Boiled Oil.**—Will some reader tell me how the boiled oil used by artists is prepared? Also, how to make a good medium or vehicle for oil painting?—G. W. C. H.

[12310.]—**Professors.**—Will some one of the ever able and ever obliging correspondents of our cosmopolitan publication be kind enough to tell me what constitutes a professor: I mean who has the right to call himself a professor? Professor Huxley or Professor Beesley I can understand, but what about Professor Pepper; or Professor Anderson, the sleight-of-hand man; or Professor Beckwith, who teaches swimming?—P. D.

[12311.]—**Hydraulic.**—I have a well on my property situate in the West of England, the water of which has hitherto been salt and brackish, and totally unfit for anything but culinary purposes. In addition to the foregoing defects, the supply usually ran short in the summer season. In order to augment the supply, and render the water more pure, I was advised to carry the rainfall water from the roofs of the premises into the well. The well in question is 25ft. in depth, and the natural supply of water generally about 10ft. A few copious showers usually fill the well to overflowing, at which time the water is suitable for making tea, grog, &c., and remains so, until from 10ft. to 15ft. has been pumped out. The pump pipe is fixed to within 12in. of the bottom of the well. Having stated the facts of the case, I should be extremely thankful if any of your subscribers would solve what to me has been a difficult problem for some months since—viz., why is it that the rainwater, which I suppose to be of the least specific gravity, is first drawn off, the pump pipe being, as before stated, so near the bottom of the well? I might also state that a neighbour, who has a well 70ft. deep, and a force pump reaching to about midway, finds the same results.—GLASTON.

[12312.]—**Brick Vaulted Arches.**—We have a reservoir in course of construction which we purpose to cover with 9in. brick segment arches of 8ft. span. We wish to know which of the two following methods are considered to possess the greatest amount of strength—viz., two separate rings of bricks, or the arch turned and bonded with headers and stretchers. We are inclined to think the last mentioned the strongest, as it would require but one key. We wish to know if the above has ever been tested.—AVALON.

[12313.]—**Portable Gas Cooking Apparatus.**—Will some correspondent who is practically acquainted with those handy little boiling and broiling stoves which boil over and broil under—such, for instance, as Leoni's atmospheric gas rings—inform me whether they are efficient, and, with gas at 6s. a thousand, economical? Is Leoni's, which appears to be the most expensive, very much better than those of other makers, and is his smallest size, which is only 8in. in diameter, sufficiently large to be useful in the kitchen of a small family, saving, for instance, the time and trouble of lighting the kitchen fire for breakfast, or cooking a plain dinner, on an emergency, for two or three persons? If not, what diameter should be chosen?—Q.

[12314.]—**Bleaching Tanned Goods.**—I should be much obliged if Mr. Bottone or any other of your chemical correspondents would tell me if it is possible to bleach or discharge the brown colour of tanned goods, tanned with oak bark.—TANNIN.

[12315.]—**Dubroni's Photographic Apparatus.**—Will some kind correspondent who has seen or used this apparatus inform me if as good negatives can be produced by it as by the use of an ordinary camera and dark room? Also is it liable to get out of order?—A. P. S.

[12316.]—**Scale.**—Will some kind friend explain the marks on a boxwood scale in a case of mathematical instruments? Under the inch scale is one marked from 10 to 50, each of which is $1/_{10}$in. Then one of ten horizontal lines, divided perpendicularly into nine above, reading from right to left, and into eighteen below, from left to right; with a scale of oblique lines at each end. The reverse side is divided apparently into 15ths, 20ths, 25ths, 30ths, 35ths, and 40ths of an inch. But at the end of this last there is a scale marked C, the divisions of which diminish from 10 to 90. What are the values of these scales?—MATHETES.

[12317.]—**Red Prussiate of Potash.**—Will some chemical friend give the mode of making red from yellow prussiate of potash?—BOB.

[12318.]—**Artificial Oils.**—Chemists say that oils of terebinth, bergamot, lavender, and cloves are isomers, and can be changed one into the other. I have often heard the above statement, as also the artificial production of oil of cinnamon and winter green; but nowhere have I seen the product, or read how it is done. Can some one give the process, or is it all a flam?—BOB.

[12319.]—**Dyeing Pulp for Sugar Paper.**—Will any of your correspondents kindly assist me as above? I am very often dyeing pulp for purple paper, and can't manage to get a slate colour. When using logwood chips I apply a little soda, when boiling after pulp is well washed I apply liquor and alum. Sometimes I use logwood extracts, but still I can't manage to get the black or dark blue shade. I generally apply 8lb. of alum to 100lb. of pulp. Is it too much?—A PAPER MAKER.

[12320.]—**Copper Coins.**—A small copper coin found on the track of the old Roman road through the parish of Carluke measures ⅝in. diameter, with the letters R D on one side quite visible. Would any correspondent tell what it is, or if it is worth anything? Also, a copper coin about the size of a halfpenny, with a St. Andrew's cross on the reverse side, date 1780, with flower on each side of cross; obverse side, a heart in centre with Scotch thistle. Would any correspondent say what it is?—J. WILSON.

[12321.]—**Chess Player.**—Can any reader explain how the automaton chess player is worked? It is at present exhibited at the Crystal Palace.—WILLIE SCORER.

[12322.]—**Bees.**—How can I keep the wasps away from my new swarms? Last year I had two hives completely destroyed by the wasps, and all the honey eaten out of them.—WILLIE SCORER.

[12323.]—**Scarecrow.**—Which is the most effectual way to frighten blackbirds and thrushes from the strawberry beds? Every year I lose many quarts by them, and have tried every kind of scarecrow I can think of, but without success.—WILLIE SCORER.

[12324.]—**Spoiled Hams.**—Having had a number of hams spoiled lately, I shall be very glad if some one can tell me how to cure them as the mild Cumberland hams are cured, and whether in a pickle or not?—J. E. P.

[12325.]—**Brazing Fine Saws.**—Will some practical brazier accustomed to band-saws inform me how, and with what chemicals, I can braze very fine saws, as I find that with borax, spelter, sal ammoniac, &c., I burn the saws before I can get the brass to run, but I believe there is a liquid chemical that makes it run quick?—E. S. S.

[12326.]—**Collodio-Bromide.**—Is it practicable to convert some bromo-iodised negative collodion (Mawson's) which I have, into collodio-bromide to be used in a wet state, chiefly and partly for dry plates, my principal object being to get the most sensitive surface I can?—TRIPOD.

[12327.]—**Horn.**—Will our friend "Jack of All Trades," or some other subscriber, kindly inform me if horn can be softened and moulded by any other means than heat, and, if so, how?—INQUIRO.

[12328.]—**Terra Metallic Tiles.**—Can any one suggest a process to remove the mouldy appearance of a terra metallic tile floor bedded in Portland cement? When the floor was laid and completed the tiles looked bright, but now they look so dull and mouldy. Frequent washing has had no effect.—PUZZLED.

[12329.]—**Practical Mechanics.**—Would you kindly permit me to inquire from some of your scientific contributors the name of any good book on practical mechanics? I have Twisden. If papers on this subject were commenced by one of the many able men connected with the ENGLISH MECHANIC, they would be received with much pleasure and profit by a large circle of readers.—AN IRISH SUBSCRIBER.

[12330.]—**Re Slide Rests.**—I should feel obliged by your allowing me to ask "J. K. P." if he would be kind enough to send the drawings promised on p. 392 of Vol. XII., No. 302, Jan. 6, 1871, in reply to "J. A. L." respecting the above. I think these are the drawings asked for but a very short time since by another correspondent.—H. E.

[12331.]—**Geometrical.**—Required, to find a point in a given straight line, equally distant from two given points not in the line.—R. G. G.

[12332.]—**Chemical.**—If an electric current be passed through a solution of hydrochloric acid, will the water or the acid or both be decomposed?—R. G. G.

[12333.]—**Purifying Mercury.**—Can any readers give me any information as to the best method of purifying mercury? I have some that I cannot clean by the usual method by filtering through a paper funnel, and when put into the barometer tube it falls and cannot rise again, with a thick black scum sticking to the sides of the tube.—BAROMETER.

[12334.]—**Eye Query.**—Would "M. R. C. S." or some other talented and obliging correspondent who knows something about the human eye, kindly tell me what is wrong with my eyes? For a long time any slight fatigue, such as reading a few pages of the ENGLISH MECHANIC, has been sufficient to make them feel hot, dry, and sleepy. Sometimes they ache painfully and are offended at the light. The aching always confines itself to the parts of the eyes that are immediately under the upper eyelids; but the hotness and smarting extends all over the eyes, even to the edges of the lids, which sometimes smart about the roots of the eyelashes. About a month ago, as I was looking with my left eye at a whitewashed wall, I observed a shadowy appearance on the wall—a little to the left and below the point of sight. I at first took this to be the shadow of a hair before my left eye, but a closer inspection showed me that there was something wrong with the eye, for as I rolled the eye about from side to side, the shadow, or whatever it is, moved along with it. At the distance of about 13in., the appearance is about 1¼in. long, like a vertical curved streak, A. A few days after the appearance of this streak, I saw with my right eye a little shadowy spot, a little to the right of and below the point of sight. The more I go to a light body—like a whitewashed wall—the better I can see these appearances, and the farther I go from it the more indefinite they become. The appearances are only seen when the eyes are moving about—from side to side shows them the best. Sometimes the spot in the right eye—at other times it is more definite than streaky in the left eye—projects on the surface of the body looked at. If the light is so dim that I can only just see to read, I cannot see any of these appearances, no matter how I roll my eyes about in order to try and discern them. If I put my hands over my ears and roll round my eyes about, I can distinctly hear them make a slight sound, as if they needed lubricating! The power of my eyes is not decreased in the slightest, for I can read the print of the ENGLISH MECHANIC at the distance of more than 2ft., without optical aid. A few months ago I had a very severe attack of smallpox, but, treated by a homœopathic physician of great skill, I am not marked. There was no pox in my eyes, but I fear that the pox has some connection with my present trouble. Am I right in so thinking? Will my sight be endangered if these appearances enlarge and spread over the eyes, or is there any danger of their doing so? What is the cause of this, and what is its cure? Yawning fills my eyes with water, which sometimes greatly relieves them, and for a few minutes renders the shadows less apparent. Is reading or tea drinking injurious to me? Would wearing smoked or other coloured glasses be of any service? A disease called rickets has made me unable to walk for nearly six years. Might this be the cause of these appearances? Replies are anxiously looked for, and will be thankfully received by—SPECTROSCOPE.

[12335.]—**Botanical Phenomenon.**—Can any botanical reader kindly favour me with an explanation of the following:—During the severity of the winter before last, 1870-71, a geranium which I have was nearly killed with the frost, the terminal branch, however, still retained its vitality, but in a very low degree, the lower parts of the stem being to all appearance quite dead. From that time to the present, a period of about eighteen months, a succession of new but small leaves have been produced, and within the last fortnight a blossom bud has appeared. The plant has been regularly watered once a week, not oftener; there has been but little addition to the upper living stem, which is very weak. I have also a specimen of *Cardamine pratensis* placed about ten months since in a globe, formerly used as an aquarium; the earth above the plant is very dry, the leaves retain their green colour; about the hundred...

of an inch of water is supplied every few days; atmosphere of globe moist.—W. R. BIRT.

[12336.]—**Vine Root.**—Would any gardener, and there must be some of that profession in the innumerable legion which reads the ENGLISH MECHANIC, kindly give me a little information on the following subjects:—I dug up a piece of vine root on a piece of ground whereon stood an old vinery, and divided it into two pieces and potted them. One died and the other has grown to a strong plant, 1ft. high, making several suckers from the root beside the main stem. Could I separate those suckers, or propagate another plant from cuttings, without injury to the vine above mentioned, and, if possible to do so, what time of the year is most suitable? The vine, I believe, is black Hamburg. —PHŒNIX.

[12337.]—**Heliotrope Seed.**—I purchased a packet of heliotrope seed of a seedsman, and he told me it would take a great heat to raise them. I tried them in a hot bed, both in a pot and likewise on the soil, covering the dung on the top of the hot bed; likewise in a pot in the house; also in the open border, and all failed. As I have some seed left, is there any other method of raising it, or is it, as I suspect, bad seed? —PHŒNIX.

[12338.]—**Hyacinth Roots.**—I turned out some hyacinth roots with the soil after the leaves decayed, and I want to know when to repot them. They have several offsets; should they be potted now, or not until the latter part of the year, when the old bulbs are planted. The soil has fallen from the bulbs, and they are now lying in a shady part of the flower border. Will they take any harm there, or should they be put away in boxes in an airy place? Some recommend September, others November, for the time of planting. I have no doubt that an answer to the above will interest many more beside myself, as I see there are many amateur florists in the MECHANIC.—PHŒNIX.

["Phœnix" will oblige by observing "Hints to Correspondents," Nos. 1 and 2.

[12339.]—**Veneers.**—Will Samuel Smither (let. 4331, p. 332) kindly help me out of a hole in getting some small specimens of choice veneers? I am making a table with small pieces, and find a great difficulty in getting any but very common sorts.—SHANINGTON.

[12340.]—**Flour Paste.**—Can any of your readers tell me how to preserve bookbinders' paste from mould and maggots? I make it up of flour, with a little resin and alum, boiled; and I always have it mouldy and maggotty before I can get it used, especially in the summer.—BOOKBINDER.

[12341.]—**Moths.**—My (carpeted) parlour is perfectly infested with moths, and spite of all efforts (lately having the carpet taken up and pepper strewn all over the floor for days), placing camphor all about, and much physical endeavour in the way of killing the creatures, no success is attained; but on beating the sofa, for instance, hundreds drop out at any moment, some fully fledged and others again as grubs. Not only is everything being destroyed by them, but it is in every other sense a perfect nuisance, rendering the room quite unoccupyable. Perhaps some kind friend who has successfully dealt with these pests will give me the information I am in need of.—A SUFFERER, Cologne.

[12342.]—**Pouncing Pattern on Printing Blocks.** —Will some kind reader tell me how the pattern is pounced on printing blocks? either floorcloth or paper-staining blocks.—NEW SUBSCRIBER.

[12343.]—**Dresser Top.**—I bought a new dresser about six months ago with a sycamore top, and it has warped very much. It stands an inch higher at one corner than the other, which makes it look very ugly. Could any of "our" readers tell me if I could remedy it? Would damp cloths put on it do any good?—J. GREENHALGH.

[12344.]—**Disappearance of Art.**—How is the disappearance of mechanical arts in countries of the East, such as Egypt, Assyria, &c., best accounted for?—A. B. M.

[12345.]—**Ontario.**—Would "our" Canadian friend "Gillem," who wrote letter 4880 in this paper of June 21st, 1872, kindly give further information in reference to Ontario as a field for emigration? In what part of the country are the extremes of heat and cold felt the least? What degrees do they register? What is the difference in temperature between the Simcoe Lake district and Toronto? What are the features of the lake district—dense forests or park like; any unoccupied land (Government) on the margin of the lake or partially cleared farm for sale, and price? What particular nationality predominates? What chances for a man to go into business or farming with a capital of £800, with a fair knowledge of either, and a mechanical turn of mind? How about society, fish, game, &c.? and any other information will be much appreciated by—DOLOMITE.

[12346.]—**Gearing Waggon Wheels.**—Not having seen anything on gearing iron axle waggons since I have been a subscriber, I take the liberty of asking if there is any one who would kindly inform me the proper way to set the arms to make the waggon run well?—U. V.

[12347.]—**Stroke.**—Would any brother reader inform me through the columns of the MECHANIC how the stroke of an engine is ascertained? Also, what means is there of finding out the size and weight of fly-wheel requisite for an engine, from a cylinder of given dimensions?—J. H.

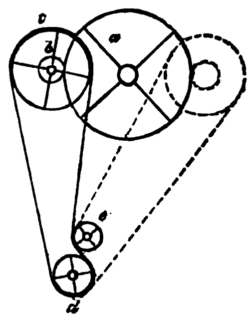
[12348.]—**Spanish Pronunciation.**—I have been for some time studying Spanish, and been taught both by my teacher and by the grammar (McHenry's), to pronounce *c* before *e* and *i*, and *z* wherever found, like the English *th* sharp. I now hear, however, that this pronunciation would, in Spain, be considered stilted and affected, and that the ordinary pronunciation of these letters resembles the English *ss*. I wish to know if this is the case; if so, to what extent the two styles vary, to what classes of people they are confined, and the style most useful for a foreigner to study?—CAST STEEL.

[12349.]—**Emigration.**—Will any fellow reader be kind enough to answer the following questions:—What part of South America is best suited for breeding cattle? Is there any place near Buenos Ayres where land is cheap or can be had by Government grant? What sort of an outfit would it be best to take? I want a good climate for an Englishman.—ALPHA.

[12350.]—**Sulphuric Acid.**—Can any of your able correspondents kindly inform me by what rule or how Dr. Ure compiled his scale of liquid, also dry, sulphuric acid in 100 parts? Also, if I have 40ft. cube of sulphuric acid, specific gravity 1720, what weight of acid, specific gravity 1750, would it be equal to? An example would oblige—CHILD.

[12351.]—**Underground Telegraph Wires in Cities.**—An American travelling in Europe and writing home from London, observes:—"A noticeable feature is the absence of air lines in cities—nearly all are under ground, and to this complexion we must come." Now, will some English telegraph engineer or electrician kindly give in "ours" the best method for running wires through cities, the location in streets longitudinally, and how they cross intersecting streets; with what substance the wires are covered to insulate them, and to protect them from mechanical violence, and the action of water? What provision is made for reaching them for repairs? Their liability to get out of order? What amount of embarassment are the lines subject to from induction, and has there been found any effectual remedy therefore? Finally, throw in such practical hints as will suggest themselves for the benefit of a new American subscriber. I have searched Culley in vain for such information, and almost the only information I have ever come across was Sabine's report of telegraph apparatus, &c., at the Paris Exposition, published in *Illustrated London News*. —DYNAM, Chicago.

[12352.]—**Centrifugal Pump.**—I should be very thankful for some instructions from some of "our" mechanical correspondents. I am driving the above pump with a 16 horse-power condensing engine. The gear as per sketch:—*a*, spur-wheel on fly-wheel shaft, 28 revolutions per minute, by pinion 4½ to 1; *c*, pulley on pinion shaft 6ft. diameter, 126 revolutions; *d*, pulley on disc shaft 2¼ft., making 375 revolutions. The pulleys are connected with a patent chain 14ft. apart, which is constantly breaking. Will it answer to put the pinion and large pulley on the right hand side of spur-wheel as per dotted lines? It would be 81° from perpendicular line. Would a double leather belt drive the pump in that position 10in. broad. The water has to be raised from 5ft. to 12ft. high. How many revolutions should a 2ft. disc make per minute?—TEACHABLE.



[12353.]—**Grinding Scythes, &c.**—Can any one inform me whether machinery for making or grinding scythes and reaping hooks has ever been invented, and if the same has been erected anywhere? The machinery having to be erected in a country where skilled labour is scarce should be of the simplest kind.—SCYTHE.

[12354.]—**Lathe Construction.**—Will "J. K. P." or some other reader be so kind as to give me the dimensions of the fast headstock of a small lathe 2½in. centres, with conical mandril and collar, length and size of mandril, and the best angle for same? Ought cast-steel collars to remain hardened or be tempered? A drawing would greatly assist.—C. N. M.

[12355.]—**Fermenting Bread with Starch.**—I am in a fix. I want to make some dough as light as I possibly can. I have tried the usual method of fermenting it with barm, but find it not to be light enough. I have been thinking if I could get some unadulterated starch—starch being the thing after being fermented that produces the carbonic acid gas—and knead it into the dough it would perhaps be a means of helping it to rise. Would it?—DOUGH.

[12356.]—**Small Malleable Castings.**—Could any correspondent tell me how to make small cast-iron castings malleable? Can any sort of cast iron be made so? A full description will oblige.—W. D. T.

[12357.]—**Stretching Vulcanised Rubber.**—Will any of your many correspondents kindly inform me if it is possible to convert a piece of vulcanised india-rubber 16in. long, 7in. wide, and 1in. thick, into a sheet 7ft. long, 3ft. wide, and less than one-sixteenth of an inch thick?—ECONOMY.

[12358.]—**To "The Harmonious Blacksmith."** —Perhaps I ought to have added to the description of my drawing on p. 665, No. 364, that the principal reason why a portion of the wooden brace was cut away at the back was to assist its being slightly bent when driving on the ends of the flat iron bar at the back. The straight part of the bar in that case would probably be made about ½in. shorter than the brace, so that when the strain on the strings was in operation it would, instead of arching the middle of the brace backwards, tend to make it perfectly straight, and the forward tension of the strings would be resisted by the iron bar behind. Perhaps the same end might be gained by leaving the brace whole, and driving a wedge between the brace and the bar; but that would take up more room. After having studied Mott's system of bracing, described by you a short time ago, I am inclined to agree with you that it will be found quite effectual, at very little expense, if properly carried out. Can "The Harmonious Blacksmith" tell me whether any attempt has ever been made to combine any kind of organ pipes with the upper treble notes of a piano in one instrument? I suppose a good organ-builder and voicer would have but little difficulty in making a "stop" to imitate the piano. Would the "stop" called "dulciana" do? and what would be the probable effect of combining the two, so as to be worked with one keyboard and set of keys? I apprehend the greatest difficulty would be to keep the two systems in unison for any moderate length of time. Would one set of pipes speak properly with varying pressures of wind, so as to give a little variety of tone and expression?—J. C. L.

CHESS.

ALL communications intended for this department to to be addressed to J. W. ABBOTT, 7, Claremont-place, Loughborough-road, Brixton, S.W.

THE CRYSTAL PALACE MEETING.

On Thursday, July 18, a blindfold match: one player against ten.—A simultaneous match: one player against twenty-five.—A consultation match, by first-class players only: two players against two. Play to commence at 2 p.m. in the Concert Hall.

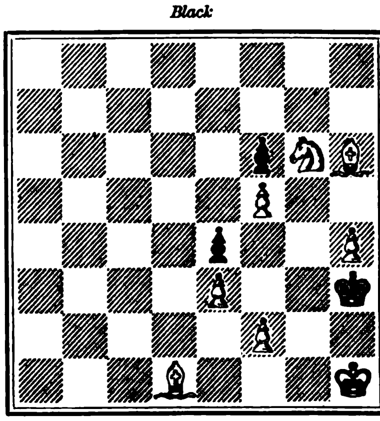
On Friday, July 19, at 3 p.m., a lecture on the "History and Antiquities of Chess," by Captain H. A. Kennedy, in the Opera House.

On Saturday, July 20th, blindfold, simultaneous, and consultation matches. Play to commence at 2 p.m. Grand matches by telegraph at 3 p.m. in the Concert Hall. The players at the Crystal Palace against Clifton, Nottingham, and Birmingham. Telegraph wires will be laid on to the room.

Players desirous of entering the lists for any of these contests should apply to the Manager, J. Lowenthal, 28, Camden-road, N.W.

PROBLEM V.—BY R. A. PROCTOR.

Black.



White.

White to play and mate in three moves.

SOLUTION TO PROBLEM IV.

White.	*Black.*
1. R to K Kt 6	1. P moves
2. B to K Kt 4	2. P takes B
3. R takes B P mate	

TO CORRESPONDENTS.

HENRY TURTON.—We acknowledge with pleasure the receipt of your interesting problem. Your reappearance, after so long an absence from the "Chess World," will be welcomed by many of our readers.

ROTA.—We advise you to study some elementary treatise on the game for three months; at the end of that period we shall be glad to hear from you again.

J. PIERCE.—Accept our best thanks for the excellent problems you have kindly placed at our disposal.

W. AIREY and A. W. COOPER.—You will observe that we publish two lists of solvers; this will meet the difficulty complained of in your letter.

T. J. MILLER.—Try again. We shall at any time be glad to render you any assistance.

G. SLATER and A. W. COOPER.—Problems received with thanks. You may expect a report in our next.

ARGO (Yarmouth).—Your problem is neatly constructed, but it is too easy for publicity. We hope this will not deter you from sending further specimens of your composition.

BRADBURY.—See answer to C. H. Yeo in our last number

ADDITIONAL solutions to Problem III. have been received from W. Airey (Worsley); S. H. W. (York); and A. L. (Dulwich).

CORRECT solutions to Problem IV. have been received from R. A. P.; A. W. Cooper; W. N. P.; W. Airey (Worsley); A. R. Molison (Swansea). All others are wrong.

Obituary.—It is with regret that we have to record the death, on the 27th ult., of Mr. Charles Hill, at his residence, Cotham-grove, Bristol. The deceased gentleman was in his seventy-eighth year, and for a long time had taken much interest in astronomical matters. Mr. Hill was in the possession of an excellent observatory, and his scientific instruments were of the first order. He generally used an 8½in. equatorially mounted reflecting telescope, by Browning, in making his observations, and was, although much advanced in years, a very assiduous observer. He was particularly interested in that department of astronomy relating to comets, and usually managed to find, soon after their discovery, all the small ones that came within the reach of his instrument. He once stated to the writer that when on board a vessel, he made an independent discovery of the magnificent comet of 1811, and wrote a paper, which was read at a scientific society, on the subject. Mr. Charles Hill was esteemed and respected by all those who were fortunately acquainted with him and his death is much regretted.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, *31, Tavistock-street, Covent Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, July 2, and unacknowledged elsewhere:—

F. R. Leyden.—W. L. Nash.—Geo. Awford.—W. G. Roberts.—W. Howard.—Thos. Fletcher.—D. H. Goodman.—Rev. R. Kerwin.—E. Greenbough.—Frederick Pipers.—E. B. Donkin.—W. E. Nash.—A. Ledger.—Jack of All Trades.—J. W. D.—E. P. W.—W. M. Collis, jun.—A. W. D.—James Stanner.—E. Milnes.—Constructor.—Charles Stolnitz.—M. Robinson.—E. J. B.—A Constant and Benefited Reader.—R. Phipson.—Vinery.—Wm. Wood.—Pathfinder.—Right Rev. Dr. Gregory.—Alfred Ledward and Co.—J. W. Buck.—P. Stoneman.—S. Bottone.—Un Francais.—Spero.—Ajanea.—Philo.—J. Gillaird.—W. R. Birt.—Atlas.—Wholesale.—J. H. Whistle.—A. C. G.—W. W. M.—One in Trouble.—Hoop Iron.—Chip.—N. Y. W.—W. C.—W. Crisp.—A Working B.—Northumbria.—Poloski.—A Young Fiddler.—W. T. L.—J. Watson.—Henry T. Vivian.—E. W.—Sarah.—Excelsior.—Artillery Volunteer.—Edinon.—E. N. D.—A Poor Man.—Highlander.—T. B.—Ancoats.—North Deven.—Schoolboy.—A Coal Miner.—Nottingham.—J. G.'s.—C. N. Abbott.—S. T.—Thetamu.—Wm. Oldfield.—Pneumatic Lever.—Veritas.—A Stoker.—J. R.—Rat-Tat.—E. B. D.—Ultramarine.—Henry Mac Cormac, M. D.—R. T. S.—John J. Lake.—B. F.—Isle of Thanet.—Marsh and Pattison.—S. A. Read.—T. C. Ebdy.—O. H. Maggs.—J. M. Withers.—R. Edwards.—G. O. Gooday.—Wm. Lea.—W. H. Neal.—H. Rensley.—John Briggs.—R. M. Smith.—A. P. Compton.—Wright and Mann.—G. Wootton.—J. M. Dale.—J. W. Durrad.—R. A. Proctor.—The Harmonious Blacksmith.—Crowquill.—C. S. Myddleton.—F. R. A. S.—George Browning.—E. W. S.—J. P. W.—E. W. R.—A Brewer.—A Constant Reader.—W. S.—J. W. Fennell.—Bobo.—Parker.—Cornubia.—W. L. B. W. Clenchen.—H. Elfes.—Sirius.—R. M. Hatch.—R. E. W.—A Lancashire Lad.—Priam.—E. H.—Bedfordiensis.—Rev. J. W. Taylor.—Analyst.—B. D. T.—Joseph Roskell.—E. Johnson.—R. Symington.—Saul Rymea.—Capt. Hans Busk.—J. Y.—L. J. W.—L. H. Scott.—Jones and Sons.—C. J. Caswell.—J. Parnell.—J. G. L. Nicholl.—Webb and Son.—E. Betham.—Dr. Carnley.—C. Hagan.—Charles Hughes.—E. L. G.

JACK OF ALL TRADES has written us, but he does not speak in such good spirits as we should have liked to see. He is now spending a few days with "Khoda Bux," in obedience to an invitation.

E. S.—We shall have some more information from "Seconds Practical Watchmaker" soon.

ESSE.—Your suggestion about articles on coach-building is good, and we will try and comply with your request.

W. R. BIRT.—Next week.

E. B. E.—Yes. We have more room to spare this time of the year, and are glad for scraps of information, and particularly from old correspondents.

VERITAS.—Yours next week.

Communications which can only appear as advertisements to hand from J. P., Diligence, A Countryman, A Mechanic.

J. H. T. M., W. L., A Working Turner, Kinko, H. J. M., Jas. Brown, J. A. Hurd, George Thompson and S. E., are referred to back volumes.

J. FORD.—There is no remedy but constant shaving.

MELVILLE PIKE.—Such a telescope as you require should be enquired for through a respectable optician. The book you ask about was recently reviewed by us and is published by Lockwood and Co. Your other queries have been many times answered in back numbers, to which we refer you.

YOUNG GLASGOW.—It is your booksellers fault. You can have any number by return of post by forwarding the necessary amount direct.

G. L. GRANHAM.—It is a respectable firm, and the instruments have been well spoken of by correspondents.

J. SLEABBEN, F. C. D., and Whitesmith.—See "Hints to Correspondents."

J. H. SUTHERLAND.—We have had more than enough discussion from time to time on Squaring the Circle. We should be glad to hear from you on some other and more useful subject.

G. J. MATTHEWS.—Your query is incomplete. It will all depend on the weight of the cylinder.

A. S. LEWES.—In the last number. See also Indices to back volumes.

MANGE.—Consult published Indices.

SENEX.—Once more we ask why assume so many aliases. The chief object of your writing at all appears to be to advertise a third-rate book of which you are author.

VERTUMNUS.—Two or three others have desired to have the last word on the Deluge controversy, but your and their letters would reopen it.

W. WATKINS.—The first query is an advertisement. The second will appear next week.

E. R. J.—What appears to be a source of trouble to you is a source of satisfaction to us. You think the ENGLISH MECHANIC deals with too many things, and treats ignorant readers with too much respect. Certainly those who are ignorant, or comparatively so, cannot agree with you. The "outside subjects" you speak of are only as fringe after all. The *bulk* of the journal is interesting to inquirers and thinkers all the world over.

CARACTACUS.—You are right. Mr. Bradlaugh's name ought not to have been dragged into the Deluge discussion at all, and we do not hold ourselves blameless for permitting it, and we trust "E. L. G." will be more careful in future.

E. B.—Please send description and drawing.

PLANCHETTE.—There must have been some "hocus pocus" influence at work. The insertion of your query would lead to another discussion on spiritualism, and we cannot afford space for it just yet.

KIRKPATRICK, E. W. B., and BALSAM.—Your queries are advertisements.

LENS.—Read Emerson's "Conduct of Life" and Locke on the "Conduct of the Understanding." When you have read them, and particularly the former, which can be had for 1s. 6d., you will most likely say "Thanks, Mr. Editor, for the advice."

THE HARMONIOUS BLACKSMITH.—Your letter on the "Piano in Canada" was crowded out.

F. N.—Reply on Angle of Reflection, &c., next week.

THE "BUILDING NEWS," No. 912, June 28, CONTAINS:—Professional Tenderness; Visit to Leicester Waterworks; Exhibition of Works of Art in Black and White; Metropolitan Board of Works' Report, 1871; Critical Notes of Great Italian Architects.—XIV; Our Present Knowledge of Building Materials, and How to Improve it; Modern Architecture in France; House Planning Competition; St. John's Church, Hull; The School Boards; Architectural Association of Ireland; Comments on the Conference; The Late Mr. Frederick Marrable; Architectural Association; The Institute *Conversazione*; The Progress of the Lock-Out; Building Intelligence; Stained Glass; Water Supply and Sanitary Matters; Correspondence:—"Modern Scottish Ecclesiastical Architecture;" Re Dublin Exhibition; Westminster Abbey; School Planning Competition; Liberal Premiums to Competitors; The *Quarterly Review* on Architects and Operative Masons; Mr. Norman Shaw and Mr. MacLaren; Intercommunication; Parliamentary Notes; Chips; Our Office Table; Trade News—Wages Movement; Tenders: Illustrations—St. John's Parish Church, Hull; Design for Detached Suburban Villa.—Price 3d., post free, 3½d. Published at 31, Tavistock-street, Covent-garden, W.C.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING JUNE 25, 1872.

1829 H. Fereday, Shaftesbury-street, Hoxton, for an improved method of and apparatus in tin and other metals for "sifting" or separation of seeds, coal cinders, and other articles and divers small substances.

1830 R. Boyd, Strand, for improvements in projectiles and in the manufacture thereof. A communication.

1831 R. F. Lewis, Herbert-street, Middlesex, for improvements in pen, pencil, and crochet-needle holders, bouquet holders or flower tubes, needle cases, and other like articles.

1832 W. S. Taylor, Edinburgh, for improvements in the propulsion and construction of tramway engines and carriages, and in the apparatus or mechanism connected therewith, which improvements are also applicable to motive-power road engines and carriages.

1833 S. Lewin, Poole, for improvements in ploughs.

1834 A. M. Clark, Chancery-lane, for improvements in railway carriage brakes. A communication.

1835 R. A. Gooding, Manchester, for improvements in apparatus for measuring liquids.

1836 T. Lambert, Short-street, Lambeth, and E. J. White, Overton, Gloucester, for improvements in self-closing valves or cocks for drawing off water.

1837 T. Hampton, Rotherham, Yorkshire, for improvements in the manufacture of Bessemer steel ingots.

1838 G. L. Turney, Addle-street, City, for improvements in boxes to hold pins, books and eyes, pens, and other small articles.

1839 E. Unwin and G. Owens, Chilworth, Surrey, for improvements in apparatus for the delivery of sheets from printing machines, paper-making machines, and other machines which deliver paper or other material in the form of sheets.

1840 R. Kuhn, New Bridge-street, City, for an improved means and apparatus for facilitating the repairing and paving of roads and other places, the apparatus being also applicable for preparing and dressing stone slabs and blocks.

1841 J. Cross, Manchester, for improvements connected with rubbers used for washing or cleansing clothes and other articles.

1842 A. C. Henderson, Charing-cross, for improvements in the construction of stereoscopes. A communication.

1843 G. C. Ogle, Ripley, Derbyshire, for improvements in mowing and reaping machines, and in the machinery or apparatus employed therein.

1844 G. Le Meunier and J. Cochet, Paris, for an improved system of publicity.

1845 W. Bull, Chancery-lane, for improvements in making salt from brine.

1846 W. B. Burrow and J. S. Burrow, Great Malvern, Worcestershire, for an improved "bin" or receptacle for wine or other bottles.

1847 W. R. Lake, Southampton-buildings, for improvements in the manufacture of copper-covered and copper-cored wire. A communication.

1848 T. Morris, T. Fletcher, M. Kelly, and C. Fletcher, Manchester, for improvements in spring mattresses and other articles for sitting and reclining upon.

1849 J. Imray, Southampton-buildings, for improvements in apparatus for working brakes in railway trains and tramway cars. A communication.

1850 J. Millward, Birmingham, for improvements in musical instruments. A communication.

1851 V. van Baerle, Finsbury-square, for improvements in the manufacture of soap or compositions for washing purposes.

1852 W. Spence, Quality-court, Chancery-lane, for improvements in apparatus for carrying leather. A communication.

1853 B. Abate, Regent-square, Middlesex, for improvements in preserving food or organic substances, and also in the machinery or apparatus employed therein, parts of which machinery or apparatus are applicable for making ice and for refrigerating purposes.

1854 A. M. Clark, Chancery-lane, for an improved camp kettle or culinary apparatus. A communication.

1855 H. E. Phillipson, Dublin, for a new or improved palliass.

1856 G. Lowry, Salford, Lancashire, for improvements in the construction of radial and other drilling machines and tools.

1857 W. Dawes, Leeds, for improvements in locomotive steam engines, parts of which improvements are also applicable to other engines.

1858 W. D. Brown, Turin, N.B., for improvements in reaping machines.

1859 W. M. Brown, Southampton-buildings, for improvements in machines for pricking and trimming the edges of heels of boots and shoes. A communication.

1860 W. Scantlebury, Seven Sisters'-road, Holloway, for improvements in the means or apparatus employed for raising and lowering window and other blinds and shutters.

1861 T. Lynch, Enishowen, Ireland, for a new or improved system for preventing collisions on railways and in machinery or apparatus therefor.

1862 W. B. Chapin, Southampton-buildings, for an improved contrivance for securing door knobs and other knobs or handles upon their spindles.

1863 E. Housman, Bromsgrove, Worcestershire, for improvements heating and ventilating churches, hot-houses, and other buildings and structures, and in apparatus to be employed for those purposes.

PATENTS SEALED.

3467 W. Cotton, for improvements in machinery or apparatus employed in the manufacture of looped or knitted fabrics.

3473 E. T. Hughes, for improvements in machinery for drawing or rolling rods or bars into straight or conical forms for shafting, axles, spindles, and analogous purposes.

3474 E. T. Hughes, for improvements in apparatus and processes for producing and applying artificial cold to the manufacture of ice, parts of which are applicable to other purposes.

3481 W. Tatham, for improvements in carding engines and drawing frames.

3489 W. Z. W. Chapman, for improvements in fastenings for carriage curtains and other like purposes.

3509 J. Wilde, for improvements in heating apparatus for stoving or "proofing" felt hats and for other purposes.

3520 A. C. Henderson, for improvements in cigar cases for effecting the simultaneous and automatic cutting and lighting of the cigars.

3851 G. L. Leclanché, for a new electrical contact for clock-work or other applications.

5 A. Silvester, for an improvement in carriage wheels.

6 J. K. Tullis, for improvements in punching holes in leather and other similar materials, and in the machinery or apparatus employed therefor.

9 S. Geoghegan, for improvements in apparatus for names marking or consecutive number branding casks, cases, boxes, and other like receptacles.

52 W. Bash, S. Bash, and G. Bash, for improvements in bobbins.

836 G. Fletcher, jun., for improvements in the evaporation and granulation of sugar, and in the apparatus or machinery connected therewith.

575 W. C. Sillar, R. G. Sillar, and C. Rawson, for improvements in treating and deodorising human excreta, and thereby facilitating the disposal and utilisation thereof.

841 J. Rawcliffe, jun., W. Bibby, and A. Fleming, for improvements in spinning mules.

936 N. H. Hughes, for improvements in cultivating land, and in the machinery or apparatus employed therefor.

8492 T. Grace, for improvements in apparatus for raising weights.

8493 J. Anderson, for improvements in reducing oxides, and in obtaining iron, sodium, potassium, phosphorus, chlorine, or their compounds, and in apparatus therefor.

3495 J. Mabson, for improvements in sewing machines, and in embroidering, cloth-cutting, and other attachments for the same, some of which improvements are also applicable to actuating or driving other machines.

498 E. W. Kelley, for improvements in horse-nail machines.

3501 W. A. Alcorn, for an improved method for the protection of bottles and other fragile substances.

3504 W. D. Ruck, for improvements in the manufacture of gas.

3517 J. A. Calantarients, for improved arrangements for preventing pipes or vessels containing water or liquid from bursting by the effects of frost or similar force suddenly brought into operation.

118 J. Madden, for improvements in cotton gins.

128 W. Spence, for improvements in the joints of the permanent way of railways.

1097 H. G. Keyworth, for improvements in cases or receptacles for receiving and retaining letters, papers, or documents in alphabetical or other order.

1167 J. Campbell, for improvements in the mode of getting at the external bottom of ships and vessels for the purpose of cleaning, repairing, and overhauling them.

1237 M. Combe, for improvements in sewing machines.

1257 W. R. Lake, for improved processes of treating phosphatic rock and other phosphatic substances for the extraction of the phosphoric acid or soluble phosphates therefrom.

1272 J. Ducomet, for an improved construction of packing case.

1278 R. McVey, for improvements in steam engines.

1285 E. Pace and J. H. Howard, for improvements in machinery or apparatus for cutting splints.

1348 T. J. Denne and A. Hentschel, for improvements in materials for finishing and currying leather.

1360 W. Ellis, for improvements in or application to machinery or apparatus for cutting wood to any required shape, pattern, or design.

1361 W. R. Lake, for improvements in the manufacture of knitted fabrics, and in machinery employed therefor.

1394 F. L. H. Danchell, for an improved filtering medium.

1408 W. R. Lake, for improvements in apparatus for producing compression upon metallic articles.

1418 W. R. Lake, for improvements in mules for spinning.

Terms of Subscription,

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom.

Volumes V., VI., VII., VIII., IX., X., XI., XII., XIII., and XIV. bound in cloth, 7s. each.

Indexes for each half-yearly volume, up to Vol. X. (except Vols. II., V., and X.) inclusive, 2d.; Post Free, 2½d. Cases for Binding, 1s. 6d. each.

*** Subscribers are requested to order Cases and Vols. through their booksellers, and not to send direct. The new regulations of the Post-office prevent their transmission through the Post.

To American and Belgian Subscribers.

☞ American and Belgian Subscribers, *especially when renewing their subscriptions, are particularly requested* to advise the Publisher of the transmission of the Post-office Order, and the exact amount for which it is made payable.

Subscribers in the United States and Belgium can be supplied with the ENGLISH MECHANIC post free from this Office, for the sum of 13s. (3dols. 25c. gold, or 15fr. 60c.) per annum, payable in advance.

The remittance should be made by International Post-office Order. Back numbers cannot be sent by the ordinary newspaper post, but must be remitted for at the rate of 5d. each to cover extra postage.

Notice to Subscribers.

Subscribers receiving their copies direct from the office, are requested to observe that the last number of the term for which their Subscription is paid, will be forwarded to them in a *coloured wrapper*, as an intimation that a fresh remittance is necessary, if it be desired to continue the Subscription.

Charges for Advertising.

	s.	d.
ALL ADVERTISEMENTS (except in the Exchange Column), per line of Eight Words	0	6
Every additional line	0	6
(No advertisement inserted for less than 1s.) Larger Advertisements Contracted for.		
ADVERTISEMENTS in EXCHANGE COLUMN for Sixteen Words	0	6
For every succeeding Eight Words	0	6

Front Page Advertisements 9d. per line.

The address is included as part of the advertisement and charged for.

Advertisements *must* reach the office by mid-day on Tuesday to ensure insertion in the following Friday's number.

AND
WORLD OF SCIENCE AND ART.

FRIDAY, JULY 12, 1872.

ARTICLES.

THE WATCH, AND HOW TO REPAIR IT.

By "SECONDS' PRACTICAL WATCHMAKER."

THE watch was, at one time, a much honoured and prized necessity; after a time it became a valuable adjunct to every gentleman, and not unfrequently (about the year 1790) the order had to be given two years before it could be possessed. The watch I am referring to is that known by the term "horizontal." The cause why so long a time was necessary for its manufacture arose out of the fact that there were but few workmen qualified to produce that particular escapement and finish of the various other parts. This special kind of watch was invented, about 1725, by the celebrated George Graham, an apprentice of the talented Tompion, watchmaker, of London. Prior to the introduction of Graham's horizontal watch, one kind only was made—namely, that so well known in these days as the "verge" watch. We have no authentic date when the primitive watch was invented or introduced. We do gather this much, that they were originally introduced from Nuremburg, but they were oval in shape, about the size of an egg, having the appearance of an oval snuff-box. Those who may be interested in such antiquities will be well repaid by inspecting the classified series of ancient watches in the South Kensington Museum; there are there about fifty or sixty, the property of Mr. Morgan.

Although the English claim the invention of the watch, it is doubtful whether they have that right. It must be admitted that they produced the convenient and useful watch, which satisfied all requirements for a long period. But rivalry met them from the French. That nation produced a prettier and more convenient sized instrument, and at considerably less price; but then, even as now, they could not be depended upon for correct (in those days) timekeeping; and again, the parts wore away so rapidly, while the old English watch was proof against every trouble, and frequently against a fall, which the French watch very seldom escaped without breakage. The scientific men of Paris devoted much time to the perfection of the watch, but although we must admit that their watch of the period just prior to the introduction of Graham's horizontal one was a model of beautiful workmanship and mechanical contrivance—which in another chapter I intend introducing—so soon, however, as the wonderfully good timekeeping of Graham's new watch became known in Paris, the scientific men of that nation endeavoured to possess one, and Berthoud, then the most eminent of Paris watchmakers, procured one, and admitted that the English watchmakers were the most eminent in the world. Graham's watches were made use of in astronomical observations. This kind of watch continued in general use, and was valued for several years, until Thomas Mudge invented the "lever watch," which soon took the place of the horizontal one. Mudge made one for Charlotte, Queen of George III. This kind of watch of late years has been very much improved, and stands before the world at the present day as the most correct in performance. It is the most durable, goes longer than any other kind without cleaning or repairing, and will endure more rough usage than any other kind. When we consider that a daily rate can be obtained from a lever watch of the best make, horology is entitled to be ranked among the sciences, for there is no science established in which that of watchmaking does not share; therefore its connection with the sciences entitles it to be ranked even with that of navigation and astronomy. The English lever watch having held such a prominent place among the world's mercantile products, induced several manufacturers abroad to introduce the principle of the lever escapement to their watches, which has ended chiefly in disappointment. The foreign watches, therefore, are chiefly of the character termed "horizontal." It will be unnecessary here to expatiate upon the relative merits of English and foreign watches, for we shall see, in remarks upon "Repairing" what has often to be done to obtain a fair result. This is quite certain, that the horizontal Geneva watch is a copy from the original invention by Graham; and although Professor Robison examined the escapement very critically, our foreign neighbours have improved very much the angle of the escape-wheel tooth as well as the train of the movements—that is to say, they have increased the numbers of beats per hour, which materially assists in the watch keeping more accurate time than it did in the days of its early invention. Again, our continental neighbours have supplied to their escapement a wheel made of steel instead of a brass one, which was applied to Graham's escapement, for it was found that unless the cylinder of Graham's watch was jewelled (that is, made of some hard stone) the escapement-wheel, after about four or five years' wear, had cut or worn a notch in both edges of the cylinder; and hence the original plan and design of the escapement became destroyed so soon as the wearing became evident. And I would just remark here that unless a Geneva watch is of a very low type the cylinder is perfect after years of wear, owing, of course, to the steel wheel of the escapement acting upon its similarly constituted neighbour, the cylinder; and watches of a very superior class may be seen with perfect cylinders after twenty years of constant use.

The duplex watch, invented by Tyrer, and the chronometer, originally by the French, but perfected by our countrymen, stand unrivalled by any other invention, inasmuch as the duplex, under certain circumstances, will keep time wonderfully close, while the chronometer, when at sea, has been known to return with a rate, after two or three years, so close that, at the expiration of that period, it has been in error only five-hundredths of a second. See Dent's and Denison's works.

It is intended in the present series to devote most of our space to the encouragement of our youth and amateurs in connection with watch repairing, for our experience teaches us that there are many moving along in this particular branch of mechanics thoroughly in the dark. It is hoped that the chapters following will be the means of our youth and amateurs walking fairly in the broad light, instead of groping and feeling their way, and not finding that which they seek. It must be borne in mind that watch repairing is not to be obtained in an ordinary apprenticeship. Many hundreds require improvement after having served their articled period, and we are hoping, by careful attention and combined action, that the novice in watch repairing will rapidly improve in the general literature as well as in the general manipulation. Tools, materials, and trade secrets, whenever brought to view, will be dealt with whenever practicable. It will be our aim if possible to vary the subject-matter; thus one chapter will contain remarks upon the "verge" watch, the next one upon the "lever" watch, and then will follow materials for the Geneva jobber, so that throughout the series variety will be studied.

We will adduce an example concerning a Geneva watch which kept excellent time during the day, but through the night it gained fifteen minutes. Many causes might occasion a similar disaster, but one that is very common is the following:—The watch referred to was a cylinder one; the notch at the bottom of the cylinder was rather narrow, so that for the web of the escape-wheel to pass through freely neither the cylinder nor the escape-wheel should have excess of end-shake, and also very necessary that the escape-wheel should be flat. These conditions had been neglected; cylinder and escape-wheel had excessive end-shake, and the wheel was out of flat. When the watch was lying on the back (dial upwards), the weight of the balance and its attachments (cylinder, pendulum collet and spring) preponderated or fell toward the balance cock, and when in that position the part of the escape-wheel out of flat towards the balance caught the lower part of the impulse side of cylinder, the escape-wheel by that means was suddenly checked, so was also the balance in progress, and instead of the balance moving its whole arc of motion it was accelerated by the suddenness of the wheel's action on the cylinder. If that watch had been held in a position with dial horizontal, and the escape-wheel observed, it would have been noticed that at every revolution of the escape-wheel a sudden check of that wheel and also the balance would take place, therefore the hastening or gaining of the train which was indicated by the hands. Mode of remedy: Most watch wheels are made flat by "bumping," as it is termed—that is, a hollow punch is fixed in the vice, the wheel laid thereon, and the arm of wheel to be raised or lowered is struck by a smooth thin hammer, after which it is usual to place it in the calipers, and by a thin straight edge of bone test its flatness, and thus proceed till correct. But the steel wheel of the horizontal escapement is very thin and very brittle; therefore, it is better to try to rivet the wheel to its pinion a little more by placing the pinion face on a hard steel stake, then hold a half-round or crescent-shaped punch on that part of the rivets of the escape-wheel pinion when the wheel has to be lowered; if it requires raising, place the punch on the opposite side, then with a small hammer strike the punch slightly; frequently a very slight blow of the hammer will suffice, but if the wheel be thin at that part it may not yield; should it not, the better plan would be to polish away the lower portion of the cylinder lip which strikes against the rim or web of escape-wheel, which is accomplished in the following manner: Remove the pendulum collet and spring by pressing it off with a very thin-edged knife, place balance with the cylinder upward upon a piece of flat good cork fixed in the vice; make a steel polisher, rather light, say three-sixteenths of an inch broad, one-sixteenth thick, and about nine inches long, with the end made nearly pointed and quite knife-like at the edge; then see if it can be moved about a quarter of an inch backward and forward in the notch of the cylinder. Having prepared the polisher, provide yourself with some oilstone dust mixed with oil, which may for convenience be placed on a small tin box lid. With this on the steel polisher, and rubbing backward and forward, the cylinder, however hard, may be polished till the wheel is quite free. The pressure of the polisher must be somewhat light, else the cylinder will be in danger of breaking. To clean the cylinder from the oilstone dust, a piece of very small crumb of bread must be used. After the bread has been made somewhat the consistency of ordinary putty by pressing and partly rolling it between the palms of the hands, and when in the shape of a cone, press it lightly where dirty oil remains, and the bread will remove it. Two or three applications of the same bread will leave the cylinder perfectly clean. It may then be made bright by the usual application of a piece of pointed cut cork.

CHEMICAL PHYSIOLOGY.*

IN the little book which Dr. Thudichum has published under the title given below, he has done good service towards the advancement of medicine, and has afforded valuable information to the student of chemistry and physiology. The first portion was written and printed as an introduction to those valuable researches, intended to promote an improved chemical identification of diseases, which he has contributed to the reports of the medical officer of the Privy Council. Finding it useful in his own teaching, Dr. Thudichum determined to publish it for the benefit of medical students and others, who will find it a concise treatment on physiological or animal chemistry, a subject which is still neglected to a large extent. The second portion is an analytical guide for the use of those who may desire to become practically acquainted with the phenomena and constituents of animal bodies. The importance of an accurate knowledge of the subject in all its bearings, more especially to the medical man, cannot well be over-estimated, while an acquaintance with the chemical processes which go on within the human economy is deserving of study, and may be turned to commercial advantage by chemists and others.

The action of the saliva in turning the starch of the potato into sugar is tolerably well known to students of popular science; but few amongst the ordinary reading public are aware that this saliva consists of a variety of fluids, some of which prepare or predispose the food to change, while others merely serve mechanical objects. Of these the saliva secreted by the parotid glands contains a peculiar ferment named ptyaline, and this principle is the only agent in

* A Manual of Chemical Physiology, including its Points of Contact with Pathology. By J. L. W. THUDICHUM, M.D. London: Longmans.

saliva which has the power of transforming starch into sugar. The diastase of malt has a similar action, and a knowledge of this fact led Baron Liebig to employ diastase in the preparation of a food for infants "brought up by hand," which food supplies efficiently the want of ptyaline and alkaline fluids in the digestive juices. But little is known of the character of saliva in disease; that it is very materially affected cannot be doubted, and further research will probably throw more light on the subject. It is known that the administration of mercury causes a change in its constituents; several medicinal salts, such as iodide of potassium, pass very readily into the saliva from the blood, and, as is well known, the saliva is the bearer of the poison of hydrophobia. From these facts we derive information of a nature probably unthought of by many; for if ptyaline is the only substance in the human economy which can turn starch into sugar—for the gastric juice cannot, and the pancreatic fluid has only a trifling influence in this direction—we see at once how necessary and important it is to thoroughly masticate all food containing starch, not only in order to obtain the full nutritive value of what we eat, but also to prevent overloading the stomach with a mass of food, much of which is probably indigestible.

The study of the chemistry of digestion, too, has led to the invention and preparation of sundry semi-medicinal articles of diet. The comminated food, mixed with saliva, when it reaches the stomach excites that organ to both a chemical and mechanical action, and a knowledge of this fact shows us that to obtain natural digestion in full vigour it is necessary to supply the healthy stomach with a large quantity of matter containing nutriment, rather than with aliments of inappreciable bulk; for although it would be possible to extract all really nourishing substances from our food and support life with them for a time, healthy digestive action would cease, owing to the inability of the stomach to act mechanically on the small mass which would be sufficient if we could live on essences. This mechanical action of the stomach, so to speak, churns the food, and the chemical action consists in the discharge from small glands in the walls of the stomach of a fluid termed gastric juice which contains 8·0 per thousand of a substance called pepsine, with minute portions of hydrochloric acid, possibly lactic acid, and some of the chlorides of the alkalies and phosphates of earths. The gastric juice possesses the power of dissolving albuminous substances; it transforms the casein, fibrin, gluten, and other portions of the food into a thickish, turbid pap, called peptones; and the ptyaline of the saliva, still continuing to act in a modified degree, forms sugar. The partially-digested food, now called "chyme," mixed with water and a small quantity of air, passes through the pylorus into the duodenum, where it is mixed with bile and pancreatic juice, and undergoing further decomposition becomes chyle, passes through the chyle-ducts into the lymphatics, and enters the blood through a door in the sub-clavian, or under-the-collar-bone, vein. Such is but a very rudimentary description of the digestive process; but the knowledge we have of the influence of pepsine in preparing food for assimilation has led to the production of an article of dietary medicine which has, we believe, been found servicable in diseased conditions where the natural juices are, on tolerably good grounds, supposed to be deficient. But little is known of the physiology of the liquids which are the active agents in duodenal digestion; the secretory acts and influences are well understood, but the employment of the secretions has yet to be elucidated in a satisfactory manner. The pancreatic juice, says Dr. Thudichum, has probably three functions, of which one is the complete solution of fragments of meat and albumen, which are invariably present in the chyme when it issues from the stomach, another is the decomposition of fat into glycerine and fatty acid, and a third the emulging of neutral fat and its transformation into a condition in which it can pass through the pores of the mucous membrane into the chyle-ducts. The main function of the liver is to secrete bile, and its action is of such intricacy, connected as it is with the main features of digestion, that probably a volume might be written on this organ alone. "The quantity of bile secreted in the human body in a day has been estimated at 1,200 grammes, or the bulk which would fill a wine-bottle and a half." It is probably the most complicated fluid in the human body; influencing fat and fatty acids in the manner of a soap, communicating to the small absorbing tubes an attraction for fat, and excreting cholesterine, which is intimately related to the chemistry of the nerves. In diseased conditions the bile is retained, causing jaundice; and by its power of precipitating pepsine it completely stops digestion when regurgitated into the stomach. The digestive processes carried on in the small intestine are unfortunately but very imperfectly known, and require, says Dr. Thudichum, particular and great researches; for this part of the body is the principal seat of such diseased processes as typhus and typhoid fever, cholera and others, amongst which, but not the least important, are summer and autumn diarrhœa, so fatal to many persons, even when special epidemic influences are absent.

Not the least interesting branch of chemical physiology is the study of the action and properties of blood-corpuscles, which carry oxygen from the lungs to the most remote and hidden parts of the body, yielding it up to the muscles or to the oxidisable matters contained in their juices, where it is immediately used if required, or is retained and stored up, this being especially the case during sleep. Blood-corpuscles are not carriers of carbonic acid, although it affects their colour and condition; this gas is conveyed in the serum of the blood, being partly dissolved therein, in the same manner as in soda-water, but to a large extent it is combined with alkaline bases, especially sodium. Dr. Thudichum's theory of the excretion of carbonic acid is not generally held or widely known, and we therefore quote the passage bearing on it: "When the blood-corpuscles of the venous blood arrive in the lungs they have undergone a change which consists in the partial oxidation of a small quantity of their hematocrystalline,* and this is transformed into an acid which I will call hematic acid. This blood-acid contains nitrogen. It is not similar to any of the acids we know; it is not volatile, but fixed. It is evolved from the blood-corpuscles and passes into the serum at the very moment when the former arrive in the small breathing-cells of the lungs. There the blood-acid combines with the sodium, and the carbonic acid is set free, and is left to take its course, with water-vapour, through the lung tissue into the respiratory passage." In a note, Dr. Thudichum says that the excretion of carbonic acid from the lungs is an act of specific secretion, to which the presence of oxygen (and nitrogen) *may be a supplementary advantage* (as favouring diffusion), but is *not essential*.

In his researches on cholera Dr. Thudichum showed that in that disease the serum, being changed in its constitution, refuses to perform its proper functions, but so acts upon the blood-corpuscles that they cease to carry oxygen to the tissues of the body; the temperature falls, and what is known as the algid condition in cholera is produced. In other diseases the hematocrystalline of a portion of the blood-corpuscles leaves them, and is decomposed—in yellow fever, *e.g.*, colouring the skin yellow. Similar decomposition takes place in poisoning by arseniuretted hydrogen, and by the bites of venomous serpents, while such poisons as prussic acid, carbonic oxide, and sulphuretted hydrogen, kill by decomposing the hematocrystalline, or by combining with it to the exclusion of oxygen. Thus, says Dr. Thudichum, the study of many diseases requires an intimate knowledge of the constitution of the blood-corpuscles. The value of this we have only just begun to appreciate, and the chemical and optical methods of investigation applied with rigorous accuracy will bring us not only the explanation of normal phenomena at present obscure, but also information on the nature of diseases and the action of poisons, which will point the way to their prevention or cure.

The Analytical Guide which forms the latter portion of Dr. Thudichum's valuable little book, is, of course, intended for the use of students in the laboratory, and for this purpose it is admirably adapted, being concise yet replete with all that it is necessary to know, directing the experimenter how to proceed in order to obtain a certain result, leaving him, as a rule, to appreciate the result of the operation by his own reflection. To the reader who has not the means of entering into these investigations and performing the operations there is much matter for consideration, and much useful information. Thus in the analysis of brain-matter we find corroboration of the German aphorism *Ohne Phosphor kein Gedanke*, for the ash of mixed brain matter contains 9·15 per cent. of free phosphoric-acid, and large quantities of acid phosphates, especially of potassium and sodium. We learn also that there is more ash in white brain-matter than in gray; that the former contains free phosphoric acid and a large amount of acid phosphates, while the latter is alkaline, and contains a much smaller quantity of phosphates.

The latter portion of the book contains woodcuts of the characteristic spectra of certain substances found in the fluids of the body, which will be of great use to the student. The whole volume (the result of many years of patient inquiry) is one of the most valuable contributions to pathology ever published, and a great step towards placing therapeutics on a thoroughly scientific basis.

* Blood crystals; a substance of a red colour, containing carbon, hydrogen, nitrogen, iron, sulphur, and oxygen ($C_{600}H_{960}N_{154}FeS_3O_{179}$); it is this substance which gives the double-banded spectrum of arterial blood, and the one band of venous blood.

NOTES OF FRENCH SCIENCE.

THE production of sounds by certain fishes has recently been studied by M. Dufossé. There are two kinds of sea scorpion, the *Cottus scorpius* and the *Cottus bubalus*—fishes of small size and ugly aspect—which are put into a state of vibration when seized or touched by the hand, and this is often accompanied by a noise or cry, sometimes a continuous note. The phenomenon may be observed either in air or water. These vibrations, M. Dufossé thinks, are voluntary on the part of the fish, and are caused by the contraction of certain muscles, placed under the cranium, at the sides of the buccal and respiratory cavities. By certain motions, the fish can alter the form of these cavities, and they act as a kind of sounding-board, producing resonance. He traces an analogy between the action of these cavities and that of the thoracic and mouth-cavities in Vertebrates.

Workers in copper, it would appear, enjoy a certain immunity against attacks of cholera. M. Burg states that in Bagdad, where the disease wrought such ravages last year, there were, between the end of April and the end of October, about 800 victims of cholera in a population of 80,000. In the bazaar there were about 100 shops occupied by nearly 500 individuals engaged in the making or selling of copper articles, and among these there was not a single victim.

M. Decaisne, in a recent note on "The Progress of Depopulation in France," gives some striking statistics as to marriages and births in that country, as compared with others. In Prussia, the number of births is 460 per cent. of the marriages, in France it is only 300 per cent. The proportion of births annually, per cent. of the entire population, is in Prussia 3·98; in France only 2·55. The annual excess of births over deaths, calculated per million of the population, is 13,300 in Prussia, and only 2,400 in France. According to the above figures it will take 170 years for the whole population of France to be doubled, as against 42 years in Prussia, 52 in Great Britain, and 66 in Russia.

A remarkable consequence of the late war has been the spontaneous appearance of certain exotic forage plants in some localities that had been occupied by cavalry. At present many of these plants (which are mostly Algerian) are flourishing in regions which were formerly very barren, but are now become veritable oases. The phenomenon is best seen in the Department of the Loire-et-Cher, at Orleans, Blois, Cour Cheveray, and other places. M. Vibaye has counted (in March, 1872) as many as 157 different species. Of these, about a third part are *Leguminosæ*, while *Gramineæ* and *Compositæ* make each about one-fifth part. Twelve species of trefoil have been observed, and ten or eleven of medicago. Where the lands are not turned to pasturage or frequented by herb gatherers, the plants are being largely propagated. Several species were found to appear by the side of a forage dépôt in Cour Cheveray, for the first time in May this year, showing that the seeds had remained in the ground sixteen months without germinating. The frost of May last, which injured vines and the young shoots of conifers and other trees, wrought no harm to the exotics. The cause of the above phenomenon is obviously the importation of forage from abroad, the seeds of which had fallen into the soil.

M. Dumont describes to the Paris Academy the mode of supplying Rhone water to Nimes. The water is subjected to natural filtration in a lateral subterranean gallery of 500 metres length, and 11 metres internal breadth. This gallery is the largest known. The water is brought by means of two steam-engines of 200 horse-power each, a distance of 9,960 metres in a pipe 0·80 metres diameter. Connected with the pipe is a large air chamber 14 metres high, on which the pumps act, not directly, but through a number of smaller air-chambers joined to it; by this method, the immense column of water, weighing nearly 5,000 tons, is made more manageable. The steam-engines, which are vertical, with direct motion, only consume 1·400 kilogramme of coal per horse-power per hour. 30,000 cubic metres of water are furnished to Nîmes (which is 27 kilometres from the Rhone), at an expenditure (including original cost of works) of not above 6,000,000 francs. A. B. M.

ELECTRO-METALLURGY.—III.

By J. T. Sprague.

1. BATTERIES.—In these papers I intend to proceed step by step as though the reader were commencing the subject, so as to deal with it systematically. If any one hopes to learn at once how to rival Elkington in the art of electro-plating, or even, having got a Smee cell and half a pint of gilding solution, to at once proceed to gild his watch case or chain, he may as well resign himself to disappointment, for it is my intention to put him through an apprenticeship, by first learning thoroughly how to deposit copper in any required condition; this is a cheap and manageable process, and all the secrets of electro-metallurgy can be learnt there, and, once mastered, success in the other departments is assured, and only slight instruction necessary for each special case. The first thing essential to be considered is the source of the force, *i.e.*, for present purposes, the best form of battery to employ. We require a battery easy of management, giving a large current at moderate cost and of tolerable constancy. Much will depend upon the amount of use to be made of the apparatus, for the conditions are very different when the instrument is to be kept steadily at work, and when it is to be used only by fits and starts: in the latter case the common Smee is to be selected before any other ordinary form—viz., a platinised silver plate in a frame with two zinc plates held to the frame with a brass clamp. A few general principles will assist in selection. Large cells should be used; constancy is impossible if they will contain only a small quantity of liquid, because the exciting liquid becomes speedily inert by being charged with zinc salt; they should also be deep, so that this salt as formed may sink by its weight below the level of the plates; if this be attended to, much waste may be avoided by occasionally drawing off the lowest portion by means of a siphon and adding fresh liquid. From want of attention to this, it is a common occurrence for a heavy deposit of zinc to form on the lower part of the negative plate, which then requires to be removed by soaking in dilute acid. This more commonly happens in one of a series of cells in which there has been some over action, or change of liquid has been neglected; it then becomes, in fact, a decomposition cell instead of an active one. In some cases, for practical reasons it is best for the elements to be in the form of plates, but in many cells they are cylinders, and then the question arises, which should be the outer one, the zinc or the negative? This question may be put in another form: if the plates differ in size, which should be largest? This has been a good deal discussed, owing to consideration being directed to only a portion of the subject. There are two good reasons why the negative metals should be largest. 1. The zinc is subject to local action or waste, which contributes nothing to the work, and, therefore, its size should be reduced to just that amount which is requisite to maintain the current required. 2. The negative plate is subject to "polarisation" or deposit of hydrogen upon it, and should therefore be as large as possible.

After a great many trials I have come to the conclusion that the best possible arrangement is one in which the negative element is a cylinder fixed within the containing vessel, in the middle of which the zinc can be suspended. The next point is the best material for the negative plate.

2. *Copper Negative.*—This is the oldest form, and still used in many factories. As a rule, it is bad economy; on the small scale it is mere folly to employ it. The copper speedily becomes covered with a black coating, the current diminishes almost to nothing, and the plates must be cleaned with acids or made red hot. If used at all, the surface should be thoroughly coated with electrotyped copper to ensure pure metal and a highly granular surface. There is one form in which copper may be usefully employed for regular continuous working—viz., as a cylinder in a large vessel, with the zinc in a porous jar, the outer vessel charged with dilute sulphuric acid, say 1 to 20, and a little nitric acid added occasionally. In the porous cell a half saturated solution of zinc sulphate or common salt may be used, and the lower part occasionally removed with a siphon and replaced with water: if the cell stands idle the copper is dissolved if free nitric acid is present, or else becomes coated with an insoluble deposit. The cell cannot be recommended except for factory use on a large scale.

3.—*Silver Platinised.*—This is one of the most valuable negatives known. Smee discovered that hydrogen adhered less strongly to rough than to smooth surfaces, and from this developed the idea of depositing platinum as a fine powder on other metals, selecting silver as best on account of its slight liability to action from acids and its high conducting power. Substitutes are frequently proposed, as copper, lead, and an alloy of lead, tin, and antimony; they are all wretchedly bad economy, and it should be remembered that the silver, even if a little costly at first, has an intrinsic value of its own, even when worn out. Rolled silver can be obtained ready platinised, or ordinary thin sheet can be lightly roughed with fine glass-paper, or by dipping in nitric acid, and the platinum deposited on it thus:—Insert in a vessel with dilute acid, and connect it by a wire to a small slip of zinc in a porous vessel in the same acid; in fact, mount it as a battery, but exposing at first only a mere touch of the zinc to the liquid; drop in a few drops of platinic chloride, and stir; gradually a faint colour forms on the silver; add more platinum salt and increase the zinc surface, and after a good adherent coat is formed gradually increase the action till the surface is fairly covered with a black coating, which touch as little as possible. The platinum solution is made by dissolving scraps of thin platinum in a mixture of two parts of hydrochloric and one of nitric acids; the solution is very slow, and is best effected in a flask with a long neck, in which is inserted a test-tube filled with water, and stood by in a warm place; it is not necessary to drive off acid or to crystallise for this use, as the free acids are of no consequence. The most satisfactory single acid battery I have ever had consists of a tall glass cylinder, the upper half of which contains a cylinder of platinised sheet silver soldered to stout copper suspension wires leading to the binding screw; all the copper and solder is carefully covered with marine glue to prevent action upon it; the wires pass up through a thin sheet of cork or pasteboard well soaked in melted paraffin which fits firm into the glass, and the silver itself fits to the sides to prevent motion; in the middle is fixed a porous jar, the upper part of which is soaked in paraffin, and passes firmly into a hole in the middle of the cork, in which are also fitted a phial neck for filling at, and a small bent glass tube for leading off gas if required; all being thus placed, a mixture of melted resin and Bathbrick-dust, or other similar powder, is poured upon the cork, the use of which is mainly to enable this to be done; the top is thus closed with half an inch of cement, leaving only the porous cell from which any evaporation can take place; the top of the glass should be first warmed and coated with melted resin, containing a little melted oil; this insures adherence and prevents sulphate of zinc forcing its way up. This cell is always ready for action upon placing the zinc rod or plate in the porous cell. The same mode of construction applies to some other cells I shall mention presently. Of course, earthenware jars will do as well as glass, and the porous cell may be substituted by a glass or earthenware tube, only reaching the liquid; as described, the arrangement is perfect for every purpose, and may be modified according to the purpose desired. The objects aimed at are a large current, constancy, due to freedom from polarisation, use as a voltameter by measuring the gas given off, working for a long time on one charge, and remaining ready at any moment and any intervals without injury or trouble; in some I have soaked the bottom of the porous cell in paraffin, led down a protected wire leading from a binding screw and dipping into a layer of mercury; these only require a rod of zinc to be plunged into the mercury, and can be left coupled up, although the zincs are removed; or they may be used as odds and ends cells to utilise any scraps of old zincs which only require to be cleaned, amalgamated, and packed into the porous cell. The silver is platinised after the cell is completed.

4.—*Graphite Negatives* may be used in place of silver, and may be platinised in the same way with advantage; connection can be made to them by a clamp with a piece of platinum foil inserted, or a deposit of copper can be made upon the upper part and a binding screw soldered on; the carbon must then be warmed and carefully soaked with paraffin from the copper down to the part which will be in the liquid. An excellent cell may be constructed on a plan similar to that just described; stand a porous cell in the middle of the jar, insert also a plate or rod of graphite carbon, prepared and connected as described, and also a stout glass tube reaching to the bottom; crush up a piece of carbon, as obtained from the gas retorts, and sift out pieces from the size of a hazel nut to that of a pea, and pack these in the space between the two jars, taking care to have as good contact as possible with the carbon connection block; when two-thirds full, fit in the cork cover, and cement as before. This may be used as a single acid cell, or if high force is required nitric acid or bichromate of potash solution may be added to the outer cell. For single acid use a wicker basket, or any convenient substitute may replace the porous cell, as its purpose is simply to keep the materials in place. As the graphite contains a good deal of sulphide of iron, the gas given off is very offensive at first, and the cells should be allowed to work some time and be emptied once or twice before they are platinised, which renders them much more constant in action. They are not quite equal in all respects to the silver cell, chiefly because of the internal resistance at the carbon contacts, but they are cheaper at first, and once properly prepared will last for years in perfect order, working with great economy. As the current forces liquid from the zinc cell outwards it is as well to bore a small hole or two in the porous cell just below the proper level of the liquid, by which it can return; of course this must not be done with cells in which nitric acid is intended to be used. This same arrangement makes the best form of manganese cell: all that is necessary is to grind together equal bulks of fine peroxide of manganese and carbon, and pack this into the interstices of the carbon; this is far superior to the Leclanché form, as it gives so much more room for the material, and brings the zinc into its proper place, the middle. With this mixture the cell becomes useless for electrotype purposes, but it is so convenient for many purposes of testing and experiment that every electrician should possess one at least; it is also the most convenient form known for use with electric bells and domestic telegraphs.

5. *Daniell's Cell* is most valuable for experimental purposes, because of its constancy, but for occasional use is too troublesome to be recommended in electrometallurgy. It is also costly, but if the battery is made up of square plates and the negative plates are themselves articles on which deposit is to be made, I believe it would be found the most convenient and cheapest of all. For this purpose it would require the negative chamber to be fitted with connecting rods, &c., in the same manner as the depositing cell to be described; something of the sort is also shown in Fig 88, p. 196, Vol. XI. The chief objection to Daniell's cell is the deposit of copper on the zinc from salt which passes through by endosmose; for long continued experiments I have found it advantageous to use large cells with two porous jars or partitions, with a good space between filled with strong solution of sulphate of zinc, using the same solution with half water in the inner zinc cell and unamalgamated zinc. By occasionally drawing off the upper part of the intermediate solution much transfusion of copper salt is avoided (especially if a few coils of zinc are inserted in the middle cells), and the zinc can be cleaned in a moment by brushing. The solution withdrawn should be put in a bottle, or jar, with a few scraps of zinc, which will throw the copper down and fit the solution for use again. This plan adds to the internal resistance, of course, but that is the only drawback, while perfect constancy can be maintained. The Grove's and Bichromate cells are not used (and the latter would be useless and expensive) in electro-metallurgy, because high electro-motive force is not required; for some purposes that even of a single Smee is unnecessarily great, but this can always be controlled by adding resistance. The batteries described are the only ones of use, and I will give such practical information as to their applies to all.

6. *Zinc.*—The best rolled zinc should be employed; it gives a higher force than cast zinc, and is more economical, because cast zinc is subject to much more local action, owing to its porous condition. Cast zinc rods may be used with equal advantage in cells where it is only exposed to sulphate of zinc, or chlorides of sodium or ammonium, because these do not act by themselves on zinc.

Amalgamation. — The coating of zinc with mercury prevents the local action of the acid; it appears to effect this by giving a smooth surface, and so favouring the adhesion of hydrogen, which may be seen covering it in little bubbles; therefore, anything which tends to roughness of surface tends to increase local action and waste of zinc and acid, a point the learner should carefully fix in his memory as an axiom. The practical lesson is, keep your zincs thoroughly clean and well amalgamated. Care should be taken to use only pure mercury; much of that sold contains lead and tin, which are mischievous. The mercury should be kept for some time in a bottle, with dilute nitric acid over it, and occasionally shaken up. To amalgamate zinc, wash it first with strong soda to remove grease; then dip it in a vessel of water containing one-tenth of sulphuric acid, and as soon as strong action takes place transfer it to a dish (such as a soup plate); pour mercury over it, and rub it well till a bright silver-like film forms; then set it up to drain on edge, and before use rub off any globules which are set free. Whenever the zinc shows a gray granular surface (or rather before this) brush it well and reamalgamate, remembering that saving of mercury is no economy, and free use of it no waste—for it may all be recovered with a little care. Keep a convenient sized jar or vessel solely for washing zincs in, and brush into this the dirty gray powder which forms and is an amalgam of mercury with zinc, lead, tin, &c., and forms roughnesses which reduce the protection of amalgamation. Let this powder collect for a time and then transfer it to a bottle, in which wash it with sulphuric acid first, and then with dilute nitric acid, and you will recover the mercury. This washing should be done whenever a plate is removed, and never less than once a day if in regular use; the fibre brushes sold at 3d. and 4d. as coarse nail-brushes are excellent for these purposes, but of course must not be left soaking with acids.

NOTES OF COMMUNICATIONS TO THE ACADEMY OF SCIENCES, PARIS.*

FIREDAMP INDICATOR.—It consists of an alarum put into play by clockwork, the balance of which is held by a scale beam, with arms of an unequal weight; this kept in position by a cotton cord previously impregnated with purified saltpetre. It is inclosed in a case of wire gauze. The firedamp penetrating into this cage is ignited on reaching the inflammable point by a lamp burning in the inside. This consumes the cotton thread, the clockwork balance is released, and the alarum sounds, warning the miners of danger and indicating the necessity for more active measures of ventilation.—M. S. V. TURQUAN.

ZOOLOGY AND GEOLOGY.—From the examination of bones found in recent strata it would appear that the Mauritius have formed part of a large extent of land or group of islands, which have gradually sunk into, or been overwhelmed by, the sea, and these islands are the remains. They have served as the last refuge of the terrestrial population of those ancient epochs. Of these are the dodo, the solitaire, the aphanapterix, Newton's water-hen, large paroquets, &c. Madagascar had not been in communication with these islands, for when first visited by Europeans they did not find any mammals except some large bats. These did not exist at Mauritius. The study of the fossil birds leads to the same result. —M. ALPH. MILNE-EDWARDS.

PREHISTORIC ANTHROPOLOGY.—From the reindeer period man has always lived amongst the majestic débris of the talus at the station Eysies, in the valley of La Vezere, Dordogne; but the principal part of the talus was formed in the Palæolithic age. Notwithstanding some levelling that has occurred, more or less, the vestiges of the successive occupations show themselves at intervals. Here are traces of the bronze age, with remains of crucibles and of charming little vases in pottery, black and very fine, with geometrical designs, identical with some of those from Lake Bourget. In other parts hearths of the polished stone period, with bones of animals, its polishers and punches in bone, its hatchets, and coarser pottery. The last have not yet been found in the undisturbed reindeer strata, but constantly accompanies the remains of domestic animals. From time to time there have been falls of rocks at this spot, and the people have returned after each fall and profited by the intervals between the blocks to light their fires. Upon an occasion one of them became a victim to a downfall, having being overwhelmed whilst reclining on the back upon the hearth, and turned in vain to avoid the descending rocks. The skeleton was found under some of these, about three yards below the surface of the reindeer period. There could be no doubt of its era, and in this it is distinguished from the other skeletons of the polished stone period. Ordinary sepulture would not explain the circumstances under which it was found. The vertebral column had been crushed by the corner of a heavy rock and the pelvis was broken. Shells were found distributed about the skeleton; amongst them *Cyprea pyrum* (Gmel) and *C. lurida* (Linn.); two were on the forehead, two near the humerus, four near the knees, two on each foot. They were pierced with a gash or notch, and would have ornamented a garment. There is no appearance of their having formed parts of a necklace or bracelets.—M. ALPH. MILNE-EDWARDS.

APPLIED CHEMISTRY: ON A NEW METHOD FOR OBTAINING THE REPRODUCTION OF DESIGNS.—Trace upon rather stiff glazed paper the design with gummed ink, and scatter over it fine powder of bronze or brass. By this means a kind of plate may be obtained that will admit of the most various designs being taken off upon prepared paper. By softening the ink with vapour of alcohol the metallic powder can be renewed when spent by use. Specimens were submitted to the Academy.—M. B. RENAULT. JOHN L. LAKE.

* Translated and abstracted for the ENGLISH MECHANIC.

SINCE the completion of the Omaha Bridge over the Missouri River, there is an unbroken line of railroad from Oakland, California, to Boston, a distance of 3,239 miles.

HARMONIUM CONSTRUCTION.

THE improvements in the construction of harmoniums recently patented by Mr. Scantlebury, of Holloway, consist in a method of coupling the octaves, a new form of pallet bar for opening the valves of several rows of reeds, and a modification of the bellows action. The invention will be readily comprehended from the annexed engravings, in which Fig. 1 is a transverse section of the action; Fig. 2, a plan of part of keyboard and couplers; and Fig. 3 a form of pallet bar for opening the valves of 8 rows of reeds. In the coupler action the inventor places what are known as "backfalls" or levers F (the fulcrum, on rail D of which is at the centre of their length, by preference) in connection with the pallet or valve G, by means of a wire eye or other suitable means at one end, and a screw *a* from the under side of the finger key acting upon the other end. The couplers are placed diagonally as shown. A sticker is also arranged in connection with the same key to act upon its own pallet or valve G. The "coupler bar" D is raised so as to bring

FIG. 1

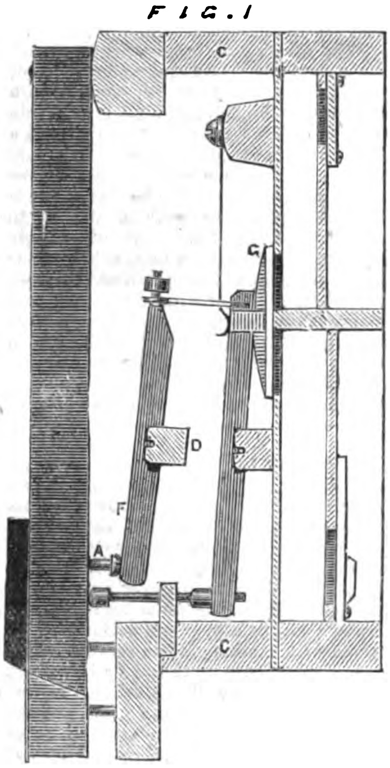

FIG. 2

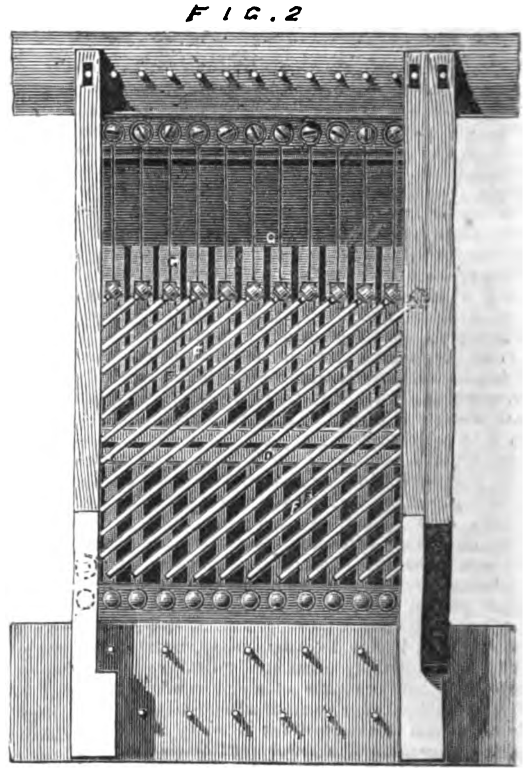

FIG. 3

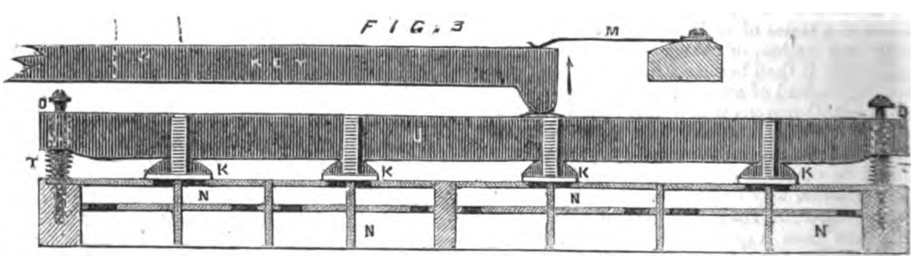

the levers in contact with the screws *a* under the keys by any suitable mechanical motion for causing the "coupler" to rise and fall without lifting the pallets G from their seats until the key is depressed.

The improved mechanism for actuating the feeder or bellows of harmoniums consists in placing a roller or wheel at the bellows end of the lever, actuated by the foot-boards, which roller works upon a plate of metal placed upon the underside of the feeder, whereby friction as found in the ordinary bellows is reduced to a minimum and the blowing is performed by the player with much less exertion. By this arrangement the bellows may be placed nearer to the motive power for actuating them.

In adapting the coupler action the inventor raises the keys a short distance from the pallets (about three or four inches more or less as required) and incloses the space with a frame C as shown at Fig. 1, forming a strong resonant chamber or sounding-board C, whereby the ton-of the instrument is said to be considerably improved. By placing upon one note-board several sets of reeds, the whole of the respective openings in connection with which are under the control of one pallet or valve, only one spring is required to each key, an arrangement which lightens the touch, and simplifies the action and construction of the instrument; for in ordinary instruments it is usual or only practicable to cover two notes by one pallet or valve, each two notes requiring a pallet spring, thus occasioning heavy pressure on the keys, especially if the note-board is large. Fig. 3 shows a section of the improved form of pallet bar J, the pallets K being fastened to it in the usual manner of fastening a pallet to its stem, by means of a strip of leather, technically called a "strap." The arrangement shown is for an eight row sounding-board or "pan" N, but the pallet bar is suitable for a larger or smaller "pan." The holes for the screws O to pass through are bored larger than required, the screws being clothed with two small pieces of cloth or other suitable material, one at the bottom of the hole and the other at the top, an arrangement which imparts a better action than if the cloth passed through the holes. Under the head of each screw O a washer of cloth, baize, felt, or other suitable noiseless material is placed, to receive or stop the rise of the pallet bar J when released by the key, and raised by the light springs T, which are (by preference) spiral springs of brass wire of sufficient strength to raise the pallet bar J and its pallets K. It will thus be seen that the springs T materially assist in imparting lightness of touch to the action. The spring M is made strong enough to keep the pallets down.

THE VEGETABLE BEEF-STEAK.

THIS fungus (*Fistulina hepatica*), which resembles a great red tongue protruding from tree stems, when once known, can never be mistaken for any other species. When young it is a dull pale purplish red, but becomes more red, and passes through brown to black as it decays; the underside is cream-colour, with minute red points occasionally, becoming yellowish red as it grows. It generally confines itself to old (and often prostrate) oaks; but in Epping Forest it is not uncommon on the beech, and it has been observed on the chestnut, walnut, willow, and other trees.

Although such a large fungus, frequently weighing from four to six pounds, its growth is very rapid, soon appearing and again disappearing, on ancient trunks in the autumn. When cut, broken, or bruised, it distils a copious red juice like beef gravy. "When grilled," says Dr. Badham, "it is scarcely to be distinguished from broiled meat;" and Berkeley describes it as "one of the best things he ever ate, when prepared by a skilful cook." There is a very slight acid flavour in the fungus when cooked, which adds considerable piquancy to the dish; it is extremely tender, succulent, and juicy, and resembles tender steak or tongue in a remarkable manner, the juice it distils being in taste and appearance like gravy from an excellent broiled rumpsteak. Of course it should be gathered when quite young, fresh, aud clean, and at once prepared for the table in the following manner:—Wash and dry, cut into in. slices ¼in. wide, soak in scalding water for five minutes, and stew with butter and herbs; yelk of egg may then be added, and serve hot; or simply stew with a good steak, adding a scallion and parsley, salt, and pepper.

RUBBER GRAPHITE PAINT.

A NEW paint, which is said to be waterproof, and to possess other advantages, is announced by the *Scientific American*. A waterproof paint, for metal roofs, fences, bridges, ships, and every kind of wood structure, which, at the same time, could be relied upon to reduce the corrosive influences of exposure to the atmosphere, is an article for which the demand would appear to be almost without limit.

The rubber graphite paint is a solution of pure indiarubber in linseed oil, which is ground with graphite into a thick, elastic, smoothly flowing paint. Compositions of which indiarubber forms a part possess in the most eminent degree the quality of resisting the action of moisture and of corrosive gases carried in the air. In the graphite, we have a pure form of carbon; and it appears to be well known that paints containing carbon in any form last longer than other kinds not having it as an ingredient—holding their body and colour when the other paints are totally destroyed. We do not see why this compound, combining as it does these two valuable elements, should not form a paint of great durability and highly protective qualities. All shades of colour from black to gray, or cream colour and the drabs, can be made as desired.

THE BELL ANEROID.

THIS instrument (invented and designed by Captain Hans Busk) indicates, by ringing one or other of a series of ten different bells, any change in the atmospheric pressure amounting to one-tenth of an inch on the barometric scale. The mechanism is simple, and is put in action by a constant battery (one of Leclanché's) composed of twelve cells.

In the annexed woodcut (Fig. 1), representing a back view of the case, with the door removed, the position of the bells is shown. They are respectively indicated by the letters A A, and are irregularly placed round the centre one. At the back of the central and smallest bell is seen one of the soft iron magnets, by means of which motion is imparted in the usual way to the hammers C C C. The other magnets are hidden behind or under the bells. F F are insulated wires leading to the binding screws D D. By means of the insulated wires G H, a connection is established with the battery, and this can be broken at will, by means of the lever E.

The dial (Fig. 2) is formed of a disc of ebonite about three-sixteenths of an inch thick. This material was selected for the purpose, because it effectually insulates not only the steel index hand,

FIG. 1

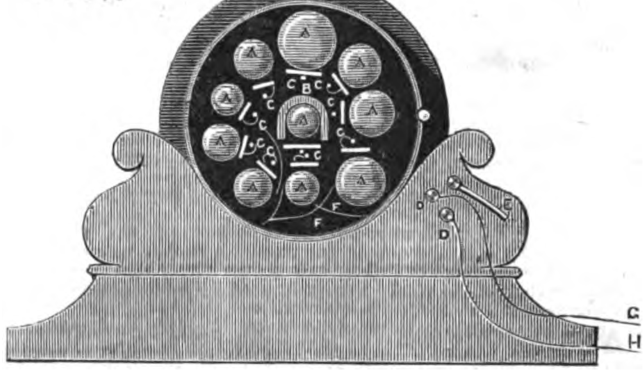

FIG. 2

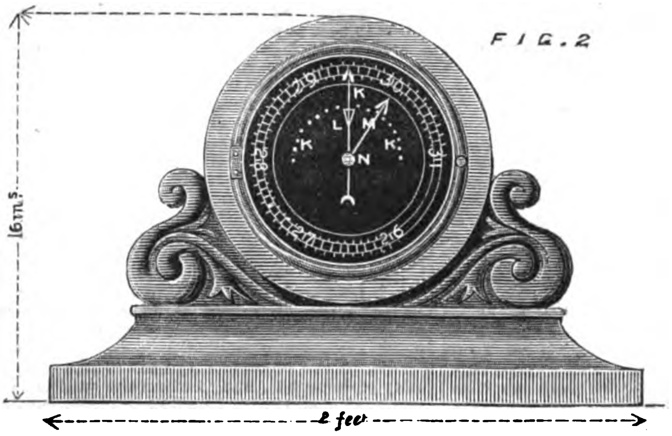


but also the sixteen terminal platinum points of the wires marked K K K. To the index hand N, a thin strip of platinum foil is attached, marked L on the diagram. The hand, as it traverses —from "one tenth" to another—the face of the instrument, necessarily brings the platinum foil in contact with some one of the platinum points, thus establishing a connection with one of the soft iron magnets; the bell pertaining to that magnet is instantly rung, and continues ringing as long as the hand remains stationary, or until the lever E is withdrawn (as shown in Fig. 1) from contact with the screw D.

There are in Captain Busk's aneroid sixteen platinum points, and their extremities are carefully burnished off so as to cause no friction, and to offer no resistance to the movement of the foil. As there are only ten bells, six of these points (three at either extremity of the scale), and, consequently, those least frequently sounded, are each conected with two bells. As all the bells have a separate note of their own, it is perfectly easy to tell, even at some distance, whether the barometer is rising or falling: the deeper toned bells give warning, when the hand moves from 29·50in. towards 28in., while the higher notes are sounded as it passes from 29·50in. towards 31in. In variable and unsettled weather, more especially at sea, it is both curious and interesting to note the rapidity with which these changes occasionally succeed each other.

The bell aneroid was completed, under Captain Busk's directions, by Mr. Browning (the well-known scientific instrument maker), and he is at present alone authorised to construct aneroids of this particular kind.

The primary object of the inventor was to devise a simple and efficient apparatus which should indicate unerringly, on board ship, or to a person in charge of a lifeboat station, any important approaching alteration in the state of the atmosphere, and the result of his experiments has proved in all respects most satisfactory. It is not improbable that this form of aneroid would frequently be of material use to the agriculturist.

INFLUENCE OF RESPIRATION ON THE CIRCULATION.

IN a paper on this subject by Dr. Ewald Hering are given the results of a considerable series of experiments on dogs, undertaken with the view of determining the influence of respiration on the circulation. He states that during an examination of the influence of the vagus on the respiratory movements, he found artificial inflation of the lungs to exert a remarkable influence on the cardiac movements. If air be blown in through a canula, and its escape prevented by a stopcock, the beats of the heart increase in frequency. In his experiments he introduced one end of a T-tube into the trachea, and attached a second orifice to a manometer, while the third was left free, so that the animal might breathe by it, or through it insufflation might be carried on; a manometer was also introduced into the carotid. It was found that, when the tension of the air within the lungs was augmented, the pressure of the blood in the arteries fell to an extent increasing in proportion to the pressure of the air in the lungs. This effect is obviously due to the greater resistance the blood experiences on entering the chest, and to the obstacle the expanded lung presents to the passage of the blood through its capillaries. The heart's beats increased in frequency at the same time, and in proportion to the tension of the air in the lung; where the cardiac movements had previously been slow, they sometimes rose to three times their previous number. The animals were always under the influence of opium. Four questions suggested themselves in regard to this increased frequency of the beats. 1. Is it due to the greater pressure under which the heart acts? 2. Is it owing to the altered conditions of resistance to the current of the blood? 3. Does it arise from disturbances in the exchange of gases; or 4. Is it occasioned by a forcible dislocation of the heart. He considers the arguments in each case at length, and finally arrives at the conclusion that the acceleration of the cardiac beats on insufflation of the lungs is affected reflectorially through the vagi; the action of the centres of the inhibitory fibres of these nerves being lowered by the excitation of the sensory fibres distributed to the lungs.

Another Liquid Glue.—The following is a good recipe for liquid glue:—Take gum of shellac three parts; indiarubber one part, by weight. Dissolve the caoutchouc and shellac in separate vessels, in ether free from alcohol, applying a gentle heat. When thoroughly dissolved, mix the two solutions, and keep in a bottle tightly stoppered. This glue resists the action of water, both hot and cold, and most of the acids and alkalies. Pieces of wood, leather, or other substances, joined together by it, will part at any other point than at the joint just made. If the glue be thinned by the admixture of ether, and applied as a varnish to leather, it renders the joint or seam water-tight, and almost impossible to separate.

REVIEWS.

British Rainfall, 1871. By G. J. Symons, F.M.S., F.R.B.S. London: Edward Stanford. 1872.

This useful but unpretending annual collection of rainfall statistics has been only recently published, its completion having been delayed by the illness of the compiler, Mr. Symons. It contains the usual amount of information on an important subject. Among the papers contributed by rainfall observers there are two that demand a passing notice—one "On Rain-gauge Experiments at Hawsker, near Whitby, Yorkshire, 1871," by the Rev. F. W. Stow; the other "On the cause of the Decrease of Rain with Elevation," by G. F. Burder, M.D. A considerable portion of Mr. Stow's paper treats on the same subject as that by Dr. Burder. Mr. Stow's view is of this character, "that if the whole of a shower were intercepted 10ft. or 20ft. above the ground, there would be just about as much rainfall at that height as actually falls to the ground within the whole area covered by the shower; but that the fall on the ground is most unequally distributed by upward and downward currents of air; the latter prevailing in those places where we generally set our gauges, and causing, therefore, an excess in the fall at one foot, over that at a height less affected by the down currents." On the other hand, Dr. Burder suggests that there is a *real* increase of rain near the earth, especially within six inches of the surface. This view is founded on an analysis of Mr. Chrimes' observations with gauges elevated from 1ft. to 25ft. at Rotherham, and the Calne observations, 1867, between the surface level and 1ft. above the surface. In the Calne observations a gauge 6in. above the surface gave a decrease of 3·3 per cent. as compared with the quantity registered in the gauge, the mouth of which was on a level with the surface, and one at 12in. above the surface gave a decrease of 4·8 per cent. as compared with the same quantity. In the Rotherham observations the decrease between elevations of 1ft. and 5ft. is 6·0 per cent., while that between 20ft. and 25ft. is only 0·9 per cent. From these results Dr. Burder draws the following conclusions:—(1) That the formation of rain is not a continuous process. The bulk of the rain comes from the clouds; little or none is drawn from the air next below the clouds, but a large addition is derived from the strata in the immediate neighbourhood of the earth, the rate of addition being continually and rapidly accelerated until the rain reaches the ground. (2) That this rain formation near the earth is simply the effect of temperature. There is one circumstance in connection with the subject of decrease of rain-fall with elevation which appears to be anomalous; it is that Colour-Sergeant Arnold finds from three years' observations at Aldershot camp that two gauges of 5in. aperture, set at an angle of 45°, their faces being kept to the wind by vanes, collect as nearly as possible the same amounts of rain at heights of 6ft. and 3ft. respectively, while a gauge of 8in. aperture elevated 25ft. gathered about 76 per cent. of the quantity collected in the lower gauge. We believe no explanation has as yet been offered of these results. There is also another circumstance not noticed by Mr. Symons; it is that the horizontal gauge at 6ft. of elevation, gathered during the three years about 70 per cent. only of the rain collected by the inclined gauge at the same height. Similar observations at Rotherham, the elevation being 5ft., gave in the four years, 1868 to 1871, 71 per cent. in the horizontal gauge, as compared with 100 in the inclined gauge. These results are so near to each other as to indicate that at an inclination of 45° for the receiving aperture, the greatest quantity of rain is arrested, or, in other words, the greatest quantity of rain falls on a surface opposed to the wind, and inclined to the horizon at an angle of 45°. The observations of Sergeant Arnold with inclined rotating gauges appear to point to the fact that the strata of atmosphere below an elevation of 30ft. is *equally charged* with rain, while his experiments on the other hand, at elevations at 6ft. and 25ft. appear to point to an absolute increase of rain in the lower strata. The close agreement of the Aldershot and Rotherham observations, in showing that at the same elevation in the lower strata a horizontal gauge gathers about 30 per cent. less than a gauge inclined at 45° kept face to the wind, appears to indicate that the elevation differences are dependent upon the horizontality of the receiving apertures, and consequently on the angle which those apertures make with the normal angle of 45°. We have dwelt upon these portions of the "Rainfall" as bearing upon the *accuracy* of the present mode of measurement, and we hope that further attention will be given to so important a subject. The investigation relative to the duration, hourly frequency, and rate of rainfall, has been continued by Messrs. Sawyer and Bruce, with somewhat similar results to those of 1870. At Brighton, the greatest number of falls in any one hour occurred between 2 and 3 p.m.; in the next hour, 3 to 4 p.m., the number of falls was only one less; the result was precisely the same in 1870. At Bogside, Aberdeenshire, the greatest number of falls occurred between 3 and 4 p.m. As a practical result, we find that the period from 11 p.m. to 3 a.m. is marked by fewer falls of rain than any other of the 24 hours; falls are more frequent between 3 and 7 a.m., after which they decline until 11 a.m., increasing from that hour to 3 p.m., and then decreasing to 8 p.m., the remaining three hours being a period of greater frequency. Among the weather proverbs is found the following: "Rain before seven, clear before eleven," which is based upon the *hourly* frequency of rain. In the last two years and a half Mr. Sawyer found there was rain before 7 a.m. on 159 days. On 68 of these days, or nearly half, there was *no* rain after 11 a.m., and on 106 days or two-thirds of the whole, the weather cleared before 11 a.m., and there was no rain until 2 p.m. or after. From these facts Mr. Sawyer concludes that the proverb is well borne out, and it is in accordance with the periods of greater or less frequency alluded to above. In his remarks on the rainfall of certain districts, Mr. Symons calls attention to the discontinuance of the records taken round St. Mary's Loch, for the Edinburgh Water Trust, and remarks that "this is to be regretted, not only for scientific reasons, but because, sooner or later, the information would have possessed an actual money value far exceeding the cost of registration;" he further adds that "niggardliness in such matters often compels tenfold subsequent outlay." We have only room to notice that under the head of "Foreign Rainfall" the condition of India is spoken of as having been very remarkable during 1871: heavy falls in some places, great drought in others. For much interesting detail we must refer the reader to the volume itself, which is fully equal to its predecessors.

Iron as a Material of Construction. By W. Pole, F.R.S. London: E. and F. N. Spon.

What we may term the foundation-stone of this book was a series of lectures delivered at the Royal School of Naval Architecture on the use and application of iron in mechanical structures. These have been carefully revised, and with much additional matter form a text-book that cannot fail to be of use or to find numerous readers amongst students of that branch of the art of construction which deals principally with iron—a branch which is rapidly spreading and ramifying in an increasing number of directions. Mr. Pole was formerly professor of civil engineering in University College, London, is a member of the Government Iron Armour Committee, and with the aid of his forty years' experience brings no small amount of information to bear in writing this handbook for the use of students in engineering — information supplemented by diligent research into, and garnering from, the works of the best and most reliable authorities on the different branches of the subject. The book is devoted essentially to the practical part, though so much of the theoretical as was thought necessary is not omitted; and it will, doubtless, prove of service in assisting the student to acquire a knowledge of the nature and properties of iron as a material of construction. Mr. Pole, while carefully pointing out that book-learning can never supply the place of practical observation, is yet convinced that the acquirement of the requisite knowledge is immensely facilitated when practical observation is guided by previous study. "Many practical engineers have devoted the best years of their lives," he says, "to its acquisition, but there are many members of the profession who have had no opportunity of doing this, and to whom the want of such knowledge must always be a disadvantage, causing them to rely on others for judgment which it ought to be their own personal prerogative to apply." With iron entering, more or less, into every building of any pretensions erected nowadays, supplanting stone in bridges, and timber in houses, it is refreshing to find a practical man like our author saying that "it is questionable whether this substitution is not being carried too far, and whether the new perishable substance is not frequently adopted for the sake of cheapness, or facility of construction, in cases where the more durable but less tractable material, stone, would be more appropriate, more noble, and more worthy of the profession." This, however, is only an "aside." The engineer who wishes to be master of his art must be thoroughly conversant with the capabilities of iron as a material of construction, and able to adapt it to the various structural purposes which our wants demand. The book is divided into chapters headed—the Production of Pig Iron, Production of Malleable Iron, On the Mechanical Properties of Iron Generally, Cast Iron, and Malleable Iron, the essential principles of the manufacture being briefly but clearly indicated, while the properties of the metal as used in construction are very fully explained.

Practical Plane Geometry. By J. F. Heather, M.A. London: Lockwood and Co.

This volume forms the first course of the "Elements of Mathematical Drawing" in Weale's well-known series, and contains the simplest modes of constructing figures contained in one plane and directions for laying out geometrical constructions on the ground. The objects of the work are to give such a course of instruction in practical plane geometry as shall enable students to comprehend the constructions given in the papers at competitive examinations, and to form a complete introduction to the volumes on Projection and Descriptive Geometry, which are to follow. Mr. Heather has adopted the simplest mode of performing the constructions consistent with great accuracy, and as this necessitated variations from the methods of Euclid, as well for those problems which are contained in the Elements as for the numerous deductions therefrom which he makes use of in the book, proofs of the methods employed are given. The theorems are merely stated, however, references being given to the propositions of Euclid in which they are found. The book appears to have been carefully put together, and is worthy to take its place in the well-known and useful "Series" to which it belongs.

Conversations on Natural Philosophy. By Mrs. Marcet, Revised and Edited by the son of the author, Francis Marcet, F.R.S. London: Longmans.

This is the fourteenth edition of a well-known and deservedly popular work, and will doubtless find its way into the hands of many of the rising generation, and replace the older editions in the "seminaries" and "academies" where it is used as a class-book. In the "advertisement" to the present edition we are told that it has been thought desirable to introduce two additional conversations on Spectrum Analysis and Solar Chemistry, and on the title-page we are informed that the book has been "revised and edited," which we should understand to mean in the ordinary course of things that the statements made therein were consonant with the known facts of science at the present time. We regret to say, however, that whatever revision and editing it has undergone has not been well done; we regret to say this, because a book which, probably, first stirred the mind of the youthful Faraday to experiment in fields where he afterwards became a most eminent worker, and which, moreover, has been held in good repute almost from the commencement of the present century, is in a measure past criticism, and deserving of honour for the good work done in previous years. The subjects of heat, light, colour, electricity, are not brought up to our present knowledge, and in several instances incorrect statements are allowed to appear. Thus we find it said that "the ether which produces light cannot be an elastic fluid," and that "water is a non-elastic fluid." Errors, too, which might have been avoided by a careful revision have also escaped the printer, for we are informed that "the steam below the piston is *not* drawn into the condenser while that above it forces it down." The "not" spoils the whole sentence. Such spelling as the "spectre of metals" and "alcaline" is decidedly objectionable, and contradictory statements, like the distance of the earth from the sun being given in one place as 95,000,000 miles and in another "about 91,000,000," might at least be avoided. Under these circumstances, therefore, we cannot but desire a speedy issue of the "fifteenth and corrected" edition.

Healthy Houses. By William Eassie, C.E. London: Simpkin, Marshall, and Co.

This is a book with an attractive title, but we are afraid that many who take it up with the idea of learning how to make a house healthy will lay it down disappointed. Mr. Eassie, it appears, was assistant engineer to Renkioi hospital during the Crimean war, and has here published what he calls a handbook to the history, defects, and remedies of drainage, ventilation, warming, and kindred subjects, with estimates for the best systems in use, and upwards of 300 illustrations. In his preface the author says, that at length the sanitary Day (with a capital D) is dawning. Of course we are very glad to hear it, but while confessing that we do not know exactly what he means, we beg leave to assert that, so far as the public is concerned, there is, individually, very little appreciation of the necessity for sanitary laws, and a vast amount of ignorance of the evils of dirt and of the diseases which follow in its wake. Local authorities, save in some few exceptional instances, exhibit an amount of supineness which cannot long be tolerated: an indifference, in fact, which evinces the utter contempt with which they regard the teachings of sanitarians. Whether Mr. Eassie's book will effect an alteration of this unsatisfactory state of things remains to be seen. As an account of what has been done to improve our dwellings, and make them healthy, his little book has doubtless a certain value—giving, as it does, a collection of inventions, patented and otherwise, connected with drainage, ventilation, and heating; but we venture to think that the amateur builder who takes up this book with a view of discovering the best method of constructing and fitting a house according to the requirements of sanitary laws, will find himself endeavouring to sit on more than two stools at once. Besides, there is naturally a very great suspicion attached to the opinions of an author who does not hesitate to advertise the different wares of which he speaks, by giving their prices and the addresses of the manufacturers. Mr. Eassie considers that the earth and ash-closet systems "have much good work to perform;" but when a thorough "water drainage" is effected they may "wisely be dispensed with." He thinks that the carbon-closet system is, "without doubt, the best dry process yet invented." Speaking of the present arrangements for collecting dust, Mr. Eassie suggests what we presume he would call an improvement, which, in fact, it might be in Utopia, the happy land in which we do *not* live. He says, "If a person accustomed to a constitutional walk before breakfast-time avoids an occasional accident from the exposure of the many-shaped boxes of dust, he may consider himself lucky; but if he escape the inhalation of some disease from the well-packed weekly hampers of dirt and offal, he is doubly fortunate." We have heard of the "dangers of the streets," but we were not aware that so many pedestrians are the "doubly fortunate" individuals which Mr. Eassie makes them. Our author then suggests that the latter evil (the "inhalation of some disease") is "unquestionably to be remedied by the use of some deodorising disinfectant." The receptacles for the dust are to be so constructed that every time the lid of one is opened a quantity of a disinfecting powder is mixed with the rubbish put in; while the receptacle is to be so placed in the area, "that the pressure of the dustman's foot would cause it to rise to the pavement level." How this is to be done by apparatus of the requisite simplicity Mr. Eassie does not tell us, neither does he inform us whose duty it would be to see that the dust-bin had its proper supply of disinfecting powder. Nevertheless, his book will be found useful by those who wish to know what has been done to insure the most healthy conditions in dwelling houses—provided they are capable of judging for themselves of the relative merits of the articles mentioned.

A Pocket Dictionary of Technical Terms used in Arts and Manufactures. English - German-French. German - English - French. French-German-English. Abridged from the Technological Dictionary of Rumpf, Mothes, and Unverzagt. London: Trubner.

A TECHNOLOGICAL dictionary is nowadays so useful, not to say indispensable, a companion of the architect, engineer, and mechanic, that we cordially welcome the appearance of these three volumes. It would, it is true, be easy to point out many errors —in fact to make fun of sundry rather ludicrous misunderstandings of the compilers, but in spite of these this "pocket dictionary" is the best of its kind with which we are acquainted. Many words might be omitted with advantage, for it is difficult to see what use the term "bluebottle," referring to the cornflower, can be to technologists, especially as that is the only "meaning" given; nor are many persons likely to require the French or German equivalent for "bihydroguret of carbon," which, with its reference, occupies two lines. In the dictionary for Frenchmen, the English term for a *dame-jeanne* is said to be a "glass-balloon put in a basket," and a "carboy" appears to be known only when it contains nitric acid. The errors, in fact, are numerous, but those who have attempted to translate technical works into a foreign tongue can readily appreciate the difficulties experienced by a lexicographer in giving the correct meaning of the various trade terms and technical phrases, especially when they are not given in the dictionaries of the language spoken by those who use the terms. As a matter of fact, the definitions of tools, appliances, and materials of different industries are often erroneous in works professing to give them, while our ordinary dictionaries omit them as a rule. It will be seen, therefore, that to collect them for three languages is a labour of no slight difficulty, and mistakes of omission and commission may be expected to abound. The arrangement, as far as typography is concerned, is very clear, consistent with great condensation, but numerous printers' errors disfigure the pages.

We have also received *New Formulas for the Loads and Deflections of Solid Beams and Girders*, by William Donaldson, M.A., A.I.C.E. (E. and F. N. Spon), a work which will interest engineers, the formulas being "strictly based on the assumption" that *ut tensio sic vis*. Mr. Donaldson hopes to secure for his essay either a prompt refutation or an acknowledgment of its truth in the altered practice of engineers. He contends that as cast-iron beams are now constructed the upper flange is repeatedly subjected to its proof stress, and is therefore liable to more frequent failure; and he considers that in wrought-iron beams one-sixth of the weight has been hitherto wasted.—*The Strains in Trusses*, by Francis A. Ranken, M.A., C.E. (Longmans), is an attempt to set in a clear light the theory and method of computing by diagrams the strains in trusses bearing a constant load. There are twenty examples drawn to scale, and the work is worth the attention of engineers and builders.—*The Screw Cutters' Guide*, by James Martin, is a handy and reliable little book for the pocket of the mechanic. It contains tables of 2,165 trains of wheels for different pitches of threads, besides sundry other information that is always handy for reference by the screw-cutter. Every amateur lathe-worker should purchase the little book.—*Esse and Posse*, by H. T. Braithwaite, M.A. (Longmans); *Mankind, their Origin and Destiny*, by an M.A., of Balliol College (Longmans); *An Exposition of the Fallacies in the Hypothesis of Mr. Darwin*, by C. R. Bree, M.D. (Longmans); *Michael Faraday*, by Dr. Gladstone (Macmillan); *Ancient Stone Implements, Weapons, and Ornaments of Great Britain*, by John Evans, F.R.S. (Longmans); *Key to Harris's Arithmetic* (Longmans), notices of which we must postpone for the present.

HOW LUNG DISEASES ARE PRODUCED.

TWENTY years ago the so-called sizing of cotton consisted in using fermented flour and tallow to give tenacity to the warp and to lessen friction in the weaving process. Thereafter it came to be seen that the brownish colour given to cotton cloths by size made from inferior kinds of flour could be reduced by adding a little china clay to the size; while this material so far reduced the glutinous quality of the flour that the sized warps would weave easily with less tallow in the size. With the increased price of tallow in the Crimean War, china clay came to be still further substituted; the practice grew more and more general till the cotton famine of 1862 brought into use the poorer short-fibred cotton, which demands a larger amount of size than the better sorts. Another practice was introduced by the lack of cotton. "Weight for length" being the chief test of the goodness of yard-wide cloth, a fictitious weight was given to cloths containing less cotton, to make it appear that they contained more; "heavy sizing" became the custom, and for this purpose a size, composed mainly of flour and tallow, with the addition of Epsom salts, chloride of magnesium, sulphate and chloride of zinc, was resorted to. In weaving warps of inferior cotton, weighted with china clay and flour mixed with deliquescent salts, the weaving sheds must be kept damp, to prevent the brittle compound of clay, flour, and cotton from breaking, and increasing the weight of the cloth by the retained moisture. A mean of 62° Fahr., the external temperature being at 48° Fahr., with an excess of moisture and a careful avoidance of any draught that could dry the tender warp, were the conditions of work in the weaving-sheds, and were found so deleterious, says the *Lancet*, that the weavers addressed a remonstrance to the Privy Council. Dr. Buchanan was accordingly told off to investigate the matter, and found in thirteen sheds a haze caused by fine dust particles. The looms were in all cases covered with opaque dust, depending as to quantity on the kind of cloth that was being made. The clothes and hair of the weavers were white with dust, causing an intense irritation to the nose and in a less degree to the eyes and throat—an irritation to which the weavers get accustomed, though at the expense of their lungs. To judge of the effects of this mode of life on the weavers, Dr. Buchanan first examined the mortality statistics, next collected the local medical opinions, and finally made personal examination of the weavers themselves. In Todmorden, for example, Dr. Buchanan found that there was a considerable excess in the death-rate from lung diseases among persons over fifty-five years of age.

All the medical men concurred that lung diseases were greatly prevalent owing to the cotton manufacture, that the cotton worker bequeaths a consumptive habit to his progeny, and that dyspepsia is another ailment peculiar to those people. With some little divergence of opinion, the local practitioners agreed that the lungs of weavers suffered more now than formerly, and that they were approximating to carders in their liability to chest complaints. The weavers themselves were positive as to their incurring shortness of breath, emphysema, bronchitis, subacute dyspepsia, and permanent epistaxis from the conditions they lived under—diseases which disappeared or were relieved by cessation from work. "Fewer weavers now pass middle age without getting something the matter with their lungs," was the remark of an intelligent over-looker to Dr. Buchanan. Experience tells that the diseases due to dusty occupations are not rapidly fatal. "During the years that their victims are only disabled no record is kept of their prevalence. When at last," says Dr. Buchanan, "they kill, perhaps after having driven the worker to some other occupation, and having made his life miserable for ten or twenty years, then for the first time they get registered." To arrest the increase in the already excessive and heightened mortality in the cotton working community, important changes in the practice of sizing, or in other ways, must be introduced; and we hope the Local Government Board will lose no time in acting on the suggestions submitted to it by Dr. Buchanan.

ENGLAND IN RELATION TO MUSIC.

THE *Daily News* in an article asks: "Are the English a musical people?" and then answers the question by the following comments. The distinguished company at the recent jubilee dinner of the Royal Academy of Music, could have no difficulty in answering the question to their own satisfaction. We agree with Lord Dudley, the President of the Academy, that the English are a musical people, whatever foreigners may say or think about it. But when one speaks of the English as a musical people, it must be understood in the sense of a people who have an ear for music, and an instinctive affection for the concord of sweet sounds, rather than the will and the power of cultivating the science and the art of music, with all the imaginative and inventive genius which we devote to machinery and to turnips, to big guns and iron plates, to horse-racing and shipbuilding, to the pastimes of the sea and the sports of the field. The native love of music appears in all its freshness and sincerity in a thousand passages of English poetry; and the sister Muses are seldom far apart, if they do not always walk hand in hand. Musicians of the future have no mercy for a tune; but the old musicians of the past were not ashamed of being tuneful, and of bequeathing to after generations immortal melodies that, like the airs in Prospero's island, give delight and hurt not. No country is richer than our own if we include, not Great Britain only, but Ireland, in ballad music. Our sweet and simple minstrels have lent to the sadness and joy of the human heart a voice which the world will not willingly let die, though the minstrel's name may be often forgotten or unknown. Still, as Sir John Coleridge, himself an enthusiastic lover of the art, had the courage to avow the other day, when he was presiding over a musical and almost professional audience in St. James's Hall, there was always something provincial about the English school of music, if, indeed, a school could be said to exist. The catalogue of our composers for the cathedral contains a host of names which, with very few exceptions, can scarcely be called famous, even at home, and have never been pronounced abroad. What do France, Germany, or Italy know of our Purcells and our Arnes, not to mention our Boyces, our Greens, our Blows, our Smiths, our Arnolds, and a hundred other most respectable writers of Anthems? This provincialism is, perhaps, rather the misfortune than the fault of our masters of the fugue; the misfortune of living in an island before the seas were bridged by steam, and in ages when very few Englishmen made the Grand Tour, and our intercourse with the Continent was confined to soldiers and diplomatists. Still, even in these latter days of incessant intercommunication, there are scarcely more than one or two names of English composers that have crossed the channel; and the Anthem which Mr. Headlam heard at the Temple Church on Sunday last, and which he modestly declares was worthy of the best days of English music, was composed by perhaps the solitary Englishman whose fame has reached Paris, Vienna, and Berlin, if indeed it has passed beyond a select circle of professed musicians in those cities; and perhaps it is as a favourite pupil of Mendelssohn that the reputation of Sir Sterndale Bennett has arrived at Leipsic, rather than on account of the true and serious merit of his works. Speaking broadly, neither the public nor even the *dilettanti* of Continental Europe know of English music or English composers as we on this side of the water know of Verdi and Wagner, and Gounod and Offenbach. Why should we shrink from this confession of comparative obscurity? If England has not given birth to world-renowned musicians, it has been a fond and beloved nursing-mother to the greatest of them. Handel, who is only just beginning to be known to the Parisians, was an Englishman by adoption, by residence, and by predilection. It is true that he was only a naturalised Anglo-Saxon, and that we have to thank the House of Hanover for his coming among us; but it was in England that he lived and worked; it was to English institutions and English glories and English charities that his mighty musical genius was consecrated for nearly forty years. It was in England that his last work was written with his own hand, and it is in our national sanctuary that the pilgrims of all countries seek his monument and tomb. No doubt it is to our dynastic connection, and to the kinship of the two races, that we owe the fact of which we have the right to boast: that as Germany is the second country of our Shakespeare, so England has been the second country of her Haydn, her Handel, her Beethoven, her Mozart, and her Mendelssohn. Their works have been more played and sung in England than in all the rest of Europe; it was by English audiences that the finest of their works were first heard, and have been heard constantly and habitually, while in the "Capital of Civilisation," fifty years after the London Philharmonic Society had possessed and performed the masterpieces of Beethoven, that stupendous genius was almost "a barbarian" to the Conservatoire; and a quarter of a century after Mendelssohn had conducted his *Elijah* at Birmingham, an enthusiastic conductor of popular concerts ventured upon the experiment of playing the Italian symphony before a public who believed that Gluck was a Frenchman and M...

beer a native of the Boulevards, and Rossini the swan, not of Pesaro, but of Passy. It is scarcely an exaggeration to say that even now, to the Parisian public (exclusive of a few connoisseurs), the great German composers are almost as unfamiliar as the great composers (if any such there be) of China or Japan. However insular and parochial Englishmen may be in their political ideas, in art, and especially in music, they are (if Mr. Disraeli will pardon the word) essentially and admirably cosmopolitan. In some respects we are a "peculiar people" but in hospitality to Art and Genius we are true Gentiles, of the broadest church. Our neighbours are usually regarded as the most sympathetic and assimilative nation of the Western World; but nothing like our English faculty of naturalising foreign musical genius (a faculty which is almost genius in itself) can be found out of these islands.

PRESERVING BIRDS' EGGS.

THE following hints on the best method of preparing birds' eggs for preservation are from the pen of Dr. William Wood, and are extracted from the *American Naturalist*.

I wish to say a few words for the benefit of those engaged in collecting öological specimens. Twenty years ago all eggs were blown with two holes—one at each end, and until within ten years most eggs have been emptied with two holes as above, or at the side. Very many of the eggs which I now receive in my exchanges are similarly prepared. At the present time no experienced collector ever makes but one hole to remove the contents of the egg, using a blowpipe in some form to accomplish this object. The following rules should invariably be followed:—

1. Prepare your eggs neat and clean. There is no excuse for having a dirty set of eggs where water, soap, and a tooth-brush can be found. Some eggs will not bear washing, as the shell is so calcareous that the characteristic markings will wash away. There are, however, but few of this class, and I believe this peculiarity is confined to the water-birds. You can see it in the eggs of the grebes and flamingo, and some others. Having once seen it you will never mistake it for anything else.

2. Make but one hole, and that a small one in the middle of the egg; cover this hole, when the contents are removed, and the specimen is dry, with gold-beater skin or the paper number indicating the bird. Use an egg drill or a pointed wire of four or six sides to make the opening.

3. If the blowpipe does not readily remove the contents of the egg, inject water and shake the specimen thoroughly, then blow again, and repeat the operation until every particle of the egg is removed.

4. If the embryo is too far advanced to remove through a moderate sized hole, blow out what you can of the liquid part and fill the egg with water, wipe it dry and put it away in a covered box in some warm place, and every twenty-four or forty-eight hours shake it well and remove what you can, and then re-fill with water. Repeat this operation several times, and after a few days the contents will become sufficiently decomposed to take away.

5. After removing the contents of any egg, cleanse the shell thoroughly. Fill it with clean water and shake vigorously, blow out the contents and repeat the operation until the specimen is perfectly clean. This is particularly desirable in white eggs, as black spots will show through the shell after a time if the least particle of the egg or blood stains remains inside.

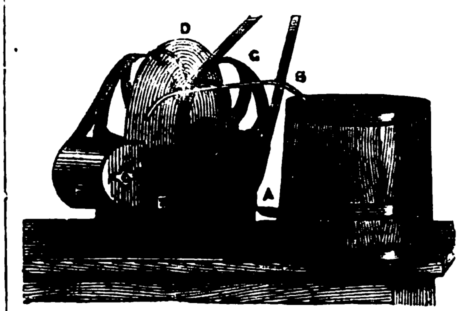
6. Save all your eggs in sets—that is, keep all the eggs each bird lays by themselves. This is the only way to form a correct knowledge of the eggs of any species, as a single egg, particularly of the blotched ones, frequently gives a very erroneous idea of the general markings—a very unsatisfactory representation of a set. For instance, in my collection are four eggs of the *Buteo lineatus*, found in the same nest, two of which are pure white and two blotched. It is not very uncommon to find great variations in markings in the same species and in the same nest.

7. Keep a memorandum of the place and date of collecting each set of eggs.

8. Use some kind of blowpipe in preparing your eggs for the cabinet. The common blowpipe, with the addition of a fine pointed tip, will answer; yet it is a severe tax on the lungs and brain if you have many eggs to blow. I have many a time been dizzy and almost blind from over-taxing my lungs in this operation. Within a few years Mr. E. W. Ellsworth, of East Windsor Hill, Conn., has invented a blowpipe which is operated by the thumb and finger, which works very perfectly and expeditiously. I would not be without it on any account. After using it for a time, and then letting it remain unused until the leather packing becomes dry, the instrument does not work satisfactorily to those unaccustomed to it. The remedy is simple. Take off the blowpipe and work the instrument submerged in a bowl of warm soapsuds, when the leather packing becomes pliable and works as well as new. I have used the same instrument for years, and it works to-day as well as when new, by following the above directions. The printed directions which accompany each instrument are intended to be a sufficient guide in case repairs are needed, and the maker can be referred to for any further information required.

DYNAMIC REFRIGERATOR.

M. TOSELLI, the inventor of a well-known ice machine, has recently constructed a cooling machine, which is denominated the dynamic refrigerator. It consists of a revolving disc, D, formed of a metallic tube bent into a complete spiral, having one end open, and with the other end communicating by a hollow shaft or axis of rotation with an external tube, A, communicating with a worm contained in a separate vessel, C, and terminating in a discharge pipe, B, with outlet into another vessel, E, containing the revolving disc to which a slow movement of revolution is imparted by a driving pulley and belt, G, making (say) one turn in a second of time. The disc is half immersed in cold water, and as the exterior surface of the disc above water is continually wet, it exposes considerable evaporating surface. At the same time a continuous stream of water is forced through the hollow spiral, parting with some of its heat under the influence of the external evaporation and radiation, which is intensified by the addition of a ventilator, F. The current, being thus lowered in temperature, refrigerates in its turn the liquid to be cooled in the vessel, C. The lowering of tempera-



ture thus obtained varies according to the hygrometric condition of the atmosphere; the minimum effect obtained under the most unfavourable circumstance amounts only to a difference of five to six degrees Fahrenheit; while the maximum difference obtained in sunlight is between 32 and 33 degrees Fahrenheit. The inventor considers that this machine will be of great service in many manufacturing processes—such as brewing, distilling, and making effervescent beverages—also in hydro-therapeutic establishments, and probably also on shipboard for the evaporation and distillation of sea-water, and its conversion into a potable fluid.

MECHANISM.*

(*Continued from p. 402.*)

THE relation which the machinist bears to the mechanist is easily defined. Setting aside the question of structure, the mechanist deals with designs; the machinist takes those designs and adapts them to his purposes. For the fitness of the designs for an end, they apply, when need be, to the mathematician. The mechanic takes the deductions of the machinist and the mathematician, and produces a machine as exactly adapted to the purpose required as the knowledge and experience of the time enables him to do. The distinction thus drawn between the machinist and the mechanician leads to modes of expression by these respective classes which, unfortunately, do not increase the respect of each for the other. For example, the mechanician aims only at a contrivance; the machinist or mechanic aims only at a commercial or manufacturing utility. A mechanician is contented with the most rude skeleton design; he does not care for either journals or plummer blocks being neatly and carefully curved out—anti-friction curves do not trouble him. On the blackboard are two skeleton drawings; here is a very rude one of two wheels and a crank—these answer the purpose of the mechanician. A mechanic would not be worthy of the name of mechanic if he executed such a piece of work; as a mechanical drawing it is perfectly ridiculous. You see by the side of it some specimens of mechanical drawing, one a diagrammatical one, and another a most beautifully-finished drawing of a locomotive, which, perhaps, appears to many to be an engraving. It, however, is done entirely by hand. There are also working drawings, such as are taken into the workshop, from which the actual machines are made. It would certainly be a great improvement on scientific books if there were some advance in the illustrations they contain, which at present are often even less worthy of commendation than the rude mechanistic skeleton one alluded to.

It is quite possible, and it would be even prudent, to make mechanism a study altogether apart from mechanics; it would not, however, be prudent on the present occasion to do so. Whilst, therefore, associating mechanism with mechanics—to which it is not allied, and mechanism from mathematics—to which it is necessarily allied, in this course of Cantor Lectures we approach the subject in a species of bondage, and must therefore ask that favourable consideration generally extended towards a comparatively strange friend by making use of our old friend, mechanics, for a favourable introduction and an occasional help.

With mechanics we are all familiar. We can neither eat, drink, nor sleep; we can neither sit, walk, nor talk, except by the exercise of those mechanical arrangements with which nature has endowed us. When, however, in the course of nature the vital energy ceases by which man is enabled to put in action the machinery of his frame, then, however beautiful and perfect the machinery may be, the object for which it was constructed cannot be performed. At this stage (the power of the machinery having gone—the kinetical element having been removed) the mechanist takes up the parts, and may be said to analyse the contrivances by which the vital energies exercise their various powers. But the mechanic cannot operate without a motive power. The mechanician cares for none. He deals with contrivances in relation to motion. His peculiar province is to devise plans by which the motion he has may be changed into the motion he wants, and the requirements he wants are singularly varied, and they fully warrant Mr. Anderson's expression of "endless," for to them there is "practically no limitation." Farmers do not make more varied demands upon the weather than machinists do upon mechanists in relation to motion. There is no end to the variety of demands made by the public upon the mechanician. One man comes and says he has motion which he wants accelerated. Another says he has a motion which he wants retarded. A third comes and says his motion is not quite continuous, he would like it to be so; another says he wants the motion to be intermittent. One man says he wants a circular motion when he has got a rectilineal; another says he wants a rectilineal when he has got a circular; another wants it variable; another says he wants it uniform; one says it must be alternate, going backwards and forwards; another says he wants his motion brought to a state of rest. Another says, here is velocity, convert it into power; and another, here is power, convert it into velocity. None of these, and the list might be wonderfully extended, are out of the province of the mechanician. For example, a knife is to be sharpened. There are various modes of doing it. The shelves of the Patent-office have many plans for sharpening knives, but we will take the representative one, in which the stone revolves. We have an apparatus here for which we are indebted to Messrs. Holtzapffel. The problem before the mechanist is to convert the perpendicular motion of the foot up and down about eighty times in a minute into a continuous motion of the stone of about 500ft. circumferential per minute. The plan adopted here is to have a treadle for the foot, by which the up-and-down motion is transferred to a wheel, from which there is a band to a small pulley connected with the stone, and by this contrivance we have got the up-and-down motion of the foot converted into the continuous rotary motion of 500ft. per minute. That mechanism is perfect for all purposes, not simply for the sharpening of a knife, or razor, or lancet, but, as a mechanical contrivance, it will do for a hatchet, scythe, or any other edged tool. The machine has left the mechanician's hands as a contrivance, but the mechanic takes it up, and adapts the question of its structure to the particular use for which it is required, using such proportion of treadle, crank, and wheel as he pleases. The mechanist has done with it when the contrivance is produced, and it then becomes the property of the mechanic. If, however, the problem had been set before the mechanist in another form, as, for example, if he had a weight falling, and that had to be converted, or if he got such a matter as the rise and fall of the tide, and that had to be converted, or, if he had got the explosive power of gunpowder, or the intense power at a short distance of electricity, or the elastic power of a steel spring, then clearly these would be new conditions imposed upon the mechanist, and a different piece of mechanism would have had to be designed for each of those cases. You have, therefore, according to the questions put before the mechanist, various machines, but one contrivance serving every purpose. In any case the mechanic takes the designs of the mechanician, and so avails himself of his own knowledge of material, and so adapts the amount of power at his disposal, and of that required to be utilised, as to make the machine.

Now it is clear that to sharpen a razor and a hatchet require from the mechanic two different machines—from the mechanician they require but one mechanistic contrivance.

Having thus explained and illustrated the position which mechanism holds in relation to other branches of mechanics with which it is allied, we should

* By the Rev. Arthur Rigg, M.A., being the Cantor Lectures delivered before the Society of Arts.

restrict ourselves to a consideration of the divisions and sub-divisions under which it may be usefully studied. To do so in the present course of lectures would be to make the subject not particularly inviting, and we must sometimes, therefore, overstep the boundaries, and take a short walk into the not very inviting mathematical and prohibited fields, and perhaps a longer one into the more inviting mechanical fields. In thus, to some extent, trespassing into tempting bye-paths from the highway which the literal meaning of the title of these lectures prescribes, the Council of the Society, and the audience, who do not despise mechanistic drawings, must permit action to take place under a precept which not existing in our Christian code, I must borrow from another:—

For what saith the Koran in chapter the third,
"Confine not thy neighbour too close to his word."

A consideration of the classification of mechanism, as suggested by Professor Willis, may form an appropriate introduction to the next lecture.

THE CONSTITUTION OF NATURE.*

WE cannot think of space as finite, for wherever in imagination we erect a boundary we are compelled to think of space as existing beyond that boundary. Thus, by the incessant dissolution of limits, we arrive at a more or less adequate idea of the infinity of space. But though compelled to think of space as unbounded, there is no mental necessity to compel us to think of it either as filled or as empty; whether it is filled or empty must be decided by experiment and observation. That it is not entirely void, the starry heavens declare, but the question still remains, are the stars themselves hung in vacuo? Are the vast regions which surround them, and across which their light is propagated, absolutely empty? A century ago the answer to this question would be, "No, for particles of light are incessantly shot through space." The reply of modern science is also negative, but on a somewhat different ground. It has the best possible reasons for rejecting the idea of luminiferous particles; but in support of the conclusion that the celestial spaces are occupied by matter, it is able to offer proofs almost as cogent as those which can be adduced for the existence of an atmosphere round the earth. Men's minds, indeed, rose to a conception of the celestial and universal atmosphere through the study of the terrestrial and local one. From the phenomena of sound as displayed in the air, they ascended to the phenomena of light, as displayed in the *ether;* which is the name given to the interstellar medium.

The notion of this medium must not be considered as a vague or fanciful conception on the part of scientific men. Of its reality most of them are as convinced as they are of the existence of the sun and moon. The luminiferous ether has definite mechanical properties. It is almost infinitely more attenuated than any known gas, but its properties are those of a solid rather than of a gas. It resembles jelly rather than air. A body thus constituted may have its boundaries; but, although the ether may not be co-extensive with space, we at all events know that it extends as far as the most distant visible stars. In fact it is the vehicle of their light, and without it they could not be seen. This all-pervading substance takes up their molecular tremors, and conveys them with inconceivable rapidity to our organs of vision. It is the transported shiver of bodies countless millions of miles distant which translates itself in human consciousness into the splendour of the firmament at night.

If the ether have a boundary, masses of ponderable matter might be conceived to exist beyond it, but they could emit no light. Beyond the ether dark suns might burn; there, under proper conditions, combustion might be carried on; fuel might consume unseen, and metals be heated to fusion in invisible fires. A body, moreover, once heated there, would continue for ever heated; a sun or planet once molten, would continue for ever molten. For, the loss of heat being simply the abstraction of molecular motion by the ether, where this medium is absent no cooling could occur. A sentient being, on approaching a heated body in this region, would be conscious of no augmentation of temperature. The gradations of warmth dependent on the laws of radiation would not exist, and actual contact would first reveal the heat of an extra ethereal sun.

Imagine a paddle-wheel placed in water and caused to rotate. From it as a centre waves would issue in all directions, and a wader as he approached the place of disturbance would be met by stronger and stronger waves. This gradual augmentation of the impressions made upon the wader's body is exactly analogous to the augmentation of light when we approach a luminous source. In the one case, however, the coarse common nerves of the body suffice; for the other we must have the finer optic nerve. But suppose the water withdrawn; the the action at a distance would then cease, and as far as the sense of touch is concerned, the wader would be first rendered conscious of the motion of the wheel by the actual blow of the paddles. The transference of motion from the paddles to the water is mechanically similar to the tranference of molecular motion from the heated body to the ether; and the propagation of waves through the liquid is mechanically similar to the propagation of light and radiant heat.

As far as our knowledge of space extends, we are to conceive it as the holder of the luminiferous ether, through which is interspersed, at enermous distances apart, the ponderous nuclei of the stars Associated with the star that most concerns us we have a group of dark planetary masses revolving at various distances round it, each again rotating on its own axis; and finally, associated with some of these planets we have dark bodies of minor note—the moons. Whether the other fixed stars have similar planetary companions or not is to us a matter of pure conjecture, which may or may not enter into our conception of the universe. But probably every thoughtful person believes, with regard to those distant suns, that there is in space something besides our system on which they shine.

Having thus obtained a general view of the present condition of space, and of the bodies contained in it, we may inquire whether things were so created at the beginning. Was space furnished at once, by the fiat of Omnipotence, with these burning orbs? To this question the man of science, if he confine himself within his own limits, will give no answer, though it must be remarked that in the formation of an opinion he has better materials to guide him than anybody else. He can clearly show, however, that the present state of things *may* be derivative. He can even assign reasons which render probable its derivative origin—that it was not originally what it now is. At all events, he can prove that out of common non-luminous matter this whole pomp of stars might have been evolved.

The law of gravitation enunciated by Newton is, that every particle of matter in the universe attracts every other particle with a force which diminishes as the square of the distance increases. Thus the sun and the earth mutually pull each other; thus the earth and the moon are kept in company; the force which holds every respective pair of masses together being the integrated force of their component parts. Under the operation of this force a stone falls to the ground and is warmed by the shock; under its operation meteors plunge into our atmosphere and rise to incandescence. Showers of such doubtless fall incessantly upon the sun. Acted on by this force, were it stopped in its orbit to-morrow, the earth would rush towards, and finally combine, with the sun. Heat would also be developed by this collision, and Mayer, Helmholtz, and Thompson have calculated its amount. It would equal that produced by the combustion of more than 5,000 worlds of solid coal, all this heat being generated at the instance of collision. In the attraction of gravity, therefore, acting upon non-luminous matter, we have a source of heat more powerful than could be derived from any terrestrial combustion. And were the matter of the universe cast in cold detached fragments into space, and there abandoned to the mutual gravitation of its own parts, the collision of the fragments would in the end produce the fires of the stars.

The action of gravity upon matter originally cold may, in fact, be the origin of *all* light and heat, and the proximate source of such other powers as are generated by light and heat. But we have now to inquire what is the light and what is the heat thus produced? This question has already been answered in a general way. Both light and heat are modes of motion. Two planets clash and come to rest; their motion, considered as masses, is destroyed, but it is really continued as a motion of their ultimate particles. It is this motion, taken up by the ether, and propagated through it with a velocity of 185,000 miles a second, that comes to us as the light and heat of suns and stars. The atoms of a hot body swing with inconceivable rapidity, but this power of vibration necessarily implies the operation of forces between the atoms themselves. It reveals to us that while they are held together by one force, they are kept asunder by another, their position at any moment depending on the equilibrium of attraction and repulsion. The atoms are virtually connected by elastic springs, which oppose at the same time their approach and their retreat, but which tolerate the vibration called heat. When two bodies drawn together by the force of gravity strike each other, the intensity of the ultimate vibration, or, in other words, the amount of heat generated is proportionable to the *vis viva* destroyed by the collision. The molecular motion once set up is instantly shared with the ether, and diffused by it throughout space.

We on the earth's surface live night and day in the midst of ethereal commotion. The medium is never still, the cloud canopy above us may be thick enough to shut out the light of the stars, but this canopy is itself a warm body, which radiates its motion through the ether. The earth also is warm, and sends its heat pulses incessantly forth. It is the waste of its molecular motion in space that chills the earth upon a clear night; it is the return of its motion from the clouds which prevents the earth's temperature on a cloudy night from falling so low. To the conception of space being filled, we must, therefore, add the conception of its being in a state of incessant tremor. The sources of vibration are the ponderable masses of the universe. Let us take a sample of these and examine it in detail. When we look to our planet we find it to be an aggregate of solids, liquids, and gases. When we look at any one of these, we generally find it composed of still more elementary parts. We learn, for example, that the water of our rivers is formed by the union, in definite proportions of two gases, oxygen and hydrogen. We know how to bring these constituents together, and to cause them to form water: we also know how to analyse the water, and recover from it its two constituents. So, likewise, as regards the solid proportions of the earth. Our chalk hills, for example, are formed by a combination of carbon, oxygen, and calcium. These are elements the union of which, in definite proportions, has resulted in the formation of chalk. The flints within the chalk we know to be a compound of oxygen and silicium, called silica; and our ordinary clay is, for the most part, formed by the union of silicium, oxygen, and the well-known light metal, aluminium. By far the greater portion of the earth's crust is compounded of the elementary substances mentioned in these few lines.

* By Professor TYNDALL.

SCIENTIFIC SOCIETIES.

SOCIETY OF ENGINEERS.

ON Tuesday week a party of Members and Associates of the Society of Engineers paid a visit of inspection to the Royal Arsenal, Woolwich, permission for which had been accorded by Colonel Campbell, R.A., the superintendent of the Gun Factories. The visitors numbered between sixty and seventy, and included Mr. Jabez Church, F.G.S., president of the society; Messrs. B. Latham, F. Colyer, G. Waller, members of council; Mr. A. Williams, honorary secretary and treasurer; Mr. P. F. Nursey, secretary; Messrs. Stephenson, Hurst, Gore, Rigg, Griffin, J. Church, Jun., Manwaring, Vallance, &c. They were received at the Gun Factories by Colonel Campbell, Captain Maitland, and Mr. Fraser, by whom they were conducted over the various departments of that establishment, the working details of which were fully explained. The first point of interest visited was the forging department, where, as also in the other shops, Colonel Campbell had made arrangements for illustrating the processes involved in the manufacture of the Woolwich guns. In the forge the visitors witnessed the coiling of a bar of iron 135ft. long, for a 10in., 18 ton gun. Under a steam hammer close by was a small coil for tubing a cast-iron gun on the Palliser principle, a number of these guns being in course of conversion from smooth-bored to rifled pieces. Near at hand was a 15 ton steam hammer pounding away at a trunnion coil for a 10in. gun, a muzzle coil being wrought at another hammer hard by. From the forge the visitors proceeded to the rolling mill, where the chief feature was the rolling of the 5in. bars from which the coils are made. The next process illustrated was the shrinking of a breach coil on the steel tube of a 10in. gun, the coil being brought up to a dull red heat, and lowered on the tube, within which a stream of water was playing, and upon which the coil shrinks in cooling. At this point were shown a number of 35 ton guns, in various stages of advancement toward completion. Ten of these 30 ton guns have already been finished, whilst a number more are in progress. The turneries, the boring department, the pattern room, were successively visited, and in each of which the various processes, carried on by the aid of some of the finest machinery in the world, were inspected with interest. Next came the shell foundry, where were seen Palliser projectiles in every stage of manufacture, from the moulding to the studding and finishing. The shells are lacquered inside with a resinous composition, to prevent rust, after which each shell is subjected to a hydraulic test of 100lb. per square inch. Here also were seen shrapnel shell of various sizes being made and filled. In another shop, submerged torpedoes of various kinds were being manufactured; and these included portions of the Whitehead torpedo, which, it is stated, has been made a success. The visitors were finally conducted over the laboratory, and witnessed the series of highly interesting processes connected with the manufacture of the service cartridges. Altogether a very instructive and pleasant afternoon was spent, which was rendered more agreeable by the courtesy of those in charge of the various departments, who afforded the visitors every information. A number of members concluded the day's proceedings by dining together at the Ship Hotel, Greenwich, in the evening.

A NEW drawing-room car on the Vandalia line has a cabinet organ and a handsome writing-desk for the accommodation of passengers.

CHEMICAL NOTES.

The Manufacture of Hydrofluoric Acid.—Mr. A. P. S. Stuart remarks that every one who has prepared hydrofluoric acid knows that sulphuric acid and fluor spar form an exceedingly hard, rock-like compound, and that it is very difficult to remove this from a platinum retort. The inconvenience may be avoided by mixing with the fluor spar about an equal weight of gypsum and the proper quantity of sulphuric acid. After the hydrofluoric acid has been expelled by heat, the mass in the retort is found to be of a pasty nature, and is easily removed by water.

Caustic Soda. — A new method of preparing caustic soda is given by M. Tessie du Motay, in *Les Mondes*. One equivalent of sulphuret of sodium is mixed and fused with one equivalent each of caustic soda, hydrate of lime, and metallic iron (cast or malleable); when these substances are heated to redness, the sulphuret of sodium is completely converted into caustic soda, and sulphuret of iron formed. M. du Motay considers that the water of the hydrate of soda or lime is decomposed by the iron, which, becoming oxidised, hydrogen is set free, oxide of sodium formed, and then sulphuret of iron; the soda being separated from the last-named substance by lixiviation with water. In another process the sulphuret of sodium is first converted into a basic phosphate of soda, and then into caustic soda by means of caustic lime.

Scarlet Dye for Wool and Silk.—Jegel proposes the following method of dyeing wool and silk scarlet by the simultaneous action of magenta and dinitronaphthol or naphthaline yellow. The less magenta is employed the better. The method is to heat a dilute aqueous solution of naphthaline yellow to near boiling, add so much magenta as amounts to two per cent. of the naphthaline yellow, and then dye. The dye liquor must not be mixed when cold. If this is done, all the magenta is thrown down in an amorphous flocculent state. If this has taken place, the subsequent application of a boiling temperature does not remedy the mischief, since a part only of the magenta thus precipitated is redissolved, the rest melting together into a greenish golden mass. In this state, the liquid is quite unfit for dyeing, and even if filtered gives no good shades.

Pure Indigotine.—According to M. Mehu, carbolic acid, with the aid of heat, has the power of readily dissolving indigo blue. On cooling, the greater portion is deposited in a crystalline state. The cold solution has an intense purple blue colour. In order to prevent the carbolic acid from congealing as it cools, a little alcohol may be added, which causes the greater part of the colour to be deposited. Instead of alcohol, camphor may be used to the extent of one-fifteenth, or benzine. By using 500 grammes of carbolic acid, we can obtain two grammes of pure indigo blue (indigotine) in crystals which, under the microscope, appear remarkably regular. Mehu employs indigo which has been previously washed, first with water, then with very dilute hydrochloric acid, and then repeatedly extracted with boiling alcohol.

Anthracene. — This hydrocarbon, under the name of "green grease," is sometimes sold as axle grease. It is found among the last products of the distillation of coal-tar, which consist, says Professor Phin, of a heavy oil, some naphthaline, and about 20 per cent. of anthracene. In the whole, the amount of anthracene in coal-tar is only from ½ to 1 per cent. In order to separate the oily products from the solid hydrocarbons, the soft mass is introduced into a centrifugal machine; the residue left is heated to about 110° F., and subjected to the action of an hydraulic press. If the crude material is thin, it is best to employ at once a filter press. The resulting mass, which contains about 60 per cent. of anthracene, is exhausted with benzole or gasoline, again subjected to the centrifugal machine, in order to separate the last portions from the light oils. There remains a greenish-white, paraffin-like mass, of a beautiful crystalline fracture, containing 95 per cent. of anthracene, from which, by sublimation, a perfectly pure product having a melting-point of 420° F. can be obtained. The anthracene may be conveniently obtained pure, if by means of a blower a strong current of air is directed into the retort while the anthracene is at the boiling-point.

Novel Railway Signal.—It is stated that a new danger signal has just been put in operation on a Massachusetts railroad. The signal consists of a globe made of sections of red, green, and white glass, upon which figures from one to fifteen are plainly marked, each figure denoting a minute. The signal is operated by the train, and moves back to the zero point when the locomotive goes by, and begins to revolve when the last car passes. It then begins to move like a clock, and the figures, which are visible through a single opening in the outside covering of the glass, denote the time that has elapsed since the passage of the train. The figures can be readily seen in day-time, and at night the glass is illuminated by a light placed inside the globe. In this way the engineer of a rear train can ascertain the time that has elapsed since the passage of the forward train.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, *31, Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

A MICROSCOPE AS AN EYEPIECE—TELESCOPE FOR STAR-GAZING—MEMOIRS OF THE ROYAL ASTRONOMICAL SOCIETY — FINDING THE MERIDIAN—HEAT OF MARS—AXIS OF VENUS — SUN SPOTS — AND TESTS FOR A 3⅜IN. REFRACTOR.

[4491.]—THE first part of the query (12274) of "Betsy Summercity," on p. 392, involves the assumption that the image formed by a Foucault speculum will not bear "magnification." What may be the precise signification attached to this word by "Betsy" it is not very easy to see, since the definition of one of Browning's reflectors is sensibly perfect with a power of 70 to every inch of aperture, and, under favourable circumstances, with greater amplification still. As for my querist's idea of substituting a Powell and Lealand microscope, with an object-glass of high power, for the ordinary Huyghenian eyepiece, a very few instants' reflection will suffice to show why that must fail. In the first place, let the original image formed in the focus of the large speculum be ever so perfect, the rays from it must pass through some eight or nine lenses before they reach the eye at all; and here we have source number one of indistinctness. In the next place, Powell's $\frac{1}{25}$ in. has an angular aperture of 160° (not a very low angle), and, what is more to our present purpose, gives a linear magnifying power with their No. 1 eyepiece of 1250, and with their No. 5 of 7500 diameters! If "Betsy Summercity," then, will remember that the light from her typical object, the moon, degrades, *not* directly in proportion to the increase in magnifying power, but *as its square*, she will see at once why the moon's image *must* become so exceedingly faint as hopelessly to counteract any possible advantage derivable from its enlargement. "Betsy" must be quite familiar with the sensible decrease in the moon's apparent brightness under a power of 200 linear, and she may thence form some conception as to the excessive dimness of the image when amplified 7500 times linear. A very simple arithmetical calculation will show her that $\left(\frac{7500}{200}\right)^2 =$ 1406·5, so that with the higher powers the light of the moon would only have $\frac{1}{1407}$th of the brilliancy that it would possess with the lower one. After this it is almost needless to notice another source of indistinctness, the magnification of the atmosphere itself.

In answer to "B." (query 12287, p. 392), I would say that, should he have decided on the purchase of a reflector, I would by all means recommend him to obtain one of Browning's Educational ones in preference to his smaller one of the same aperture. The "Educational" possesses several advantages: among others its increased length of focus, which, of course leaves less of the magnifying to be performed by the eyepieces; and also its mode of mounting, which is, in effect, equatorial, and enables the observer to follow a star by simply turning one handle. A 4½in. reflector is, of course, theoretically superior to a 3in. achromatic, both in light grasping and (considerably) in separating power. I must, however, tell "B." (and others) that he must not expect to get the same exquisite disc on a fixed star with *any* reflector that he would obtain with a good achromatic, albeit in the former the image would be smaller. Although having reference to a different subject, I may, perhaps, as well answer the second part of "B.'s" query here, and say that the "Memoirs of the Royal Astronomical Society" are published by Messrs. Williams and Norgate, 14, Henrietta-street, Covent Garden, London; and that while, doubtless, some odd volumes are still procurable, I question extremely if he will be able to obtain either Vols. I., II., or the first part of Vol. III. separate from a set.

If "Youngster" (query 12300, p. 393) will turn to p. 648 of Vol. X. of the ENGLISH MECHANIC, he will find a description, illustrated by a diagram, of the simplest mode with which I am acquainted of obtaining the meridian of any given place.

Who, if it be not a rude question, told Mr. Johnson (reply 12164, p. 390) that the heat of Mars "to ordinary animals would be destruction"?

Let me assure Mr. Proctor (let. 4449, p. 406) that I by no means employed the word "imagined," to which he takes exception, in the sense of merely fancying or inventing. All I intended to convey was that De Vico *supposed* from his observations that the axis of Venus was inclined 53° 11′ 26″ from a perpendicular to its orbit. Mr. Proctor will scarcely contend that he *demonstrated* it to be so. Every observer who reads these lines knows perfectly what an excessively difficult object Venus is, and I should certainly regard any alleged determination of the precise inclination of her axis as one to be received with very great caution. I must plead guilty to not having consulted Webb before penning my reply on p. 380; but Mr. Proctor's letter having induced me to refer to that invaluable book "Celestial Objects for Common Telescopes," I find its author saying in a footnote on p. 50: "But De Vico's style wants explicitness, and there are strange traces of inexperience or inattention in the Jesuit College, rendering the memoirs of that date less satisfactory than those of the present Director, Secchi, a man of a very different mould."

Might I venture to refer "A." (let. 4453, p. 406) to Mr. Proctor's "Sun" (a second edition of which has just been published by Longmans and Co.) for a little necessary rudimentary information?

I have much pleasure in responding to the request of Mr. Durrad (let. 4474, p. 411) for some star tests for his 3⅜in. object-glass; and would advise him to examine π Aquilæ, λ Ophiuchi, 73 Ophiuchi, Struve 2403 Draconis, Struve 2878 Pegasi, 20 Pegasi, and 36 Andromedæ, all of which are now conveniently situated for observation. He ought also to elongate or distort ζ Boötis, and ε Equulei.

SOUND (OR UNSOUND) THEORY.

[4492.]—INVERTING, perhaps, the proper course of proceeding, and beginning my notice of letter 4416, p. 382, by reference to the postscript at the end of it, I really must beg "The Harmonious Blacksmith" to accept my most earnest assurance that I had no intention whatever, proximate or remote, of "chaffing" him, in what I wrote concerning his suggested fiddle. As he is good enough to speak in too flattering terms of my scientific acquirements, I will, if it will afford him the slightest gratification, say that I think it very possible that my acquaintance with astronomy, both observational and mathematical, as also my knowledge of geology and optics, may a little exceed his; but, having made this most handsome concession, I must ask him to be equally candid, and to admit that I am only speaking the bald literal truth when I say that, while I know a little of theoretical acoustics, I am simply not worthy to hold a candle for him to examine the internal structure of any one of those musical instruments of which he has such a profound practical knowledge.

Having thus I trust, once for all, set myself right in this matter, I will say, in reply to "The Harmonious Blacksmith's" question, that I should, decidedly object to a corrugated soundboard *at all*. A soundboard, as it seems to me, cannot be too elastic, and it is an elementary fact in applied mechanics that corrugation is employed to give increased rigidity to the material which is so treated. As Tyndall points out with reference to any imperfectly elastic wood, I should expect a corrugated soundboard to use up the greater part of the vibration communicated to it in the friction of its own molecules, and so to convert the motion, not into *sound*, but into *heat*. Theory I imagine to be wholly opposed to this form of construction.

And, while on the subject of musical instruments, I am tempted to advert to a passage in the letter (4421, p. 382) of "Suffolk Amateur." I refer to that in which he appears in doubt whether the diagram of "The Harmonious Blacksmith's" funny fiddle on p. 254 represents "a section of a box or body," or "a series of six open soundboards, connected by a jointed sound-post?" With reference to this I would remark that all my own notions of the possible effect of the combined violin and violoncello were formed on the supposition that the sketch in question really did represent "a section of a box or body." Assuming it to be intended for an elevation or perspective view of the proposed instrument, and that such instrument is only meant to consist of an open framework, such as is shown in the engraving, I must certainly modify my original expression of opinion as to its probable effect, and say that, under such conditions, I should expect a listener to repeat with reference to its tone what ladies say when they cry—"This is indeed weakness."

THE BEARING REIN.

[4493.]—I AM very glad to notice the letter (4434) of "Old Ploughman," on p. 384, with reference to that wholly needless piece of brutality, the bearing-rein. The excuse which we sometimes hear urged for it, that it makes a horse hold up his head and display himself, is a wholly fallacious one. Any man, with moderately decent hands, can do this by judicious use of the reins, without torturing the animal at all. Moreover, the bearing-rein is not only cruel, but it is dangerous, for, in the first place, a horse cannot use his eyes properly with his chin rigidly reined in; and in the next should he make a mistake going down hill, he is already as tightly borne up as he can be, in all probability comes down "all of a heap," and is not unlikely to bring his companion down with him. This last consideration may possibly operate with some who would regard the mere pain to which their animals may be subjected with tolerably equanimity.

A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

[4494.]—BEING a veterinary surgeon, I can claim some knowledge of the suffering to which that noble animal the horse is subjected by the use of the bearing rein. I have long desired to publish a touching protest on this subject, and shall be glad to receive any communication from the humane and praiseworthy "Ploughman."

Liverpool. J. T. LITTLE, M.R.C.V.S.

A GIANT PLANET.

[4495.]—THE objections raised against my views on the subject of Jupiter's condition, and against views which, though attributed to me, are not mine, seem based on a careful avoidance of all that I have written on the subject. I fear that, after all, I may have done "Hyrab Seen" injustice.

"L.'s" letter (4448, p. 405) is particularly open to this objection. (Of course I cannot object to his not reading what I have written, only such reading seems a desirable preliminary before objections are urged against what I have written).

"L." seems also to have misread the remarks of Webb and De La Rue on Jupiter's gibbosity in quadrature. Neither of these observers have recognised the phase in Arago's sense. Webb says that he has recognised and recorded "the *approach* of the gibbous form in a slight shade along the limb furthest from the sun." This darkening is perfectly obvious to observation in Jupiter's case, and with good telescopes in Saturn's. It is indicated in the frontispiece of my "Saturn and its System," the views in which (as stated in the preface) are shaded in accordance with mathematical calculations. But it is actually dwelt upon in the paper "L." is supposed to be criticising, in these words—"We would not insist too strongly on this inference" (namely, that Jupiter's inherent luminosity adds only to the brightness of the central parts of his disc), "because the darkening due to oblique incidence is, under certain circumstances, very obvious to direct observation." The parenthesis thrown in shows that "L.'s" reasoning, based on a mistake as to Webb's meaning, is applied to a mistaken view of a theory which he mistakenly supposes me to entertain. For I have distinctly said of Jupiter, in the very paper in question (as well as elsewhere), that he "does not possess any large degree of inherent lustre." (This refers, of course, not to the lustre of his real surface, but to his lustre as seen from without.)

"L.'s" remark about Mr. Browning's recognition of the orange belt is based on an insufficient examination of Mr. Browning's words. Moreover, so far as my remembrance extends, the Greenwich reports (as worded) imply *not* that the orange colour has been constantly observed, but that it has never been noticed at Greenwich. Mr. Lassell, who is an independent authority of the highest standing, has acknowledged that there has been a change.

"For my own part," adds "L." (*apropos des bottes*, apparently), "I see no reason why we should not allow that planets have atmospheres differing from our own in such a way that the heat and light rays of our sun are so mollified or intensified as to make Mercury and Venus as habitable as Uranus and Neptune for beings adapted to their respective situations." Neither do *I* see why we should not *allow* any theory whatever, provided we are too idle to examine the evidence for or against it. We might allow, for example, that the readers of the ENGLISH MECHANIC are eager to know what this or that correspondent for his own part sees no reason for not allowing; but practical experience shows that those readers care much more for reasoning than for mere statements of opinion.

Mr. J. W. Durrad (let. 4474, p. 411) will find how far my theory about Jupiter's internal heat agrees with the invisibility of the satellites in Jupiter's shadow, and how the comparative darkness of the satellites and their shadows in transit is adduced in its support, by reading what I have written on these respective points.

"E. L. G.'s" letter (4447)—full of excellent matter—would be more to the purpose if it were not based on "Hyrab Seen's" very singular presentation of my views. "E. L. G." bases a part of his reasoning on the supposition that the planet's total light is "three or four times" his possible reflection. This is not the case, or near it. Jupiter's light is three or four times that which he would give if his general reflective power were equal to that of Mars or the moon. Mars gives back something over ·2 of the light received, the moon something considerably short of this. Jupiter gives out something over ·6 of the light he receives. As stated in my article, Jupiter does not shine quite as brightly as if his whole globe were of snow or ordinary terrestrial cloud. And (also as there stated) if he were white and pretty uniform in lustre, there would be no occasion to believe in inherent luminosity at all; though there would be abundant reason for believing his real orb to be red-hot or even white-hot. My whole reasoning is based on his actual aspect—his belts, their behaviour colour and so on; on observed facts, not on assumptions of any sort. Moreover my theory does not go nearly so far as those who have hitherto dealt with my article seem to opine.

"E. L. G.'s" remark about comparative luminosity of red-hot or white-hot iron and sun-illumined white objects, seems incomplete. He says "this admits of easy proof," but he does not state the results of experiment. Now, there is an easier method of testing the matter than his. Let full sunlight be admitted through a tube into an otherwise dark chamber, and within that tube let a piece of white card be inclined at such an angle to the sun's rays that its illumination is one-twenty-seventh of what it would be if the card were square to those rays, and let that card be viewed through a tube by one eye. Let the other eye be directed through a similar tube upon a piece of red-hot iron. Under these circumstances we are comparing the illumination of a white object on Jupiter with the light of red-hot iron; and any of your readers who may try the experiment (as I have done) will hesitate greatly, I conceive, to affirm that the former is *many* times greater than the latter: But let them remember that the comparison is not with a white object so illuminated, but with an object reflecting about one-third of the light of a white object like paper or snow, and let them further remember that a large part of Jupiter's light-reflecting surface is presumably cloud covered, and reflects white light, and they will see that I have not theorised very wildly in putting forward as a probability the suggestion that the small balance unaccounted for is due to Jupiter's inherent luminosity. Then let them remember that I derive only a subsidiary argument from Jupiter's luminosity—that I adduce a complete array of other facts, not one of which has been questioned, and finally, that my theory is a very moderate one, having nothing to do with the question of Jupiter's inherent luminosity (viewed from without), with the habitability of his satellites, or like points,—being, in fact, simply this, that the movements in the Jovian atmosphere are mainly due to his own intense heat.

RICHARD A. PROCTOR.

THE ANCIENT CONSTELLATIONS.

[4496.]—I HAVE not time to discuss this subject (let. 4478, p. 411), but am glad my remark has called forth "E. L. G.'s" very interesting letter. I *do*, however, mean to say, and that with some degree of confidence, that the stars of the Argo region suggest in the most striking manner the figure of the poop of a ship—not of one of our modern ships, but rather like the stern of an ancient galley or of a large and well curved canoe. Our modern maps mar the resemblance, but taking the stars as they are, and without regarding the modern constellation boundaries, we have an unmistakeable half-ship. The principle on which the ancient constellations seem to have been formed is described in the introduction to my large star-atlas. If the description were shorter I should quote it as it stands.

The streams of stars from the water-jar of Aquarius are too obvious (as seen in suitable latitudes) to escape recognition. One such feature would suffice to suggest the whole figure, but the jar also is well marked.

I am surprised "E. L. G." does not make any reference to Aratus. There is much in Aratus which, taken in conjunction with the evident signs that he borrowed from a much earlier authority, serves to throw a most interesting light on the ancient constellations.

I have been rebuked by that unquestionable authority the *Saturday Review* for attaching any degree of weight to Bryant's "Analysis of Mythology," in the paper on Achilles' shield and its astronomical interpretation, which closes my "Light Science for Leisure Hours." I fear I am not convinced, and share a good deal of "E. L. G.'s" respect for some part at least of Bryant's labours.

Hydra coincided with the Celestial Equator in old times, and all the fish constellations except the Dolphin were originally south of the equator, only half the northernmost of the pair of Fishes being north of the equator. Corvus, the Crow, is I think, very clearly pictured in the stars forming the constellations. Our map-makers, who have turned Ara upside down (so that the Centaur is carefully applying his sacrifice to the bottom of the altar!), have also inverted Corvus.

RICHARD A. PROCTOR.

HOW THE TREBLES OF ORDINARY COTTAGE PIANOS MAY BE CHEAPLY IMPROVED, WITH SOME REMARKS ON METAL BRIDGES, STUDS, AND WREST-PLANKS.

[4497.]—I ONCE thought my three rather lengthy articles on the possible improvement of good sound old pianos, together with several others, printed from time to time, containing further suggestions, must have well nigh expressed all I could have to say on this subject, but it is the unhappy characteristic of my mind that it can't avoid the annoyance of being taught by further experience. So thoughts involuntarily crop up which occasionally appear to my, perhaps, partial judgment to be worth communicating, one of the evil effects of which is that I now proceed to bore my fellow readers again.

In most cottage and other upright pianos which have been and are now being made by good manufacturers, but little other defects exist than those which result from the employment of the inferior common action without an effective check for the hammer, and want of power and purity in their treble sounds.. How to remedy the former I have before shown at considerable length, so I now proceed to suggest cheap methods of enabling the treble to be rendered sufficiently powerful to compete with the bass and tenor, usually the best parts of ordinary pianofortes.

In most of such instruments the only method employed for determining the length of the vibrating portion of a string is to cause it to bear sideways against a wire pin driven into what is improperly termed the bridge, which is a mere fillet glued on the wrest-plank, because it is cheaper and more convenient to do this than to rebate the wrest-plank below, and incline its surface backward above where the string rests. For keeping the string from chattering on the surfaces on which it is supported, it is usually deflected in two directions—viz., downward and sideways, the said deflections being technically termed its side and down bearings.

A very little consideration will enable us to perceive the defects of this method of supporting and stopping the vibrations of strings. The pins—which are their real bridges—are, for preventing the strings from slipping off, inclined more or less (the less the better, so that they be not quite upright). It necessarily follows that the tendency of the hammer's blow must be to drive the strings into the wood and away from the pin. This, although of little or no importance when the hammer strikes the string from one and a half to two inches away from the pin, becomes a very great defect when its blow is delivered from an inch to less than a quarter of an inch from the pin, for it disturbs the string's connection with the latter to an extent sufficient considerably to deteriorate the clearness of the sounds produced. The less acute the angle formed by that portion of the string above the bridge-pin the less can the hammer's blow disturb the string's adhesion to the pin, simply because the more the string is deflected the harder it must press against and resist momentary separation from the pin. This fact was and is very well known to all practical pianoforte-makers, and as, *cæteris paribus*, the firmer the connection of the string with its pin or other support the clearer and purer will be the sounds obtained by its vibrations, we need not much wonder that—until bridges of a more scientific character than thin wire pins, against which the strings can only bear sideways, were introduced—pianoforte-makers went on unmercifully increasing the side bearings of thin strings (in other words, increasing the angle at which strings were deflected, too often without proportionally increasing the thickness of their pins) until they were estopped by the poor strings being broken at the bridge-pins.

This is no imaginary statement. Well I remember that the breaking of strings from this cause very often occurred in instruments, especially so in some cottage pianos and in the grands made by the late Mr. Zeiter from thirty-five to fifteen years ago. Probably the inferiority of the wire might have had something to do with it, for (although much better than the old German iron—certainly not steel—wire it superseded) our English steel music-wire of a quarter of a century ago was far inferior in tenacity to that now commonly produced. As it was the bending of the wire more sharply than it could bear, and not at all its subjection to excessive tension, which caused it to break, the natural and cheapest possible remedy is to substitute thicker bridge-pins—yes, even as thick as ordinary key pins, which must needs support the strings more firmly than thin pins can; and, to prevent the possibility of the strings chattering against the pin below its centre, after driving it into the wood, to file a flat surface extending up to its centre as shown in Fig. 1.

For bichord notes it would be a yet further improvement, at an inconsiderable increase of cost, to employ bridge-pins about two-tenths of an inch in diameter—more properly designated studs for single strings—whose top surfaces are filed in the manner shown by Fig. 3. Such pins or studs support the string not only sideways, but also underneath, instead of allowing it to rest on the wood of the so-called bridge. Such a pin forms a true stud or metal bridge, two things which differ only in length, for a metal bridge may be regarded as many studs united. The underneath and upper portions of the top surface of the stud or pin (Figs. 3 and 4) must, of course, be filed away before it is driven into the wrest-plank, but I prefer to file that portion on which the string rests or bears downward after driving; of course, no so-called wooden bridge can be required for either this or any other of these studs.

Considering that the sounds we obtain from the vibrations of pianoforte strings must (*cæteris paribus*) increase in clearness the more firmly they are supported on their wrest-plank bridges, it need not surprise us much that even without any consideration of the great facilities metal wrest-planks afford for bracing, they came into use at a comparatively early period, the earliest, I remember, being that patented by Schweiso, A.D. 1831, although I have a strong recollection that the invention is of yet earlier date. For horizontal grand pianos, whose strings are above their wrest-planks, metal wrest-planks are far preferable to those of wood, because not only is metal (say cast iron) much less liable than wood to be put into vibration so as to affect the timbre of the sounds, but, what is yet more important, a metal wrest-plank may be made sufficiently rigid if only one-third the thickness of a wooden one near where the hammers strike the strings. This allows the heads of the hammers to be reduced in length above their shanks to any extent which will afford space for attaching their felt coverings, and the shorter the hammer-head be made the less it can vibrate sideways on a given length of centre wire when it works or [illegible] equally free. A [illegible] and yet greater adv[illegible] from that [illegible] the wrest-plank [illegible] be[illegible] being thin—[illegible] of thick, which [illegible] the hammer [illegible] within abo[illegible] near as th[illegible] actions. [illegible] tance of perpendicularly (see No. 853, &c.) it is quite needless to repeat why it conduces to the production of sounds which are at once more powerful and of finer quality.

Metal wrest-planks, however desirable for horizontal grand pianos, are hardly worth their additional cost, which is considerable, for upright instruments whose "backs" are constructed in the ordinary way. The wrest-planks of such instruments, being behind their strings, may be made of any required thickness without being in the way of either their hammer-shanks or hammer-centres. Consequently, the latter may be as near their strings as the needful strength of the material of their butts and the avoidance of any risk of their strings touching the latter, when vibrating, allows. In the high treble, whose strings when vibrating do not, perhaps, move one-hundredth of an inch, the hammer-centres may be within two-tenths of an inch of the strings, but probably no human ears are "long" enough—however asinine their owners may be—to distinguish any difference in the timbre of the sounds produced when that distance is increased to eight-tenths of an inch.

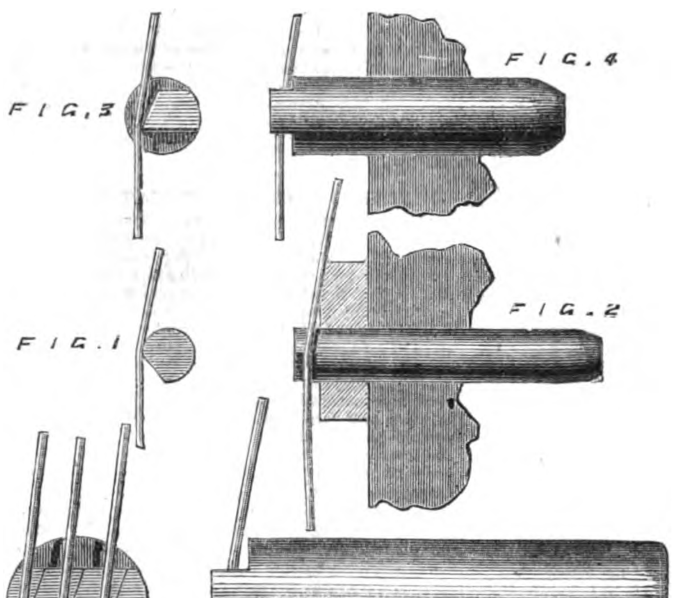
For the purpose of obtaining a sufficiently firm support for the strings of upright pianos whose actions are in front of their strings, several contrivances have been resorted to. A very common one is the imbedded wire bridge (fully described in the second part of my article on the bracing and bellying of cottage pianos, printed in No. 378, p. 358), which, by the way, is seldom so well carried out as I therein advised. Besides this wire bridge, solid continuous bridges of metal, of glass, and of stone ware or porcelain, have been employed, all of which, I believe, have been found to answer very well when properly bedded and firmly secured to the wrest-plank. However applicable these contrivances may be to new instruments in the course of construction, they are, however—unless thick pins or some analogous contrivance for guiding the strings be employed—not conveniently applicable to pianofortes originally made with common pinned wrest-plank bridges whose strings are deflected sideways. A continuous cast metal bridge might indeed be grooved or notched so as to keep the strings in their proper positions, although it would be difficult to do this to an imbedded wire. Examples of such notching may be seen in the treble brass bridges of some old square pianos, especially in those made by Messrs. W. Rolfe and Sons about twenty years ago, but after all I greatly doubt if this would afford any improvement in the trebles of upright pianos which could not be obtained by the use of such studs as those represented by Figs. 3, 4, 5, 6, and 7, none of which are very expensive to construct, and all of which are far easier for an amateur to fix than any continuous metal bridge I have seen.

I have made studs like those represented by Figs. 3 and 4 out of thick brass wire; those represented by Figs. 5 and 6 may be made of cast copper or brass rods which are kept in stock at most mechanical tool shops in the locality of Clerkenwell. I have found it cheaper, however, to use Fig. 7, which may be cast from a wooden, or, preferably, a metal pattern. Fig. 7 resembles an ordinary grand pianoforte stud, excepting that—for upright pianos—it don't need to have holes drilled in it. If made seven-sixteenths of an inch diameter, it may be grooved or notched for four strings, but as few pianofortes have more than three, even in their high trebles, it need not be more than ⅜in. full diameter. Fig. 7 need not have a screw cut on its shank because it is intended to be driven into the wrest plank; its head is, however, from ⅜in. to ½in. thick, which is greatly in excess of the thickness of the collar of a grand pianoforte stud; of course, this additional mass of metal affords a yet more firm support to the strings which bear downwards on it, and enables them to resist the blow of the hammer far better. Personally, I much prefer such studs as those represented by Figs. 5, 6, and 7, to those represented by Figs. 3 and 4, but the latter might be easier for amateurs to construct and apply, because the only thing necessary would be to extract the old bridge-pins, bore out their holes, and drive in either Figs. 2 or 4, supposing it be not intended to alter the scale, which amateurs who are not accustomed to marking off might find to be a difficulty to them. Supposing the amateur to possess sufficient ability to make a good pattern of Fig. 7, but little difficulty would be found in preparing the castings for use. If fine castings, moulded (or at least poured) with their faces downwards (which they ought to be, for obtaining a perfect and solid face for the strings to bear on), the notches which confine the strings might be cast in ready to receive them, and but very little trimming or dressing of the castings would be needful. Were such studs to come into general use —and I don't think anything much better will soon be contrived—I believe they could be manufactured and sold with profit for eighteenpence per dozen.

After what I have written on scales—*i.e.*, the lengths, &c., of pianoforte strings—in Nos. 372, 376, and other numbers of English Mechanic, I need hardly say that most existing cottage pianos would be greatly improved by the substitution of longer, if not thicker, strings in the treble. To effect this with such bridge-pins as those represented by Figs. 1 and 2, it is needful to remove the wooden bridge, and, after plugging the bridge-pin holes with hard wood, substituting a new one. This, although easily done in the workshop, would, I fear, be a difficult job for an amateur to do satisfactorily, unless he were an expert worker in wood, and well provided with tools. It is one of the advantages of using thicker pins without altering the scale that any person of ordinary ability can extract the original bridge-pins, enlarge their holes, and drive in new ones. Should, however, it be determined to lengthen the scale, without which no great improvement can be hoped for, I can't conceive any method of doing this which is more within amateur ability than taking off the old wooden bridge —or rather so much of its length as supports the strings of those notes whose length it is determined to increase—marking the places of, and boring the holes for, studs like those represented by Figs. 3 and 4—or yet better, such as those represented by Figs. 5, 6, and 7—and driving them into the wrest-plank. Being very "unpractical," I proceed to describe how I do it, and perhaps some of my practical (?) readers will be kind enough to describe better methods of effecting it if they can.

Having removed the old bridge or such portion thereof as may be needful, scraped, and fine glass-papered, the surface of the wrest-plank, I mark thereon the positions of the holes for the studs. As marking off correctly don't invariably compel correct boring, I take a bradawl about one-tenth of an inch diameter, and having previously ground its end into a conical point about ½in. long, I "prick" the plank to the depth of about ⅜in. After pricking all the holes I proceed to bore them with a small common centre-bit, which makes a hole about one-twentieth of an inch less diameter than the stud to be inserted, afterwards finishing each hole to its correct size with a spoon bit. A small brace is preferable to a large one for this kind of work. For such studs as those shown by Fig. 7, a pin bit—literally a pin drill properly formed for cutting wood—whose pin, about ⅜in. long, accurately fits the hole bored out to size by the spoon bit—is employed to enlarge its upper part to fit the thickest portion of the stud. Of course a guard collar is used to prevent the recesses which receive the heads or the enlarged portions of the studs being bored to unequal depths, and, before driving in the studs, don't forget to varnish the newly-scraped surface of the wrest-plank. It is also prudent to anoint each stud with a semi-fluid cement composed of white lead ground in oil, whiting, and a little oil gold size, which in a few days becomes much harder than the beech or other wood employed for wrest-planks, just as the steam boiler maker's "Beaumantique," which he employs to stop leaks, becomes, as he said, "stronger than any iron, sir," which, by the way, I take the liberty of doubting. Now, my "Beaumantique" saves a good deal of mere detail work, such as facing the shoulders and turning the sides of the heads of the studs to gauge in the lathe, for even if the stud's head be a trifle too small to fill the recess, my "Beaumantique" not only fills in the trifling empty spaces between the heads of the studs and the walls of the recesses, but also insures that the shoulders of the studs shall have firm solid beddings, which is of great importance if the head of the stud be made as thin as it usually is for grand pianofortes, but less so if it be from ⅜in. to ½in. thick, for then its great mass affords the strings a sufficiently solid support.

As it is desirable, if only for the look of the thing, that the holes which receive the studs shall be upright, I may as well describe a simple method by which I applied the automatic guide principle—so almost universally now carried out in mechanical operations—for insuring the verticality of those holes.



A hole about three-sixteenths of an inch in diameter was bored in a piece of hard wood about 2in. thick. A wire which fitted the hole, and had previously been carefully straightened, was introduced and tried in three directions by the square, a slip of wood being planed exactly to the thickness required to fill the space between the blade of the square and the wire at the place of greatest departure. The wire was then turned half round in the hole, and the square applied in the same three directions as before. The deviations being almost exactly alike, proved the wire to be very nearly straight, for they did not differ the twentieth part of an inch in 6in., an amount which could not cause any sensible deviation from verticality in a hole only 1in. deep. The wood was planed until its surface was at a right angle to the wire, and then gauged to uniform thickness. Of course, the hole was then perpendicular (instead of "slantendicular") to both its surfaces; and to insure that the holes in the wrest-plank should not be "slantendicular," I put the point of the same spoon-bit, with which the hole in this wooden guide-block was bored, through it, and into the "pricked" hole in the wrest-plank. The guide-block was at first clamped firmly down on the wrest-plank, and it guided the spoon-bit so perfectly that all the stud-holes bored in it were upright, but after some trials I found the use of the screw-clamp quite unnecessary; for when this guide-block was held down firmly by an assistant, and the spoon-bit rotated by a bow, instead of the small brace, it acted equally well, producing a bore which was quite an upright character, indeed, "the correct thing;" thus much time was saved.

It necessarily follows that if the supports of the strings be at a greater distance above the hammers' heads, the latter must be raised—at least in the treble—to enable them to strike the strings near enough to their bridges (studs are but short bridges) to produce clear sounds of pleasing quality. Although it is often better not to raise the hammers in the neighbourhood of middle C, and even several notes above it (provided the new longer strings be also considerably thicker than the original ones), this seems to be a *sine quâ non* in the treble. I think the cheapest way of doing it is to cut off the old hammers, bore out both them and their butts—if bored somewhat larger than before so that thicker shanks may be inserted, all the better—and to substitute new shanks of sufficient length to raise the hammer-heads high enough to cause them to strike at the (supposed) proper distance below the bridge or stud. This alteration is very easily effected in the workshop in which drilling-lathes and other proper tools abound, but is hardly a suitable job for the amateur, who seldom possesses them in abundance, and as it could be done for a merely trifling cost by any small work maker, I should not recommend amateurs to attempt it themselves.

While about it I may remark that it would seldom be required to alter the lengths of more than about three dozen hammers. As the production of sounds of greater power and finer quality depend so very greatly on the quality of hammers, which are seldom first-rate, even in what are termed good instruments; also that in most instances this job would be done to a piano which had been, more or less, used and worn; I would suggest that instead of using the old treble hammers, which ordinarily become much more worn by a few years' use than those in the tenor and bass, it would be real economy to incur the trifling additional cost of substituting new hammers of the very best quality for the old ones. I should certainly do this myself, being of opinion it is a much better "investment" (in the "line" of life assurance) to be hanged for a sheep than for a lamb. Being also one of that numerous sect who are followers of the celebrated "Josephus Grumbeltonius," in other words a—with common things in general, and especially with common pianoforte actions—very dissatisfied fellow, I "kalkalate" I should be strongly tempted to substitute one of the actions represented by Figs. 1 and 2 on page 95 of ENGLISH MECHANIC, No. 368. This, again, however desirable, would hardly be work for amateurs, but may I not be allowed to ask, why not have it done, if not by yet for us, *secundem artem*, by a professional pianoforte-maker for a reasonable monetary consideration? assuming any such professional can be found whose pecuniary charges are "reasonable," which may be doubtful. Of course, however, we must expect to pay pretty dearly for our "fads," &c., which often give much trouble to workmen.

DESCRIPTION OF THE FIGURES.

N.B.—All these figures are drawn about double the real size for facilitating the exhibiting of details, and the top surfaces are left unshaded for the same reason.

Figs. 1 and 2 represent the section of an ordinary wooden wrest-plank bridge *in situ* with a pin about 1/8in. diameter inserted, having a flat filed on its surface, so that the string cannot possible touch and jar against it below its centre. N.B.—The string is shown in Fig. 1 deflected sideways, in Fig. 2 deflected downwards, and, as it would appear, looking at it from the bass towards the treble.

Figs. 3 and 4, a thick bridge-pin, or more correctly, a thin stud about three-sixteenths of an inch in diameter, whose top is filed as shown in Fig. 3, so as to afford support for the string not only sideways, like Fig. 1 and all ordinary bridge-pins do, but also underneath, instead of employing the common wooden bridge for that purpose, which thus becomes quite unnecessary. Of course this pin is a true metal bridge or stud of small diameter, capable of supporting only one string, and a pair will be required for each bichord note, unless a stud like those represented by Figs. 5, 6, and 7—which is thick enough to support two, three, or even four strings—be preferred.

Figs. 5 and 6 represent this stud sufficiently enlarged in diameter to receive and support several strings. Three are shown, but either two or four might be used if the stud be seven-sixteenths of an inch diameter, and the strings near together. Practically, four No. 24 wires need not occupy more than 1/4in. in width, if made to diverge on the long bridge so that they cannot clash. The four unisonous strings of No. 25 wire on the fiddle G of my experimental grand piano only occupy a space 1/4in. wide.

Fig. 7 differs from Fig. 6 only in having its shank reduced in diameter for three-fifths of its length, and might be made out of Fig. 6 by turning down that portion in the lathe, but is far more cheaply formed by fine casting.

Figs. 1, 2, 3, 4, would, of course, be made of drawn brass or copper wire, and my only purpose in designing Fig. 6 was that it may assist those who cannot get fine brass castings executed. It may be made of the cast brass or copper rods, which are commonly kept in stock at some mechanical tool shops, especially those in which clock materials are sold. The top surfaces of Figs. 3, 5, and 7 should be bevelled sufficiently to prevent the strings from touching them more than about one-twentieth of an inch above their lower edges. Should it be determined to make the down bearing adjustable, which I very much prefer, the upper bevil ought to be greater to prevent the strings' contact when its downward deflection is increased. The sides of the notches are in Fig. 5 shown quite sufficiently bevilled to prevent the strings' contact above the surface it bears against sideways. For instruments whose strings have no side bearings on their upper bridges, of course, there can be no need to make notches in the studs, similar in form to the teeth of a saw. A round-bottomed groove (like the half of a drilled hole, which is about as much larger than the string as steel wire would be, which is a single size larger than that employed for the string) is, in my opinion, the very best possible bed for the string to rest on.

Were it not that I have seen amateurs, and workmen too, do very odd things, I should have refrained from cautioning the intended operator, that all these studs must be driven in with a punch—not by the hammer's own face—which should bear on the flat surfaces above and below the projecting part, which is grooved or notched to receive the strings, or those grooves or notches will certainly be disfigured.

THE HARMONIOUS BLACKSMITH.

STEAM-GUNS AND ANTI-NAUSEATING BOATS.

[4498.]—RATHER more than a year ago, Mr. Henry Bessemer announced that he had constructed an efficient steam-gun, which imparted the required velocity to the projectile although its barrel was not inconveniently long and the pressure of its steam not inconveniently great. Mr. B. also was said to have a vessel building in which the passengers were to be hung on gimbals, and so perfectly insulated from the pitching and rolling of the ship that sea sickness would become quite a thing of the barbarous and ignorant past, probably also a basin of mercury in the cabin might then be employed as an artificial horizon. Can any fellow-reader inform the ignorant blacksmith if these good things are yet realised, and suffering humanity not only saved from sea sickness, but also from the expense of gunpowder when engaged in works of necessity and benevolence to pigeons, partridges, pheasants, and peasants, the latter of whom at least are our fellow-creatures, even if military?

THE HARMONIOUS BLACKSMITH.

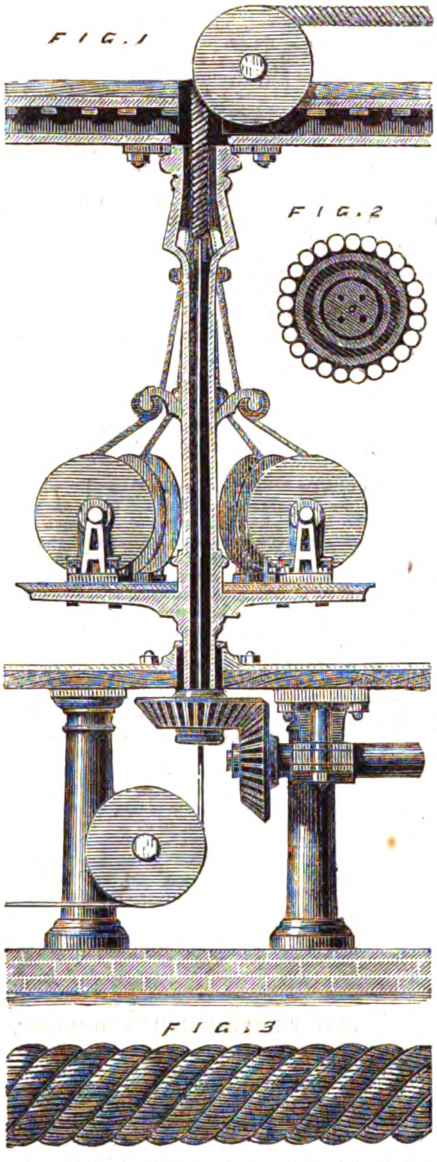
PLATO.

[4499.]—IN letter 4431 (p. 384, No. 379), "T. H. F." asks if I can inform him "whether there is a heap of débris near the centre of the floor of the crater." May I ask, in return, if he has met with a statement, printed or written, to the effect that there is such a heap? I do so because his query seems to indicate that he has been looking for it in consequence of having heard or read about it. So far as my observations extend I have never seen anything of the kind. I would also ask if he *really* saw, with 2in. aperture, the two white spots in the *hollows* of the shadow shown in his sketch, which, I think, will satisfy "E. B. F." as it does me.

W. R. BIRT.

WIRE-COVERING MACHINES.—III.

[4500.]—IN concluding this my last letter on the manufacture of oceanic telegraph cables, I think, as I have described every principal feature, nothing further is necessary. Such machines, I believe, have never been illustrated before. The diagram No. 1 shows the manufacture of the cable. I have shown only half



section. It will be seen the covered electric wire has an external covering of wire, and is covered so as to exclude all contact with water. The creels of outside wire are arranged on a revolving circular table, the covered guttapercha wire passing through the centre of machine; from below small, bands with steel springs inclosed prevent creel paying out too fast. No. 2, end section of cable; No. 3, side view of cable.

JOSEPH WILLIAM FENNELL.

A CHEAP SUPER FOR COTTAGE HIVES.

[4501.]—VISITING the apiary of a market gardener who farms a few hives, I was struck with the ingenuity he had shown in improvising a very useful and cheap super which he had in use, and as the idea may be welcome to many who cannot afford the glass ones on account of their cost, I hope you will give them the benefit of my observation. A moderately large flower-pot must have its bottom carefully chipped out, and a sheet of glass to which can be fixed a guide comb to entice the bees to ascend fastened thereon with putty and inserted over the hole in top of straw hive, and you will have a super that the bees will readily utilise for the storing of honey, and which is as open to observation as can be necessary.

R. SYMINGTON.

THE MYBORG BEE CABINET.

[4502.]—I AM very sorry that owing to absence at the seaside I did not see Mr. E. T. Grays' letter (4371, p. 354) soon enough to be able to reply to it earlier. I saw the description and engraving of the so-called "Improved Beehive," otherwise the "Myborg Bee Cabinet" (let. 4187, p. 251), and like Mr. Grays have waited to hear what anybody might have to say about it, and the result is a request for my opinion of it. Without prejudice, as the lawyers say, I am of opinion that there is not one feature in the so-called improved beehive which is any improvement at all, and I do not see anything in it worth imitating.

In the first place the comb frames run parallel with the front of the hive, which is against the natural habit of bees, or, perhaps, I ought to have said their instinct, and instinct seldom fails, and reason seems to argue that combs which are at right angles with the entrance to the hive must be easier of access than those which by running directly across the entrance obstruct both light and ventilation. Side-opening hives are now of the past in America, where bee culture is foremost and Myborg Bee Cabinets happily unknown. A new cabinet without any bees in it, like a new theory, will work like a charm, and the frames can be handled and slid about with perfect ease, and as long as there are no combs in the hive, which it must be borne in mind run parallel with the glass windows at back, the whole of the interior of the hive may be seen, and it would really appear as if bees ought to be quite at home there, but when the thing is filled with combs the matter is very different. By the bye, the expositioner of this wonderful hive does not say how he makes the bees build perfectly straight in the frames, nor how he gets the frames out if the bees propolise or build crosswise, and sometimes bees feel crosswise and build just like that. That's a bright notion putting a swarm into a partition containing three frames at top and three at bottom, and expecting the bees to carry their ideas of co-operation and subdivision of labour to such an extent as to form separate gangs, so that, as Paddy says, "they can hold fast below while them atop gets a fresh holt." Why should the dead air-spaces be crammed with hay? Chaff would be better, but dead air is the best non-conductor of all if it is dry, and the Myborg Bee Cabinet is rather dry!

The extraordinary "advantages of this hive" are "always being able to see all going on inside" (got transparent combs as well as windows, I suppose); "able to take any frame out in a few minutes;" exactly, No. 1—*i.e.*, that next front can be taken out after taking out all the others "in a few minutes," if the bees were not crosswise when they builded! "The bees also are not annoyed by the roof of their dwelling being taken off every time one wishes to examine or see to their welfare." Well, perhaps not; perhaps they rather prefer that burglary should be committed by the back way—*i.e.*, by pulling down the back wall of the house, and turning out all the inmates with their furniture and effects, to enable their self-styled master to get at their front door.

Mr. Grays wants to know how a swarm is to be introduced when the cabinet is completed? I do not know, but I once heard of a cabinet-maker who made a mouse-trap and could not set it. The next question implies that it would be better to insure "dead air space" all round the hive as well as at back and bottom, and this I cordially agree to without hay or chaff. Question No. 3 refers to a former letter of mine, in which also is quoted an opinion of Mr. Langstroth, as to tall hives being very good things when laid down. In that letter I asserted that the Woodbury hive is too small, and I adhere to the statement, although to novices in bee matters (I do not mean such "novices" as Mr. Grays) I generally recommend it as good for experimentalising, but for an expert it is hopelessly and ridiculously small, and totally unfit for bee culture for reasons given in the said letter, page 533, Vol. XIV., No. 350. If the compartment formed by Nos. 2 and 3 of the cabinet was simply laid on its back, it would be what Mr. Langstroth calls "a tall hive laid down," and it is curious to observe how nearly that approaches the hive which I have used for years, and have always found the best for all practical purposes (see letter). The Myborg would be, if laid down, about 18½in. from front to rear, and 12in. high, containing six frames, whereas the hive I have used and found so good is 17in. from front to rear, 11in. high, and contains eight frames; but that which I now recommend is described in p. 533 as aforesaid, subject to slight deviations.

I may say in passing that I shall shortly submit a photograph of this hive in several "forms" to our Editor, with such a description as a wayfarer need not err in, so that those who run may read, and those who read may make their own hives.

Question No. 4, which Mr. Grays thinks of most importance, refers to waste of heat in the tall hive, and he asks "Can this in any way be obviated?" Yes! lay the tall hive down.

"Novice," one of the most acute American bee keepers, writing in the American *Bee Journal*, says, in the June number of that invaluable periodical: "Well, Mr. Editor, we did examine carefully the thirty tall hives, and then an equal number of the flat ones, and the result was only *much more marked* [the italics are not mine] than we had supposed, from observations for the past three or four years. There seems to be a dislike to enlarging the brood circle *downward*, which they must do, as the brood is invariably in spring near the top bars. In the Langstroth (*i.e.*, the flat hive), the broad circle enlarges horizontally, and the result was to instantly transfer all the combs to the standard Langstroth frames. We have now got it all done neatly, and draw a long breath of relief when we realise that we shall no more be bothered with close-fitting tops and side openers." That, Mr. Editor, is the opinion of one of the foremost practical bee masters in America, although, like Mr. Grays, he calls himself a "Novice," and there are few people who can speak from larger experience. C. N. ABBOTT.

NEWSPAPER SCIENCE.

[4503.]—IN spite of the rubs which certain of our popular newspapers continually receive, they will persist in airing their science. Not long ago the "daily," whose "largest circulation in the world" is a very unfavourable testimonial to the intellectual calibre of its readers, displayed its ignorance by asking, in a manner which would be offensive if it were not idiotic, "What is a Joule?—or who is he, if a Joule is a human being, and not a vegetable—a weapon of offence, or something to drink, or a Phantom?" From a paper in the *Nautical Magazine* "we gather that the transformations of energy are in their nature similar to the operations of commerce; but with this difference, that in thermodynamics the relative values never vary. This, it seems, is the universal theorem of a Joule; and a red-hot poker must always bear the same relation to sixpence as the contents of a tea-kettle at boiling point bear to a five-pound note. . . Under the new dispensation the sovereign, 'to which all other forms of energy can be referred,' is to be an (*sic*) unit of heat. On the obverse is stamped 'Joule's equivalent,' and on the other side is inscribed 772 foot-pounds. One unit of heat is the amount required to raise the temperature of one pound of water one degree, and the equivalent for this coin is 772 foot-pounds of work—that is, the work required to be expended to raise one pound weight 772 feet. . . But what is the new 'Joule's equivalent' to be made of?—cobwebs, leather, or fresh butter?—and who wants to raise a pound weight 772ft.? As a problem of proportion, the theory is, of course, philosophical enough; but it would be just as easy to fix a unit of cold as well as a unit of heat; and, under any circumstances, until Joule comes into the open and tells us who he is, what he means, and when his equivalents are to be put into circulation, society, we fear, will decline to recognise a sovereign as a Joule, or thirty shillings as a Joule and a half."

Is it possible that 200,000 Englishmen daily digest such utter inanity as this? More recently, however, the same paper delivered a homily on the danger of eating wild plants, and as usual fell into errors which would be ludicrous if they were not dangerous. The occasion of this "lecture on Fleet-street Botany" was the death of two lads near Chester, poisoned through eating some deadly plant. The *Gardeners' Chronicle* has applied the stick very judiciously, though scarcely with sufficient severity, and I quote a portion of its remarks:—"Our contemporary speaks of the poison as having been afforded by the roots of the 'common hemlock, *Conium maculatum*.' 'Those who have seen a celery bed in full seed,' says the *Daily Telegraph*, 'will know how difficult it is for any but a practised botanist to distinguish the deadly *Conium maculatum* from its harmless [?] sister Umbellifer, *Apium graveolens*.' There is a little mistake here, as the writer would find if he indulged too freely in the 'sister Umbellifer' in its wild state. A parallel is then drawn between the case of these poor boys and that of Socrates, the symptoms are agonisingly detailed, and their severity explained by the fact, that 'hemlock, with scarce an exception, is the most deadly plant in our English Flora [?]—an opinion backed up by a quotation from Gerarde's "Herbal."' Our contemporary probably means water hemlock, though he distinctly says *Conium maculatum*, which is poisonous no doubt, but not nearly so much so as the *Cicuta* or the *Œnanthe*. To give further point to his remarks the leader-writer in the *Telegraph* goes on to tell us of ladies mistaking wild garlic for lily of the valley! and has a hit at 'crass gardeners' for mistaking the root of 'deadly monkshood' (aconite) for horse-radish, a mistake that has unfortunately too often been made, but not, we venture to assert, by any 'gardener,' for, contrary to our contemporary's assertion that it would puzzle Gerarde himself to distinguish the two roots (! !) we venture to think that to any one at all accustomed to look at plants no two things can well be more dissimilar than the root of aconite and the root stock of horse-radish. Certainly no gardener properly so-called would ever make so terrible a blunder. In the same strain our contemporary descants on other poisonous British plants, including the wood hellebore, 'spring's white rose' (! !) 'the sweet viscid pericarps of the yew, and the black deadly white cherries of the *Atropos belladonna*' (! !), &c."

The *Telegraph* goes on to assert that "all Umbellifers are deadly," which they probably are in one sense—viz., that a man may eat parsnips and carrots with impunity for fourscore years, yet they will eventually kill him—and it winds up with the very proper inquiry, "How long will it be before we recognise that a little knowledge of Nature and her ways is worth all the idle lore with which pedants, learned and unlearned, have encumbered the history of the Heptarchy and of the early Roman Kings?" There are signs on the horizon that it will not be long before a little "everyday science" is taught with the rudiments, but in the mean time would it not be as well if those who assume to teach the masses were themselves to obtain a little "knowledge of nature." The *Echo*, too, has recently been guilty of similar conduct, seizing on fragments of scientific intelligence, and with a ludicrous misapprehension of their meaning, endeavouring to turn them to use in paragraphs intended to be funny, but which must be utterly lost on its readers, for those of them who know nothing of the subject cannot understand the laboured joke, and those who do, can only pity the ignorance of the scribbler, and regret the waste of "energy" expended in accomplishing—nothing. SAUL RYMEA.

THE INDIAN PELLET-BOW, CROSS-BOWS—THE MODERN CATAPULT AND AIR-GUNS.

[4504.]—I AM not quite clear regarding "Suffolk Amateur's" design for an improved pellet-bow. Query, is the tube to be moved by the string? If so, its weight must considerably detract from the velocity which would otherwise be communicated to the pellet, and if not, how can the pellet be impelled unless the tube be slotted throughout such portion of its length as the string moves along, as in some toy cross-bows.

If any kind of bow be preferable to elastic india-rubber cords or compressed air, which seems to me very doubtful, would not a cross-bow be best? Truly, you have more "stock" to carry, but it gives "more power to your elbow," at least, it enables its force to be accumulated for use. We can employ a far more powerful bow, and bend it by a lever or suitable arrangement of levers, although requiring several hundred pounds to do so. Now, "drawing the long bow" is something beyond the powers of a truthful man if more than 80lb. be needed. A cross-bow may have two strings and a cup or pouch between them for the pellet or bullet; a tube might also be used if desired, which being no heavier than that for the long bow, would not require so large a proportion of the total force to move it. Cross-bows also throw bolts or short arrows, which may be feathered, but after all I can't help thinking the arrangement of elastic indiarubber cords, known as the modern catapult, is preferable, it being much lighter than a cross-bow with a heavy steel spring, *à la* arbalast, but I like a good air-gun yet better; however, the latter is not so convenient to accumulate the force in, as the stretching of a number of elastic cords singly in succession.

THE HARMONIOUS BLACKSMITH.

CUCUMBER CULTURE.

[4505.]—YOUR horticultural readers who like cucumbers may possibly obtain a wrinkle or two from the following experience of a correspondent of the *Horticulturist*:—

I had a narrow border, not more than 2½ft. wide, on the edge of a high fence. I planted three cucumber hills in the border, and laid some brush (such as is used for peas) between them and the fence. As soon as they crept up to the brush, I pinched off the ends, which thickened rapidly around the roots, and in every direction, throwing out the most vigorous foliage and profusion of flowers. I did not allow the cucumbers to grow, but watched them, and such as I wished to reserve for the table I picked as soon as they became of proper size; and all the rest were gathered every day for pickles, every day pinching off the bud at the end of each shoot. In this way the hill continued fresh and productive until they were touched by frost. Some judgment can be formed of the value of this practice when I add that more than a barrel of pickles were made from three hills, besides allowing a supply for the table. Whenever a leaf began to look rusty or yellowish, it was removed, and the cucumbers and leaves were cut off with large scissors, so as not to disturb or wound the plant. There is an advantage in having them run upon brush instead of trailing over the ground, because they are much injured by being trodden on. By being kept low on the bushes they can be easily and thoroughly examined over every day, which is essential, because if cucumbers are overlooked, and grow very large, it stops the yield of that plant.

E. Y.

SETTING OUT BUTTERFLIES AND MOTHS.

[4506.]—I HAVE read with much interest the papers on entomology in recent numbers, and derived some useful hints therefrom. But I tried the system of setting butterflies recommended on p. 266 some years ago, and found it very troublesome and unsatisfactory. Allow me to describe another method. My setting-boards are flat, made of very soft wood, a groove in the centre with a layer of cork in the bottom. Pin the insect to the cork so that the wings are on a level with the edges of the groove; arrange them with setting-needle, and place a small piece of glass on each wing. Hold the edge of the wing with the setting-needle, and put the glass edgeways near the root of the same; then let it fall gently, taking the needle away at the same time. With a little practice this can be easily done, not half the time or patience being required as for cardboard setting. Another advantage is that the insect is thus set in a natural position, and a good view of the underside is obtained by reversing the butterfly when it is pinned down. No collection is complete unless the upper and underside of the male and female of each specimen is shown. AJANEA.

ALCOR.

[4507.]—I HAVE little doubt that this is brighter than it was twelve years ago. To-night (July 5), at 10h., I stood 7ft. from a street lamp-post, so that the top of the lamp was projected 5° below Alcor, with the broad side of the flame shining full in the eyes, and the star was seen without difficulty. This is not a proof of its greater brightness, but points rather strongly to that view. T. H. BUFFHAM.

STEAM CARRIAGES ON COMMON ROADS AND ON TRAMWAYS.—THEIR RELATIVE ECONOMY.

[4508.]—THE advantages of the substitution of iron wheel-tracks for ordinary stone roads, and of some cheaper force (say steam) for the haulage of carriages by horses, are subjects which have exercised my mind for some years. I have tried to think out these subjects, and subjoin my ideas, but fear some of my conclusions are hardly so favourable, so far as its exclusive application to tramway-cars, as might be wished by their proprietors. It is, however, even if unpleasant, wiser to look at and investigate the unfavourable than to ignore it.

The only advantages, so far as I know, of iron, or rather steel, wheel-tracks for tramway-cars, are their enormous durability, and the saving of rather more than half that resistance by which the motion of a carriage is resisted on a macadamised road kept in good repair. It is nothing but this diminution of resistance which enables one large carriage, drawn by only two horses, to carry double the number of passengers an ordinary omnibus does. This is a clear saving of half the cost of horse-power; it also effects a saving of half the cost of wages, only one pair of men being required, however large the carriage, instead of the two pairs of helps needed for two smaller carriages. There is also, as I believe, a considerable saving in the cost of maintaining tramway carriages in repair compared with that of maintaining ordinary public carriages; the former are also, I presume, longer lived. I think I have stated all that can truly be said in their favour.

There can be no doubt that, so long as horses are employed, the cost of working the traffic on tramways must be very much less than it can be on any roads we can expect to have constructed of broken stones, *à la* Macadam; but it must be admitted the cost of "preparing the way" is, in the case of a tramway, "pretty considerable." I fear we may expect to find the cost of its maintenance will be "pretty considerable" also, at least near London, for I have observed nearly all the ordinary vehicular traffic—which, in some localities, is also "pretty considerable"—is conducted over the tramway pitching by persons who contribute nothing to the cost of "maintenance of way."

I cannot perceive the relative advantages of tramways over good common roads will be anything like so great as they now are, when some cheap motive power becomes substituted for horses. Steam, perhaps, costs only one-sixth as much as they do, consequently the saving will be tenpence out of every shilling of the present cost of traction on the tramway; but then the latter will then have no advantage over the common road, excepting that the same amount of haulage can be done on it for twopence, which will cost fourpence on the latter. A suitably-designed carriage, with wheels from 5ft. to 6ft. diameter, by 4in. to 6in. wide would run almost as smoothly on the common road as on the tramway, were it provided with thick indiarubber packing between its wheel-tires and wheels; it would be at least as easy, I believe far easier, to ride in than any tramway-car in existence; perhaps, also, quite as durable, for the destructive blows to which ordinary wheels are now subjected would be absorbed in the then extremely elastic hoop-tires of its wheels.

It seems to me the only practical question is, "Can such a carriage be worked cheaply enough to compete with the tramway-car?" No doubt the latter has the great advantage of being propelled for about half the cost of the former; but, to enable us to effect this saving, we are compelled to incur great expense. We have not only to make the road, at a cost of several thousands of pounds per mile, but also to keep it in repair for our own use (for which, when once well made, the road would probably endure for very many years), also for the use of all those—their name is legion—who condescend to travel on it. *Per contra*, our improved common road enlarged omnibus is not heavily weighted by these expenses, although it would carry just as many passengers as the tramway-car now does, and will cost no more for wages—one pair of honest (?) men being enough for each carriage. A further saving might be effected by constructing and working carriages to carry more passengers; but this could hardly be done in the case of tramway-cars, which must have a short wheel-base, because their tracks are necessarily laid in our existing roads, and therefore only admit of curves of extremely short radii for changing their direction—by the way, the adoption of the bogie principle might greatly diminish this evil. Longer carriages would not be so objectionable on common roads, because, not being confined to one track, they could be turned in much less space—yea, even turned half round—without a turn-table, which, by the way, a carriage on a tramway could not be. The engine might, indeed, be reversed.

The owners of a carriage which runs on a common road have the great pecuniary advantage of not having to pay for making the road. Doubtless they do help to pay, because, in common with their neighbours, they contribute to highway rates; but ordinary carriage proprietors, or rather the proprietors of ordinary carriages—whether they be of that celebrated class which indisputably demonstrates its respectability by keeping a gig, or of that, I fear, somewhat less respectable class who own "omnibii"—pay nothing additional for the use of the road since we ceased to conserve turnpikes. Under our enlightened commercial system, which delegates the making of our highways—railways and tramways are nothing else—to private enterprise, the proprietors defray the cost of constructing them, and can only obtain their profits by charging higher fares than would be required, did society make and mend its own ways. THE HARMONIOUS BLACKSMITH.

SPINNING-TOPS AND GYROSCOPES.

[4509.]—"A., Liverpool" (let. 4487, p. 412) apparently wants me to explain, and wants "E. H." to demonstrate, the second law of motion (by some reckoned the third). This is a little unreasonable. In his present stage "A." must be content to take a few things for granted, and amongst these are the laws of motion, which are by no means axiomatic, as some mistakenly imagine.

I would invite him to inquire *how much* the direction of motion of a swiftly travelling ball brought to the ground by gravity is actually changed. He will find that said direction of motion is, more or less, changed during the fall, according as the velocity is less or greater.

His asking "E. H." to drop assertions and catch cannon balls is amusing, but it is not reasoning. "E. H." is quite right on this point; or else the whole modern science of dynamics is wrong, and astronomy, too, must go by the board. But the celestial bodies persist in demonstrating by their movements what "A." so persistently questions. The moon moves (*in vacuo*) much more swiftly than the swiftest cannon ball, and terrestrial gravity is reduced greatly at her distance; yet she yields to the earth's attraction as obediently as a pebble dropped from a child's hand. She not only falls continually towards the earth from the line she is momentarily following; but her direction of motion is continually being changed, so that in about a week it is changed through a right angle. I have, as "A." opines, "experienced the resistance" (not at all "extraordinary," however) "which a swiftly rotating-wheel offers when," &c., &c. But this resistance is not wholly insuperable. For instance, if it were, our steamships —as well paddle-wheel as screw—would not answer the helm.

RICHARD A. PROCTOR.

[4510.]—IF I fully concur with "E. H." in rejecting what "Philo" calls the ordinary explanation of the spinning-top, it is not that I have any pleasure in pulling down established ideas. I desire to serve only the cause of truth and utility. The false nature of the common theory long since forced itself on my observation. I have also a solution to offer at the end of this letter, which I should like to submit to the criticism of Mr. Proctor, "Philo," and other able correspondents who have kindly noticed my previous remarks on this subject. It may possibly prove the true solution of this question.

Will Mr. Proctor allow me to suggest that the "almost insuperable difficulty" experienced in clearly expounding the ordinary theory lies in the impossibility of avoiding contact with the laws of mechanics and plain facts with which it cannot harmonise. These form so many rocks and shoals which the most skilful pilotage cannot avoid. If the popular theory comes off from the encounter with a semblance of soundness, it is only by the most dexterous craft that that appearance can be maintained.

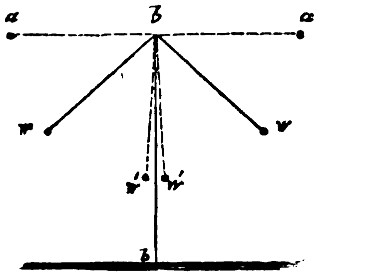
"In the case of a top flung through the air," he says, "the top's weight has time to act, and does eventually so act as to change the direction of flight." The reader naturally implies, then, that it is only *eventually* that it does so. He therefore carries away the idea that there is a *measure* of space passed over by the projectile in its flight, in which its direction is *not* altered by gravitation. Carrying this idea to the spinning-top, he may well imagine that in so small a space as that passed over by any particle in a top's body in "whisking round," as "A." expresses it, "to the other side," that particle will have no time to gravitate downwards. In imagination he may even extend this space to the whole distance travelled over by the particle from the commencement of the top's spinning to the end. Here, however, the fact that a top has spun in vacuo one hour and forty minutes affords a measure of space over which its weight cannot change its direction surpassing the utmost latitude of imagination to settle down upon.

This, however, in the above sentence, the reader is left to imply. I can hardly credit my senses when I read the next quotation, in which the writer broadly states that "the weight of the top is insufficient to change the direction in a brief interval." Here, surely, the vessel runs headlong upon a rock. Calculations in gunnery are, I believe, grounded on this among other fixed principles, that gravitation, always active, must act simultaneously with projectile force. The motion "sufficiently" rapid! Mathematicians will surely correct the sentence, and write *infinitely*; neither will the practical man be satisfied with the information that if the rifle bullet does not sink two inches or two-eighths of an inch in a hundred yards, it does not sink at all. Is the parallelogram of forces to be set at nought in this solitary case, which demands that when two forces act from different directions upon any body the consequent direction of the motion of that body must be a resultant or accommodation of those original directions? The archer and slinger know well that their shot will drop short of the mark at any distance if they are not made, by elevation, to drop into it. Again, what is the speed necessary in order to maintain the spinning motion? A very low degree suffices. In some cases the rotating force is so nearly expended before the vertical position is lost that the top scarcely retains force enough to roll more than a few inches.

Mechanical principles require, and common-sense requires, that the particle shall be lower when it has passed from the one side of the axis to the other, if there is *nothing to save it from so falling but want of time*. Its course, then, based on the principles of velocity and space, is not a horizontal, but an inclined plane, and if the projectile speed of the particle render that plane of descent very circuitous and long, the very speed which so prolongs it secures proportionate rapidity in the descent of the particle to the ground. "E. H." has hit the most glaring blot in the balance theory. The idea of supporting the centre of gravity by making it spin round the point of support is shown to have no necessary connection with the self-support of the spinning-top; for experience proves that the top will not fall, though the circle in which the centre of gravity circulates—nay, even the circle which an outside particle of the top describes—be wholly outside the point of support, or the vertical line which represents it.

Mr. Proctor appears to prove his case when, assuming a somewhat leaning position of the axis, the descent of a particle as it approaches the lower side is compensated, he infers, by its ascent to the upper. But the whole case is not here stated. Does he identify the force of gravitation with the projectile force communicated to the particle or not? If he does not, then gravitation will accelerate the downward motion and retard the return of the particle upward. In other words, it will pull it downwards at every point of its circuit. If he does, then this summary disposal of gravitation involves a result contradicted by facts, for then would a top spin with its axis in a horizontal position, without any need of a point to stand on, or a plane to support it; for it must not be allowed to escape observation that the value of his reasoning depends entirely upon the idea that the action of gravitation is wholly absorbed by and identified with the rotary force communicated to the particle. If it is not, nothing is proved. If it is, an impossibility is proved.

The suggestion I have now to offer is this: W W, being two particles in a top adjoining the revolving axis (t t), are acted on by gravitation. I assume them to be detached from their rigid connection with the body of the top, and capable of moving in obedience to a second force acting upon them from the point t—viz., centrifugal force. Let them be attached to this point by connecting links capable of motion in the plane of the axis. Without entering into the mechanical analysis of the resolution and composition of the forces named, the steam-engine governor practically proves that the weights W W will rise to an intermediate position (t W') between the limits shown by the dotted vertical and horizontal lines. These particles or weights will rise to a higher, or sink to a lower, level according as the centrifugal force is greater or less. It cannot reach the horizontal line (a, a) unless the centrifugal force be infinite, or gravitation (in other words) *nothing* in comparison with it.



Centrifugal force then, I infer, has not the power of retaining a particle in a horizontal plane against the action of gravitation. It has, however, the power of raising it from any lower to any higher position approximately near to the horizontal plane, though with more and more cost of power as higher levels are reached.

The same reasoning which applies to any pair of particles applies to the whole series of which the body of the top is composed. Now, as these particles are all rigidly connected, and cannot rearrange themselves at higher levels in the body of the top, and yet the lifting necessarily accompanies the exercise of the centrifugal force, the effect will be, I conclude, to lift the body of the top itself; just as when I pull at a small twig, the effort which detaches it, if detachable, will otherwise draw the plant itself towards me.

This centrifugal force acting with the greatest effect on those particles situated at the greatest distance from the axis, the point and lower part of the top will be the least affected by it. Hence, while the more bulky part of the body is most subject to the lifting power, the point is most affected by gravitation. It therefore rests on the table or other supporting surface, and as the body is lifted higher and higher is, so to speak, dragged under until the axis is vertical, aided probably as M. Paris suggests, by the shape of the point as by an inclined plane.

The non-propensity of a top when spinning, even in a very inclined position, to slip and fall even upon the most glassy surfaces, becomes a strong confirmation that the support of the point by the table is not the primary support of the top's weight. A man shod with nailed shoes standing on such a surface dare not lean to the slightest degree from the vertical position.

I should assume from the facts and phenomena observable from the action of the governor, that the impossibility of raising the balls to a higher level than the horizontal plane (a a), or even up to that level, amounts to a demonstration that a top constructed on the same principles cannot by any amount of centrifugal force be lifted off the table, and that the pressure of its point on the table must always be positive.

The test of this theory is manifest, but I have not at hand the means of applying it. The top should weigh less when spinning than when at rest, and less when spinning rapidly than when spinning slowly. Is it a known fact that the lower end of the vertical shaft of the governor presses less upon its bearing when in action than when at rest? J. M. TAYLOR.

Seer Green Vicarage, near Beaconsfield.

[4511.]—MR. PROCTOR (let. 4411, p. 381) says, but does not show, that I misapprehend the subject. The question is most certainly not at what rate? Mr. Proctor simply confuses the question by saying I confounded "A.'s" incorrect reasoning on one subject with his totally distinct line of reasoning on another. Mr. Proctor must have read my letter very carelessly not to have observed that I was obviously referring to "A.'s" ideas about the top (ideas extremely like Mr. Proctor's, whatever he may say), and not to those about the bullet. Mr. Proctor wants reasoning rather than assertions. I gave him quite enough reasoning on his attempted popular explanation of "one case, and one feature of that case." As to assertions, I admit I have made in your columns a great many on this subject, but the one quoted by Mr. Proctor is simply the statement of a positive fact verifiable by the experiment of simply spinning a top.

It is quite possible to correctly and intelligibly explain the many curious actions obtainable with a gyroscope without abstruse mathematics, but it certainly cannot be done in few words. It would also require several explanatory diagrams. Whenever the time arrives that the editor thinks the subject is of sufficient interest to justify it, I shall be willing to prepare a series of articles explanatory of the subject.

Mr. Proctor has not given me the information I desired about nutation; but I gather that nothing new has been recently brought forward on the subject, and I can, therefore, refer to the old authorities. With reference to the quotation from Herschel, I would remark that it does not necessarily follow that an explanation is correct because certain calculations associated therewith happen to agree with certain observed data.

Glasgow, June 29. E. H.

A BRIEF CONTRIBUTION TO THE EARLY HISTORY OF THE PIANOFORTE.

[4512.]—AT what date the pianoforte's predecessor, the dulcimer, first had a set of manuals added to it, and was thereby converted into a keyed dulcimer or "forte piano," with finger keys, we have no record. Probably, the earliest mechanism employed was a sort of upright drumstick stuck in the key, not unlike the mop or old man's head, afterwards used to lift a hinged hammer, which before its application for that purpose was employed to strike the string directly just as the tangent of the clavichord does. Indeed, a clavichord (which instrument we have the strongest reason to believe is far more ancient than the piano, at least in Germany and other parts of Western Europe) would become such a pianoforte as I have supposed, if its strings were tuned by plucking them when their total lengths were in vibration, and by covering the tops of its tangents with some soft material to prevent the harsh clang which would be elicited by striking its strings with an unclothed metallic surface, like the clapper of a bell. Of course, the touch of such an instrument must have been very unsatisfactory; it would resemble what we experience when we play on a piano whose hoppers do not escape, but block its hammers dead against its strings. Instead of holding its keys down firmly, which must be done when playing on the clavichord in its normal condition, we should be compelled to do what I was once much amused by seeing a clever salesman in a pianoforte warehouse do in the case, or rather instance, of a new unregulated piano whose hammers all blocked—viz., allow the key to rise a trifle instantly after striking the strings. If this necessity existed, we need not be very much surprised to find that it was said of the piano that it required a "peculiar touch." I think, also, the "Peculiar People" must have been required to play on it.

I have some reason to suspect the earliest improvement on this mere drumstick standing up from, but *fixed*, in the key was a modification of the harpsichord jack, or more properly an upright striker (resting on, but not affixed to, the key), which being suitably guided in sockets was lifted, or rather jerked up, by the key, the latter being prevented from descending in front and ascending at back far enough to raise this striker higher than within about ⅛in. of the string. As, under these circumstances, the striker must rebound from the string, it could not remain in contact therewith, i.e., blocked, and, therefore, could not prevent its vibrations. By employing very long keys, and placing these loaded strikers about five or six times as distant from the key balance as the latter is from the front end of the key, a tolerably powerful action, which strikes a blow of sufficient force to vibrate ordinary springs, may be constructed; but it must, even for the bass, be inferior to one having hinged hammers.

The earliest pianoforte of which any authentic record exists is that of Christofali, of Padua, A.D. 1711. In his action nearly all the best arrangements now known exist. The hammer moves on a centre wire, it is lifted by a true hopper, *i.e.*, one that escapes from under the notch or shoulder in the hammer butt, an[d] it is provided with a hammer-rest, which acts [as a] check, inasmuch that it prevents the hammer [re]bounding. The hopper is supported on a le[ver] mediate between the hammer and the key, allowing the latter to be taken out without disturbing the remainder of the action. This lever also carries the (underneath) damper, and (by the descent of its hinder arm) removes it from the strings when its front end is raised by the key to cause the hammer to strike. My practical readers will see Christofali's mechanism was considerably in advance of most of those commonly employed until that comparatively late period when some of its peculiarities were adopted by Sebastian Erard, afterwards by the late Mr. Squire and others.

The writer of the article "Pianoforte," in the fourth edition of the "Encyclopædia Brittanica," says the Germans had attempted to make what he terms keyed dulcimers, which without specifying what that was, he states were all constructed "on one principle, which required a peculiar touch of the finger difficult of acquisation, which spoiled it for the harpsichord." He adds, Mr. Mason "removed all these imperfections by detatching the mallet (hammer) entirely from the key, and giving them only a momentary connection." This statement, if true, would seem to indicate that the Germans had constructed pianofortes, or, as the writer terms them, keyed dulcimers, on the system above described for converting a clavichord into a pianoforte, but the statement must be taken *cum grano salis*. The Germans may have done this, but they certainly went beyond this before Mason did, even if they did not carry improvement so far. I have been unable to ascertain what kind of action was employed in Farinelli's piano made at Florence, A.D. 1730—by the way, Dr. Burney also states Farinelli possessed a transposing harpsichord, which, I believe, was far from being the first of its kind—very probably it may have been Christofali's action, or some modification of it. From its early date, and the yet earlier time of the publication of Christofali's invention, we may infer pianos were probably made in Italy before they were constructed in Germany, although it is related that Silberman made two at some early period which were not approved by S. Bach. I have found no record of their date or the kind of mechanism he employed, but he seems to have constructed several before A.D. 1747. His pupil Stein does not appear to have turned his attention to the piano very early, but was more known as a maker of harpsichords and clavichords; some of the latter he constructed with strings nearly double the usual length, and, by causing the tangents to strike them exactly in their middles, to produce sounds an octave above those they uttered when simply plucked. He also invented the *vis-à-vis* harpsichord, literally two harpsichords in one rectangular case, with keys at each end for two or four performers, just like Chickering's double-grand pianoforte in the 1851 Exhibition. When, however, Johan Stein did give his attention to pianos, he did so to some good purpose, for he invented the so-called Vienna action, which I am told is yet used in Germany, especially for cheap square pianos. Stein also employed levers moved by the performer's knees—like those afterwards used in the claviol by the late J. J. Hawkins, who facetiously said that as they were neither manuals nor pedals, of course they must be "needles," rather a sharp and pointed remark—to actuate the many stops then employed in pianofortes. Similar levers are now employed in harmoniums.

The first square pianoforte is said to have been made by John Adam Spaeth, which I take leave to doubt, and the first square piano with a soundboard nearly as large as its case (whose hammers were above its strings) was, it is asserted, constructed by Hildebrand. As early as A.D. 1760, Hancock patented the organised pianoforte, or, combination of organ pipes with the piano, an instrument afterwards constructed by S. Erard, with a shifting keyboard for transposition. The idea was by no means new, for as if to prove its antiquity, an organised harpsichord is now in the Loan Exhibition at South Kensington Museum, bearing the name of Crang, Londine, A.D. 1745. Verily there is little or nothing new sub sol. "What is has been, and what will be has gone before," so I will say no more.

THE HARMONIOUS BLACKSMITH.

LUNAR OBJECTS FOR OBSERVATION, AUGUST, 1872.

[4513.]—AUGUST 7, Mare Crisium, the east border, with the two promontories at the "pass;" August 8, Guttemberg (see ENGLISH MECHANIC, No. 323, June 2, 1871); Navigators' Nook, containing craters named after celebrated navigators, Magelhaens and others (see "Monthly Notices of the Royal Astronomical Society," Vol. XXIV., p. 20); August 9, Taruntius, objects in its interior; August 10, Posidonius and craters north of it. Notices of them have been given in former numbers of the ENGLISH MECHANIC, as well as in No. 308, p. 516. August 11, Mare Serenitatis, with longitude of terminator varying from 24° to 12° on the equator; the ridges of the Mare may be studied to advantage; August 12, Sabine, Ritter, *Gwilt Brothers*, two small craters north-east of Ritter, named in commemoration of the architects Joseph and George Gwilt; August 13, Archytas and the craters between it and Egede; August 14, Short, Newton, Cabeus; August 15, Ramsden, the valley and clefts in its neighbourhood; August 16, Anaximenes and *Herschel* II., which is the finest of a fine group of craters near the north-east limb, imperfectly described by Beer and Madler. See "Reports of the British Association for the Advancement of Science—Transaction of Sections," pp. 10—12, also "Monthly Notices of the Royal Astronomical Society," Vol. XXIV., p. 20. August 17, Scheiner, Blancanus, Gruemberger; August 18, Crüger, Byrgius, and *Rosse*, a large formation between Phocylides and Segner.

W. R. BIRT.

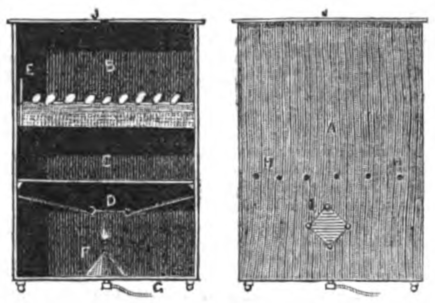
THE PHENOMENON OF ARGOSTOLI.

[4514.]—I CAN assure Mr. Rodwell (let. 4472, p. 410) that I am quite contented and able to live without a theory of where the water is gone to. Professor Ansted, in the volume I quoted, gives his theory, but confessedly only disposing of the water, not the salt, and not of even the water in a way I thought worth copying as among possible ones. In that category there is certainly one, propounded, I believe, by Dr. Frankland, and which must suggest itself to any reader of Mr. Mallet's earthquake theory opportunely brought up in p. 404. Of course, if internal shrinkage is creating vacuities for the exterior to "crush down" into (which I do not believe), there will be abundant room in pores to drink the sea dry in time, and for the atmosphere to follow or accompany it (whether our wisdom have by that time added the "coal-stores" to its weight or not); and it would become a question of some interest whether a cometfall occasionally might delay this awkward prospect by bringing some fresh water or air, and whether this be not rather to be desired than deprecated.

E. L. G.

AN IMPROVED INCUBATOR.

[4515.]—THE outside case A is made of stout wood dovetailed together, wood being less affected by change in the temperature of the atmosphere; B is the egg

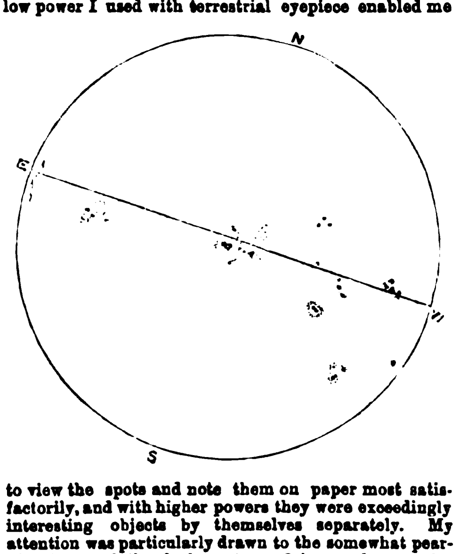


chamber, the eggs lying upon layers of flannel next a thin layer of sawdust. C is the boiler of tin, having a pipe communicating with the egg-chamber, which supplies the moisture required, avoiding the use of wet bags of sawdust, &c., which need continually changing. D is a tin plate suspended above the funnel burner F, radiating the heat, and preventing the flame touching the boiler. G is the gas-pipe, the burner let through the bottom of the case. H H are holes to carry off foul air (the burner emits no smoke). I is the aperture to light and observe the burner; J is a glass top covered with flannel, preventing the condensing of the moist air into drops.

TINTUB.

SUN SPOTS.

[4516.]—THE sketch I send herewith shows the appearance of our great luminary the sun at 30min. past 6 p.m. on Saturday evening, June 29, 1872. The low power I used with terrestrial eyepiece enabled me



to view the spots and note them on paper most satisfactorily, and with higher powers they were exceedingly interesting objects by themselves separately. My attention was particularly drawn to the somewhat pear-like shape of the dark spots, and in nearly every instance pointing E. and N.E.

JAMES H. WHISTLE.

COLOURED SUNS.

[4517.]—I AM glad to see that this neglected but interesting subject is cropping out in the pages of "our" MECHANIC. Mr. Buffham's letter, in your last issue, shows how necessary it is for observers to adopt a more definite nomenclature, or rather to avoid the use of merely descriptive terms altogether, and to pursue instead the very practical method first suggested by the late Admiral Smyth, by employing coloured discs for comparison. I have for many years used the valuable diagram of colours published in Smyth's "Sidereal Chromatics," and I hope shortly, with your permission, to publish a portion of the results of my observations.

BEDFORDIENSIS.

THE SUN'S MEAN PARALLAX.

[4518.]—THE mean distance of the sun, to astronomers and mathematicians, has been a subject of deep interest and scientific inquiry—in other words, the discovery of the sun's mean parallax, which, after much independent researches and calculations, has been given at 8·91", 8·92", 8·96", and 8·86". Between the two latter there is only a difference of one-tenth of a second of an arc, which, in the distance, makes 1,082,300 miles of difference. Between the two former there is only a difference of ·01 part of a second of an arc; yet, in the distance, there is a difference of 102,650 miles.

The value 8·86" appears to be the true value (very nearly), from the following simple principles of calculations, which include the application of the area of a circle, whose diameter is unity, the greatest distance of the sun, that of the mean distance being regarded as one, the angular diameters of the sun and moon, and the doctrine of ratios, one result of which has been the finding of the sun's mean parallax, the angle or corner which the semi-diameter of the earth makes at the mean distance of the former at 8·858074", which gives a mean distance of the sun, from the centre of the earth, at 92,183,210 miles.

Taking the moon's semi-diameter as given in the appendix to the *Nautical Almanac* of 1886, the greatest at 16′ 46", and the least 14′ 24", from which we obtain the moon's mean angular diameter equal to the logarithm 3·27058585, that of the sun being 3·2831141, both in seconds of an arc, the logarithm of the mean diameter of the earth 3·8983604, and the arc equal to radius being expressed in seconds, the logarithm of which equals 5·3144251. The application of the foregoing values is as under—viz., 3·27058585 : 5·3144251 : : 3·8983604 : 5·94219965, the fourth term or value thus found being subtracted from radius thus, 10·0000000 − 5·94219965 = 4·05780035, the square of which equals 8·1156007, and this value being divided by the logarithm of the area of a circle to diameter one, thus, 9·8950899 : unity : : 8·1156007 : 8·2505108, the numerical value of which equals 57′ 7", the moon's mean parallax.

The logarithm of the sun's angular diameter is as under—viz., 3·2831141 : 5·3144251 : : 3·8983604 : 5·9296714. And, doing the same with the fourth value thus found as we did in the case of the moon's fourth value—viz., 10·0000000 − 5·9296714 = 4·0703286, the square of which equals 8·1406572. $\frac{0.0144664}{9.8950899} =$

B

0·1198765 : unity : : 2·602063 : 2·4826865, and 2·4826865 : unity : : 8·1406572 : 5·6329142, the numerical value of which is equal to 8·858074", the sun's mean parallax. And, subtracting thus, 8·1406572 − 8·1156007 = 0·0250565, and taking this value from the logarithm 0·1198765 − 0·0250565 = 0·0948200, and 0·0948200 :

B

unity : : 2·6020680 : 2·5077480, and 2·5077480 : unity : : 8·1406572 : 5·6329142, the numerical value of which equals 8·858074", the sun's mean parallax as before found, and 5·6329142 : 10·0000000 : : 3·5973364 : 7·9644162, equal to 92,183,210 miles. By multiplying the logarithm of the moon's angular diameter by the logarithm of one second of an arc, thus, 3·27058585 + 4·6855749 = 7·95616075, and logarithm 5·94219965 : 3·8983604 : : 7·95616075 : 5·9128215. And logarithm

B

0·0250565 : unity : : 2·6020630 : 2·5770065. And 2·5770065 : unity : : 5·9123215 : 3·3353150, equal to the moon's mean diameter = 2164·287 miles. And, in like manner, multiplying the angular diameter of the sun, we obtain the logarithm 7·9686890, and 5·9296714 : 3·8983604 : : 7·9686890 : 5·9873780, the numerical value of which equals 865,721 miles, the sun's mean diameter.

5·9873780	3·8983604
3·8983604	3·3353150
2·0390176	0·5630454
	2·0390176
	B = 2·6020680

VERIFICATION.

A MORNING SUNSET.

[4519.]—BEING very fond of witnessing the phenomenon of sunrise in summer, on the morning of June 16 I found myself, with that object in view, at Chanctonbury Ring, a clump of trees on one of the summits of the South Downs, given in the ordnance survey map as 780ft. above the sea level. The sun rose shortly before 4, and the sight was grand in the extreme. But about 4.30, on walking round the clump, I saw something like a sunset in the west. Bright rays of light were radiating up from a point apparently about 1° below the horizon, varying in breadth and brightness, generally 30° in length, with the points merging into the surrounding sky, in fact, as before stated, presenting exactly the appearance of a sunset, when the body of the sun has disappeared a few minutes. The sky was sprinkled with small light clouds thickening into a mass towards the west; there was also a little mist, but the Isle of Wight was distinctly visible, also the sails of a ship moving up Chichester Harbour, distant twenty miles. The rays were visible for two hours, when they seemed gradually to fade and finally disappeared. A friend who was with me agrees in this description, but is equally unable to account for it. I thought if you could afford me space in your valuable journal some of your scientific readers would give me an explanation.

W. W. M.

COLOURS OF CLOUDS.

[4520.]—"T. W." (letter 4426, p. 383) asks, "Why are the clouds at various times of the following colours? He then enumerates certain tints which it will be more convenient to arrange under three heads—

Intense white	Dark gray	Ruddy brown
Yellow white	Blue gray	Blue brown

In the first place, those clouds which appear to the eye as most intensely white are, in reality, very very light blue; they are generally high up in the firmament, and have reflected on them some of the blue of the atmosphere. This very light blue appears so surpassingly white from the same cause that makes snow look so intensely white when there is a blue sky above, and our linen so beautifully white when the laundress has mixed a judicious quantity of blue in her starch; this very light blue is perhaps the nearest approach to pure white which we ever see in nature.

Yellow white clouds are those which, from their position, reflect to us less of the azure blue of the atmosphere, and more of the direct yellow rays of the sun.

Dark gray and blue gray are only seen on the shaded sides of clouds, or on clouds in the shade of other clouds intervening between them and the sun. The blueness of the gray depends on the amount of azure reflected on it from the sky. Brown tints in clouds are not often seen, but they do sometimes occur, especially in the lower surfaces of clouds passing over cities or land of a somewhat russet hue. I suppose that the russet hue is reflected upwards, and mixing with the gray of the shaded underside of the cloud produces a brownish tint. I never remember to have seen a brownish-looking cloud passing over the sea.

These remarks may perhaps in some measure explain the reason of some of the colours of the clouds in ordinary daylight; but what shall we say of the exceptional colours of the clouds at sunrise and sunset? I must confess that here I am at a loss. Can any correspondent in "our" journal explain the cause of the gold and crimson and purple of sunset, and the far different primrose salmon colour and rose-pink of early dawn? And what is the cause of the strange hue of some thunder clouds—a most peculiar colour like nothing else unless it be burnished copper? How "T. W." can successfully predict certain coloured clouds on certain days passes my conception. I am not profoundly sceptical with regard to meteorological prognostication. I have no doubt that ere long—

Old experience will attain
To something like prophetic strain.

But "T. W.'s" colour prediction seems to be something quite new, but there may be something in it. There certainly is some difference in the colour of the clouds at different times of the year. There is a creaminess in the clouds on a fine autumn day quite different from the silvery whiteness of some of the clouds of early summer, and in winter and early spring there are still further differences. "T. W." says his object is not to provoke discussion, but I always thought that it was understood that any correspondent starting a new subject invited discussion thereon. BOBO.

MICROSCOPE CASTINGS.

[4521.]—PERMIT me to rectify an error in my letter (4479) on the above subject. The objectives of my microscope are 1½in., 1in., ⅔in., ½in., and ¼in. I may also add that I am adapting the ⅔in. as an achromatic condenser; the cost of the apparatus, which will include a polarising plate, diaphragm, and mica plates, will not exceed half-a-crown.

I can indorse the statement of "J. D. H." (let. 4480) as to the difficulty in procuring castings of microscopes from opticians. I have applied to every manufacturing optician in one of the largest provincial towns, and could find only one who was willing to supply me with a set, for which he asked the very moderate sum of twenty-five shillings, at the same time informing me that I should only save about five shillings by purchasing the fittings, and making the instrument myself.

I do think there is a good opening for an enterprising man who would supply not only the unfinished, but also the finished parts of optical instruments, at a moderate charge. Why, in the name of common sense, should the thin glass covers for slides be charged 3s. 6d. per ounce by the optician, when the manufacturer's price is about 10d.? Surely a profit of (say) 100 per cent. ought to be sufficient. MICROS.

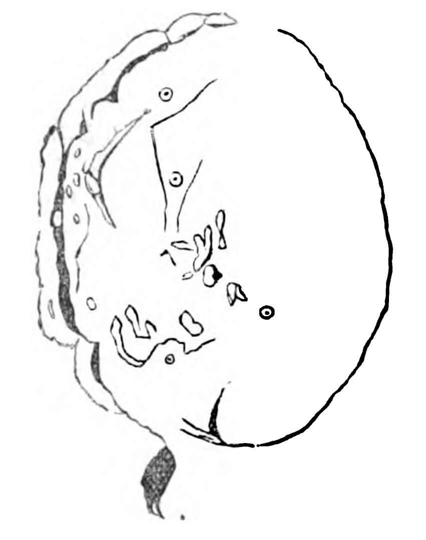
COAL AND THE ATMOSPHERE.

[4522.]—DOES "Philanthropist" (p. 385, No. 379) really imagine that all the carbonic acid daily produced on this earth remains to poison and contaminate the air, and to take up the place of free oxygen? &c., because, if so, he has but a very poor idea of the magnificent adaptation of things in nature. Is he not acquainted with the fact that this poison (if it be a poison) is what vegetables live on, and that they, under the influence of sunlight, consume it as fast as we produce it, assimilating the carbon and restoring the oxygen for animals to breathe and burn?

I have not the remotest fear of the effects of the exhaustion of our stores of coal, for if such a catastrophe were much more imminent than it really is, should we not discover a fresh fuel long before it took place? (I have an idea that we shall burn water before long). But at any rate, philanthropists need not torment themselves with the fear that the store of oxygen in our atmosphere is going to "give out," whatever they may think about the coal. SIRIUS.

GASSENDI.

[4523.]—Mr. NEISON has directed my attention to the south-western part of the floor of Gassendi, which he describes as a *dark patch* under high illumination. This, and indeed the whole of the southern portion of the floor, is interesting on account of the peculiar tint which it exhibits as compared with the rest of the floor. The part to which Mr. Neison alludes is *lower* than the rest of the floor, and is separated from it by a ridge on which the south-western of Schröter's two craters is situated. It is also lower than the adjacent surface of the Mare Humorum, from which it is separated by a low ridge stretching across the "pass" 22 in my sketch of Gassendi, Vol. XIV., p. 99. In Mr. Elger's sketch, Vol. XIV., p. 228, the southern part *a* is described as "darker than the floor." On this I remark that "coincident with the darker portion is a depression or hollow well seen at sunrise." Mr. Neison, under date of June 29, 1872, writes as follows:—The south-west portion at sunrise is perhaps slightly lighter than the rest of the floor, but as the sun rises the tint deepens until it becomes considerably darker than any portion of the lunar surface near. This spot is also noteworthy as being free from all ridges or mounds, and, as far as I can remember, free from all *streaks* at the sun's meridian passage. The rest of the floor of Gassendi becomes lighter as the sun's altitude increases, and is seen covered with streaks, and although it is not easy to observe them with precision, on account of the perplexing and irregular forms assumed by the ridges which are of similar colour, I think these streaks vary slightly in visibility. The tint of this spot may differ slightly in different lunations from alterations in the meridional solar altitude, or luni-solar declination, if I may so term it, but by comparing the tint with the rest of the floor of Gassendi and the Mare Humorum, which must vary from this cause in exactly the same manner, this difference must be practically eliminated, consequently I think we may assume that this spot is affected by solar altitude in exactly the same manner as Plato, and unlike a very large extent of the lunar surface by becoming darker instead of lighter as the sun's altitude increases." These remarks by Mr. Neison are highly interesting in connection with certain phenomena observed in Plato, and which may now be regarded as exponents of solar action.



On February 20, 1872, 7h. 10m. to 10h. 20m., the Rev. T. W. Webb specially studied the western part of the floor of Gassendi, which he sketched. The sketch preserved in his note-book is such an admirable companion to that of Mr. Elger, of March 5, 1868, that I forward a copy of it for publication, should you (Mr. Editor) deem it desirable. It is at a later stage of illumination than Mr. Elger's or Mr. Birmingham's, in No. 375, May 31, 1872, p. 277. The two projections *b* and *c* in Mr. Elger's sketch are quite distinct in Mr. Webb's. Mr. Birmingham's, which appears to be at rather an earlier epoch of illumination than Mr. Elger's, agrees with it in a larger extent of shadow from a portion of the western border, arising either from a hollow near the border or from increased height of the wall. Mr. Webb's sketch has a marking perfectly in accordance with the outline of the shadows in Mr. Elger's and Mr. Birmingham's drawings. Mr. Webb's sketch shows the retreat of the shadow from this marking. In his notes, Mr. Webb says: "The outpouring of the contents of the 'Spoon' over the floor of the larger crater was most evident; from want of half tones in the drawing, much less obvious there than in Nature." May I ask Mr. Birmingham if his feature *a* represents the outpouring mentioned by Mr. Webb? The depressed portion of the N.E. part of the floor of Gassendi is shown more or less in the three engravings; also the narrow opening in the S W. border of the "Spoon," through which it may be supposed the ejecta passed. Mr. Webb says "the much greater depth of the 'Spoon' is not exaggerated;" and of the three drawings, Mr. Birmingham's, being at the earliest epoch, brings out this feature with the greatest distinctness. In glancing at the remote history of Gassendi in selenological time, do we not perceive here in the "Spoon"—in the elevated mound forming its S.E. wall, more or less in the position of Mr. Birmingham's *b*; in the narrow pass of its S.W. border, and in the different aspects indicated by a different shading in Mr. Birmingham's sketch—evidences of explosive action, which, while confined to the N.W. portion of Gassendi, was accompanied either with the production or deepening of the "Spoon," and thus indicating that in studying the structure of Gassendi we have to take into account, as in other parts of the moon's surface, as well as on our own globe, successive instances of such action, separated, it may be, from each other by long intervals of selenological time? W. R. BIRT.

BALSAMED OBJECT-GLASS.

[4524.]—"C. B." (let. 4366, p. 358) will not find it answer to balsam two glasses if the curves differ much. It shortens the focus a good deal, and it is hardly possible to get the balsam hard or so homogeneous as to show properly. Where the curves are alike I have found it very useful, and it makes a considerable difference to the light. It is very easily done, and should not be hardened too much. Where this is not done I have not found any separation take place. Of course, any rough usage may produce it, but not fair care. E. T. S.

RADIUS OF SURFACE OF OBJECT-GLASS.

[4525.]—MR. CASH (let. 4380, p. 355) is evidently so far from correction for achromatism with his object-glass that any suggestion for improvement must be useless until he has approached perfection in that respect. I have no doubt if he would only take the trouble to make it something like achromatic, he would find most of his strange phenomena vanish as if by magic. I do not fancy, either, that Mr. Oldfield is right in supposing the crown lens to be worthless from veins, for if so it would have been very difficult indeed for Mr. Cash himself not to have discovered them, as they are easily seen. I do not think, therefore, that he had better hastily throw aside his lens, but that he should alter its focus until the combination is properly corrected for colour. If he is determined to commence with new pieces of glass, I should strongly advise him to perfect a smaller glass as a model for further operations. With respect to the tools, Mr. Cash will find soft iron a very good material for grinding; but of course tools made of this metal are more difficult to finish than those made of brass, and they are rather apt to rust. It seems a pity when tools are properly formed and their radii ascertained that they should be re-turned; it would be better to preserve them for further use, as most probably if Mr. Cash should succeed with one object-glass he would not be contented until he had made another or two, and the tools already finished might be found useful, the serious operation of preparing new tools being thus, after a time, avoided. HENRY T. VIVIAN.

GOVERNMENT AND AMATEUR SCIENCE.—III.

[4526.]—IN my first letter I called attention to the unbroken series of the moon made under the auspices of the Government at the Royal Observatory, Greenwich, from its establishment to the present day; a great scientific work well worthy the patronage of the Government of a maritime and enlightened nation. In my second letter I glanced at the sources of patronage other than from the Government, and adduced the subject of binary stars as a branch of astronomy left entirely to amateur efforts. I now proceed to notice the little probability of patronage being extended generally to amateurs engaged in original scientific research. It is very rarely indeed that an amateur is possessed of such ample means that he himself can provide instruments, forms for registering, recording, and discussing his observations, and then presenting his results to the public in a *printed* form. In most instances gentlemen of fortune employ assistants to work out their views, and it is frequently the case that an amateur in the humbler walks of life enthusiastically devoted to the pursuit of science succeeds in obtaining an engagement with a gentleman involving duties in the discharge of which he not only satisfies his cravings for knowledge, but by the munificence of his patron contributes to augment the general store. All amateurs are, however, not so favourably situated. With small means and restricted leisure an amateur perseveres in the pursuit of knowledge, loving it for its own sake. It is this class of amateurs of all others that needs assistance, and that assistance may be rendered by the loan or gift of instruments, but more effectually by grants of money for some especial work. This suggests a notice of the channels through which such assistance may be administered. For this purpose there is nothing direct from the Government. Government aid to science is at present confined to Government establishments for working out definite scientific objects, or to Government expeditions for observing certain phenomena. It is true that a sum of £1,000 is annually voted to the Royal Society for encouraging original investigation. It is consequently the Royal Society that administers this and its other donation funds to the aid of such objects as may form the subjects of application, and an amateur to be a recipient of a portion of these funds must obtain the support of the majority of the committee appointed to administer them. Another channel through which assistance is rendered is the British Association for the Advancement of Science. At its annual gatherings sums varying in amount are voted by the General Committee to sub-committees appointed to superintend such scientific works as have received the consideration of the committees of the sections by which the particular branches of knowledge are cultivated. To obtain assistance through either of these channels, considerable interest is necessary. No doubt each application is thoroughly and well canvassed in the respective committees before a grant aiding the object is recommended; nevertheless, there is but little probability of an application meeting with success unless it be introduced and supported by gentlemen of known reputation in the particular branch of science with which it is connected.

Taking into consideration the large army of amateurs, and the very limited resources for aiding them, amateur science must at the very best be but *desultory*. While its triumphs have been great, perhaps, with the exception of the Government work at Greenwich, greater than any achieved by Government aid, still it has been of a desultory character, notwithstanding the societies which have been formed for its culture. Returning to the subject of binary stars, measurements of distance and position angles are comparatively easy, so that there is little fear of this branch of the science falling behind, provided there is an early publication of measures. It is here, at the outset, that we meet with want of system. Each observer chooses his own channel of publication, or it may be that he does not publish his observations at all, and they are ultimately lost. Now, before work in the second department can be efficiently accomplished, from this desultory mode of procedure, much labour must necessarily be incurred in looking through several publications, as the "Monthly Notices and Memoirs of the Royal Astronomical Society," and others, for records of measures which might be saved for the future by a little systematic arrangement, aided by a money grant for defraying the expenses of compiling and printing; the third department, that of computing the orbits of binary stars, requires a higher order of mind to cultivate, and must be left to the ability and convenience of gentlemen who are willing to devote their leisure to it. There can be no doubt that an autherised repository for the reception of double-star measures, with a provision for the issue of catalogues at stated intervals, would greatly facilitate the computation of orbits, and thus, with a moderate grant of money, the portion of astronomy devoted to double stars, while it remains as an amateur pursuit, would lose much of its desultory character, and assume that of a systematised branch of inquiry, a result within the reach of amateur astronomers, provided they set themselves energetically to the work.

W. R. Birt.

ARTIFICIAL MANURES.—STONE-COAL.

[4527.]—Stone-coal is a name used at Bridgwater for a smokeless coal or anthracite used by maltsters and for close stoves, coming from Wales through Cardiff, I think. I shall be glad to read further remarks from "Saul Rymea" on artificial manures. Has he any experience of the value of manure prepared on Mr. Moule's plan? I have tried blood manure, but am doubtful as to its value. Potash, I believe, exists in large proportion in the liquid manure of the stall and stye. If so, I have fully proved the truth of "Saul Rymea's" statement of the value of potash for the potato plant. The first experiment with this manure for potatoes arrested my attention by its success; so decidedly that I have not in twenty years forgotten the lesson. The excellent quality of the crop, the small percentage of diseased tubers and more than average weight, at a time when the disease produced its most disastrous effects, were remarkable. I thought at the time that manure, by promoting moderate but very healthy growth, gave the plant a power of resisting the progress of the disease, and every subsequent crop I have grown for many years has confirmed that impression.

Superphosphate applied last year to my failing crop of seedling onions at once revived the plant, and followed by a dose of house sewage, gave me an excellent and sound crop of onions on land which I am told has never, in my predecessor's time, produced a tolerable crop, if any crop at all, of this vegetable.

J. M. Taylor.

Seer Green Vicarage, near Beaconsfield.

THE NEGRO.

[4528.]—In confirmation of "Sigma's" remark (let. 4458), I quote the following from Sir A. Alison's "History of Europe," c. 47, p. 70:—"Jews are to be seen in many places (in India), whose Old Testament coming no further down than the Babylonish captivity, indicates that they have strayed to the east after that remarkable event." I quote the following from "The Races of the Old World," by Charles M. Brace (Boston: Scribner and Co.):—"A tribe of Jews is described by Mr. Tristram (quoted by Dr. Beddoe, Ethnological Trans., 1861), living in the oasis Waregla, about 32° north latitude, who are almost as black as negroes, without the slightest trace of negro features. Their lineaments are as distinctly Jewish as any clothes-dealer in Houndsditch. They were dark as the black Jews of Abyssinia; their hair was frizzled without being woolly. He considers the colour the effect of climate."

H. J. C.

[4529.]—Our learned "E. L. G." has made this question more interesting than I ever could have done, but the matter in hand—viz., the origin of the negro—still remains *in statu quo*, unless, indeed, by the Nephilim is meant a black-skinned people. But then I am placed in the dilemma of supposing that there were two distinct species of human beings on the earth—men and the sons of God. Which of these were descended from Adam? Josephus bridges this difficulty by stating the sons to be fallen angels. This I see agrees with the idea of heathen mythology having commenced with primal man (if I may use the term). If Adam was the father of these fallen angels, who was the father of the Nephilim? I do not deny, but I rather believe, that among Noah's posterity the Nephilim were continued, although called by other names, as Rephaim, Anikim, and the Sons of Anak, or of the Giants. There is no word of their being black-skinned, and, indeed, the fact that a white man could never produce a black progeny (supposing Noah's son to be their continuer) proves that they were not black. Some have questioned whether Adam was a black man, but his name implies otherwise. However, Josephus writes that Adam's third son, Seth, and his descendants, inhabited a country by themselves, were happy, studied astronomy, inscribing their discovery on pillars, one of which remained in the land of Syria at the time Josephus lived. This Seth or Sesostris he supposed to be a King of Egypt, and as the Egyptians were a dark, if not black, people, this seems to give some insight as to the origin of the negro. I know that Josephus is said to make a mistake in his supposition (the supposition may be more of ours than his); but considering what a truthful writer he was in general, and the opportunities he had of obtaining information from manuscripts now, alas! no more, may he not have been right? Of course, if we can palm off Seth as the great father of the black race, the question is so far settled; but how Seth become black himself we cannot know, although the knowledge of this secret might have been destroyed among a thousand others in the famous Alexandrian library. I ask some of "our" correspondents for some proofs of the great antiquity of man (one hundred thousand years is the latest estimate) in connection with the origin of the negro. Has he been considered at all as the maker of flint weapons or spear heads? Has a veritable negro's skull been found with them, for there would be no difficulty in deciding between a negro's cranium or a monkey's. I write this advisedly, for might not apes have had sufficient instinct to be able to make and use such implements? I think so even without consulting Darwin.

Fiddler.

PIANO IN CANADA.—To "H. D. W." and Others.

[4530.]—Weakness is far from being the only cause of pianofortes failing to stand well in tune. I believe that defect oftener results from the blows delivered by their actions (hammers) being too forcible for the weights and tensions of their strings to resist without becoming unduly stretched. The natural remedy for this is to substitute thicker and longer strings, or, what comes to about the same thing in practice, to tune the new thicker strings sharper, and thereby practically lengthen the scale.

If the instrument in the possession of "H. D. W." be a genuine Holdernesse and Holdernesse, which I rather doubt, I am very confident its complaint cannot be "weakness in the back," for I never yet saw a pianoforte made by that firm—I have examined some hundreds—whose back was not excessively strong in proportion to the tensile force of its strings. I possess an instrument of their make myself whose back has not been strengthened, the C's of which were originally of Nos. 21, 17, and 16 wire. I had them restrung with Nos. 25, 21, and 19, causing what "H. D. W.'s" Yankee neighbours would term a "pretty considerable" increase of tension. Perhaps, however, they, and my practical friends who manufacture pianos, may become surprised indeed when I tell them that besides the additional strain required to bring those unusually heavy wires up to pitch, I have since—more than a year ago—raised the pitch of the instrument until the strings originally struck by hammers moved by the A keys now sound C; in other words, it is a minor third above concert pitch, and its strings sounding middle C are now 26¼in. long, of No. 21 wire. Notwithstanding this very severe trial of its poor back, I can discover no symptoms of spinal weakness, and the instrument stands in tune admirably at its present high pitch.

Should "H. D. W.'s" piano really be weak in its back, there is no difficulty in administering what our respected fellow correspondent, Dr. Ussher, would term "tonic medicine;" in other words, in making it stronger, and I, being the physician "H. D. W." has "called in," now proceed to prescribe for it as under without indulging in unclassical "pharmaceutical Latin."

Considering that wood is easily procurable in his country, and the probability that "H. D. W." is more of a chopstick than a blacksmith, I would suggest that additional wooden bracings be introduced between the present ones, probably six or seven in number. If the new bracings be made of thick material, say 4in. or 3in., perhaps it will be found needful to groove them about ⅜in. wider and deeper than the belly-bars project into them; but, probably, if made of wood from 1½in. to 2in. thick, one new brace might be placed in contact with each side of every one of the present bracings, and leave room for the belly-bars between them. This would require double the number needed if thick wood be employed. In both cases the new bracings must be securely attached by screws or bolts to the wrest plank, to the bent side, and to the string plate, the latter being drilled or bored for the reception of the bolts or screws, and I need hardly add the new bracings must be firmly abutted under the wrest plank, and on the bottom, or on the string plate (if the instrument's back be made without a wooden bottom, and the lower ends of its braces in contact with the string plate, which is preferable). I think the best method of insuring sound abutments against both is to fit each brace accurately against the bottom of the wrest plank, and to insert a beech, or other hard wood, wedge, driving it in moderately tight, between the lower end of the brace and the string-plate or bottom. Of course the wedges must be formed correctly to the angle to which the bottom of each brace is cut, or rather a trifle more acute, so as to insure perfect contact between the bottom of the brace and the surface beneath it *at the front*, or part nearest the strings, which part is subjected to by far the greatest force of compression by their tension. "H. D. W." will find some useful information on strengthening cottage pianos in my rather lengthy article on the improvement of existing pianofortes, printed in Nos. 238, 239, and 240 of "our" journal.

Another method—described in the above article—by which the present wooden bracing may be strengthened is the application of bars of angle or T iron to their backs in the manner practised by the late Thos. Rolfe, about 1854. (See description thereof, in which it is so fully explained that I have nothing to add.)

Being a "blacksmith," I have a very natural proclivity to resort to iron for bracing pianofortes. For cottage instruments, especially those not originally designed to be braced in front of their soundboards, I consider the form thereof designed by Kohlman preferable to any other I have seen. "H. D. W." or any other man "standing in need" of additional support—I mean whose piano stands in need thereof, and therefore don't stand in tune—might introduce two or three iron bracings on Kohlman's system if they be constructed in the manner shown by Figs. 3, 6, and 7, fully described in Nos. 362 and 365 of the English Mechanic; but probably the space between the strings of each note—especially if a trichord instrument, which is very unlikely if it be a genuine Holdernesse—is not sufficient to admit a steel plate, O, ¼in. thick. To obtain the requisite strength, it may be made taller and thinner, say 3in. high by three-sixteenths of an inch thick. Messrs. Holdernesse (probably for facilitating the shifting of the hammers so that they may strike single strings fairly) ordinarily place their unisonous strings rather wide apart; consequently, even in their bichord instruments, the space between the uncovered strings of two consecutive notes seldom much exceeds three-tenths of an inch.

Unless "H. D. W." has had considerable experience in the art and mystery of "toning," I would not advise him to "meddle and muddle," or rather "needle" up the coverings of the hammers of his piano. Strange to say, although not difficult to do, this is a thing few tuners—or indeed any other men—do satisfactorily, and I have observed it is far easier to most of them to mar than to make the tone better. This I learned long ago by woeful experience to my cost. Picking up the top surface, however much it may temporarily improve the quality of the tone, don't last long, neither does glass papering, or brushing the surfaces of the hammers with wire-card or bristles. The proper method is to insert the needles considerably within the striking surfaces, and manipulate them *secundum artem*, which artistic manipulation, alas! is just the thing most tuners can't do. I learned this art of our late fellow correspondent "W. T.," who was a remarkably good toner as well as tuner, and he learned how to do it properly from a gentleman who then (many years ago) was intrusted to "tone" Messrs. Broadwood's grands, so we may be certain he had the advantage of having a good instructor. I may add that, being a clever fellow, he "bettered the instruction" in some details.

Harshness in the quality of the bass tones is often a consequence of *deficiency* of tension. In most pianos the strings of the lowest F—usually the lowest bichord note—are seldom tight enough to produce powerful and firm sounds, and but too often they will bear their pitch raised to A, or even to B. In an instrument whose 12 lowest strings did not differ much in length, and the covering wires of which were rather far from the bridges, I promoted—they were not gazetted—all the bichord covered strings from FF to G, 14 notes, in manner following—that is to say, the strings of—

G to G♯	C♯ to D♯	G to A♭
F♯ to G	C to D	F♯ to A
F to F♯	B to C♯	F to G♯
E to F	A to C	
D to E	G♯ to B	

Two pairs of new strings covered more heavily being used for F♯ and G.

I disposed of the single strings thus (they were all covered on No. 21 wire):—

The strings of D♯ and E were exactly alike, so I made of them an excellent pair for F♯.

The strings of D and D♯ were exactly alike, so I made of them an excellent pair for F.

The string of C♯ served for E.

The string of C served for D♯.

The string of B served for C♯.

The string of A served for C.

Three new strings heavily treble covered on No. 24 steel wire were made for the three lowest notes, and they are the finest bass notes in the piano. Probably I need not inform any practical man that I could not have taken such liberties with the strings, had not their tension originally been considerably less than it ought to have been. The increase of power and improvement in the quality of the tone which resulted was very remarkable in the two lower octaves, so much so that I doubt if the maker could have recognised his own handiwork by its sounds.

Shifting strings is a very ticklish operation, and unless performed in what an old workman I formerly knew termed "judgmatically," is almost certain to break them at the part uncoiled from the wrest-pin, but I believe skill, patience, perseverance, and last, not least, money, will, in time, as the late Sir Isaac Coffin said, accomplish all possible, and many so-called impossible, things. I found by costly experience that the "judgmatical" way of taking off a string was to pull it sideways from the pin pretty strongly while turning the wrest-pin backward, which it is seldom needful to do much more than half a revolution (the less the wire is uncoiled the better); having done this insert a pointed piece of steel—a strong marking awl serves admirably—into the top of the coil, and prise the bent end of the string out of the hole in the wrest-pin. The string may then be taken off. Should its intended new position require a string the same total length, or but one or two coils round the wrest-pin shorter, don't cut anything off its length, but merely slip the coil over the previously inserted wrest-pin, by which it will be turned; insert its bent end in the hole thereof, and "put on the screw"—I mean draw him or her up (for I forget whether a piano string is, in workshop parlance, masculine, or, like a ship and a steam-engine, feminine).

N.B.—This wrinkle is worth knowing, even by those eminently "practical" (and of course scientific) men, ye tuners (who I found when employed to shift some of the strings of a piano usually broke a much larger proportion thereof than even the "unpractical" blacksmith himself did, and who, although not exactly what is termed a "screw," has a wholesome horror of all waste), for it might save tuners some expense when shifting the strings of any piano which is their own property. Of course, if the piano belongs to a customer it don't matter how many covered strings are broken, for, by the custom of the trade, they, like children, must be paid for. In that case, the case of the piano, I mean the case of its strings, becomes very like the case of the nails which was a sort of "packing" case, concerning which the 'cute carpenter's apprentice afforded the individual at whose cost the works were being executed, the very satisfactory information that although swept away with the rubbish they would not be lost, because "you will find them all (packed) in the bill." Well, I suppose, all this kind of thing makes good for trade, to-wit, the trades of the pianoforte manufacturer and covered string maker, but it is rather queer political economy.

THE HARMONIOUS BLACKSMITH.

PERSPECTIVE.

[4531.]—I AGREE with much that "M. A." says (let. 4428, p. 388). I was speaking rather of the proportions of individual objects than of the relative scale of many different objects included in a single picture. My chief object in writing was to show that theoretically as well as practically, all lines really vertical must be drawn parallel in a picture, and that the convergency imagined by Dr. Carpenter is simply an absurdity. To reason on the matter seems almost equally absurd, but the actual mathematical proof may be given somewhat as follows:—Let A and B be any two vertical right lines; C, the plane of projection also vertical; P, the eye of observer. Then lines from P to A lie in a plane (Euclid XI., 3); and this plane is vertical (Euclid XI., 18), and therefore intersects the vertical plane C in a vertical right line (Euclid XI., 19)—that is, the projection of A is a vertical right line. In like manner the projection of B is a vertical right line. These projections are therefore parallel right lines (Euclid XI., 6). *Q. E. D.*

RICHARD A. PROCTOR.

DR. CARPENTER AND PERSPECTIVE.

[4532.]—IF you are not tired of this subject, I should like to ask M. Paris for an explanation of his letter (4427, p. 388). What is the fact, and with whose theory does it agree? I have a vague idea that he means he has made a drawing on a sheet of glass, and finds it agree with his theory. If so, I am puzzled to know how he did it, and think he ought to send you a copy of the drawing, so that your readers may have the benefit of his discovery.

"M. A.," in his letter (4428, p. 388), introduces a new subject which is very interesting, but has nothing to do with perspective. If there is any particular object in the view which the artist wishes to impress on the mind of the public, he may enlarge it as much as his conscience will allow him, but if he draw it out of perspective, it will certainly convey a false idea of its form. There is no doubt that photographs of distant mountains do not convey a correct impression of their magnitude, but place a pair of them in the stereoscope, and the mountains immediately assume their right proportions, which shows that each photograph must have been a correct representation of what each eye saw. The position of "violent perspective" may be avoided by the artist, but if he try to "temper or modify" the perspective, the result must be failure to represent the reality. As, however, the public do not have the real view by the side of the picture to compare with it, they do not care so long as the picture is good in itself.

B. D. T.

[4533.]—I AM curious to know whether among artists the attempt of Cruikshank to picture a converging, or I would rather say tapering, giant, is considered such a "complete failure," as Mr. Proctor seems to think it. To my eye the effect is not so absurd, and although I confess to no great feeling of awe when looking at the striding monster, I think that if the picture itself were considerably enlarged and more space allowed for him to stride in, the giant would look decidedly imposing. "E. L. G." (let. 4189) dwells upon the rectification by the eye of objects or lines on paper. Admitting that it must rectify to some extent, and of course allowing that "at the point of sight perspective is perspective, and absolutely true," I yet find that the eye in some cases will not sufficiently rectify to set distorted things aright. To take the old case of a series of columns viewed from the front in so-called parallel perspective, and drawn within the limit angle of 60°. As every one knows, the columns either way from the centre turn out thicker, whilst being further from the eye they should be thinner, nor will the eye, from the point of sight or any other point fully rectify the distortion. It is a perspective, and perfectly correct as such, but not a representation of what appears in reality. A common thing among draughtsmen is to take part of a circle for the plane of projection in order to avoid errors of this kind. On letter 4427 I would remark that it is time the illustration of tracing on a sheet of glass found in so many books on perspective were dropped. It involves an impossibility, since the eye cannot focus the objects beyond the sheet and the points on the sheet at one and the same time.

A. C. G.

ON THE CATALYTIC ACTION OF SPONGY PLATINUM.

[4534.]—I THINK I cannot better answer the questions of "H. H. G." addressed to me than by a short letter on the above subject.

That property of platinum of causing the combustion more or less rapid of combustible gases mixed with air, we call "catalytic" or "contact-action," because the platinum has no chemical attraction for the gases in question, but causes their combination without any change in itself.

This property is not peculiar to platinum, but is exhibited in a less degree by some other substances, chiefly porous bodies or metals in a fine state of division. But the property is more marked in platinum, not only in the spongy state, but when in sheet or wire. If a platinum crucible be heated to redness over a Bunsen burner, the gas quickly extinguished and turned on again immediately, the bottom of the crucible will continue at a red heat for hours, without ignition of the gas, by its slow combustion. But by obtaining it in a spongy state, by heating to redness ammonic-platinic chloride, a far greater surface of the metal is exposed to the action of the gas, and a greater catalytic activity is the consequence.

This property depends, doubtless, upon the power of platinum to absorb or "occlude" these gases, and thus bring them into a state in which they can more readily unite. It has been thought that this peculiar state is really an electric change in the condition of the gases, but it seems reasonable to conclude that, whatever it be, it depends upon this property of "occlusion."

A mixture of hydrogen and air (as in the hydrogen lamp), impinging on the surface of the finely divided metal, slow combustion (*i.e.*, chemical combination of hydrogen and oxygen) sets in, gradually accelerated as the temperature of the platinum is raised by the combustion, until eventually (and this is the work of a few seconds) such a temperature is reached that the mixture of hydrogen and oxygen between the jet and the platinum combines with a slight explosion, and ignites the hydrogen as it escapes from the jet. It is well known that, in course of time, the sponge loses somewhat of its activity. Whether this arises from the absorption of water, or whether the intense heat to which it is subjected condenses the metal and lessens its porosity, I am not certain. I have revivified it (so to speak) by heating to redness, but generally find it easier to replace it with some freshly-prepared sponge. I trust that "H. H. G." will see in this an explanation satisfactory to him. If he wishes to enter into a theoretical consideration of the phenomenon, he should read in Watts's "Dictionary" the articles on "Contact-Action," and "Absorption of Gases by Metals."

ANALYST.

ERRATUM.—In letter 4481, p. 411, *for* "few moths come out," *read* "few moths come to light much before midnight."

Obituary.—The death is announced of Mr. Ernest Theophron Chapman, a chemist well and favourably known by sundry original investigations presented to the Chemical Society, but more especially from the process of water analysis designed by him in conjunction with Professor Wanklyn. Mr. Chapman had accepted the post of director of a wood-distilling works in the Harz, and on June 25, whilst preparing some explosive compound for the use of miners, an accident occurred, which sent a promising and talented student of science to a premature grave. Mr. Chapman was a contributor to these columns during his residence in England, and although only twenty-seven years of age, had already attained an honourable position in his profession. His untimely fate will be regretted by many; for in his death Science loses one of the brightest ornaments among the ranks of her younger devotees.

A New Dryer.—M. Mène states that if 12 parts of best shellac and 4 of borax are dissolved in 100 parts by heat, and when cool, mingled with turpentine, an excellent and rapid dryer for oil paints will be produced. The solution may also, he says, be used as a varnish.

EXTRACTS FROM CORRESPONDENCE.

The Suspended Shilling (Qy. 12155).—It strikes me that "another reason" is still wanted to account for a similar phenomenon. How is it that if you carefully cut off the flower-stalk of a dandelion when the seed is nearly ripe, and blow three times, the number of seeds left on will correspond with the strokes of the parish clock? Isn't this a scientific fact, known to all the professors of buttercup-gathering in the world?—SAUL RYMEA.

The Negro.—I hope those who write on this question won't forget the *wool*. I do not speak positively, but I believe that no other race of men, *black* or white, have hair possessing the peculiar characteristics of the negro's wool. There is also a peculiarity, I think, in the joint of the leg and foot.—SAUL RYMEA.

Dr. Packman's Steam Engine.—"One" says: —"This engine must be a very clever invention, if everything stated be correct. But there is an engine very similar to it, which Dr. Packman would, perhaps, like to see. It is constantly at work. There is neither smoke, coals, nor water tank; it has a chimney, though. It is on four wheels, being of the shape called portable, and is out of doors all weathers; and I have not the least doubt, if Dr. Packman will visit Messrs. Howard's Agricultural Implement Works, Bedford, which are thrown open to visitors free, with the option of giving something to the sick fund, and inquire for the above engine, he will see something which, perhaps, resembles his own."

Tannate of Soda as a Preventive of Boiler Incrustation.—"Tyne Engineer" says:—"I notice in No. 378 that a composition, 'tannate of soda,' is used in America for removing and preventing scale in boilers; also the remark that none is made or imported into England. I have used this tannate of soda for upwards of 2½ years, which answers all my purposes, and which is now manufactured largely on the Tyne for the said purposes, and making its way most wonderfully."

Piano Alliance.—I wish to suggest that the Piano Alliance, or Club, should have a wider range in its objects, and should be, instead, a Piano, Harmonium, and American Organ Club.—V.

USEFUL AND SCIENTIFIC NOTES.

A Story of the Sea.—American papers state that the Agassiz expedition, at the latest accounts, was off Sandy Point, Patagonia, and that among the scientific curiosities noted by some members of the party were immense quantities of kelp. This is the largest known alga or seaweed, and grows on these coasts in from 6 to 20 fathoms of water, in vast beds, warning the mariner to beware a near approach, unless he wishes to be entangled in an inextricable network. It throws up from the oceanic depths stems of immense length, some of them from 700ft. to 1000ft., the greatest development reached by any member of the vegetable race now in existence. Patches of this seaweed were passed in open sea, with large sea-lions lying on its surface, who were apparently navigating in this novel manner with much satisfaction to themselves, and afforded much amusement to their scientific observers.

Storing Wheat and other Grain.—M. Lovel has brought before the French Academy a plan of storing wheat in portable sheet-iron granaries, in which a vacuum is maintained equal to at least from 3in. to 4in. of mercury, this being found sufficient to destroy all insect life (although a more perfect vacuum is preferred) and to insure the evaporation of any moisture in the grain. The apparatus is of cylindrical form, placed vertically, and with convex top and bottom. The top is provided with an opening through which the inlet of the grain is led, with a valved pipe through which the air is exhausted, and with a gauge by which the degree of exhaustion is indicated. The grain is removed through an opening in the bottom. In one experiment, where living insects were introduced in large quantities with the grain, it was found that they were all killed before doing mischief, and at the end of six months the wheat was found to be in as fine condition as at the outset.

Brandy from Sawdust.—In the immense lumber districts of the United States, where the great industry is that which goes on in the saw-mills, the sawdust that accumulates is worse than of no value, for some cost has to be incurred in removing it. The Commissioner of Agriculture, in his last published monthly report, states that the sawdust can be made to yield, under distillation, a good article of brandy. Pine and fir timber being the varieties of timber most plentiful in these regions the method of treating them is described, but it is added that, in all probability, many other kinds of wood would prove better adapted than pine and fir to the production of brandy. The sawdust of the pine and fir timber is mixed and moistened; then to 9 parts of moist sawdust there are added 33·7 parts of water, and ·7 parts of hydrochloric acid, so as to make 43·7 parts in all. These are boiled under steam pressure for 11 hours, when it is found that 19 per cent. of the mass is grape sugar. The acid is neutralised with lime, and the mash is supplied with yeast. After 96 hours' fermentation the distillation proceeds, and the brandy that runs off is perfectly free from the smell or taste of turpentine. The *Chicago Tribune* remarks upon the statement of the Commissioner of Agriculture that the preparation of spirit from waste sawdust is actually easier than from valuable grain.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[10644.]—**Angle of Incidence and Reflection.**—At the request of "Jack the Flukeman," I have much pleasure in forwarding a few of the experiments of M. Athanase Dupré. I shall be happy to send more, but I am afraid the room they would occupy would be objected to. As the few I have sent are sufficient to establish the principle that the co-efficient of restitution diminishes with the increase of velocity and weight of ball, and as they are not, in so far as I am aware, to be found in any work in the English language, they may be acceptable to some of the readers of the ENGLISH MECHANIC. With regard to "Billiardist's" problem, I did not pretend to solve it—in the first place, I am sorry to say, I know little or nothing of the game, or the meaning of some of the terms used. I simply stated that it was a mistake to attribute the cause of the particular motions indicated to an increased momentum of ball, causing an increased co-efficient of restitution, as all experiment proved the contrary. I hinted at what I thought might be one cause, but not being sufficient of a billiard player to know the effects of the various ways of hitting the balls, the amount of rotary motion thereby communicated to them, the effect of the friction of the table, the amount of rolling motion thus communicated, the effect of the soft elastic cushion as compared with a hard elastic body in varying the ratio of angles of incidence and reflection, &c., I hoped that some one more qualified would take the matter up, but I have not yet seen a proper explanation given.

Extracts from Experiments made by M. Athanase Dupré on the Collision of Ivory Balls.

Balls employed in the experiments:—

No.	1	2	3	4	5	6	7
Diameters	1·24	1·47	1·71	2·07	2·12	2·21	2·38in.

Also a black marble slab 37in. × 13in. × 2·2in.

FIRST SET OF EXPERIMENTS.—The marble slab being horizontal, the balls were let fall from various heights h, rebounding to the heights h^1, given in milimetres, carefully measured by means of cathetometer:—

Ball No. 1. h	h^1	$\frac{h^1}{h}$	$v = \sqrt{\frac{h^1}{h}}$	Ball No. 2. h	h^1	$\frac{h^1}{h}$	$\sqrt{\frac{h^1}{h}}$	Ball No. 7. h	h^1	$\frac{h^1}{h}$	$\sqrt{\frac{h^1}{h}}$
mm. 20	16·00	·810	·894	mm. 20	14·25	·712	·844	mm. 20	13·77	·688	·829
40	31·48	·800	·887	40	28·33	·708	·841	40	27·03	·676	·822
60	46·33	·787	·879	60	42·00	·700	·837	60	40·10	·667	·817
80	60·38	·772	·869	80	55·42	·693	·832	80	52·43	·655	·809
100	74·08	·755	·861	100	68·89	·689	·830	100	65·03	·650	·806
120	87·37	·741	·853	120	81·80	·682	·826	120	76·83	·640	·800
140	100·30	·728	·846	140	94·75	·677	·823	140	88·47	·632	·795
160	112·72	·716	·840	160	107·4	·671	·819	160	100·00	·625	·791
180	125·83	·705	·836								
200	138·60	·699	·833								

From experiments with ball No. 1 we get $h^1 = \cdot 799083\,h - \cdot 000554\,h^2$. Ball No. 2, $h^1 = \cdot 71425\,h - \cdot 000268\,h^2$. Ball No. 7, $h^1 = \cdot 68575\,h - \cdot 000380\,h^2$.

SECOND SERIES OF EXPERIMENTS.—Same marble slab, placed vertical, and balls suspended from ceiling by threads 10ft. 2in. long, so that when at rest they just touched the marble; the balls were let go at various angles v, and the angles v^1, to which they rebounded, carefully measured with the following results:—

Ball No. 1. v	v^1	$\frac{v^1}{v}$	Ball No. 2. v	v^1	$\frac{v^1}{v}$	Ball No. 7. v	v^1	$\frac{v^1}{v}$
49·1	45·5	·927	50·0	46·0	·920	20·2	18·2	·901
99·8	92·2	·924	99·8	91·4	·910	70·2	61·8	·880
199·0	180·5	·908	199·3	179·8	·903	170·1	145·6	·856
297·8	264·1	·887	298·4	264·5	·886	269·8	226·6	·840
396·2	350·9	·886	397·1	351·2	·884	369·4	303·0	·820
494·0	433·9	·878	495·5	432·6	·878	468·0	380·0	·812
592·8	509·1	·859	594·5	504·5	·849	568·3	463·0	·815
690·2	587·7	·852	692·5	586·2	·846	667·5	536·5	·804
787·2	669·7	·851	790·1	668·2	·846	766·7	606·9	·792
883·8	746·3	·844	887·5	741·3	·835	865·7	681·0	·790
980·0	819·0	·836	984·6	815·5	·828	964·6	753·6	·781

v and $v1$ are the lengths in millimetres of the arcs of approach and rebound, and consequently are proportional to the respective velocities with which the balls strike and are reflected.—F. N.

[11589.]—**Dry Steam.**—"Superheated steam" (as our engineers term it)—*i.e.*, "dry" or drying steam—cannot be defined as "merely a higher pressure steam;" and "A." has not yet apprehended their meaning in the least, or he would not say that the "superheated" necessarily "contains more heat and less water in a given bulk," but would know that either wet or superheated steam may be of any density, any temperature, and any pressure. His new question is whether I suppose additional heat can be applied to steam "without converting it into higher pressure steam." Yes, to steam apart from water, it certainly *can*, provided the steam have room to expand; but to steam in contact with water it *cannot*. This is the essential distinction he has to keep in view. In a boiler there can never be superheated steam, raise the temperature as high as you will, so long as there is any water; for steam, to be superheated, must be heated away from water. Suppose now you have a boiler and its steam-chest, but at any moment you close all connection between them, the steam in each being of course identical, say of 250° temperature, and therefore 30lb. pressure (against vacuum). Now, let both be equally heated till one, the boiler, has its steam at twice this pressure, or 60lb. (against vacuum), which will happen, according to "Philo," p. 386, by heating it 46°. What does "A." suppose will be the pressure in the equally heated steam-chest? It will be under 33lb. instead of 60. The same heating that has doubled the elasticity of the wet steam has not added a tenth to that of the steam having no access to water, which it has made "superheated" or *dry* steam; indeed, in the language of meteorologists, steam "of 46° of dryness," or about the utmost dryness ever measured in the atmosphere of deserts, either under African sun or Siberian frost. Atmospheric steam (which "Caloric" will find by no means "a new term," but the correct and only name for the air's condensible part, used by Herschel, Glaisher, &c.) is always, unless in a raincloud, superheated one or a few degrees; that is, it has a few "degrees of dryness," rarely 10° in England; but there is no limit to the degrees of dryness possible in steam, as thus expressed, or the degrees of "superheating," as engineers say. There is another mode in which drought and moisture, indeed, are sometimes denoted, by percentage of saturation, so that 30 of drought means the same as 70 of moisture—namely, that there is only 70 per cent. of the pressure of steam that would be possible at the actual temperature; but statements of this kind are very uncertain, and though Glaisher has published an elaborate set of tables for estimating them, the real percentage, or the weight of steam present in a cubic foot, are really hypothetical till more shall be known of the law of density in steam near saturation, which is very different from that of elasticity, or from the gaseous law prevailing approximately in steam superheated more than 10°, and more nearly the drier it is. The only reliable way as yet of defining dryness is by the thermometric degrees the steam is superheated, or how many degrees its actual temperature exceeds its "dew-point," or the degree to which bodies must be cooled to condense it, or be wetted by it. Now, in the above steam-chest, the temperature we have supposed 296°, but the steam is no denser than when it was at 250°, and the chest or part thereof would have to cool to 250° before any would condense into water or dew. It is, therefore, at 296°, rightly said to be 46° dry. But the boiler steam, also at 296°, has not a single degree of dryness. If cooled to 295°, some would condense. It is simply wet steam. Atmospheric steam, where it is not raining, is dry steam (and usually some few degrees dry), even if resting on the sea, because it is not in equilibrium therewith, or does not prevent the sea evaporating. But the water in a close boiler, as long as its temperature is constant, is not evaporating at all. At 296° the steam has a certain density, and the rest is water. Not another particle of the water can become steam till either steam is let out or the temperature rises; as truly as not a particle of the steam can fall as liquid till either the temperature is less or the boiler's capacity reduced. "Caloric" and "A." must therefore observe that wet steam and dry or "superheated" steam may each be of any pressure, any temperature, and any density; but in wet steam these three are so connected that when one is given both the others are fixed, while in dry there is no such fixity. Thus, wet steam, to have double the atmospheric pressure, must be of 250° Fahr., and weigh a certain number of grains per cube foot. But steam weighing less than those grains may have that same double atmosphere force if it be hotter than 250°. It will not then be wet, but dry or superheated steam, and the degrees above 250° be its degrees of dryness or superheating. On the other hand, no steam, below 250° can have this elasticity, nor the density of the wet 250° steam, though it may have that of dry double atmosphere steam of a certain degree of dryness. All wet steam (and, therefore, boiler steam) is the coldest that can be either so dense or so elastic, and the densest that can exist with no greater heat, and the most elastic with no greater heat. Dry steam of the same pressure will necessarily be both hotter and less dense, but dry steam need not have the same pressure, nor any fixed pressure, or temperature, or density. In the case above supposed, the boiler steam and that of the steam-chest, both at 296°, would have their densities as 2 to 1, but pressures only as 60 to 33. Again, in the steam-chest, as originally shut off, at 250°, and as heated to 296°, the wet and dry steam are necessarily of the very same density, but the latter one-tenth more elastic, from containing more heat and no less matter. If allowed to expand one-tenth, without loss of temperature, it would be at the same pressure as it was at 250°, but contain more heat and less water in a cubic foot, being still superheated steam of 296°, and 46° of dryness. It might expand also to the low density and pressure corresponding to wet steam of 100° or of 0°, and would then be 196° dry, or 296° dry. So, if the steam in the air have only the density and pressure of wet steam of 32°, but its actual temperature be 40°, it is said by meteorologists to be 8° dry, which is the same that engineers mean by 8° of superheating. Now, when the atmospheric steam is a few degrees dry (as it usually is even in England), high pressure steam superheated many degrees (as Mr. Lee's appears to have been) would escape without forming visible cloud, which is all that "Caloric's" phenomenon (p. 106), seems to imply.—E. L. G.

[11650.]—**Black Varnish for Microscopic Objects (U.Q.).**—In answer to this query, which seems to have been overlooked by "our" more able microscopists, the best varnish I know of, for general use, is asphalte and gold-size in equal quantities. When made rather thicker it may be used as a cement for shallow cells for dry mounts, and has a very neat appearance. Asphalte is sometimes used alone for the above purposes, but is more likely to "fly" than if used with gold-size. For making cells of any kind of cement, a turntable is indispensable, as it is almost impossible to build a neat cell without it. It is thus described by Davies: "On Preparing and Mounting Microscopic Objects.—At one end of a small piece of hard wood is fixed an iron pivot about ½in. thick, projecting ½in. from the wood, which serves as a centre upon which a round brass table, 3in. in diameter, revolves. On the surface of this are two springs, about 1½in. apart, under which the slide is forced and so kept in position, whilst the central part is left open to be worked upon." Two or more rings are engraved on the table, which are useful in determining the size of any circle to be drawn. A few camel's-hair pencils and a little practice are all that is then required.—C. W.

[11742.]—**Painting Iron Bedstead.**—For the first coat reduce white lead to a working consistency by addition of equal parts of turpentine and boiled linseed oil; for second and third coats, use turpentine alone as a vehicle, the small quantity of oil with which the lead has been ground will be sufficient to bind it. Mix fresh paint for each coat, and allow each to dry well before the next is put on. A small quantity of blue is sometimes added to prevent the tendency to turn yellow. The paint mixed and applied as above will be beautifully white and flat, that is without gloss; should a glossy surface be desired, it may be varnished with clear copal varnish. Instructions for gilding and bronzing will be found at p. 168 of this volume, and gold-powder, which must be applied as directed for bronze, can be obtained of Messrs. Brodie and Middleton, who advertise in the same number. This powder is used for illuminating, and also in the manufacture of the finer descriptions of paper-hangings. To prevent the gold sticking where it is not wanted, the work may be washed over with diluted albumen before the application of the gold-size; the albumen and superfluous gold is removed when the gilding is finished by the aid of a sponge and clean water.—EDINON.

[11766.]—**Piano in Canada (U.Q.).**—A reply from "The Harmonious Blacksmith" appears among the letters.—ED.

[11773.]—**Cleaning Plain Blue Silk (U.Q.).**—Wash and pare some potatoes, cut them into small pieces, and cover with cold water. Let them stand five or six hours, pour the water into another vessel, and with it sponge the silk on the right side, rubbing briskly till clean; then, when not quite dry, smooth on the wrong side with a hot iron.—AJAXEA.

[11879.]—**Thermopile (U.Q.).**—I would advise A. C. Lowe to try bars or wires of German silver and iron for his pile instead of bismuth and antimony. They will be much cheaper and easier to work, and they produce a current of considerable power.—SIGMA.

[11883.]—**Sustaining Weight of Cast Iron Column (U. Q.).**—A solid column of the given dimensions will safely bear 165 tons. A hollow one, having the metal ½in. thick, will safely bear 84·5 tons. —EXCELSIOR.

[11892.]—**Steel Combs** (U. Q.).—I beg to inform "Dusty Miller" that they are made with steel pins or teeth and a metal back, composed of equal parts of lead and tin. The pins or teeth are placed in a mould, and the mixture run on them afterwards. They are dressed with a file. As "Dusty Miller" is not very explicit respecting how many teeth he wishes to put in his combs, or what length he wishes to make them, I am unable to inform him as to size of wire, &c.—R. H.

[11893.]—**B. Sc. of London** (U.Q.).—Professor Oliver's "Botany" (Macmillan), thoroughly got up, together with Dr. Lindley's pamphlet on "Descriptive Botany," are sufficient for the pass examination. The two plants given have to be described only, and Lindley's will do this well. Huxley's "Introduction to the Classification of Animals" will suffice for the zoology; but if thought too concise and dry, Nicholson's "Zoology" is excellent. A little physiology must be studied too, and for this Huxley's little book is by far the best.—SIRIUS.

[11910.]—**The London Encyclopædia** (U.Q.).—This valuable work, published by Thomas Tegg, was completed August, 1829, in 22 volumes, price £18, and was obtainable at the publishers, 73, Cheapside, London, as it probably is now.—THETAMU, Horsham.

[11984.]—**Tea Testing.**—As no one has replied to this query up to the time of writing, I venture to send what I know of the matter. The only method, then, of testing tea is by the taste, in the ordinary manner of the brokers or "tea-tasters." I do not see how any machine or chemical could possibly be introduced into the question. The value of tea is governed by its flavour, and men are paid good salaries for "tasting" it previous to buying for the firms employing them. Of course, "stomach" or "mouth" out of order, the "tea-taster" can't do his work, and it is partly in consequence of the self-denial he has to put in force that such large salaries are paid.—SAUL RYMEA.

[11990.]—**Ice Making.**—There are several machines suited to the requirements of "Anon." Many of them have been noticed in the ENGLISH MECHANIC, and to farther specify them would be very much like advertising. Carré's and Tellier's are tolerably well known, and serviceable machines.—E. M.

[11997.]—**Warming Greenhouses with Gas.** —To "HOUBLON."—I am exceedingly obliged to "Houblon" for his reply to my query in the number for June 28th; and as the cost of gas appears to be so low, I am inclined to try his plan, which I will do next autumn. If he can favour me with a drawing within the next two months or so, he will confer a favour on —H. B. E.

[12007.]—**Purification of Iron.**—How does Mr. Buel expect to utilise the superheated steam in purifying iron? The hydrogen *might* combine with the sulphur and phosphorus; but how about the oxygen? The process has never been used.—MIDDLESBRO.

[12013.]—**The First Watch and Clock Made.** —It seems to be rather difficult to prove when the first watch and clock was made, although we have some accounts of old dates on many watches. I have heard many tales of how time was measured previous to watches or clocks being heard of. It is said that some of the ancient kings had candles made to measure time, by means of figures placed on the outside, which indicated the hours as the candle burnt down; and I have heard of time being measured by means of a jar of water. The jar had a small hole in the bottom, and figures running down from the top to the bottom (inside), and when the jar was filled with water it escaped from the small hole, which of course lowered and indicated the hours from the figures inside. Another very ancient method was the sand glass, the sun and moon dials, &c. I have heard it said that the first clock made went by the force of water, something like our country mills at the present day.—A GLASGOW HIGHLANDER.

[12017.]—**Electro Iron.**—Does not the article on p. 54 supply the information required? If not, specify what is required, and I will try to explain.—ANODE.

[12033.]—**Waterproof Fishing Socks.** — Get some sheet indiarubber—that with a canvas or linen backing. Cut out the socks, stitch the edges, and cement all down with rubber dissolved in naphtha. You can buy the solution ready prepared. If you do not comprehend, write again. Rubber solution laid on canvas would not be "too sticky," but the prepared sheet is much better and cheaper.—E. M.

[12054.]—**The Needle Lock.**—No very detailed description of this lock can be required. It consists essentially of a number of steel wire springs or needles so arranged on the bolt, that when the proper key is put in they are lifted so as to enter holes in a plate, and allow the bolt to be shot back. A number of depressions or dummy holes are made in the plate, so that any attempt to tamper with the lock is foiled by the springs or lever bars entering the dummy holes, and so rendering it impossible to get the bolt back. It is one of the best locks ever invented, for only a key made for it will open it.—SAUL RYMEA.

[12090.]—**Strawberries.**—I think that the chief reason for consolidating the soil in which this plant is grown consists in the suitability to the requirements of the roots thus attained. Stone fruits in like manner thrive in extremely hard ground, forming hard fibrous roots, highly conducive to health and fruitfulness. It is an important part of the gardener's art to study the requirements of different plants in this particular. Potatoes like a comparatively open condition of the ground, yet if too open a total failure of the crop may result. I experienced this a few years since, when my potato-ground included the site of an old hayrick, and the rubbish dug in prevented a proper settlement of the soil. Nothing could look more promising than the plant, and no case of failure in produce more total. Stems half an inch thick; roots long and tough, with a very firm hold of the soil; potatoes the size of peas or beans, distorted in shape. These were the singular features of the case, and the same thing has been experienced in this neighbourhood by using abundance of dead leaves as a manure. It seems that a certain amount of resistance is necessary for the swelling of the tubers. Mr. T. D. Fish has, on this principle, advocated the use of the garden-roller and paviour's rammer on the seed-bed intended for onions. I have used an iron rammer to consolidate the soil in boxes for stone fruits with very encouraging results. I have found that digging between the rows of potatoes during the early period of their growth favours that growth greatly, but I intend to try the effect this year of hard treading close to the stems on a small plot of late potatoes about the time of the swelling of the tubers. I am inclined to think this will tend to prevent the distortion of such sorts as Sutton's red-skin. It is worth a trial. Perhaps some of your correspondents will try the same experiment.—Rev. J. M. TAYLOR, Seer Green Vicarage, near Beaconsfield.

[12092.]—**Curl in Peach.**—"Derf Errac" will find his trees look very different if, just before the buds break, he paints them over with some soft soap and sulphur boiled a few minutes in water; use cold; and every now and then give them a syringing with a weak solution of sulphuret of lime. I make mine myself, but I dare say it is easily bought, though I never asked if it was kept. In this way he will keep his trees clean, and free from aphides.—E. T. S.

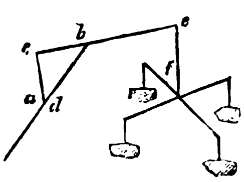
[12094.]—**Preserving Caterpillars.**—The Rev. J. T. Wood recommends hot sand as the best substance with which to fill preserved caterpillars.—AJANBA.

[12130.]—**Electricity.**—I am obliged to "Sigma" for his notice of my question, but what I meant was how far might it be possible to imitate the effects of a galvanic battery by means of common electricity? Some of Faraday's experiments in electro-magnetism can be done by it, and the same effect of a very quick succession of shocks; and the magnetising and the contrary of a needle by the mere stream of it from the conductor without contact with the needle; and then the best way of firing gunpowder brings it nearer to galvanism. I made some experiments once about this but have not seen similar ones mentioned.— E. T. S.

[12131.]—**Electricity Applied to Engraving.** —I have tried the thinly coated plate business, but it proved a complete failure. If you use a thick ground it is impossible to draw on it.—XYLOGRAPHER.

[12144.]—**Timber Houses.**—"Rat-Tat," at p. 389, advises the valuable precaution of inclosing a layer of dead air all round the building to make it damp proof, and he might have added nearly cold proof also. I wish he would inform us if he has tested the difference in effect of a thick and thin layer of inclosed air, for I suspect the difference is very slight, and it may be in favour of a thin layer, for air when nearly motionless carries heat very slowly, and a thin layer of inclosed air must be more nearly motionless than when it has more room to move in.—PHILO.

[12156.]—**Mice Eating Peas.**—I see various plans given to prevent this. I think the most effectual is to put the peas into a deep and widish drill, and then to cover them with dry sand, and rake the earth over all. If the mice come the sand keeps falling down, and so baffles them. I have never known it fail. When the peas are just up the birds do the mischief, and to keep them away fix a stick slanting into the ground, *a*; fix another on the top, so as to be movable, and fix a string *c d* from *e*; hang a string with two sticks, *f* crossed. To the four ends hang some pieces of bright tin. The wind moves these in all directions. They reflect the sunbeams, and most effectually keep away the birds.—E. T. S.



[12172.]—**Constipation.**—An insatiate devourer of books and a greedy seeker after knowledge in every shape and form, I still, in the midst of many and pressing avocations, find time for the perusal of the delightful and profitable columns of the ENGLISH MECHANIC, and am desirous of showing my gratitude accordingly. Constipation is the malady of civilised life. I have seen something, nay, a good deal, of savage life, and I never (speaking of savage life) came across anything of the kind. Under natural conditions the bowels act like "clockwork." Their periodic and regular evacuation is just as needful to animal life as is the motion of the stars to life, or at least being, in the sidereal spaces. When the feculence is not fitly discharged, the more fluid portions thereof are absorbed, the breath is vitiated, the secretions are tainted, the hemorhoidal vessels become pressed upon and obstructed; in short, the whole system is disordered and deranged. A habit of periodicity ought to be established, and this may be realised at any given hour. But the best and most convenient period, perhaps, is after the first meal of the day, or after breakfast. This meal concluded, the individual ought to rise and not assume again the ordinary seat until after the bowels have acted. Nature is more readily solicited in the erect than in the sitting posture, the period of the discharge, of course, excepted. Man, it is to be observed, is, perhaps, the only warm-blooded animal in which one evacuation of the bowels suffices within the twenty-four hours. All other creatures evacuate their bowels more or less repeatedly during the day and night. Had this been the case with man, it would have greatly militated against his dignity and comfort. When Nature asks so little, and when the periodicity of the function is so very very important, human beings ought surely to prove compliant. If we turn lazy and inattentive, the bowels become lazy and inattentive also, and the wholesome economy of our material existence is outraged. The principal if not the only cause of constipation in civilised life is the habitual use of white bread. Our food is too concentrated. There is not a sufficient abundance of coarse neutral material. Green vegetable food is not adequately resorted to. The inferior animals that browse on green food, as the ox tribe, know nothing of constipation. We cannot thus browse, it is true, still we might eat more green food than we do. But in any case the excessive resort to white bread should be avoided. The yellow Indian corn meal, simply wetted with boiling water, adding a pinch of salt and a pinch of sugar, makes beautiful and most wholesome bread, either as cakes or loaves, taking care only to butter the tin rim or pan in which the dough is placed. Rice bread and rye bread are excellent, and so are barley scones and oaten cakes. All these, being eaten, tend less to constipation than does white bread. But, in any case, the certain and unfailing remedy for constipation is the employment of the entire wheat. Let people only consume the furmity or frumenty, that for generations was the food of our forefathers, and constipation will become a thing unknown. Frumenty consists of the whole grain of wheat, kept just covered with water, and simmered for a matter of four hours or so beside the fire. Furmity may be eaten cold or warm, with milk, soup, preserves, sugar, or, simply, a little salt. It may be eaten before, at, or after every or any meal, and when prepared, must be kept in an airy place and in an uncovered vessel. Wheat crushed or cracked, well boiled into porridge, ordinary meal porridge, whole meal puddings, also brown or whole meal bread or biscuits, constitute very good food, but I find the entire wheat, well cooked and plentifully eaten (and if there were adiquate demand people would prepare it for sale) a perfectly efficient and entirely reliable remedy for constipation.—A PHYSICIAN.

[12176.]—**Hydrogen Flame.**—The easiest way to avoid explosion is to use a bottle or tube in which to form the hydrogen, which has a hole at the bottom as I described at p. 399 in reply to query 11835. If "Whitaker" has not got a small tube with a stopcock he can use a bit of tobacco-pipe closed with a piece of soft wax, but a still smaller opening is better, and a stopcock is convenient to regulate the size of the flame.—PHILO.

[12182.]—**Roses.**—Run a sharp penknife through the shoot to be layered, slightly twisting it so as to open the bark. The incision must be made at a joint. Secure it with a hooked peg and tread the soil firmly about it. It will soon form roots, and can then be removed. This works very well for moss roses, and I do not see why it should not do for others.—SARAH.

[12197.]—**Roses.**—Baroness Rothschild, Duke of Edinburgh, Prince C. de Rohan, La France, La Belle Lejounaise, Comtesse d'Oxford, Emilie Hamsburg, Gloire de Dijon.—SARAH.

[12197.]—**Roses.** — Very Select Roses. Proved. Eugene Appert, Prince Camille de Rohan, Souvenir de Count Cavour, Jean Cherpen, all very dark; Senateur Vaisse, Mad. Victor Verdier, Princess of Wales, Alfred Colomb, medium; John Hopper, Anne Alexieff, Centifolia Rosea, Comtesse Chabrilliant, blush; Baron Maynard, Belinden Kerr, White Provence, Mrs. Bosanquet, white.—CORNUBIA.

[12214.]—**The Game of Quoits.**—If the quoit does not allow the whole of the place where the peg ought to be to be seen, it does not count as a ringer, but if it should go over one half of the stick and leave enough for the thickness of the other half to go between the quoit and broken part of stick it is a fair ringer. You must measure the nearest part in sight, but are not allowed to move the clay from the top of the quoit, but measure over it. Eighteen yards is a very good distance, but it is often played at twenty-one yards. I have never seen the rules in print, but have played a good deal myself.—J. G.

[12226.]—**The Portuguese Language.**—Your correspondent need not continue a needless search further for any system upon Portuguese, for two reasons. Several years since I went out to Brazil to superintend the erection of some machinery, and endeavoured to procure a Portuguese grammar, but was informed by Mr. Stanford, of Charing-cross, that there was not one in existence. I took merely a dictionary, but even this I had very seldom recourse to since the language spoken in Brazil is not pure Portuguese; the best way to acquire a thorough mastery over it is to learn it by actual acquaintance with the natives. If your correspondent has a good knowledge of Latin he can readily pick it up. Spanish is only a source of trouble in acquiring it, though similar apart, but different when heard together; this I know from experience, since I was formerly and am now acquainted with the Spanish language. Respecting the latter part of your querist's request for information about Brazil, there are many things necessary to know prior to saying or recommending any peculiar locality. The principal things to be considered are—health, trade or calling, means, intentions as regards pursuits, married or single. If your correspondent can furnish a general, if not a detailed, idea of the above, I will endeavour to answer for his and others information, I having been in the Empire some five years.—J. GILLAIRD.

[12237.]—**The Organ.**—The defect may be caused by the pallets not bedding properly on the bars, or by the key action being screwed up too tight, thereby opening the pallets, or by the openings of the bars behind the pallets not being covered. The first cause is the most serious, and would necessitate taking down the soundboard and bedding the pallets and re-leathering them. The other causes are easily to be remedied.—PNEUMATIC LEVER.

[12258.]—**Organ Construction.**—Several sketches of couplers have appeared in former numbers. The following would be a good selection of stops for a small chamber organ of eight speaking stops:—

GREAT ORGAN.

1.	Lieblich Gedacht	8ft. wood and metal.
2.	Dulciana	8ft. metal.
3.	Principal	4ft. metal.

SWELL ORGAN.

1.	Salicional	8ft. metal.
2.	Vox Celestis	8ft. metal.
3.	Gemshorn	4ft. metal.
4.	Flute	4ft. wood.

PEDAL ORGAN.

1.	Bourdon	16ft. wood.

—PNEUMATIC LEVER.

[12255.]—**Hair.**—My beard, of about the same age as C. Watson's, inflicted upon me at one time the same annoyance as that alluded to, with the addition of (literal, not argumentative) hair-splitting. The "knots like nits" that C. Watson alludes to, are nothing, I think, but the broken and frayed ends of the hair, which seems to break without separating, as a tough stick would do. I cured my beard by applying "brilliantine" every other morning—much against my convictions. I suppose any good oil of a non-drying character would do as well. I think it is dryness, but scarcely a "disease."—H. H. G.

[12256.] — **Preserving Garden Produce.** — I think the most likely thing to suit "Emigrant" would be a garden pit. Considering the cold of Canada it should be a good depth. The pots should be set in ashes, if possible, and a frame with a good thickness of straw or fern for the covering. Take care to give as little water as possible. In the same place, carrots and parsnips might be kept buried in sand. The pit is the best where expense is concerned, and very effectual.—E. T. S.

[12260.]—**Cleaning Back of Teeth.**—"Beauty" need only inquire of the first respectable chemist, and he will get a complete answer to his query, as the course he suggests is common to most cleanly people.—R. M. HATCH.

[12260.]—**Cleaning Back of Teeth.**—As a dentifrice charcoal in the state of an impalpable powder is unrivalled, at once whitening the sound teeth and sweetening the breath, by neutralising the fetor that arises from those which are carious or from a scorbutic state of the gums. Therefore, if "Beauty" takes a small quantity of charcoal, powdered, and applies it with a cloth to the back of the teeth three or four times a week she will need no other remedy. Tried.—WOODMAN.

[12260.]—**Cleaning Back of Teeth.**—"Beauty" may find that the tongue, during the mastication, does all the work of a tooth-brush at the back of the teeth. If the teeth are irregular, which cannot be supposed of such a fair querist, a peculiar form of tooth-brush is used, one in which the back is bent at the middle to a certain angle, so that the teeth in brushing are inclosed in the angle formed, and the back and front brushed at the same time. I have never seen these brushes in use, and the suggestion, which "Beauty" may find useful for some of her friends, may be original.—RAT-TAT.

[12262.]—**Press for Cutting Paper, Card, &c.**—An ordinary machine in which books or other articles are submitted to pressure would do for "Country Printer's" purpose. The cutting edges may be set in suitable form, and soldered to the top or bottom of the working parts of the press, and made to descend on the paper or cardboard. Descriptions of contrivances for cutting paper and envelopes have been given in back numbers.—RAT-TAT.

[12263.]—**Circular Saw Driving.**—If Mr. Davies does not like using a drum or pulley on his main shaft above 3ft. 6in., he must use the 9in. pulley on the intermediate shaft, and attach only a 2½in. spindle to the saw, which would not work well. He must, therefore, use a fly-wheel or drum of larger diameter on the main, say 6ft., 9in., and 4in., or 6ft., 3ft., and 4½in. pulleys on respective shafts.—RAT-TAT.

[12263.] — **Circular Saw Driving.**—Pulley on main shaft 42in., driving pulley of 16in. on counter-shaft; on last-named shaft, a pulley of 60in., driving pulley of 9in. on saw spindle, will give 700 revolutions per minute.—S. J.

[12263.]—**Circular Saw Driving.**—James Davies can obtain the speed he requires for his circular saw by putting a 42in. drum on his main shaft, and a 13in. pulley and 48in. drum on the intermediate shaft. Thus

$$\frac{40 \text{ revolutions} \times 42\text{in.} \times 48\text{in. drum}}{9\text{in.} \times 13\text{in. pulleys.}} = 488 \text{ revolutions}$$

—WOODMAN.

[12264.]—**Freemasonry.**—Let "Edgar" purchase "An Authentic Key to Freemasonry Revealed," 1s. Or, better still, if he purchases the following book, 3s. 6d., Carlile's "Manual of Freemasonry."—UN FRANCAIS.

[12265.]—**Pig Feeding.**—If "C. R." wants his pig for his own eating after he is fed, I would advise him to use barley meal in preference to bran and Indian corn, as the latter does not make the flesh so sound or well flavoured as the former; and, so far as my experience goes, barley meal is the cheaper.—WOODMAN.

[12266.]—**Photographic.**—The cause of your negatives fading away on exposure to light most likely is that your fixing solution is not strong enough. This cannot be too strong. Fill a large glass bottle as full as possible with hyposulphite of soda, leaving room for a small quantity of water, as the solution is used add more water. Thus you will get different strengths, the best of which, of course, you will use. The whole of the creamy film which is on the plate after developing must be dissolved, which leaves the picture clear and distinct.—J. H. H.

[12268.]—**Strengths of Wrought-Iron Shafts.**

$$\frac{(\text{Diameter in inches})^3 \times \text{rev. per min.}}{200} = \text{horse-power.}$$

$$\frac{(2\tfrac{1}{2})^3 \times 170}{200} = 18{\cdot}28 \text{ horse-power.}$$—S. J.

[12270.]—**Charcoal Furnace for Model Boiler.**—It would be best to allow the boiler to sit in a cast-iron vessel somewhat larger, with a small opening at top for the smoke and blast steam to escape. By this arrangement the spirit lamp mentioned could be used, leaving a space at the bottom for either lamp or charcoal, with furnace door and draft holes underneath. A lamp of the dimensions given, with three jets, ought to raise steam enough.—RAT-TAT.

[12273.]—**Water Power.**—"Bœtis" may allow the water to descend through a wide tube for about 12ft. from his mill. There will be a considerable rush of air and water through the bottom of the pipe by which he can utilise by employing a fan-wheel.—RAT-TAT.

[12273.]—**Water Power.**—As "Bœtis" neglects to give the measure of water that flows in any given time through his ½in. tap, no practical reply can be given to his query.—S. T.

[12275.]—**Test for Arsenic.**—The following is Bettendorff's test for arsenic (Zeitschrift f. Chem. [2] V. 492). When a solution of stannous chloride in fuming hydrochloric acid is added to a solution of arsenious or arsenic oxide in the same acid, a brown precipitate is formed, which, after proper washing and drying, consists of metallic arsenic mixed with a small quantity of stannic oxide. In an aqueous solution of arsenious or arsenic acid, stannous chloride produces no precipitate; but on adding strong hydrochloric acid till the liquid fumes slightly, precipitation takes place. Arseniferous hydrochloric acid of specific gravity 1·182 to 1·185 gives an immediate precipitate; the same diluted to specific gravity 1·100 no precipitation takes place. From this it may be inferred that the reaction occurs only between stannous chloride and arsenious chloride; further, that in a solution of arsenious acid in hydrochloric acid of specific gravity 1·115 part of the arsenic is present as chloride, but that hydrochloric acid of specific gravity 1·100 dissolves arsenious acid as such, without converting it into chloride. The reaction above described is extremely delicate and capable of detecting one part of arsenic in a million parts of solution. On antimony compounds stannous chloride exerts no reducing action, even after prolonged heating; hence, the above described reaction may be used to detect arsenic in antimony compounds, the solution having been previously saturated with hydrochloric acid. Another useful application of the same reaction is to the preparation of hydrochloric acid free from arsenic, 412 grammes of specific gravity 1·164 were mixed with a fuming solution of stannous chloride, the precipitate separated by filtration, and after twenty-four hours the hydrochloric acid distilled, the receiver being changed after the first tenth had passed over, and the remainder distilled nearly to dryness. The acid thus obtained gave not the slightest indications of arsenic, either by Marsh's test or by precipitation with hydrogen sulphide. In testing for arsenic acid with silver nitrate, the delicacy of the reaction is impaired by the solubility of silver arsenate, not only in free nitric acid and free ammonia, but also in ammonia nitrate. According to C. Avery (Sill. Am. J. [2] xlviii., 25), the reaction is greatly facilitated by adding to the solution of arsenic acid in nitric acid a few drops of a strong solution of an alkaline acetate, and then a drop or two of ammoniacal silver nitrate. Another very good mode of testing is to drop the nitric acid solution of arsenic on recently prepared silver carbonate, the red silver arsenate then showing itself very conspicuous on the white ground. Metallic arsenic and arsenious acid are easily oxidised by a mixture of potassium chlorate and nitric acid to arsenic acid, which may then be estimated as ammonio-magnesian arsenate. — Watts' "Dictionary of Chemistry."—R. E. W.

[12277.]—**Aniline Black.**—The following is from Watts' "Dictionary of Chemistry:"—Boil together 1 litres of water, 2 kilogs. of starch, 2 kilogs. of roasted starch, 2 kilogs. of aniline, 1 kilog. of sal ammoniac, and 1 kilog. of potassic chlorate. When the mixture has cooled, and immediately before printing, add 1 kilog. of cupric sulphide and 2 kilogs. of tartaric acid. The cupric sulphide may be conveniently prepared by dissolving 1 kilog. of flowers of sulphur without the aid of heat in 4 litres of caustic soda of 38° Bm., and adding this liquid to a solution of 5 kilogs. of cupric sulphate, in 120 litres of water, the solution being heated to 120°. Also by mixing 100 grms. of light aniline (heavy aniline gives brown instead of black) with 80 grms. of hydrochloric acid, 10 grms. of manganese oxide, and 1,000 grms. of water. The precipitate is washed by decantation, and then mixed with ammonia, whereupon its colour changes from green to black, and if the absorption of oxygen from the air be assisted by due agitation, the colour becomes developed throughout the entire mass.—R. E. W.

[12284.]—**Essence of Phosphorus.**—Essence of phosphorus is made by dissolving one gramme of phosphorus in 100 grammes of rectified ether. This should then be diluted in the proportion of one part of the solution to ten of rectified spirits of wine, and one drop is a sufficient dose.—R. M. HATCH.

[12285.]—**Logarithms.**—See answers to query 9886 towards the close of last volume.—EXCELSIOR.

[12294.] — **Engraving by Graphotype.**—Graphotype is not superior to wood engraving at all. In the graphotype process, if the lines of a tint are under a certain width apart, the brush will not clear it sufficiently, and, consequently, it will print dirty. Another fault is, that the ends of the lines are not lowered; therefore they print hard.—XYLOGRAPHER.

[12296.]—**The Nightingale.**—I have waited a week, expecting some of our friends in the East Riding to reply to this query, to which I can reply in the affirmative. There has been two nightingales heard nightly in Aketon wood, about two miles from Castleford, during the whole of the spring months of the present year. They were so near together that they could be heard at one and the same time. I myself only went on one occasion, and then only heard one of them, but two of my sons whom I left behind heard them both the same night; as did scores of my neighbours both before and after that time.—BOD.

[12300.]—**Direction of the Terrestrial Meridian.**—If "Youngster" will take the trouble to consult replies to queries in the last few volumes he will find numerous directions for finding a meridian line, which I suppose is the line he wants. I am too much engaged at present, or I would refer to the volumes for him. Try about May, June, and July, 1870.—W. R. BIRT.

[12304.]—**Phrenology.** — The period of characteristic development differs very much in different individuals, and I should recommend "Saul Rymea" to go into his garden, make a few observations in writing respecting the period of development of his plants indoor and outdoor, apply the same or synonymous terms to the human plants he sees every day, and he will arrive at a correct solution of his query. Some children manifest their characteristic qualities at a very early age, are precocious—*i.e.*, developed too early, a diseased condition, often superinduced by parental vanity—the sequel, early death. Others arrive at thirty years of age before they show a spark of intellectuality, others are idiotic and never do. "Saul Rymea "(says "if "the brain exercises any influence on the shape of the cranium, to which I reply that all growth is from within, and would ask, does the bark of a tree obstruct its growth? And now for the horns of the dilemma. "Saul Rymea" guesses correctly in supposing the brain capable of influencing the shape of the cranium before the latter has assumed its osseous nature, but "Saul Rymea" must learn that education, as he applies the term, is quite a misnomer, for he seems to labour under the fashionable error of regarding it as a cramming process, whereas the etymology of the word itself furnishes a complete solution of our friend's difficulty. The fact is, our education begins before our birth. But to be brief, and not lay myself open to the charge of monopolising space, I conclude by asking "Saul Rymea's" attention to the following:—(1) The pre-natal influences are nearly everything—to prove it read biography. (2) The soft and impressible state of the infant brain: mere physical pain, as in teething, often produces death, by shattering its nerves to pieces—these are the mother's words—by convulsions. (3) The sutures of the cranium, which Nature has not forgotten to provide, to facilitate the synchronous growth of brain and cranium. "Saul Rymea" should ask any old woman about this point. (4) As regards education, I now refer, of course, to post-natal influences; it is a fact that every look, smile, frown, angry word, or tone, educes similar feelings in the child; but "Saul Rymea" will find it necessary, in all his inquiries, to remember that in each of these influences Lord Bacon's concise remark, "it feedeth what it findeth," applies with incontestable force. "Saul Rymea" must not, however, think my remarks in the slightest degree tainted with materialism, fatalism, &c., as the views I have expressed are perfectly consistent with a progressive spirit; and since no child is consulted as to when and where, in what age and country it will be born, neither can it eradicate after its birth any of its powers; the only thing it, or "Saul Rymea," can do is to modify their manifestation.—ULTRA-MARINE.

[12304.] — **Phrenology.** — Phrenologists will not allow that they are in the dilemma "Saul Rymea" supposes, for they allege that the bones of the skull as they grow are moulded so as to fit the brain, and that they continue to grow long after education commences, and that if the intellectual faculties and moral sentiments be more educated by exercise than what they call the animal propensities, the fore and upper part of the head gives more and becomes larger in proportion than the hind part of the head. They further allege that the shape of the head may alter very considerably, though more slowly in adults, and does alter if some organs of the mind, as they call certain portions of the brain, be more exercised than others. I do not consider what is called phrenology either precise enough or proved enough to rank with established science, but it is far more like a science than its opponents would represent it, and a great deal of useful knowledge is taught by phrenologists, along with not a little that has but little foundation in true observation. —PHILO.

[12304.]—**Phrenology.**—"Saul Rymea" asks at what period of life the organs are developed. As our motto is *Res non verba quaeso*, I will answer him as briefly as possible. There is no period of life at which the organs will not grow if vigorously exercised. In childhood the propensities preponderate. Then the intellect becomes developed, and next the moral faculties. There is no definite time for the development of organisation after birth; circumstances tend greatly towards developing particular organs. If "Saul Rymea" is at all conversant with anatomy he must know that the brain is first formed before the boney particles are laid down, consequently the bones of the skull adapt themselves to the brain, and are not completely ossified for several years after birth. Now for the dilemma into which he presumes phrenology to be placed—viz., that the organs cannot grow after the skull becomes ossified. Two processes are continually at work in the human frame—viz., absorption and deposition. Presuming an organ to be actively exercised, there is a considerable friction between the convolutions in action and the corresponding interior part of the cranium, and as a matter of course the waste matter is carried off by the absorbents. So active is this that in many cases of madness the skull becomes quite sore and painful to the touch; in some cases quite worn through. I possess the skull of a drunkard worn in this manner in the region of the temples. Let "Saul" take a skull of any person (if known all the better), and place a light within it, and he will see the active organs where the light shines through. As to his belief or non-belief it matters little, the facts are the same, and we can say with Gall, This is truth, although at variance with the philosophy of ages.—W. CRISP.

[12304.]—**Phrenology.**—"Saul Rymea" appears to think that the organs of the brain, according to phrenology, are indicated by "bumps" on the skull, whereas, in general, the surface of the skull is perfectly smooth, and it is only when an organ is developed in excess of the neighbouring organs that an elevation or protuberance is presented. The brain of a child at birth weighs about 10oz., and that of an adult from 2½lb. to 3¼lb. (Cuvier's weighed 4lb. 10oz.); and as the brain of a child completely fills the skull, the latter must, of consequence, be considerably expanded and enlarged to contain the additional volume of brain when it reaches maturity. Any anatomist, without appealing to phrenology, will satisfy "Saul Rymea" on this point. Cuvier states that the brain moulds itself in the cavity of the skull, which it fills exactly in such manner that knowledge of the bony part gives us information at least of the form of the exterior of the brain. It is patent to every one that the brain and skull of a child are considerably smaller than that of an adult, and hence both of them must be enlarged to a considerable extent before they arrive at maturity. How could this occur if the bones of the head are not "distorted by the soft mass of the brain"? The skull is not an adamantine barrier confining the brain within specific boundaries. Although a strong, it is a changeable covering, and will always accommodate itself to the development of the brain during its growth. There are many instances on record where in certain diseases of the brain the head has been enlarged to twice its normal dimensions. How could this happen if the skull did not expand to meet the requirements of the enlarged brain? I hardly know what "Saul Rymea" means when he states that "either the brain must have received its peculiar development before education steps in," &c. Surely, he does not suppose that education either creates or develops organs. It only intensifies their action or gives them more vigour, but Nature herself gives the tools, and education only applies them to their legitimate use.—NORTHUMBRIA.

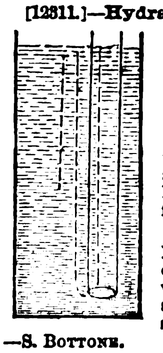
[12305.]—**Locomotives.**—The principal advantage is that the heat is more fully utilised in a long-barrelled locomotive than in a short one, and, as a consequence more steam generated by the greater area of heating surface. There are also many disadvantages; a greater waste of boiler tubes by the blast cinders, and cost of repairs: but some engineers think that the one or two advantages of long-barrelled locomotives more than counterbalance their numerous defects.—RAT-TAT.

[12306.] — **Botanical Names.** — The botanical name of the Persian or French willow is *Epilobium angustifolium*, the flowers, which are purple, grow on a long spike; the plant is a native of Britain—it will grow almost everywhere, even in the confined air of London. Its congener, *Epilobium hirsutum*, is a fine, showy plant, with large rose-coloured flowers. It thrives well in damp situations.—W. R. BIRT.

[12306.] — **Botanical Names.** — The French willow is *Epilobium angustifolium*, natural order, *Onagraceæ*. I cannot find such a name as rose-pea in any of my books. It may be *Ononis campestris*, a plant with pea-like, rose-coloured flowers, and leaves accompanied by spines and prickles.—CORNUBIA.

[12311.]—**Hydraulic.**—The well being 25ft. in depth, containing 10ft. of brackish water, there are 15ft. of rain water added to it, which, being intimately mixed, renders it tolerably palatable, and as long as the water is above the spring level, of course, no more brackish water will flow in. "Glaston's" error appears to be that he imagines that the two kinds of water ought to keep separate. Now, beer and water, differing considerably in specific gravity, can only be filled into a tumbler and caused to keep separate by interposing a silk handkerchief, and the slightest disturbance, such as pumping, would inevitably cause instant commingling. I very much doubt the possibility of any two sorts of water being introduced into one receptacle without instantly intermixing. Also, it must be taken into account that when the natural spring level is added to, that it will flow back out of the well until the one balances the other.—A., Liverpool.

[12311.]—**Hydraulic.**—The light water is on the top not only in the well but also in the tube, and therefore the light water comes out of the tube and the top of the tube is immediately again filled up with light water. The water moves round as the dotted lines show. The water moves like the air in this respect. If you open a barrel of beer, wine, &c., in the lower part you will get the fluid from the top.—H. MEYER.



[12317.]—**Red Prussiate of Potash** may be prepared by acting on a solution of yellow prussiate with chlorine till it no longer gives a blue precipitate with iron persalts, evaporating and crystallising. —S. BOTTONE.

[12318.]—**Artificial Oils.**—The oils mentioned are isomers, but have not as yet been converted into one another. Oil of cinnamon and oil of winter green can be prepared artificially. See Roscoe's "Chemistry," 1871 edition.—S. BOTTONE.

[12319.]—**Dyeing Pulp for Sugar Paper.**—Add a small quantity of green copperas. You can get it as dark as you like by increasing the dose.—S. BOTTONE.

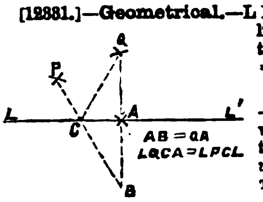
[12321.]—**Chess Player.**—I have stated in my chess columns in the *Gentleman's Journal*, and also in the *Echo Americano*, that the automaton chess player at the Crystal Palace is moved and worked by a man who is concealed in the figure. I wrote a longer article on it about three or four years ago, which appeared in two or more German papers and was afterwards translated for the Dutch paper *Sissa*.—H. MEYER.

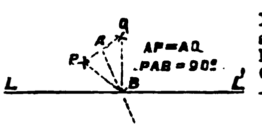
[12328.]—**Scarecrows.**—Try a set of model windmills, carrying pieces of looking-glass on the arms. Proved.—S. BOTTONE.

[12331.]—**Geometrical.**—Let the given points be called A and B; join them. If the line A B be at right angles to the given line it is impossible to solve the problem, unless the points A and B be equidistant from the given line. If A B be not at right angles, bisect it, and through the point of bisection draw a straight line at right angles to A B. Produce it, and it will cut the given line in the required point. Prove by Euclid's "Elements," Book I., Prop. 4.—CERVUS.

[12331.]—**Geometrical.**—With any radius exceeding half the distance between the points (their full distance is a good radius to take) strike arcs from each of them intersecting; and a straight line through their two intersections has any point in it equidistant from the two centres; consequently will cross your given line at the point required.—E. L. G.

[12331.]—**Geometrical.**—L L¹ = the given straight line. P and Q are the two given points. B P = B Q.—H. MEYER.





[12336.]—**Vine Root.**—Cuttings from the vine may be struck in the early spring months, *under glass*.—S. BOTTONE.

[12338.]—**Hyacinth Bulbs** are dried and stored in paper bags hung up. Plant out in October or November. —S. BOTTONE.

[12340.] — **Flour Paste.**—A few drops of carbolic acid, or a few grains of corrosive sublimate, added to each pound of paste made, will prevent mouldiness. Essential oil of cloves is also recommended.—S. BOTTONE.

[12348.]—**Spanish Pronunciation.**—The "th" sound is the only correct pronunciation; the "ss" is slovenly.—S. BOTTONE.

[12348.] — **Spanish Pronunciation.** — I wish some competent traveller would answer one part of this query—namely, whether what the grammars say of every *z*, or every *theta* (as Spaniards call it) really applies to that letter when final, as in the words *vez, paz, cruz*? I have heard natives of Spanish America, except when decidedly vulgar, so constantly give the *th* sound (sharp as in *think*) to both *ce, ci*, and the initial and medial *z*, as to leave no doubt of its correctness; and also give the final *d*, as of *Verdad, Madrid*, very near our flat *th*, as in *the*; but a final *z* I have only heard sounded like English *z*, and I should like to know whether this is an Americanism?—E. L. G.

[12348.]—**Spanish Pronunciation.**—I beg to assure "Cast Steel" that the Castilians and inhabitants generally of the Northern provinces of Spain do most certainly pronounce the *c* before *e* or *i*, and the *z* before any vowel, as *th* (hard), and not as *s*. They talk of Zaragoza, which they pronounce as if written Tharagotha, and they say Ciencia (pronounced Theénthia), meaning science. These peculiarities I myself have heard in North Spain, especially in Old Castile, but I was told that in the southern provinces, especially in Andalusia, the sounds given above are changed to that of *s* sharp, and such words would be pronounced Saragosa, and séensia. Though the Castilian is the purest form of prenunciation, I am inclined to think that the Andalusian form is of wider use, and it is the one which is almost invariably used in South America and the Spanish settlements.—WM. WRAY.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "C. W." has answered 11650; "The Harmonious Blacksmith," 11766; "Ajanes," 11773; "Sirius," 11879, 11893; "Excelsior," 11883; "R. H." 11892; "Thetamu," 11910.

QUERIES.

[12359.]—**Sulphurous Smell after Thunderstorms.**—A gentleman asked me the other day if I knew what was the cause of the sulphurous smell which succeeds a thunderstorm. I replied that it was generally attributed to the formation of ozone. But he said that it is a well known fact that there is no ozone in China (according to the usual tests), and yet the same peculiar smell is noticed. If any of your correspondents can verify or explain the circumstance, I shall be greatly obliged.—B. C.

[12360.]—**Pivots.**—Will any brother inform me the best way to harden small drills for putting pivots into staffs, &c.?—NO SOFT SOLDER.

[12361.]—**Carbon or Charcoal Pipes.**—I wish to make some tobacco pipes of the above material. Will any reader describe the process?—W. ALLAN.

[12362.] – **Formula.**—What is the formula for finding the content of the middle frustrum of a circular spindle? —W. ALLAN.

[12363.] — **Recovering Indigo.** — I should feel obliged if any of "our" chemical correspondents would inform me how to recover indigo from other blues, grease, and dirt. I have a great quantity, and it should contain about 25 per cent. of indigo.—J. B.

[12364.]—**Hoist.**—I have made a hoist from a sketch by H. R. Gwastad, given in your very valuable journal, Feb. 9, 1872, reply 10551. Everything is fitted up in the best possible manner, friction pulleys are 4in. wide, and turned driving pulley on A shaft is 12in. diameter, strap 2in. wide. It will lift 60lb. well, but I want to lift 140lb. This it will not do. Will H. R. Gwastad or some other obliging correspondent tell me through your journal where I am at fault, as I have been at a considerable expense in fitting it up?—BOLTON TROTTER.

[12365.]—**Elder Flower Wine.**—To each gallon of water put 4lb. of fine brown sugar, one lemon, and 1lb. of raisins. The raisins are to be picked, chopped, and put into the cask; boil the sugar and water, and pour it over the elder flowers, and when new milk warm, put a little yeast, and for each gallon of liquor put half a pint of elder flowers, which must be picked off when just ready to fall off the trees; pick them clear from stalks, then let all work in the tub a day or two, then turn into the cask on the raisins, and when done working bung up and keep for two months. The above is an excellent recipe, with this exception, the wine is never brisk and sparkling as it ought to be. Can any of your readers inform me wherein I fail to make it so?—WAYNFLETE.

[12366.]—**Pianoforte without Strings.**—I am much obliged to "The Harmonious Blacksmith" for his kind attention to my query respecting soundboards (12175). In his reply (p. 357) he alludes to a piano without strings, the patent of Mr. Goldsworthy, and also to one which he possesses, formed with vibrating spring bars, of which, probably, the sounding wire of an American clock is a rude yet apt illustration. Doubtless, as "The Harmonious Blacksmith" is a most ingenious and scientific mechanic, this piano of his is not only curious but harmonious—even an improvement on Mr. Goldsworthy's instrument, and, therefore, a description of it could not fail to be highly interesting to the readers of the English Mechanic. I trust he may regard it in this light, and be induced to give his fellow mechanics such a practical account of it as will set them all either constructing or thinking. A piano of this class has the pleasing peculiarity of remaining continually in tune, never requiring but the first tuning, a quality eminently desirable on shipboard. I think, too, it could be constructed more cheaply than the ordinary instrument.—E. B. Fennessy.

[12367.]—**Oval Turning.**—I require to turn a number of pieces of hard wood of an oval form about ¾in. in thickness, and 3½in. length of oval—having only a simple lathe I am confined to circles. Can any of "our" correspondents kindly inform me if any special form of lathe is required for ovals, or can it be managed by a chuck? If so, where are such chucks to be procured, and the probable cost? Any information on the subject of oval turning will be acceptable.—Photo. Bristoliensis.

[12368.]—**Imitation Bronze.**—I am exceedingly obliged to M. W. Bolton for the imitation bronze recipe, the effect of which is excellent. I, however, find a great difficulty in dissolving the corrosive sublimate. Ought it to be boiled in the vinegar, or would it be better to dissolve it in some kind of acid?—J. W. C.

[12369.]—**Water Powder.**—I want to get an instrument to make water powder (French poudre d'eau). On the continent I have met with a small apparatus in indiarubber of English make and patent, much cheaper and working nearly as well. Can any subscriber give me some information, as the makers I have asked about it do not know such instrument?—L. J. V. G.

[12370.]—**Liquid Rosin.**—Will "Fiddler" allow me to ask him if he has tried the colophonium or liquid rosin lately advertised, and with what result?—L. J. V. G.

[12371.]—**Truss.**—I shall be much obliged to any of your readers who can inform me where I can get a truss for rupture, that can be worn when bathing; or whether there is anything of the sort made specially for the purpose. The suffering is so intense when swimming that I am afraid I shall soon have to forego that pleasure unless I can get relief.—Nosbor.

[12372.]—**German Concertina.**—I have been repairing a German concertina of my own at home, and I should like to know if any of "our" readers can tell me how to get out of my trouble, for I have made a set of four plates of tongues in steel instead of metal, but I cannot make them speak. I have tried every way, but I have failed.—Amateur.

[12373.]—**Softening Spring Water.**—I have a deep well of excellent spring water, but unfortunately too hard for general domestic use. The interior circle of well is 3ft. 6in. diameter, with an average depth of 2ft. in water, which does not flow over at any time, nor fail in supply even in extreme dry seasons. I wish to know if some chemical production cannot be periodically put into the well, in proportion to the daily consumption of water, and thereby render the same more soft and effectual for its many services. As each bucket of water dipped from the well would probably weaken the action of any chemical influence through the continued supply from the spring, would it be more effectual if contained in a tank for daily use? Perhaps your talented and instructive correspondent, Mr. Bottone, will favour me with his suggestions for relief in this difficulty.—Gillem, Ontario.

[12374.]—**Ancient Wrought Iron.**—We are told by Mr. Forbes, F.R.S., in his report on the progress of the iron and steel industries (Feb., 1872), as a proof of the antiquity of iron smelting in India, and also of the large forgings in wrought iron which could be executed by a people who now appear to have entirely lost the art, the fact that Mr. Mallet has directed attention to a wrought-iron pillar situated at the mosque of the Kutub, near Delhi, which must be more than 1000, and may be as old as 1500, years; yet is as large as the screw-shaft of some of our largest steamships; that part of the column above the level of the soil being 48ft. high, with a diameter of 14ft. 4in. at the base, and 12in. at the top immediately below the elaborately chiselled capital. Are there any among your obliging correspondents who can throw more light upon this eventful period of early handicraft *v.* the present age of machinery?—Gillem, Ontario.

[12375.]—**Metallic Stain for Wood.**—I have heard of such giving a very dark—almost black appearance to deal; afterwards to be varnished. Will one of "our" correspondents oblige me with name and mode of preparation?—Gillem, Ontario.

[12376.]—**To "The Harmonious Blacksmith."**—It would give me great pleasure to comply with the request contained in the postscript to letter 2416; but I scarcely know what it is on which my opinion is desired. If our friend will kindly lighten my darkness on this subject, he will oblige—Beacon Lough.

[12377.]—**Fall of a Bullet.**—I was about sending a question on the following subject, when I happened to see Mr. Proctor's letter on "Spinning Tops and Gyroscopes" in your last issue. In this letter he says:—"It is, of course, perfectly true that gravity draws down the most swiftly travelling bullet—fired horizontally—so that it reaches the ground as quickly as a ball dropped from rest from the same height." In a book on practical mechanics a similar sentence to this is modified by the words "from the top of a high tower," being added to the phrase "fired horizontally." I can conceive of a bullet fired, and a ball or bullet simultaneously dropped, from the top of a tower 200ft. high reaching the ground simultaneously; but it seems to me impossible that a ball dropped from the height of 4ft. from the ground should take as long in falling as a bullet fired horizontally from the same height. I should be much obliged if Mr. Proctor would make this matter a little more clear—by diagrams if necessary—now that he has performed a similar operation for the upward deflection of bullets.—Puzzled.

[12378.]—**Bat Making.**—What tool does a bat maker use in smoothing; and how do they make them hard so that they will not dent with the ball? Which is the best glue for gluing in handles? Where can I get cane for handles?—Tim.

[12379.]—**Packing Piston Rings.**—Referring to query 12158, concerning packing rings of piston, I would like to know whether "A., Liverpool" intends the piece of sheet brass to be fastened inside. I would also like to ask if gun metal would do for rings, as I have an iron cylinder I would like to put up.—Dundalk.

[12380.]—**Light.**—Let there be a darkened room with no entrance save a door facing the sun; in that door let a hole be bored, and a ray of light comes in; cover the hole; what has become of that ray of light?—Dai Bach y Ship.

[12381.]—**Education.**—In common with many other subscribers I have boys to educate, and as I am not tied down to any part of the country, I should be glad to know what towns offer the greatest advantages. I want an education to fit them either for professional or business life, and it must be cheap. There are, I believe, some institutions in which boys are educated with a view to the royal and merchant navy; also a college where the relations of medical men enjoy certain advantages as to fees, &c. I should prefer a seaport town or the neighbourhood of London, but this is not essential. Any particulars will be very acceptable to—Paterfamilias.

[12382.]—**Electrical.**—I should feel grateful to Mr. Tonkes or any other electrician, if he would inform me in what book the particular subject of determining internal resistance of a battery by means of a tangent galvanometer, the power of the two cells, amount of external resistance brought in by the introduction of coils. Although this is an old subject, yet in the books on the subject which I have studied, I have found it either entirely omitted or else skimmed over. Accordingly, if Mr. Tonkes would explain it fully or else name some book in which it is so done, I should be most deeply obliged, showing how the sine galvanometer differs from the tangent in construction. In reading a work on electricity, I saw it mentioned that a machine entirely made of guttapercha with rubbers of hareskin was both less expensive and also more powerful than a plate glass machine of the same size. I should be obliged if any of your contributors that have tried it would state their experience, and also the cost as compared to an average plate machine.—E. N. D.

[12383.]—**Working Perfect Plane Surfaces.**—Will any reader kindly describe a good method of grinding perfect plane surfaces, and polishing the same?—R. Roberts.

[12384.]—**Coppering Carbon.**—Will some reader of the Mechanic please have the kindness to tell the easiest way of preparing carbon, so that copper plate may be soldered to it?—F. J. Wall.

[12385.]—**Sulphur in Wall Papers.**—I have recently had an air-tight glass case papered with an ultramarine paper, and find silver goods put in it discolour very rapidly, and as this stultifies the object of a glass case, I should be obliged if any "mechanic" would suggest a remedy to me. My idea is that there is sulphur in the colour, from the character of the tarnish. If so, I suppose there is no remedy but tearing off the paper and putting a new one.—Gour.

[12386.]—**The Prevention of Incrustation in Steam Boilers.**—Having proved that the use of a few pieces of oak (the greener the better) in a steam boiler prevents incrustation, I should like to inquire the why and wherefore of this. A dark powder results from the use of the oak, which half an hour's work will remove from the boiler, whereas formerly it occupied two of my workmen for two days, at intervals of a month, to chip off the incrustation with hammers, this being, besides, a hot, arduous, and irksome task.—J. D. K.

[12387.]—**Amateur Organ Building.**—Thanks to "J. D." for kind attention to query 11837. I am sorry I did not mention at the time that the only room I have available is 18ft. long by 3ft. 6in. wide, so that I shall, under these circumstances, have to elongate the dimensions given, making the same area—viz., 7ft. by 2ft., allowing for Bourdon, which will have to be put at the back. Will bellows of these dimensions be more difficult to make, and will double feeders be advisable to make it do its work well? Would it be better to make the Bourdon on a larger scale than 6in. by 5½in. CCC, for the organ in the above mentioned query, or will it be powerful enough on a 2½in. wind? Which is best, a Bourdon of small scale, well blown up, or one on a large scale, moderately winded? Of course, where room is the greatest consideration, the former is best, but which is really most efficient? I am glad to see that "J. D." is better, and hope to see soon a continuation of his interesting papers, as no doubt a great many besides myself are at a standstill for further instructions.—Y. Z.

[12388.]—**Onions.**—Will any reader tell me which is the best kind of onion seed to sow at the end of July, in order to have very large onions for exhibition next summer, and yet have the property of keeping well. I have tried the Tripolian onion, but it does not keep very well after it is taken up.—A Coal Miner.

[12389.]—**Dirty Mercury.**—I have a lot of mercury which seems to be adulterated with lead, tin, or some other combustible. Will any kind reader of the English Mechanic please to give some information as to the best way of cleaning out the adulteration? Also, how is a barometer tube cleaned after being filled with the above?—C., Glasgow.

[12390.]—**Chemical.**—The writer would be obliged to any of your readers who can inform him of one of the best works on elementary chemistry suitable for a —Home Student.

[12391.]—**National Losses.**—Have any political economists formed any estimate of the absolute loss under all heads which we, as a nation, are called on to make good annually?—Excelsior.

[12392.]—**Bee Management.**—In November last I became the possessor of three stocks of bees in straw hives. I know nothing of bee management, and the result was that two out of the three stocks died in May; the remaining stock is very light. In taking up the hives I found on the floor board a number of maggots ½in. long, and protected with something like wool. In taking out the comb I found that the maggots had made roads through it in all directions. I also found six maggots on the floor-board of my remaining hive. I have made a wooden hive 11in. square. My wish is to transfer the bees from straw hive to the wooden hive, how to do so I know not, as the straw and wooden hive are not the same size and shape. I wish to know how to transfer them, and when.—W. T. L.

[12393.]—**To Steady a Sketching Board.**—May I trouble a correspondent to advise me about steadying a drawing-board, to which is attached an optical instrument, such as a camera lucida, in any place? I suppose a tripod stand is the most likely thing, but even that puzzles me in endeavouring to steady it, on stone pavement, for instance, and how about the wind?—Poloski.

[12394.]—**Fret Saw.**—I have a fret saw, which makes a rare clatter. What is the best arrangement for making the least noise?—Chip.

[12395.]—**Extracting Wax from Old Comb.**—How can I extract the wax from some old comb? I have tried boiling and straining it, but can get no wax. I have been turning out some old hives, and want to do something with the comb, which is mostly black with age.—W. Hawkins.

[12396.]—**Rouge.**—Will any kind friend tell me the practical method of preparing rouge or plate powder as made in factories (rouge and putty powder works) from sulphate of iron?—L. T. W.

[12397.]—**Boatbuilding.**—Will some reader kindly inform me what sort of wood the ribs and planking of boats are made of, whether the ribs are bent or cut to the required shape? Also, what shape the planks are cut so as to get a straight gunwale; are they cut tapering on both sides or only one?—W. S.

[12398.]—**Silver and Gilt Articles.**—Can some of the numerous readers of this journal give me a few hints on the best means of cleaning and restoring to its original colour old gilt, parcel gilt, and silver articles, without injuring the articles? Also, tell me how frosted silver can be cleaned and whitened? Is there any work on this subject from which I could get any information? Is frosting, burnishing, oxydising, &c., beyond the skill of an amateur?—Spero.

[12399.]—**Organ Building.**—Will any of "our" readers interested in organ construction kindly give a description of the viol d'amour stop? Also say if there is any difference between the Wald and Claribel flutes, and which is the best way to arrange the pedal Bourdon when the room is only 8ft. high: to lay the pipes down and have vertical windchest, or to elbow them as reeds are sometimes done?—Y. Z.

[12400.]—**Parrots.**—Can any reader tell me the name of a pair of parrots that I have? Breasts and tops of heads bright scarlet, throats blue, backs red and black, lower parts of wings green and blue, tails light blue underneath and very dark blue on top, slate coloured feet, horn coloured bills. They are about 12in. or 13in. in length, half of which is tail. I also want to know if they are likely to breed, for they feed each other like pigeons.—F. S. M. W.

[12401.]—**House Painting.**—I am about to do some painting. Will any of "our" readers inform me what proportions of white lead, turps, boiled oil, and driers to use?—J. W. C.

[12402.]—**Grease on Leather Bands.**—Can any fellow subscriber inform me if it is possible to take out grease from leather bands, so as to look new again?—Wholesale.

[12403.]—**Brass Moulding.**—Can any reader inform me what process lead has to undergo before it will mix with copper and zinc? I have been told that it can be killed by some chemical.—Nottingham.

[12404.] — **Trigonometrical Theorems.** — The following theorems can be deduced from Legendre, liv. III., pr. 18, or from Euclid VI., 3.—

$$\text{Sec. } 2\,A = \frac{\tan.\,2\,A - \tan.\,A}{\tan.\,A} : \quad (1)$$

$$\text{Sec. } A = \frac{\tan.\,A - \tan.\,\frac{A}{2}}{\tan.\,\frac{A}{2}} : \quad (2)$$

Will some mathematician furnish the deductions, either from Euclid or Legendre, and prove the same by trigonometry?—Thetamu (Horsham).

[12405.]—**Boiler for Model Steamboat.**—Can any subscriber tell me what should be the shape and size of a boiler I should want for a model paddle steamboat 3½in. depth of hold, 4½in. beam, and 2ft. 8in. long? the size of my cylinders are four-fifths of an inch diameter, and 1½in. deep. What material would be best?—A. W. D.

[12406.]—**Worm-Eaten Violin.**—I have an old violin, rather badly worm eaten, can any one tell me how to prevent further decay?—F. S.

[12407.]—**Checkering Tool.**—Can any correspondent inform me how to make a checkering tool for checkering hard wood or ivory; also how to make steel rings, 2in. long, 1in. diameter, ⅛in. thick, which must be sound?—A Trimmer.

[12408.]—**Quill Pens.**—How are quills prepared to fit them for making pens.—Spero.

[12409.]—**Transferring Pencil Drawings on Paper to Boxwood for Engraving.**—Can any of your numerous readers inform me how to transfer pencil drawings on paper to boxwood for engraving the same.—E. B.

[12410.]—**Chemical.**—Will any of your subscribers kindly inform me of one, or some of the simplest and most effectual ingredients, or basis of ingredients, which would have the power of preventing marine, animal, and vegetable matter from adhering to iron, but at the same time free from any damaging or corrosive effects on iron? The substance I inquire about need not possess adhesive qualities. I want to apply it in conjunction with a composition which has the last named quality.—W. J.

[12411.]—**Expansion Joints.**—Will any subscriber give description of one or two of the best expansion joints for a long cast-iron gutter? State how far apart it is advisable to place them.—Excelsior.

[12412.]—**Skew Bridge.**—In a skew bridge should counterforts be placed at right angles to abutments, or parallel to face of arch?—Excelsior.

[12413.]—**Harmonium.**—Will "Pneumatic Lever" oblige me with a design for a 4½ row harmonium with dimensions?—P. M.

[12414.]—**Cleaning Feathers.**—Will any one let me know how to clean white feathers on the skin from grease and blood stains?—A. S.

[12415.] — **Provision for Child.** — What is the present value for five shillings per week to be paid with a child twelve months old until thirteen years old? How can I calculate this, or what must I allow for the child's risk of dying?—J. R.

[12416.]—**Spinning.**—How many revolutions per minute does the spindle make in spinning? How many twists are there per inch in twist, and also how many weft? I desire that the answer be particularly for cotton, but answers for other materials will be gratefully accepted.—J. R.

[12417.]—**Hardening Spiral Springs.**—If some brother reader would kindly inform me I should feel obliged. I have been hardening them in water and letting them blaze off with tallow, but I find them sometimes too hard, and more often too soft; they are $^1/_{16}$in., ⅛in., and ¼in. steel wire. I have tried putting them in oil without letting down, but they are too soft. The springs you buy are hardened very well, but you cannot always get them to suit you.—SPRINGS.

[12418.]—**Resistance of Steel Plate to Air Pressure.** — Will any one let me know what would be the greatest air pressure a ¼in. steel plate chamber would resist, and if an atmospheric engine has ever been tried on a railway?—A STOKER.

[12419.]—**Photography.**—Will some one kindly tell me what is the fixing solution for pictures taken on the bichromate of potash and gelatine, or gum mixture; and also describe the whole process, if there is anything at all peculiar in it?—A.

[12420.]—**American Chucks.**—Could you, or some of "our" subscribers to the ENGLISH MECHANIC, give myself and others detail plans of the American scroll chuck, the Warwick chuck, Excelsior chuck, also the Beach chuck? They are extremely expensive to purchase for some of us humble mechanics, and we might possibly make them at our leisure if we had detail plans. Not required to scale; we could make our own proportions. If this request could have attention it would greatly oblige myself and other friends. Could we also be favoured with the mode of cutting the spiral flute on the drills as sold by Buck, &c.?—CHARLES BOWLER.

[12421.] — **Enlarging Photographs.** — Can any reader kindly inform me how photographs may be enlarged by the aid of magnesium light?—INDUSTRIOUS WILL.

[12422.]—**Steam Power.**—Would any competent engineer enlighten me on the following:—I have a portable steam engine driving a machine making 1000 revolutions per minute, and I find it very difficult to keep up steam, the engine crank shaft making 140 revolutions per minute, stroke 18in., diameter of cylinder 8½in. Would it be better to introduce a counter shaft with an additional fly-wheel and reduce the speed of engine?—PAT.

[12423.]—**More Light Wanted.**—In a range of shops three stories are built along two sides of a piece of ground. How is it possible in a cheap way to give more light to the corners where the shops come together at right angles? The owners of the property adjoining will not allow any windows to overlook them so that there is a considerable space in each shop that cannot be used.—ANTE LUCEM.

[12424.]—**Preserving Green Peas and Gooseberries.**—As green peas and gooseberries will soon become plentiful I should be glad if some correspondent would give us the method adopted for preserving them fresh in tins for winter use.—J. N.

[12425.]—**The Belgian Glass Trade.**—Can any reader of the MECHANIC give any information about the Belgian glass trade, when it was established, who by, and where, its present extent, and any other particulars of its history and development?—E. HOLMES.

[12426.]—**Piano.**—Having purchased a piano a few weeks since, when I got it home and began to practice on it I was surprised to hear a terrible rattling of the wires, which, on examining, I found to proceed from a part of the soundboard having become divided and waved. Could any of my brother readers tell me the cause, and a remedy?—A SUBSCRIBER.

[12427.]—**Entomological.**—Can any of your entomological readers tell me of what insect the maggot found in decaying cabbage-leaves is the larva? The maggot can often be found in the mid rib of the lower leaves when they have turned yellow, as it seems to bore its way upwards from the stem, travelling along the natural canals or passages in the substance of the leaf-stem. The same or similar larvæ may be found in other members of the tribe of Brassicæ when the lower leaves decay. I should like to know what they are, and how they got there.—MIMOSA.

[12428.]—**Air Vessel for Pump.**—How can I ascertain what size to make an air vessel for an ordinary force pump? The pump has a 2in. barrel, and delivers a pint at each stroke, the water being forced out through a valve at the top part of the barrel. Is it immaterial what sized air-chamber is used, so long as it is large enough, or must it be suited to the other dimensions of the pump? If the latter, what is the best material and shape of which to make it? It is wanted to deliver a constant stream through ⅜in. rubber hose with ⅛in. delivery jet, fitted with tap to regulate the quantity of water.—F. S.

[12429.] — **An Engineering Inquiry.** — I am twenty-one years of age, and have always had a taste for engineering, but unfortunately, never had an opportunity of learning that particular business until now. What would you recommend me to learn so as I may be fitted for a situation as engineer on board a steamer, and also how long should I serve in a foundry or machine-shop.—J. A. P. SPENCE.

"**Flint Jack" Again.**—The notorious forger of antiquities (who gives the name of Edward Simpson, of Whitby) has, it appears, being very active of late. He has turned up at Stamford, where it is stated he has been busy manufacturing rings, monastic seals, and flint arrow heads. Mr. A. C. Elliott, of Stamford, has had the man photographed, and intends to circulate copies, that the young collectors may recognise the fabricator on his first visit.

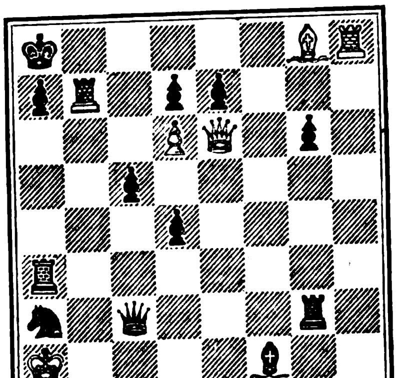
CHESS.

ALL communications intended for this department to be addressed to J. W. ABBOTT, 7, Claremont-place, Loughborough-road, Brixton, S.W.

THE "WESTMINSTER PAPERS."—The *Westminster Papers* is now recognised as the leading exponent of British chess, and for raciness and general ability nothing like it has ever appeared in the periodical literature of the game. None of the affectation of learning and research which characterised most of its predecessors is to be found in its pages; its news is not "ancient history," and its problems and games are neither "curious reprints" nor, as the phrase is, "selected from various sources." Every number contains a summary of the proceedings of the fraternity in all parts of the world during the past month, the latest games of the best English and foreign players, accompanied by judicious notes and instructive analyses, and at least thirteen problems of more than average merit. We may add, although the subjects are out of our province, that the *Westminster Papers* is also the received authority upon whist, each number containing three or four games from actual play by the finest contemporary whist players in London, besides articles on croquet and other games of skill.

PROBLEM VI.—BY HENRY TURTON.

Black.



White.

White to play and mate in two moves.

SOLUTION TO PROBLEM V.

1. B to K Kt 5	1. P takes B
2. B to K 2	2. Anything
3. B or Kt mates acc	

TO CORRESPONDENTS.

E. L. G.—We should like to re-publish the article on "Republican Chess," but to do so would lead to many inquiries which could not be satisfactorily replied to.

E. T. GRAYS.—We shall, in an early number, commence publishing positions in the form of enigmas. If you will send us your name and address, the problem you mention shall be forwarded.

A. W. COOPER.—Problem I. is easy. Problem II. is a good problem, and if it stands the test of further examination it shall appear.

W. AIREY.—Problems of more than four moves deep are not favourably received by the majority of solvers. We propose to give yours as an enigma.

G. SLATER.—Problem I. admits of a solution in two moves—

$$(1)\ \frac{\text{Q to R sq. (ch.)}}{\text{Q interposes}}\ (2)\ \text{B mates.}$$

The other is an interesting composition, and it shall be published in due course.

J. P. (Bedford).—The problem in four moves can be solved thus—

$$(1)\ \frac{\text{K to B 2}}{\text{P moves}}\ (2)\ \frac{\text{R to P}}{\text{K moves}}\ (3)\ \frac{\text{B takes B}}{\text{anything}}\ (4)\ \text{R mates.}$$

The one in three moves in which the W K stands on Q R 3 is also wrong—1 B to Kt 4, &c. The other is correct and pretty, and it shall speedily appear.

G. C. HEYWOOD.—Send the promised problem. We shall be glad to hear from you at any time.

G. WHITFIELD and A. L. (Dulwich).—Problems safely to hand.

S. M. BANKER.—Your communication *not* relating to chess has been forwarded to the proper quarter.

SOLUTIONS to Problem IV. (continued).—Wiseaf (Dulwich); Hermes; J. Beresford (Vauxhall); C. J. L. (Portsmouth); G. C. Heywood (Great Torrington).

CORRECT solutions to Problem V. have been received from W. N. P.; H. Dyer (Cardiff); J. Wareham; A. W. Cooper; W. Airey (Worsley); C. Yeo (Paignton); Inductorium; E. T. Grays; C. J. L. (Portsmouth); G. V. Grand (Newcastle); G. Whitfield (Atford); S. M. Banker; A. L. (Dulwich); J Beresford (Vauxhall). All others are wrong.

USEFUL AND SCIENTIFIC NOTES.

THERE is but little doubt that many broken wheels result from expansion at the hub caused by heated journals. Since the American railroad companies have adopted a strict system of inspection of cars and wheels they have had far less breakage of wheels.

Drinking Fountains.—Some information as to the cost of these public conveniences was disclosed at the meeting of the Metropolitan Drinking Fountain and Cattle Trough Association held lately. There are more than 300 troughs and fountains under the care of the society, and all are visited, cleaned, supplied with cups, and reported at the office every week. The cost of the fountains for repair and water supply averages nearly £10 a year each, but the cost of the cattle troughs varies with their size and locality. The small dog troughs are supplied entirely with the waste water from the fountains, but for the larger troughs the water-rate alone is in some cases as much as £30 per annum, more than 1,200 horses, besides other animals, frequently drinking at one trough in twenty-four hours.

A Novelty in the Building Trade.—An Exeter correspondent writes:—"A twenty-roomed house, complete with grates, stoves, and fittings, has just been brought by ship to Exmouth, for transmission by rail to North Tawton (North Devon). The house was built in Norway for a gentleman at North Tawton named Vicary. It is mostly built of wood, and, it is said, can easily be taken to pieces and put up again in any locality desired. The house will be unshipped at Exmouth, and conveyed over the London and South Western line to its destination. Great interest is being taken in this novel cargo alike by employers and employed in the building trade. Until, however, the house is put up and inhabited any opinion upon the stability or suitability of the structure must be withheld. It should be stated that men have been brought from Norway to put it up, so that the owner will be altogether independent of home labour."

Schools of Art in the Potteries.—The Schools of Art in the Potteries have this year been very successful in the examination of works sent to South Kensington. Hitherto the district has not reached the dignity of a gold medal award, but this year two have been taken—one by Hanley, and the other by Stoke School. The gold medal for Hanley is awarded to Joseph Ellis, for modelling; and that for Stoke to Robert Abraham, for painting from nature. Hanley School also takes two silver medals and three Queen's prizes, and seven pupils have free studentships, besides which the works of twelve students are selected for national competition. Nearly double the number of students have been successful this year in comparison with last year. Besides the gold medal, Stoke School has been awarded a bronze medal and eight free studentships. In the case of Stoke, also, there is a great increase in prizes over last year. The monetary results of the examination to Hanley School are 40 per cent. in advance of last year.

Testing Inflammable Oils. — A method of testing petroleum and other inflammable fluids, and also of determining their specific gravity, has been patented in the United States. The apparatus consists of an upright glass cylinder supported in the top of a chamber formed in the upper part of a base or stand. A lamp is placed in the base, the heat from which is transmitted through the chamber to the lower part of the glass cylinder, and the chamber may be made to contain air, water, &c., as required to regulate its intensity. The glass cylinder contains a thermometer, which is fixed therein, and is closed at the top with a brass cover. The burning fluid to be tested is made to completely fill the glass cylinder, so that the thermometer is entirely submerged, and cannot be affected by the surrounding atmosphere. An orifice in the brass cover is opened to allow the escape of vapour from the fluid under test, and, when necessary, the lamp is lighted. A flame is held over the orifice, and at the moment the evolved vapour is ignited the temperature of the fluid is correctly indicated by the thermometer. In ascertaining specific gravities by this instrument a hydrometer is also placed within the glass cylinder in such a manner that its scale tube is free to move up or down through a hole in the brass cover. The surface of the fluid tested is plainly visible through the glass cylinder, and the scale may be accurately read.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 81, *Tavistock-street, Covent Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, July 9, and unacknowledged elsewhere:—

Rev. W. H. Dallinger.—A. S. Lewis.—Mrs. Ethel.—J. T. Petty.—Thomas Scully.—F. R. A. S.—Paper Maker.—S. Bottone.—M. B. Adams.—Gillem.—Collier and Son.—Cutter.—LL.D.—Dr. Hy. MacCormac.—Lecturer.—C. F. Hornby.—W. E. Lee.—James R. Gooden.—Whitley Partners.—Whiteman and Mann.—C. Hodges.—Henry Warry.—Conrad Bergman.—Rev. J. H. Cole.—James Peters.—Marsh and Pattison.—W. S. S.—F. R. A. S.—The Welsh Shepherd.—Falstaff.—J. W.—J. H. Schucht.—L. T. Holehouse.—Arotes.—Glatton.—C. N. Williamson.—A Member.—H. R. Bayly.—H. R. Roberts.—R. M.—H. Science.—J. Barwick.—T. H. Ward, Surgeon.—A Patternmaker.—Jigger.—A. A. F.—Tel. Eng.—Conatus.—Zakynthos.—Constant Subscriber.—S. R. S. G. B.—G. H. A.—E. Johnson.—The Harmonious Blacksmith.—A. L.—J. Bateman.—Jno. 495.—G. M.—Wm. Thompson.—Upholsterer.—Afternoon.—Paperhanger.—Jonathan Turner.—Bob.—J. E. Lines.—Inquirer.—J. Selwin.—C. Watson.—E. H.—P. S. T.—Subscriber.—Caer Glou.—Tom-Tit.—Iron Ore.—H. G. S.—Sirius.—John Wright.—Phœnix.—Private Student.—C. Gaudibert.—T. W.—Alfred H. Allen.—P. W. H. J.—George Wright.—J. W. Fennell.—Hipparchus.—W. and B.—R. and S.—Old Boots.—Homewood.—W. J. Ball.—John Yeoman.—Rev. A. Willan.—G. W. Roberts.—John Lane.—Rev. H. C. Key.—Suffra.—G. W. S.—T. A.—J. W. E.—R. Owen.—R. A. H.—D. C.—Clinchey.—Zurich.—Sarah.—J. D.—X. M. S.—David W. Braid.—Wm. McCulloch.—J. W. G.—W. T. R.—A. Hoskins.—J. H. Whistle.—Marcus Wicks.—L. Newton.—E. Fowler.—Amateur Photographer.—Rat-Tat.—W. Hill.—H. B. E.—T. H. M.—Johan.—George Henshaw.—Joe.—Saxum.—Seed Grower.—Horti.—R. R. Smith.—Aleph.—McGregor.—Esor.—W. M. Colles.—R. P.—Science and Art.—Lines.—J. W. Abbott.—S. M. Banker.—Simplex.—Inquirer.—Philo.—Hone Ko Jo.—S. Bottone.—C. B.—S. G. H.—Arthur Rogers.—Sigma.—Xenophon.—Pembroke.—R. Crawley.—Three Years' Subscriber.—Brickmaker.—J. P. W.—E. J. H.—P. W.—J. H. Johns.—Pedestrian.—Shell Collector.—E. Burnside.—G. H. G.—W. P.—Sheet Anchor.—Utile.—E. M.—W. G. Roberts.—Rev. A. Jarrow.—A Surgeon.—J. B. Yonge.—E. B. Moysey.—J. Foster.—J. Pell.—Wm. Grosvenor.—T. C. Ebdy.—Robert Hartley.—C. P. Stannard.—John France.—J. J. Haselgrove.—E. R. S.—J. Henry.—Secretary of Smithsonian Institution.—M. B. Adams.—Secretary of Society of Engineers.—A. Williams.—R. Botterill.—East End Mechanic.—T. W. T.—W. L. Warren.—G. W. Bacon and Co.—Orlando Hanks.—James Largon.—J. H. W.

C. F. C., Holborn Admirer, Young Snip, and J. P. James.—Your queries are advertisements. See "Hints to Correspondents."

E. J.—Not practicable.

E. B. J.—See first article this week.

Jack of All Trades has given us a call on his way home after passing upwards of four weeks at Matlock, and a week with "Khoda Bux." He promises a letter for the next number.

Sirius.—Your letter, as you will see, was superseded by one from Mr. Proctor and one from "E. L. G."

Zoo Andra.—Your query would be of no service to any one but yourself.

E. S.—Yes, it came to hand, and was found unsuitable.

Parker.—Your first query is an advertisement, and your second is only useful to yourself.

W. H. Fleet.—We do not know the address, and if we did it would be contrary to our rules to give it you.

W. B.—We do not know why Mr. Tonkes is silent.

W. Webly.—An American publication, and American publications are very frequently echoes of English journals.

E. N. H. asks, "Why does not the English Mechanic devote a small portion of its space to legal as well as medical questions? Points of law are continually arising on which light might be thrown by some of our correspondents."

John Matthews.—You cannot vulcanise rubber discs after they are manufactured. The soft rubber is mixed with sulphur, and afterwards submitted to heat and pressure—the latter process being the vulcanising.

John Manhinney.—The data are insufficient to advise upon. You say the wall is "slightly damp" in one place, and in another speak of the "damp spot." If the dampness is confined to a spot it might probably be easily remedied. See Vol. XIV., pp. 313, 337, &c.

Ancoats, T. B., Atlas, E. N. D. (first query), Hoop Iron, W. Watson, A Working B., are referred to back volumes.

A Poor Man.—The method given on p. 336 to mask the taste of castor oil will do very well. Milk, sherry, or lemon-juice are also good.

A. C. G.—For music-ruling pens see pp. 50, 104, 159, and 209, Vol. XIV.

Excelsior.—We do not understand your third query on Political Economy.

Communications which can only appear as advertisements to hand from J. Y., H. Elfes, Drum Maker.

E. Johnson.—It is quite true; the matter has been fully discussed in back volumes. See indices.

J. Streabber.—See "Hints to Correspondents."

G. Richardson.—AEI form the Greek words meaning "For ever."

J. Gillaird.—Your reply only promises the information, but really contains none. If you like to send sketch and details we will insert them. Your other proposal does not seem at all practical, or one likely to be entertained.

Ignoramus.—The compass was known and used by the Chinese. The phrase used by St. Paul does not apply to a compass, but means that he sailed in a circular direction.

Simere Sperens.—Your suggestion about perpetual motion is not worth the paper on which it is written. Read some elementary scientific book.

R. P. says:—"I quite agree with your querist (12329) that a series of good papers on mechanics for beginners would, in these days of science examinations, be very valuable to many of your readers. If some one could do for statics and dynamics what Messrs. Sprague and Bottone are doing for their respective subjects, the usefulness of your paper would be much increased."

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING JULY 2, 1872.

1864 W. E. Newton, Chancery-lane, for improvements in stench traps, and in apparatus for making the same and other curved or partly curved articles. A communication.

1865 W. E. Kochs, Manchester, for improvements in piers, jetties, and landing stages, and in means for effecting the transference of railway trains to and from ferry-boats and floating vessels, and for staying the said trains when on board such boats or vessels.

1866 J. T. Fitzmaurice, Porthpean, Cornwall, for improvements in apparatus for lowering boats.

1867 W. Robertson and J. G. Orchar, Dundee, and M. A. Muir and J. McIlwham, Glasgow, for improvements in apparatus for winding yarn or thread.

1868 G. Maxwell, Lancashire, for improvements in the construction of machinery or apparatus used for making bricks and tiles.

1869 T. Davis, Warrington, for improvements in furnaces for heating metals.

1870 J. Calvert, Oldham, for an improved lamp for moulders or artisans.

1871 I. Fenno and P. Howe, Boston, U.S., for improvements in machines for cutting cloth and other textile or fibrous material.

1872 S. T. Waite, Smith-street, Northampton-square, and J. J. White and J. O. Wise, Sekford-street, Clerkenwell, for the lighting of fires.

1873 G. T. Bousfield, Loughborough-park, Brixton, for improvements in rotary ploughs. A communication.

1874 J. G. Horsey, Broad-wall, Lambeth, for improvements in the manufacture of brushes and brooms, and in the machinery or apparatus employed therein.

1875 E. Turner, Leicester, for improvements in door springs.

1876 S. B. Smith, Birmingham, and J. W. Willans, Middlesbrough, for improvements in the process of and apparatus for smelting iron ores and other ores, and reheating iron and other metals, parts of which improvements may also be applied to other purposes.

1877 G. Burge, jun., Rochester, Kent, for improvements in kilns for burning cement, lime, and other substances.

1878 J. Tourre, Avignon, France, for improvements in obtaining colouring matters derivable from madder, manjeet, and other allied roots.

1879 W. Birch, Penrose-street, Walworth-road, for improvements in the mode of and apparatus for treating horny and other analogous animal substances for the purpose of converting them into an elastic substance to be used in place of whalebone, bristles, and for other purposes for which such elastic substance may be applicable.

1880 W. M. Brown, Southampton-buildings, for an improved apparatus for extracting ammonia in the form of liquid ammonia from crude ammoniacal liquors. A communication.

1881 E. Milner, Springfield, Lancashire, for improvements in the method of producing white pigments from lead.

1882 B. Wrigley, Arundel-street, Strand, for improvements in kilns for burning bricks, pottery, and lime.

1883 J. Campbell, Founders-court, City, for improvements in the modes of decreasing the rolling of vessels.

1884 J. Arthur, Sandycroft, Flintshire, for improvements in screw bolts and nuts.

1885 J. Horsley, Cheltenham, for an improvement in the manufacture of an explosive compound and a new mode of firing explosive compounds.

1886 J. Thomas, Middlesbrough, for improvements in furnaces for generating gas and melting metals.

1887 J. Kirby, Preston, for improvements in machinery or apparatus to be used in frames for winding linen or other yarns.

1888 J. Tabor, Leadenhall-street, City, for a mechanical arrangement or "tell tale" for registering the number of packages taken to or from vessels, vehicles, warehouses, and other places.

1889 W. R. Lake, Southampton-buildings, for improved check tickets and methods of forming packages of the same, chiefly designed for use on railways and steamboats. A communication.

1890 L. D. Newell, Aldersgate-street, City, for improvements in ships' berths and sofas.

1891 B. Burleigh, Adelphi-place, Camberwell, for improved lever apparatus for railway switches.

1892 G. A. Dorsett, Rotherhithe, for improvements in obtaining anthracine from heavy oils and in apparatus employed therein.

1893 W. Beale, Bridgwater, for improvements in apparatus for turning over the leaves of music.

1894 T. Redmayne, Sheffield, for improvements in the construction of desks, seats, and music stands, applicable to the use of schools and other purposes.

1895 J. F. Swinburn, Birmingham, for improvements in breech-loading small arms.

1896 G. Davidson, Aberdeen, for improvements in machinery for washing fibrous pulp or material for the manufacture of paper.

1897 H. P. F. Palmer, Carnarvon, for improvements in cases or crates for containing roofing slates while in transit and other articles requiring packing cases to preserve them from injury.

1898 T. Atkins, Saint Albans, Herts, for improvements in pumps, parts of which improvements are also applicable to other purposes.

1899 P. E. Chappius, Fleet-street, for improvements in the manufacture and application of reflecting surfaces for the better reflection and diffusion of light.

1900 J. Sagar, Leeds, for improvements in machinery or apparatus for raising and forcing water or other fluids.

1901 E. Salt, Darwen, Lancashire, for improvements in rag engines, washing engines or beaters employed in the production of pulp or paper "stuff."

1902 E. P. H. Vaughan, F.C.S., Chancery-lane, for improvements in furnaces, stoves, and other apparatus for consuming fuel. A communication.

1903 B. Hunt, Serle-street, Lincoln's Inn, for improvements in apparatus for shearing or clipping sheep, horses, and other animals. A communication.

1904 A. Taylor, Stockport, for improvements in apparatus used for bleaching yarns and cloth.

1905 W. E. Newton, Chancery-lane, for improvements in the manufacture of vinegar and in the acidulation or treatment of various liquids, and in the apparatus employed therein. A communication.

1906 W. Phillips, Farndon, Cheshire, for an improved pea range adapted for supporting and protecting peas during their growth, for protecting half-hardy plants, and as a forcing frame.

1907 J. Ricketts and A. Lutschaunig, Liverpool, for an improved mode of and apparatus for defacing postage stamps.

1908 J. Woods and E. Woods, Warrington, for improvements in apparatus employed in drawing wire.

1909 M. Burke, Liverpool, for improvements in screw propellers.

1910 J. Hartley and Z. Sugden, Halifax, Yorkshire, for improvements in boilers for heating of water for warming buildings and other like uses.

1911 J. L. Norton, Ludgate-hill, and J. H. Carter, Mark-lane, City, for improvements in decorticating, hulling, or polishing wheat and other grain or seed, and in dusting bran, and in apparatus employed for such purposes.

1912 W. Young, Blandford-square, Middlesex, for improvements in printing and in the production of printing surfaces, also in apparatus to be used for these purposes.

1913 A. M. Clark, Chancery-lane, for an improved distress rudder and drag for vessels. A communication.

1914 J. Townsend, Glasgow, for improvements in furnaces or apparatus for obtaining heat or gases from coal or other substances containing carbon.

1915 W. Harvie, Glasgow, for improvements in lenses and in lamps wherewith such are or may be used.

1916 W. Macrone and W. McKenzie, Glasgow, for improvements in the production of stereotype plates, and in apparatus employed therefor.

1917 S. J. Wallis, Spalding, Lincolnshire, for new or improved mechanism for discharging both locks or barrels of a double-barrelled gun by one trigger.

1918 W. Sissons and P. P. White, Kingston-upon-Hull, for improvements in steam pile-driving apparatus.

1919 C. W. Siemens, Great George-street, Westminster, for improvements in the means of obtaining and applying magneto-electric currents, and apparatus therefor. A communication.

1920 C. Caselton and H. Toogood, Hull, for improvements in saw frames or machinery for cutting tile, slate, and other laths, boards, deals, battens, and other woods and materials usually cut by saws.

1921 J. Merrylees, Glasgow, for improvements in weaving ornamental fabrics, and in apparatus therefor.

1922 T. Gibson, Stamford, Lincolnshire, for an improved machine for cutting lump sugar.

1923 J. E. T. Woods, Hammersmith, and J. Clark, Kensington, for an improved alloy for anti-acid metal and for other purposes.

1924 E. G. Brewer, Chancery-lane, for improvements in the modes of and in the means or apparatus for operating the rotating parts of sewing machines and of other analogous machinery. A communication.

1925 R. E. Middleton, Cannon-row, Westminster, for improvements in machinery or apparatus for breaking stones, ores, and other like substances.

1926 R. G. How, Carshalton, for improved mechanism for indicating and recording the speed of railway trains.

1927 W. Corney and S. S. Turner, Westborough, U.S., for improvements in stop motion for looms.

1928 P. Poggi, College-street, Chelsea, for an improved mechanical combination, constituting improved motive-power machinery adapted for industrial and other purposes. A communication.

1929 R. W. Simpson, R. Hopps, and D. Johnson, Leeds, for improvements in machinery for scribbling wool and other fibrous substances.

1930 O. McC. Chamberlain, New York, U.S., for an improved attachment for sewing machines for folding plaits.

1931 J. S. Christopher and J. F. Lackersteen, Lombard-court, City, for improvements in the manufacture of hydrogen gas.

1932 B. F. Stevens, Henrietta-street, Covent-garden, for improvements in apparatus for raising, lowering, and securing, ships' boats. A communication.

1933 G. Whitaker and J. Ashworth, Rochdale, for an improved process for preparing wool or other animal fibre for carding or combing.

1934 A. M. Clark, Chancery-lane, for an improved apparatus for feeding and drying whitelead and other pulpy or semi fluid substances, and for feeding oily and pasty substances. A communication.

1935 R. A. Purkis, Cheam, Surrey, for improvements in the mode of and apparatus for refrigerating liquids.

1936 W. H. Denham, Southsea, P. V. Denham, and A. A. Denham, Putney, for improvements in water-closets and in apparatus connected therewith, parts of which improvements are applicable to other purposes.

1937 W. R. Lake, Southampton-buildings, for improvements in gathering, ruffling, or plaiting apparatus for sewing machines. A communication.

1938 A. Hookham, Southwark-bridge-road, for improvements in money tills.

1939 M. Paul and J. Haythorn, Dumbarton, N.B., for improvements in and connected with steering apparatus.

1940 W. Wright, Sheffield, for improvements in taps and apparatus for flushing water-closets, and in taps for other purposes.

1941 J. R. Cazier, North East, U.S., for an improvement in the application of safety valves to steam boilers.

1942 J. W. Ward and J. C. Rouse, Halifax, for improvements in jacquard machinery or apparatus.

1943 J. S. Cooke, Yorkshire, for improvements in machinery or apparatus to be employed in dyeing wool, silk, cotton, flax, or other fibrous substances in the hank or skein.

1944 J. H. Johnson, Lincoln's Inn-fields, for improvements in sifting or bolting machines. A communication.

1945 J. Millward, Birmingham, for improvements in hydrants for supplying fire-engines from street mains. A communication.

1946 J. G. Tongue, Southampton-buildings, for improvements in the manufacture of artificial flowers, foliage, fruit, and other similar objects or ornaments. A communication.

1947 W. M. Parker and J. R. Robson, Alton, Hants, for improvements in steam and other motive-power engines and pumps.

1948 F. J. Cheesbrough, Liverpool, for improvements in the process of manufacturing oil and oil cake from seeds, and in the machinery to be used therein. A communication.

1949 J. Fletcher, Lancashire, for improvements in machinery for forging and riveting.

1950 G. Yule, Wakefield-street, London, for improvements in cylindrical and other rulers for office and general use.

1951 J. H. Johnson, Lincoln's Inn-fields, for improvements in preserving butter and other fatty matters, and in the apparatus or means employed therein. A communication.

1952 A. C. Kirk, Glasgow, for improvements in steering apparatus and in motive-power apparatus for working the same, or for working, winding, hoisting, or other apparatus at a distance.

1953 H. Giroud, Paris, for a new or improved system of rheometric regulator used with a gas burner only.

1954 S. Chatwood, Bolton, and J. H. Collins, Falmouth, for improvements in separating or dressing tin and other ores.

1955 T. S. Derham and C. W. Thalrlwall, Leeds, for improvements in machinery for manufacturing bricks.

1956 T. H. Phillips, Barbican, City, for an improved apparatus or appliances applicable for heating, cooking, and lighting purposes.

1957 W. R. Lake, Southampton-buildings, for improvements in fastenings for uniting and securing the parts of bedsteads and for other like purposes. A communication.

ARTICLES.

ON SELF-DECEPTION IN OBSERVATION.

BY RICHARD A. PROCTOR, B.A. (Cambridge).

Honorary Secretary of the Royal Astronomical Society.

MOST of those who have at any time had occasion to make observations in connection with a strongly entertained theory must have been led to notice the readiness with which the mind lends itself to such a view of observed results as may be most in favour of the observer's theory. When a series of measurements is being made, which should run in a certain way if a certain theory is correct, it will unquestionably run more nearly in that way if the observer looks with favour on the theory than if he is opposed to it. If colour-tests, light-tests, or estimates of shape be in question, then still the predominant theory will exert its influence. No matter how conscientious the observer may be, he finds it almost impossible to avoid falling into an error of the sort, unless in his eagerness to be strictly impartial he avoids Scylla to fall into Charybdis, actually favouring the evidence against his theory rather than do aught in its support not strictly justified by the facts.

Let it not be supposed that the self-deception here spoken of is practised only by inferior observers, or that it is of the nature of "a mistake made on purpose." The very best observers have repeatedly found themselves going astray in this particular way; and by their readiness to admit that they have done so have shown that no desire unfairly to advance their theories has been in question. The longer an observer's career has been, the more clearly does he recognise the necessity of watchfulness over himself, unless he can devise some arrangement by which he will be rendered unconscious of the bearing of his observations on his theories. The worst of the matter is, that observations *ought* to be made in subservience to some theory, since otherwise they will almost certainly be wanting in precision and system. The best observations ever yet made have been conducted in connection with theory, and in every instance where observations have been made by those who boast that they have no theory at all on the subject under observation, the results have been of little value. Indeed, I may notice in passing, that those make a great mistake who attach exceptional weight to observations made by persons who have no special views on the subject of observation. Though the object of this paper is to dwell upon the errors made by observers strongly prepossessed in favour of a particular theory, I should be sorry indeed to seem to give any support to the notion that the best observations will be made by persons having no theory at all. To say that a person has no theory at all on a subject, is to say that either he knows very little about the subject, or that he has no brains worth mentioning. No man who has a respectable supply of reasoning faculties can fail to form opinions as the facts relating to any subject are brought to his knowledge. It would, indeed, be very unwise for him to arrive at conclusions at an early stage of his study of the subject. He should be prepared to modify his opinions; and he may regard hereafter as unlikely the views which he had at first entertained as probable. But we may be well assured that one who forms no opinions as his study of a subject proceeds, who is not ready to form hypotheses explanatory of the facts brought to his knowledge, who is continually waiting to know more before entertaining any theory at all, will never have an opinion worth listening to. Not only is it true, to use Sir W. Herschel's words, that to observe without theorising is to "depart from the very purpose for which observations are made," but the observations themselves suffer when they are carried out in so purposeless a way.

My object, then, is to indicate the necessity for the devisal of methods for freeing the mind from the influence of preconceived opinions, not, assuredly, to advocate such an avoidance of theory as can only be attained by the weak-minded. It is for the former purpose that I adduce some instances which seem to throw light on the subject of self-deception in observation. They are at once interesting and instructive.

In the first place, I will cite a series of instances relating to a single subject.

It is well known that the family and school of Cassini maintained that the polar diameter of the earth is longer than the equatorial diameter, while Newton and his followers maintained the contrary opinion.* Originally, Cassini had believed the earth to be oblate, and from a passage in the article, "Figure de la Terre," by D'Alembert, in the original "Encyclopédie," it appears that Cassini inferred that in consequence of this oblateness the length of a degree would *decrease* from the equator to the pole. Starting with this erroneous assumption, the school of Cassini "*arrived at the same result by observation and measurement.*" When it was shown that the assumption was erroneous the Cassinians maintained the accuracy of their observations, and thus necessarily adopted the theory that the earth is a prolate spheroid, the polar axis being the greatest diameter. But "there can be no doubt," says Mr. Todhunter, "that at least Maupertius and Clairaut, who were the most eminent of the French party sent to measure the Lapland arc in 1736, "held the correct Newtonian theory as to the figure of the earth; and their result was *rather too decided* in its confirmation of this theory. Now the geodetical angles could scarcely be influenced by the opinions of the observers, because it would not be obvious in what way the result would be affected by an error in the angle. But on measuring the base it would of course be obvious that the larger was the value obtained the stronger was the evidence for the oblate form. Similarly, in estimating the amplitude of the arc, the smaller the value obtained the stronger was the evidence for an oblate form. In these two parts of the survey, then, it would be necessary to be on the watch lest the conviction of what the result ought to be should influence the impression of what the observation really gives. It is curious that Maupertius and his party seem to have thought at first that their success was too decided, and, therefore, their amplitude too small, and that on their second determination *they should have made it between three and four seconds larger than at first.*" Svanberg was sent to Lapland with a strong expectation that he would obtain a less value of a degree of the meridian than that of Maupertius; and according to the best estimates of the value of a degree for the part of Lapland where the arc was measured, Svanberg's value was *below the true value.*

Striking as are these facts, however, the eclipse observations of last December afforded yet more remarkable evidence of the self-deception which may arise from the effect of a preconceived opinion.

It may be remembered that Dr. Oudemans had expressed the opinion that the solar corona is due to the illumination of matter close by the moon. This theory is mathematically defensible so far as the shapes of the coronal rays and rifts are concerned,† if only certain phenomena are observed during totality. It is perfectly clear, since the theory explains the rays and rifts as due to the passage of the solar rays past valleys and mountains on the moon's limb, that as the moon passes athwart the sun's face the rays and rifts should change in position, shape, length, and so on.

Now, as a matter of fact, the evidence obtained during the eclipse of December, 1870, had completely disposed of Oudemans' theory. It is perfectly well known that the doubts expressed as to the agreement between the photographs taken by Willard, at Xerez, and by Brothers, at Syracuse, were based on imperfect drawings of these photographs, and though these doubts were not ostensibly withdrawn, the photographs themselves completely disposed of them. But to Oudemans, at Batavia, this news did not penetrate. He set forth to view the total eclipse of last December with unshaken faith in his lunar cosmical dust theory, and with a perfectly clear recognition of the phenomena which *should* make their appearance if the theory were true.

Far away, to the west of Dr. Oudemans, was stationed Mr. Lockyer, at Baicull. To him the theory still remained dear, that the corona is, in the main, a phenomenon of our atmosphere. What were the particular appearances which he expected to see in demonstration of this hypothesis deponent sayeth not—probably we shall never know. But that he did expect to see such appearances—nay, that whatever they were he did actually see them, will appear in the sequel.

At Baicull, also, and at Dodabetta, 8,000ft. above the sea-level, were stationed certain inanimate, but very efficient, observers, who were certainly not prepossessed in favour of any theory, and who possessed to a very remarkable extent that quality which has been called by Doré "collodion in the eye:" I refer to the photographic apparatus set up by Mr. Davis at Baicull, and by Col. Tennant at Dodabetta.

The moon's shadow came and went, and the observers, animate and inanimate, did their work; the results are most instructive.

The totality was scarcely over when there went forth from Mr. Lockyer, at Baicull, to the observers at Jaffna (just preparing for totality) this startling telegraphic message, "*The corona is almost wholly an atmospheric phenomenon.*" In some unknown way the atmospheric glare theory which had possession of his mind caused the observed appearances to seem demonstrative of its correctness.

Dr. Oudemans, in the east, was similarly favoured. He writes to Mr. Lockyer, "My observations and those of my party" (inoculated, we may fairly imagine, with the lunar theory) "have given me the conviction of the existence of an optical phenomenon besides the purely solar phenomena; *not of an atmospheric origin* (*there is no question whatever of this*), but of rays variable during the totality, too variable to be attributed to solar matter emerging from the body of the sun itself. I could follow the rays and rifts as far as the moon's edge."

But alas for the rival theories which had thus so completely demonstrated themselves and disposed of each other! the inanimate photographic observers had been at work, and had done their work in such a way as to dispose of both the rival theories at once. At each station five photographs had been taken (not counting one imperfect one at Dodabetta). Each photograph of each set shows a multitude of rays and rifts very peculiar in form. I suppose that upwards of a hundred well-marked features can be counted in each picture. These features are absolutely identical in all the five pictures of either set. The pictures of one set are absolutely identical with those of the other set. Comparing the pictures of either set of five, we see the moon measurably traversing the corona as the eclipse progressed, thus definitively disposing of the lunar theory;* while, comparing the two sets, we find the features photographed at Baicull, on the west coast of India, close by the sea-level, absolutely identical with those photographed at Dodabetta, on the Neilgherries, 8,000ft. above the level—thus definitively disposing of the atmospheric theory.

In passing, it may be remarked that perhaps it was a little hard of Mr. Lockyer to publish the parts of Dr. Oudemans' letter which relate to the lunar theory of the corona. Oudemans wrote in complete unconsciousness of the photographic evidence which has been so long in the hands of European men of science; had he heard of the photographs he would doubtless have wished to withdraw his remarks on the lunar hypothesis. Still, the lesson derived from these matters is so

---

* I quote from a most valuable paper, by Mr. Todhunter, "On the Arc of the Meridian Measured in Lapland"—*Transactions of the Cambridge Philosophical Society*, Vol. XII., Part I.

† It is completely answered, I conceive, by the objections I have urged against it on account of the smallness of the total quantity of light which would be received from the region in question, as compared with the quantity received—*according to the theory itself when all its consequences are considered*—from matter beyond the moon. I submitted this objection to Sir John Herschel, and in his reply he expressed his perfect agreement with what I had urged on the subject.

* Dr. De La Rue (once, by the way, an advocate of Oudemann's theory) informs me that in Col. Tennant's negative the features of the corona can be seen (and identified in the several pictures) to a distance of one and one-seventh diameters of the sun. In Lord Lindsay's series, the negatives of which I have had the pleasure of examining, with oxyhydrogen illumination, precisely as set for the engraver to work from, the features can be traced very nearly as far. They are not by any means mere straight rifts or rays, but of most remarkable figure, here a short spiky projection, there an irregularly-shaped obelisk of light, in another place a long ray of double curvature, in yet another a complicated knot of streaks—altogether the most marvellous astronomical picture my eyes have yet rested on. Janssen's description, with its marked reference to "special shapes altogether irreconcileable with an atmospheric theory," is strongly recalled and fully justified. Yet the photographs show but a portion of the extension of these strange figures. That excellent observer, Capt. Tupman, who drew a capital picture of the corona, agreeing well with the photographs, could trace these features much farther.

By the way, when are the reports of the eclipse expedition to be available for study? What occult cause is preventing us from hearing what was done?

instructive that perhaps Mr. Lockyer did well in bringing it before us. We cannot be taught too emphatically that in observation extreme caution is required lest preconceived opinions should mislead us; and this lesson may now be said to have been enforced by example as well as by precept.

In conclusion, I may remark that I formerly took strong exception to the assertion that one who theorised respecting the corona, in that stage of the inquiry which we had reached two years ago, "simply made himself ridiculous." It may be (such is human weakness) that it was the application of this remark to myself which led me to take exception to it. But I think I may now not unfairly point to the results recently obtained as affording strong evidence in favour of my view, that no man can make himself ridiculous by announcing carefully-considered views, even though those views should prove to be erroneous. It is a mere matter of detail that my ideas respecting the corona have been justified, and are now accepted by all whose opinion is of any weight. But I would venture to express a hope that at the present time Mr. Lockyer no longer regards the enunciation of possibly erroneous views respecting the corona as altogether so ridiculous a proceeding as it once appeared to him. If so, the recent eclipse observations will have had this pleasing result, that while they have enabled Mr. Lockyer to illustrate (unconsciously) a teaching which is of the highest importance and value to all observers, they have conveyed to himself a not uninstructive lesson.

THE WATCH, AND HOW TO REPAIR IT.

By "Seconds' Practical Watchmaker."

(Continued from page 421.)

THE little box of wheels called a watch seldom at first sight has bestowed upon it much thought, and when it is thought about, it more frequently happens than otherwise that that thought arises out of its apparent unwillingness to register time with its accustomed regularity; and should the watch be one the regularity of whose general performance is prized by its possessor, the thought then, in the majority of instances which have fallen under my notice, is this: "My watch never requires alteration. He must have been a very clever person who invented the watch." And with this kind of soliloquy the watch is returned to its place of keeping.

The series of articles on the above-named subject will be designed with the intention of attracting attention to a common fact, that the watch deserves a great deal more care and thought from the general wearer than is usually allotted to it, for the readers will have placed before them some facts relating to the care and management necessary for each kind of watch, as well as a description of each particular construction, for this "little monitor of our daily engagements" has connected with it a host of scientific connections, for from its commencement to completion its associations with the sciences entitle it to more careful attention from persons who profess a love for philosophic inquiry than has come under my notice after several years of observation on the subject.

The history of the watch will be traced from the earliest existing models, and when the connecting link by model fails, quotations from the most reliable authorities will be made use of. By these means it is intended to trace the history of the watch from its earliest period to the present time. This section of the subject, I am inclined to think, is a very important one, for we can look back on an age, not long departed, when the subject (watchwork and watchmaking) was considered of such importance that the most influential and the wisest men of that time deemed it an honour to be connected with the art. Thus, out of their united energies, was the "toy-watch" made a scientific wonder. So that in these days of mechanical and scientific progress, by a knowledge of the past with the present improvements, many additions may yet come before the world from those who, without the knowledge of the gradual improvements of the watch, would not think of turning their thoughts to the subject. Mr. Charles Frodsham has thus stated, referring to the subject: "Indeed, I think there is little doubt that there has been more time spent by great minds upon clocks and watches than upon any other art or science, and they may be truly said to have been the nursery of engineering and mechanical skill." The history of the watch is a combination of several years' incessant application among those who may with fairness be termed its pioneers, because, as previously stated, prior to the year 1720 there was but one kind of watch, and the special arrangement of its parts was the same as we now term the verge watch. Other arrangements were adopted as the watch became improved from its originators—although in the present day we might, with a degree of truth, term such instruments "pocket clocks," for they were six or seven inches in diameter and two and a half inches thick, several of which may be seen at the South Kensington Museum, Section 34, from Nos. 7445 to 7461, including seventeen choice specimens; and although they are catalogued as "Clocks," their construction is identical, with respect to their time-keeping arrangements, to the original watch referred to; and although these ponderous instruments, from their dimensions, may surprise some readers, many among us can remember the ponderous watch when removed from the fob of our relative or neighbour. Many watches are at the present day in use weighing about eight ounces.

The watch continued for several years without much marked improvement, but when the era in watchwork dawned, especially among the English, there was no effort dormant. As I have stated, the subject was of such importance that it attracted the attention and the persevering study of the best mechanics, mathematicians, astronomers, and divines, out of whose combined assiduity the problem of time-measuring, to purposes the most useful, came — namely, the carpenter Harrison's timepiece for determining the longitude at sea, by which means vessels were not only more safely conducted across the ocean, but with more speed and precision directed to their destinations. This wonderful piece of mechanism was nothing more than an improved large watch of that date—namely, A.D., 1736, and no wonder that the production of such a marvellous instrument should have gained the Parliamentary reward of £20,000. But, then, we must not forget that Harrison laboured at his idol machine nearly all his life—about forty years. This identical instrument is now at the Royal Observatory, Greenwich, and is treasured by the officers of that institution. It was the production of this wonderful automaton which caused men of genius to direct their attention towards improving the pocket watch, and from such emulation came another marvel — namely, the horizontal one, commenced by Tompion and completed by Graham, as previously stated.

It is more than probable that few persons are aware that the different terms applied to watches by which they are distinguished, such as vertical, horizontal, duplex, and chronometer, refer to the kind of escapement applied; nor is it generally known, even among working watchmakers, that all the escapements introduced to good watches, whether at home or abroad, were invented by Englishmen. It is true that many ingenious contrivances have been introduced at different times by French and other artists; but they themselves have ceased to apply them, and with the exception of the vertical escapement, they generally adopt those principles only which were devised by English watchmakers.

In this first chapter it is intended chiefly to introduce the watch in its popular form, leaving details to follow, and thus, while we have somewhat before us the horizontal or first improved watch, a few words more concerning the foreign one will be necessary.

The foreign watch is frequently denominated a Geneva by persons who do not know that there is any difference between the two terms, Geneva and Swiss, which of late years have become so familiar amongst the English.

The Geneva watch is, in many instances, miscalled, for it more frequently happens that the so-called Geneva watch is a Swiss one; which latter watches have been imported in such vast quantities as to cause no little astonishment concerning their disposal. This statement probably may require some explanation.

The watches made in Geneva are usually of superior make and finish, and are, therefore, high in price. Few, comparatively, are made there, which may probably be accounted for by the fact that in many instances an English watch can be obtained for very little more than has to be charged for the Geneva one. Swiss watches, on the contrary, are produced in great quantities. They are made with great rapidity by machinery, to facilitate which most of the parts are left very soft, and are less carefully finished than those of the Geneva kind; and further, the watch made at the latter place is examined and completed with more care than the Swiss one. Thus the difference in price of the Geneva is double that of the other. But the casual purchaser, or wearer, cannot judge of the relative qualities of the two kinds, and not unfrequently pays for the Swiss watch a price equal to that which would be charged for the Geneva made one. This fact is before us, that the Geneva watch is very durable, while the Swiss one wears out quickly. There is an unerring rule by which the one may be selected from the other—namely, by opening the back of the case and examining the stamp. The Geneva one will have the inner part of the back of the case stamped, and in the inclosure of such stamp will be seen the letter G., without such no watch is of Geneva manufacture. On the other hand, the Swiss watch-case will frequently—but mark, not always—have a stamp resembling zig-zag of two lines, but all Swiss watch-cases do not bear the stamp. Therefore, any watch-case having no stamp is not of Geneva manufacture. In closing this introductory chapter I am induced to quote a few lines written by that painstaking antiquarian, Mr. E. J. Wood, in a volume entitled "Curiosities of Clocks and Watches from the Earliest Times." He thus proceeds: "How many of the folk who so often, in the course of a day, pull out their watches to see the hour, give a thought to the history of those mechanical contrivances for measuring the flight of moments. Very few, we think. It is sufficient for most people if their watches keep correct time, and whatever historical interest may be appertaining to the little machines, lies shut up and unobserved among the wheels and springs which the cases inclose. Let us take our timekeeper out of our pocket, and to the tune of its unceasing nervous voice—like an audible theme—we will jot down some gathered notes from its scattered history, with the ambitious hope that he or she who may peruse our collectanea and notanda may the more prize, for dear memory's sake, the large old-fashioned family silver watch, with the ribbon and pinchbeck seals, which now lies neglected and almost forgotten in his or her relic-drawer; but which was a highly-valued part of the personal effects of grandfather before he went into that land wherein time-measurers are not needed. Only a little sketch of imagination is required in order to give to the small admonitory moralist which lies on the table before us an articulate utterance, so pregnant in its 'tick, tick,' as if it were counting old grandsire Time's gains of golden moments into heaps, one by one, as each falls sounding into the past."

(To be continued.)

LESSONS ON CHEMISTRY.*

By Selimo R. Bottone.

(Late of the Istituto Bellino, Novara, Italy.)

(Continued from p. 397.)

198.—Being now in a position to understand somewhat of the theories which we briefly laid before him at the commencement of the lessons, the student will do well to follow us in the review which we propose making of many of the compounds which we have studied, especially with relation to the ancient and received theories, nomenclature, &c.

We have pointed out the *fact* at paragraphs 9 and 10 that all bodies, in combining with each other, unite in certain definite proportions; or, if one body can unite with another in several proportions, yet the numbers representing these proportions will invariably be multiples or submultiples of the number representing the proportion in which the first combination took place. As a knowledge of this fact is of the highest importance to the chemist, the student is particularly advised to bear it constantly in mind, and to commit to memory these combining proportions. By so doing he will be enabled to calculate, without difficulty, the quantity of certain given elements required to form a given compound; or, *vice versa*, he will be in a position to specify the exact amount of a given compound requisite to eliminate two or more given elements. The compounds of chlorine with hydrogen, with oxygen, and with sulphur, also those of sulphur with oxygen and hydrogen, furnish us with numerous examples of the law of *combining proportions*.

Hydrogen (36) being the lightest body known and entering into combination with almost every

* The right of translation and reproduction is reserved.

known element, has been generally* accepted as the standard or unity of comparison for determining the combining weights of bodies. Hence it is customary to give its combining weight as 1·00. Now, we have seen, at paragraph 53, that chlorine combines with hydrogen, and at paragraph 54 we have learnt that one volume of hydrogen requires exactly one volume of chlorine to saturate it. On weighing the volumes of chlorine and hydrogen employed, we find that the volume of chlorine is 35·5 times as heavy as the equal volume of hydrogen: hence we are justified in stating that *the combining weight of hydrogen being* 1·00, *that of chlorine is* 35·5. In other words, hydrochloric acid contains, by weight, 35·5 parts of chlorine united to 1 part of hydrogen.

199.—Both chlorine and hydrogen combine with oxygen, the former in several, the latter in only two proportions. Thus, taking a given volume of hydrogen, weighing, for example, 1 gramme, we shall find that the quantity, by weight, of oxygen required to form with it the first compound, *water*, is exactly 8 grammes, while to form the second compound 16 grammes of oxygen are requisite. Chlorine forms several oxides (see Section 6B), and the quantities of oxygen in grammes required to form these oxides, with 35·5 grammes of oxygen, is tabulated below:—

	Chlorine.	Oxygen.
Chlorine monoxide	= 35·5	$8 = 8 \times 1$
Chlorine trioxide	= 35·5	$24 = 8 \times 3$
Chlorine tetroxide	= 35·5	$32 = 8 \times 4$
Chlorine pentoxide	= 35·5	$40 = 8 \times 5$
Chlorine heptoxide	= 35·5	$56 = 8 \times 7$

From the composition of these compounds we are led to infer that the relative combining weights of oxygen, hydrogen, and chlorine, are respectively 8, 1·00, and 35·5. So far we have kept ourselves within the strict boundary of fact, but the mind of man is so constituted as to render him desirous of being able to see or imagine a *cause* for every *effect* that comes under his notice. Hence several theories have been propounded, with the intention of explaining these invariable "combining proportions" of the elements. These theories, though plausible and possibly correct, do not seem to admit of direct proof, therefore the student must always bear in mind that though the law of "fixed" and "multiple" combining proportions is a physical fact, yet the theories deduced therefrom are only *hypothesis*, which may at any moment be disproved on the discovery of new and antagonistic *facts*.

200.—The first general attempt to explain the law of combining proportions was made by Dalton, in 1804. This celebrated chemist applied an idea which had been held by several Greek philosophers to chemistry, and the result of this application was the "Atomic Theory."

The atomic theory supposes all matter to be constituted of congeries of infinitesimally small, indivisible particles, called *atoms*. The atom of each element possesses uniformly the same size and weight, though the atoms of different elements differ from each other both in size and weight. In order to understand this more clearly let us represent the atoms of the elements under consideration by circles, thus:—

Hydrogen ......

Oxygen ....

Chlorine ....

Carbon ....

According to the theory, each of these different atoms has a constant weight, different for each element, and we can represent the difference in weight by placing a number in the circle, which will point out the relative weight of each atom, thus:—

Hydrogen ... 1

Oxygen 8

Chlorine ...... 35·5

Carbon......... 6

Granting the above suppositions to be correct, it is easy to understand why combination can only take place in certain fixed proportions. Let us suppose that hydrogen be about to unite with oxygen. It will be at once evident that less than one atom cannot enter into combination at a time, the atom being indivisible. Hence the simplest compound which can possibly exist will be one consisting of 1 atom of hydrogen united to 1 atom of oxygen, thus:—

1—8

It also becomes evident that if other compounds containing hydrogen and oxygen can exist, the proportions in which these two elements will unite must always be multiples of the weight of their atoms, *id est*, multiples of 1 and of 8. Such, in fact, is found to be the case. We have, therefore, water—

1—8

And hydrogen dioxide—

1—8—8

Hydrochloric acid............ 1—35·5

Sulphur monoxide........... 16—8

Sulphur dioxide.............. 16—8—8

Sulphur trioxide .... 16—8—8—8

Carbon monoxide .... 6—8

Carbon dioxide .... 6—8—8

201.—This theory is so consistent with observed facts, and gives so satisfactory an explanation of the reason for which combination can only take place in definite proportions (differing, however, for each element), that it was almost universally adopted by chemists. Consequently, it became customary to designate the weights in which elements combined with each other by the term "atomic weights." Some chemists, while admitting the plausibility of the theory, were adverse to considering the theory as fully proved, and consequently preferred giving the name of "equivalents" to the weights in which elements combine with each other.

202.—Another theory which modified considerably the one just described soon arose. This, the "molecular theory," was based on observations made by Avogadro, Boyle, Mariotte, Gay-Lussac, Ampère, Dulong, Petit, &c. The principal facts brought to light by these observations were the following:—

1st. When two elements (in the gaseous state) unite *in equal volumes*, the volume of the resulting compound is equal to the sum of the volumes employed; in other words, *no contraction takes place*. To render this clearer, the following graphic illustration of the result of the action of one volume of chlorine on one volume of hydrogen, may be of service:—

$\boxed{Cl} + \boxed{H} = \boxed{H \quad Cl}$

2nd. When two elements (in the gaseous state) unite in *unequal* volumes, the volume of the resulting compound *is less than* the sum of the volumes employed, and in all known cases is equal to two volumes only; *id est, contraction takes place*. The following illustration of the result of the action of one volume of oxygen, on two volumes of hydrogen, will elucidate this:—

$\boxed{H} + \boxed{H} + \boxed{O} = \boxed{H_2 \quad O}$

Here we see that when two volumes of hydrogen unite with only one volume of oxygen, *only two volumes* of water gas are produced, *and not three volumes*, as might at first sight be expected.

We will give another example of this case, as is well to fix the fact in the reader's mind. One volume of nitrogen unites with three volumes of hydrogen to form two volumes of ammonia, thus:

$\boxed{N} + \boxed{H} + \boxed{H} + \boxed{H} = \boxed{N \quad H_3}$

Making these facts his starting point, Avogadro devised the following theory, which, with some slight modification, is the accepted theory of the day:—

203.—Matter is constituted of indivisible particles, termed *atoms*. These atoms being gifted with the power of attraction, *cannot exist separately for any appreciable space of time*, but tend to unite in little groups of two or more atoms, termed molecules.*

The molecules, though infinitesimally small, and indistinguishable by the most powerful means at our disposal, *can exist separately*. All bodies when brought to the state of gas, contain in equal volumes an equal number of molecules,† in other words, *the size of the molecule of all gases is the same at equal temperatures*. The molecule of all gases is constituted of two atoms. Hence the relative weight of equal volumes of any simple gases will be the relative weight of their respective atoms.

204.—This is, briefly stated, the theory of molecules, as proposed by Avogadro. Let us now see how far it is in accordance with facts. We weigh a given volume (say 11·2 litres) of hydrogen gas, and we find it to weigh exactly one gramme. On weighing equal volumes of the following gases, we obtain the results tabulated below:—

11·2 litres of oxygen	weigh	16	grammes.
„ chlorine	„	35·5	„
„ bromine gas	„	80·	„
„ iodine gas	„	127·	„
„ nitrogen	„	14·	„
„ sulphur gas	„	32·	„

If then, the above theory be correct, these numbers represent the relative weights of the atoms of these seven bodies, and we find that they agree perfectly with the results obtained by experiment. We observe, however, a peculiarity with regard to the relative weights of the volumes of hydrogen and oxygen, which, taken in conjunction with the weight of oxygen necessary to saturate the weight of one volume of hydrogen, seems at first blush at variance with the experiment.

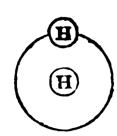
We have seen (200), that 1 gramme of hydrogen unites with 8 grammes of oxygen to form 9 grammes of water. This would lead us to suppose that the relative weights of the atoms of hydrogen and oxygen were respectively 1 and 8.

We have also seen (204) that the weights of two equal volumes, one of hydrogen, and the other of oxygen, are as 1 to 16. According to Avogadro's theory, the inference would naturally be that 1 and 16, and not 1 and 8, are the true atomic weights of these two elements. Both these theories cannot be right; the question then is, Which is correct? Without further evidence, it would be very difficult to decide; but on applying other tests with which subsequent discoveries have furnished us, the balance of probabilities seems to point in favour of Avogadro's view—viz., that the atomic weight of hydrogen being 1, that of oxygen is 16.

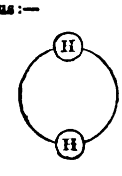
In the first place, granting that condensation takes place during combination between an unequal number of atoms, we find an additional reason for believing that the above numbers represent the true atomic weights of hydrogen and oxygen in the fact that when hydrogen and oxygen unite, contraction does take place, exactly

* For several years continental chemists took oxygen as the standard, fixing its combining weight at 100.

* It is not inconsistent with sound reasoning to believe that these atoms are spheres, and that in the molecules they perform revolutions round a common centre, which may either be one of the atoms or else the common centre of attractive force. To illustrate this let the annexed cuts represent the molecule of hydrogen. We can imagine, first, that one atom performs a revolution round the other thus:—



Or, secondly, that both atoms are revolving around a common centre, thus:—



Either of these views adapts itself to the explanation of the behaviour of gases during combination.

† At equal temperatures.

to the amount indicated by the theory. Thus, let us take two volumes of hydrogen—

$\boxed{H}$ $\boxed{H}$

each weighing one gramme, and one volume of oxygen—

$\boxed{O}$

weighing 16 grammes, and we shall find that after combination the product will occupy only two volumes, while weighing 18 grammes.

We therefore conclude that the constitution of this compound (water) is $\overset{1}{H}_2\overset{16}{O}$, and not $\overset{1}{H}\overset{8}{O}$.

205.—So far either theory explains the fact of "combination in definite proportions," while Avogadro's theory goes a step further, and gives us the probable reason of the contraction which takes place in the volume of gases when combination ensues between unequal volumes. Several facts have conduced to render this latter theory more probable; none have had so much influence as the experiments of Messrs. Dulong, Petit, and Regnault on the specific heat of the elements.

WEATHER MAPS.

THEIR CHARACTERISTICS AND TEACHINGS—AN UNOFFICIAL WEATHER REPORT.

By W. R. BIRT, F.R.A.S., F.M.S.

A FEW words will suffice for the first part of this subject. Lines of equal pressure and temperature, the prevailing winds and weather, as clouds, rain, hail, or snow, and the roughness of the sea, are the principal features of these maps. We see at a glance the distribution of "weather elements" over Great Britain and Ireland, France, Belgium, Denmark, and Norway, and we have, in addition, the numerical values of these elements given on the opposite page.

A word or two in addition on these characteristics. The lines of equal temperature show us the distribution of heat over the countries mentioned, and mark out the direction of the zones of warm and cold air. The lines of equal pressure exhibit regions of high and low barometers, and combined with the wind make us acquainted with localities of storm and calm. The isotherms, or equal temperature lines, need no comment, but as regards the isobars, or equal pressure lines, it is necessary to mention that they do not represent the existence of any one given phenomenon, *per se*. And on this we are the more disposed to *insist*, as we have reason to believe that the "laws" already ascertained of the motions of vast bodies of air, to which the designation "atmospheric waves" has been given, *have not been recognised*. As the barometric curve at any one station is a compound effect of several co-existent phenomena expressed as to succession in time, so the isobar is merely the effect of the same co-existent phenomena expressed as to geographical distribution. To read the one requires as much study as to read the other, but when read each contributes to elucidate the phenomena which give rise to them.

There is nothing of greater utility in reading natural phenomena than *theory*; even if the theory employed be worthless it enables the theorist to connect and classify facts. In order to set forth a portion of the "teachings" of the weather maps we shall make use of a theory which, we apprehend, will connect many of the facts recorded, and to elucidate these facts the more fully we shall present the reader with a series of barometric curves projected from readings at eight distinct stations, viz., Thurso and Christiansund, on the extreme north-west of the area embraced by the weather maps. Plymouth and Valencia on the south-west, Rochefort and Biarritz on the south, and Brussels and Dover towards the eastern part of the same area. The theory is that of "Atmospheric Waves," already given in "our" journal, Vol. XIII., Nos. 323, 329, and 331, pp. 248, 398, and 449. To exhibit the passage of these waves with greater distinctness, we shall examine the barometric effects on three lines—(1) Biarritz, near the south-east angle of the Bay of Biscay, Plymouth, and Thurso; (2) Biarritz, Dover, and Christiansund; (3) Valencia, Dover, and Brussels. The waves from the north-west with north-east and south-west winds will be designated by large Roman characters, A, B, and so on, and those from the south-west with north-west and south-east winds, by *small Italic* characters, *a*, *b*, &c.

Although the movements of the barometer are very complex on account of the simultaneous progression of the two sets of waves, accompanied in some cases with waves of smaller dimensions riding on their slopes, it is quite possible to determine the elements of passing waves by noting the connection between the barometer, the wind, and the weather. From the 18th to the 30th of March inclusive a well marked wave of the N.W. system (B) transited the Board of Trade area; its *anterior trough* impinged on our shores on the 18th; its *anterior slope*, characterised by keen north-easterly winds, accompanied by hard frosts in some parts, and by showers of snow and hail, mingled with rain, in others, occupied four days in its passage; on the 23rd its *crest* extended in the direction, Christiansund, 30·27; Thurso, 30·21; and Valencia, 30·10, rising at Thurso and Valencia, wind north-east, temperature from 30° to 40° Fahrenheit, cloudy, with snow showers, thunder, and hail. From the 23rd to the 27th the barometer *fell* at nearly all the selected stations, yet the posterior slope had not made its appearance, for the relative geographical distribution remained the same, *i.e.*, the gradients of its *anterior slope* extended from north-west to south-east, or, in other words, the *crest* lingered over the north-west portion of the area, passing Plymouth on the 26th, the barometer meanwhile falling. The wind, however, continued northerly until the 27th, when the southerly and south-westerly winds became established as the *posterior slope* passed, and as the *posterior trough* approached. On and after the 27th until the 30th, the isotherms of 40° and 50° extended northerly and north-easterly, correspondent with the establishment of the south-westerly wind. The *posterior trough* passed Thurso on the 28th, barometer 29·16; Christiansund and Valencia on the 29th, the barometer reading at Christiansund 29·06, and Valencia 29·02; Plymouth and Dover on the 30th, barometer at Plymouth 29·26, and at D... 29.33.

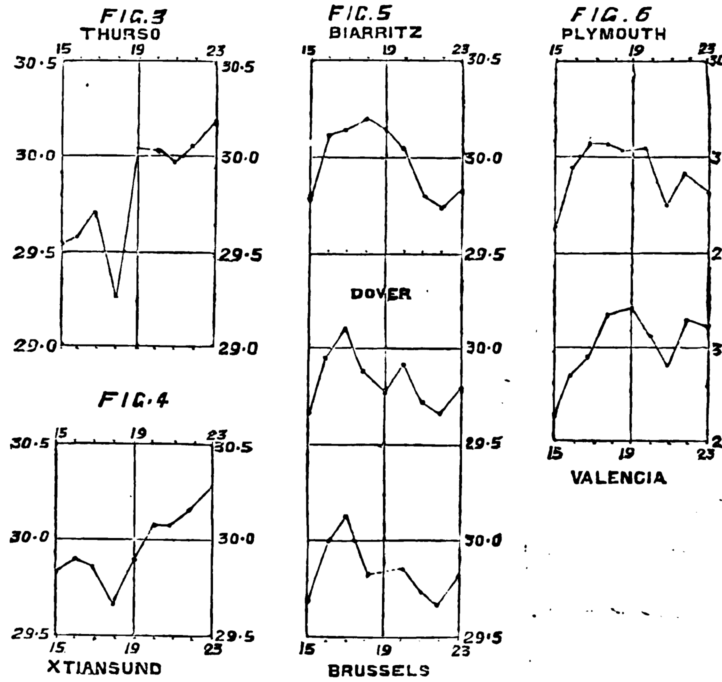
FIG. 5 BIARRITZ

FIG. 6 PLYMOUTH



The close connection so very clearly shown by the aid of the weather maps between the barometer, wind and weather generally, and in particular instance the contemporaneity of progression of the weather with the transit of waves, are important features for study.

The late Sir John Herschel, in the year ... speaking of the winds as connected with ...

metrical movements, refers to those which arise from barometric *oscillation*, and which are connected with such oscillation in a direct and intimate manner. Every wave-like movement in a fluid consists of two distinct things—*an advancing form* and *a molecular* movement. Now the *advancing form* is indicated to us by the barometer, the *molecular movement* by the wind, and between these two phenomena there subsists of necessity a close and purely dynamical connection. "It would," says Sir John Herschel, "be no small meteorological discovery, if by the study of the characters and progress of barometrical fluctuations, we could either make out any law of the greater ones which would enable us even roughly to predict them or any peculiarity in their physiognomy by which we could recognise them in their earlier stages, as by this we might possibly be led to the prediction of great storms."

The theory employed supposes that the barometric movements of the sixteen days from March 15 to 30 inclusive were due to two sets of oppositely directed winds; one blowing from north-east, which were compensated by south-west winds, the other from north-west with south-east compensating winds. These winds, advancing laterally and *simultaneously* from north-west and south-west, occasioned much complexity in the treated more as simple than complex exponents of phenomena, and the question has been put, "Is the statical force—*i.e.*, the excess of barometric readings at one station, as compared with another, an exponent of the existent wind?" We shall not enter upon the mathematical treatment of this question, but simply remark, as it appears to us, that the difficulty of arriving at any definite conclusions as to weather forecasts or storm previsions, for which purposes statical force has been employed, mainly results from the *non-recognition* of the existence of the two simultaneous sets of waves, of which we find abundant evidence in the weather maps.

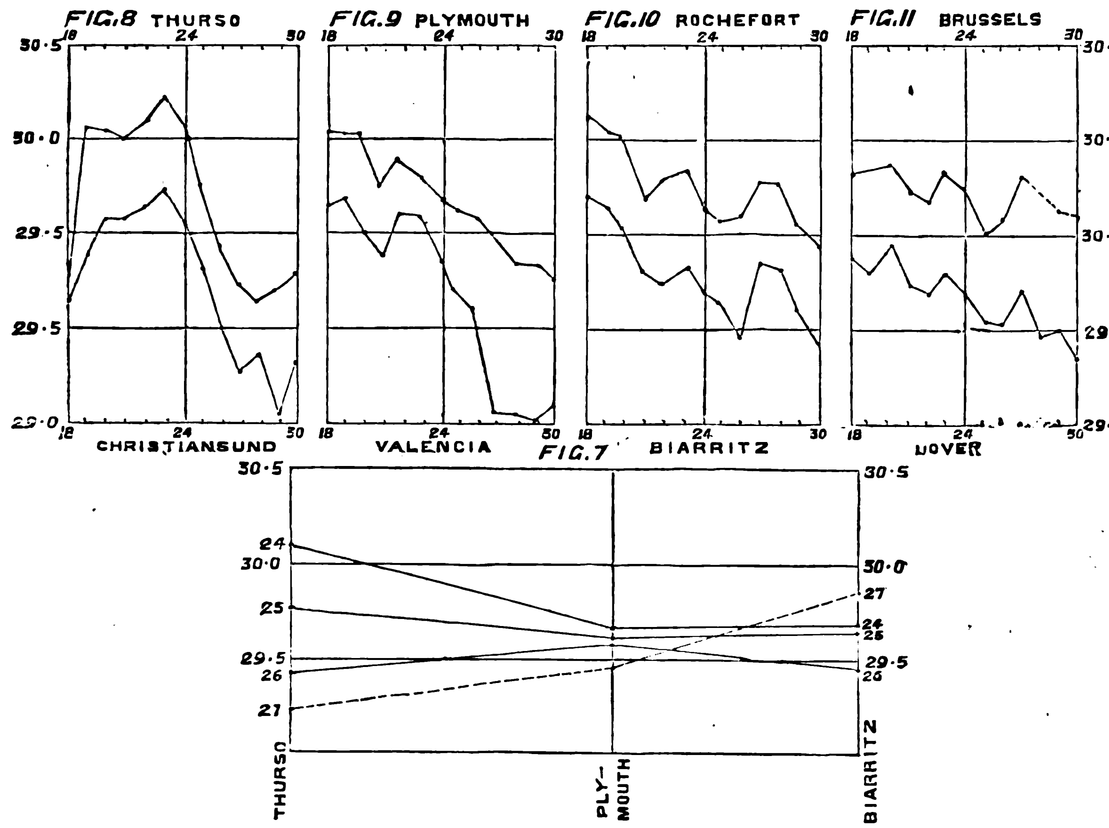
Illustrations.

Fig. 1.—Barometric Sections.—Biarritz, Dover, and Christiansund, March 18, 23, and 29. The dotted lines (18th and 29th) show the dips towards the north.

Fig. 2.—Barometric Sections.—Biarritz, Plymouth, and Thurso, March 18, 23, and 28. The dotted lines (18th and 28th) show the dips towards the depression near Thurso.

Figs. 3 and 4.—Barometric curves at the northern stations, Thurso, and Christiansund, showing the minimum of the 18th, produced by the anterior trough of wave *b*.

In order to exhibit the barometric affections resulting from the transits of the two waves B and *b*, eight curves, arranged in pairs, have been selected; these are so given as to show the gradual *diminution of range* from the north-west towards Brussels, the curves of greater range being placed on the left, with the largest range of each pair below its fellow. The localities are Fig. 8, Thurso and Christiansund on the extreme north-west of the area; Fig. 9, Plymouth and Valencia on the south-west; Fig. 10, Rochefort and Biarritz on the southern part; and Fig. 11, Brussels and Dover towards the eastern part of area. A mere glance at these curves is sufficient to show that the greatest range occurs in the north-west, the least in the neighbourhood of Brussels; also that during the thirteen days from the 18th to the 30th, inclusive, the movements of the barometer at each pair of stations selected were such as to lead to the expectation that the entire area may be divided into barometric districts of specific types, such as the Hyperborean, including the north of Scotland, the North Sea, and Norway; the Atlantic, referring principally to the western shores of Ireland and the entrance to the Channel; the Biscayan, as the north of Spain and the west of France; the Mediterranean, comprising the south of France, and the *Nodal*,



phenomena and also in the maps; but by the help of sections and curves it is possible to unravel this complexity. Taking as a principle that the winds are regularly disposed on each side of a line of barometric *maxima* or *minima*, north-east winds require, according to "Buy's Ballot's Law," that a maximum should exist to the right, or in the north-west, and south-west winds require that the same maximum should be found also to the right or in the south-east. The same principle applies to the north-west and south-east winds, so that with the weather maps before us the direction of the wind in most cases points out the quarters in which we may look for high or low barometers. As just noticed, the simultaneous existence of these winds render the maps very complex, some days the north-east winds being predominant, on others the north-west or south-east, but if sections be drawn, as, for example, that from Biarritz to Thurso on the 18th (see Fig. 2), when the crest of wave *b* passed the southern station and the troughs of waves B and *a* intersected not far from Thurso, we shall gain a clearer idea of the distribution of pressure than from the isobars alone, and if these sections be accompanied with curves, as, for example, the eight herewith given, we may be able still more distinctly to trace the passages of the crests and troughs across the area. Up to the present time isobars have been

Fig. 5.—Barometric curves at the eastern stations, Biarritz, Dover, and Brussels, showing the maxima of the 17th and 18th, arising from the crest of wave A, and those of he 20th from the crest of wave *b*. The opposition of the maximum at Biarritz, to the minima at Thurso and Christiansund (Figs. 3 and 4, and 5), indicates approximately the semi-amplitude of wave *b*, but the area is too small for the determination of the amplitude.

Fig. 6.—Barometric curves at Plymouth and Valencia, showing the maxima, forming the crest of wave *b*, and the minima of the 21st produced as the anterior slope of wave B passed over.

Fig. 7.—Barometric Sections, Biarritz, Plymouth, and Thurso, March 24 and 25, showing the anterior slope of wave B, the higher readings occurring at Thurso, wind north-east, and at Plymouth wind north north-east, which is quite in accordance with "Buy's Ballot's Law." The section on the 26th shows a crest passing Plymouth, which although not sufficiently pronounced to raise the barometer, is, nevertheless, apparent on the Plymouth curve as a slight bulge (see Fig. 9). The section of the 27th (dotted line) shows that the posterior slope of wave B had passed on to Biarritz, wind at Plymouth south-west accordant with "Buy's Ballot's Law."

of which Brussels may be regarded as the centre. From the data supplied by the Meteorological Office, the laws of barometric sequence and range in each of these regions may be determined.

It will be seen from the curves that at the southern and eastern stations maxima of the barometer occurred on the 27th and 28th of March, and on consulting the weather tables for these days it will be found that at Paris the barometer attained a maximum on the 27th, but it was not until the 28th that maxima passed Lyons and Toulon. Sections from Toulon to Thurso on these days show that these maxima were the crest of wave B passing off towards the south-east. The sections are as follows:—

Stations.	March 27.		March 28.
Toulon.........	29·91	...	30·14
Lyons	·90	...	30 00
Paris	·82	...	29·73
Dover	·71	...	·46
London	·66	...	·41
Liverpool......	·59	...	·30
Leith	·46	...	·20
Nairn	·38	...	·20
Thurso.........	·23	...	·16

On the 28th the posterior trough of wave B passed Thurso, so that the amplitude of the posterior slope, or semi-amplitude of the wave, was

represented by the space between Toulon and Thurso, and this was about the extent of the amplitude of the anterior slope. It is probable the entire wave extended over double the distance of Thurso from Toulon.

MICHAEL FARADAY.*

THE life-story of Michael Faraday is one of the few which cannot be told too frequently. The son of a journeyman blacksmith, by the force of his innate genius he made his name known in every part of the globe, and by a limited circle of friends he was loved and revered, not so much for his scientific attainments as for his moral worth and kindly good-nature. For this reason we cordially welcome the appearance of the little book by Dr. Gladstone; for although Dr. Tyndall has written the life of Faraday from a scientific point of view, and Dr. Bence Jones has published a biography, hitherto there has been no volume which showed us Faraday as a man as well as a philosopher. Dr. Gladstone, however, has succeeded in combining enough of the scientific record of his life with much of those inner and, as presented to the general public, unseen features of his character. It appears that in a review of the "Life and Letters," Dr. Gladstone mentioned that he thought of giving to the public his own reminiscences of the great philosopher, and urged by his friends he has put the idea into shape, the result being this little book, designed for those of Faraday's "fellow-countrymen who venerate his noble character without being able to follow his scientific researches." For the various facts mentioned in this volume Dr. Gladstone is indebted in some instances to the works of Prof. Tyndall and Dr. Bence Jones, to the Corporation of the Trinity House, to several friends, and to his own personal recollections; but where practicable he has preferred to illustrate the character of Faraday by documents or incidents not previously published. The book is divided into five sections, under the following heads—the Story of his Life, Study of his Character, Fruits of his Experience, his Method of Working, and the Value of his Discoveries. The character in which Michael Faraday is first introduced to us is as an "inquisitive boy," minding his baby sister, playing at marbles, learning the three R's at a day-school, and residing at Jacob's Well-mews in the neighbourhood of Manchester-square. He was the third child of James and Margaret Faraday, and was born in Newington Butts, on September 22, 1791. His parents being only poor, hard-working people, young Michael was sent to work as soon as he was able and an opportunity offered, his first situation being as errand boy to a bookseller named Riebau, an intelligent man, with a "leaning to astrology," who was so satisfied that he afterwards took him as an apprentice without a premium. Once in the shop, with permission to look at the books on the shelves, Faraday made every use of his position, devouring such works as Mrs. Marcet's "Conversations on Chemistry," and Watts's "Improvement of the Mind," and carefully reading, as well as binding, the various scientific books which found their way to Mr. Riebau's premises. At this early period of his career of scientific research we find the ruling characteristic of his treatment of natural phenomena strongly developed, for, although doubtless he accepted the statements of Mrs. Marcet as correct, he was not satisfied till he had demonstrated their truth—at least of those for which his limited means permitted the necessary expenditure. Thus he made an electrical machine with a phial, but afterwards obtained a "real cylinder," and constructed other electrical apparatus in a similar rudimentary manner—a manner which served him through after life, even for some of his most accurate investigations.

The most important feature of this period of his life, which probably formed a turning point or a starting-point in his career, was his attendance at the lectures on Natural Philosophy delivered by Mr. Tatum, the needful shillings being furnished by his elder brother Robert, an "investment" the latter could never have regretted. Here Faraday made his first acquaintance with scientific lectures, and at the same time, with other earnest students, with some of whom a life-long friendship was formed—notably with Benjamin Abbot, who was well educated, and held a responsible post in the city. It was in Mr. Abbott's house—in the kitchen, and from the end of the kitchen-table—that Faraday made his early experiments and delivered his first lecture. The lectures delivered by Tatum fell on no careless or inappreciative ears: his words found no unprepared seed-ground in the brain of Faraday, who took copious notes, and afterwards wrote out a clear copy, with descriptions of the experiments and neat drawings of the apparatus,—binding the whole afterwards in four volumes, with exhaustive indices, and dedicating them to his master, Mr. Riebau, as evidence that the permission to examine the books in the shop had not been used for idle purposes. At this time there was a lodger at his master's, M. Masquerier, a French emigré and distinguished artist, who, struck with the intelligence of the lad, lent him his books and taught him perspective; and among the visitors to the shop was a Mr. Dance, who took Faraday to hear some of the lectures of Sir Humphry Davy, which he followed with eager and intense interest, taking copious notes, which he afterwards wrote out in the same manner as he had done with Tatum's. Soon after this Sir H. Davy injured his eyes by an explosion of chloride of nitrogen, and Faraday was fortunate enough to obtain the post of amanuensis, probably, says Dr. Gladstone, through the introduction of his artist friend, Masquerier. This, however, lasted a very short time, but the appointment was so far fortunate for the youthful philosopher that it appears to have determined him to write to Sir H. Davy, telling him his desire to study Science, and forwarding the notes of his lectures. Davy wrote an answer, and in the personal interview which followed, advised the bookseller to stick to his business, promising him the work of the Institution and his own besides. Soon after this, however, the laboratory assistant at the Royal Institution was discharged, and Sir Humphry remembered Faraday, who was thus installed in the post on March 1, 1813, at a salary of 25s. a week and a room in the house. His duties were to assist and attend the lecturers and professors, to keep the models and instruments free from dust, and to take charge of the apparatus and furniture of the laboratory and lecture-room generally. From the very first Faraday began experimenting; for a few days after the appointment he was extracting sugar from beet, and before the middle of April had been exposed to terrible risks in assisting Sir Humphry with his investigation of chloride of nitrogen, no fewer than four separate explosions occurring, in one of which he was suddenly stunned and rather severely wounded.

About this time he joined the "City Philosophical Society," consisting of some thirty or forty members, composed of the middle and lower classes, who met together for mutual instruction and improvement; half a dozen of these would meet to criticise the work of each other, with results which Faraday describes as "most valuable," from the "discipline being very sturdy and the remarks very plain and open." Seven months after his appointment, Sir Humphry, wishing to travel, took him as an amanuensis, and for a year and a half, in the company of that great philosopher, he wandered about France, Italy, Switzerland, and passed through Germany, the Tyrol, and Holland, keeping a journal, the most interesting and valuable portions of which are reproduced by Dr. Bence Jones in the "Life and Letters." "This year and a half," says Dr. Gladstone, "may be considered as the time of Faraday's education; it was the period of his life that best corresponds with the collegiate course of other men who have attained high distinction in the world of thought. But his university was Europe; his professors the master whom he served, and those illustrious men to whom the renown of Davy introduced the travellers. It made him personally known, also, to foreign savants, at a time when there was little intercourse between Great Britain and the Continent; and thus he was associated with the French Academy of Sciences while still young, his works found a welcome all over Europe, and some of the best representatives of foreign science became his most intimate friends."

In 1815 he obtained a "somewhat higher position" and an increase of salary, which was further augmented to £100 per annum in the following year. It was in September, 1815, that he took the position formerly occupied by Brande, as the change of handwriting in the laboratory note-book shows. His first lecture was given on January 17, 1816, at the City Philosophical Society, and in the same year his first paper was published in the *Quarterly Journal of Science*. Just before his marriage to Sarah Barnard, the daughter of a silversmith in Paternoster-row, which took place in 1821, he was appointed superintendent of the house and laboratory, and in February, 1825, became director, a position of greater responsibility and influence. One of the first innovations consequent on this was an invitation to the members to spend a scientific evening in the laboratory, and thus arose the well-known "Friday evenings," which in his hands and in those of his successors, have done much to popularise science. "Up to 1833 Faraday was bringing the forces of nature in subjection to man on a salary of only £100 per annum;" then John Fuller founded a Professorship of Chemistry, and appointed Faraday to the post with the endowment of nearly £100 a year for life. But during the earlier part of his career Faraday made commercial analyses, and did other professional work, which in 1830 and 1831 brought in an income of certainly £1,000 a year, but just then he discovered the evolution of electricity from magnetism, and the choice had to be made between science alone and a limited purse, or professional work, a full purse, and an abandonment of those investigations which were to lead to great discoveries. "The choice was deliberately made: Nature revealed to him more and more of her secrets, but his professional gains sank in 1832 to £155 9s., and during no subsequent year did they amount even to that." In 1836 he accepted the appointment of scientific adviser to the Trinity House, which made a slight increase in his income; but the story of his life shows that the talents which he brought to bear on scientific research would, turned in other directions, have enabled him to retire in middle age on a large fortune. To Faraday, however, the pursuit of science was the *summum bonum* of earthly existence; to him science brought a reward which he could have found in no other direction; and as he frequently expresses it, his life was all he desired. Honours were showered upon him in all directions, but he refused the highest honour in the power of science to confer—the presidentship of the Royal Society, saying to the friend who so worthily follows him, "Tyndall, I must remain plain Michael Faraday to the last; and let me now tell you that if I accepted the honour which the Royal Society desires to confer upon me, I would not answer for the integrity of my intellect for a single year." In 1835 he accepted a pension from the Government, and in 1858 the Queen offered him a house at Hampton Court, where he spent the greater portion of his remaining years, and died on the 25th of August, 1867. He was buried in Highgate Cemetery, and the world mourned the "prince of investigators," the blacksmith's son, who was decorated with no fewer than ninety-five titles and marks of merit, and was a member of so many learned bodies that M. Riess, the celebrated Berlin electrician, once addressed a letter to him as "Professor Michael Faraday, Member of all Academies of Science, London."

These are a few of the salient points in the career of the "great philosopher," the story of whose life is a grandly-shining beacon to guide the toiling followers of his footsteps, and English mechanics and students of science will do well to carefully read and commit to memory the words of Dr. Gladstone's little book. The volume teems with anecdotes which exhibit the character of the man, and "his method of working" is a chapter that cannot be too frequently studied. His opinions on those questions of public importance which it has become more imperatively necessary to solve at the present day, when the full effect of his work is beginning to be felt, are marked by clear common-sense. He was examined on the scientific education question before the Public Schools Commission in 1862, and his opinion was emphatic—"That the natural knowledge which has been given to the world in such abundance during the last fifty years should remain untouched, and that no sufficient attempt should be made to convey it to the young mind growing up and obtaining its first views of those things, is to me a matter *so strange* that I find it *difficult to understand*. Though I think I see the opposition breaking away, it is yet a very hard one to overcome. That it ought to be overcome I have not *the least doubt in the world*." Faraday thought that science should be taught at an early age. He would teach "all those things that come before classics in the programme of the London University—mechanics, hydrostatics, hydraulics, pneumatics, acoustics, and optics. They are very simple and easily understood when they are looked at with attention by both man and boy. With a candle, a lamp, and a lens or two,

* Michael Faraday. By J. H. Gladstone, Ph.D., F.R.S. London: Macmillan.

intelligent instructor might teach optics in a very short time; and so with chemistry." Faraday, the prince of lecturers himself, naturally saw that lectures alone "would give a very poor knowledge of natural things," the student must experiment for himself. This was his own habit: he accepted nothing on trust that it was possible for him to verify. Mr. R. Mallet, F.R.S., gives a remarkable instance of this. On one of his visits to the philosopher he took some slips of Muntz's yellow metal, and showed him that, though flexible and tough, they were made instantaneously brittle and rigid when dipped into solution of per-nitrate of mercury. Faraday, however, "took one of the slips, bent it forwards and backwards, dipped it, and broke it up into short bits between his own fingers. He had not before spoken. *Then* he said, 'Yes, it *is* pliable, and it *does* become instantly brittle.'" This method of convincing himself was the natural habit of the man, and it cannot be doubted that to it much of his success as an investigator was due. Many of Faraday's most important experiments, too, were made with the simplest means, and his skill in devising the necessary apparatus for elaborate investigations was unparalleled. An instance is given by Sir Frederick Arrow, the occasion being an expedition of the Elder Brethren to witness the trial of the electric light at Dungeness. "Before we left Dover," he says, "Faraday, with his usual bright smile, in great glee showed me a little common paper box, and said, 'I must take care of this; it's my special photometer—and then, opening it, produced a lady's ordinary black shawl-pin—jet, or imitation perhaps—and then holding it a little way off the candle showed me the image very distinct; and then, putting it a little further off, placed another candle near it, and the relative distance was shown by the size of the image." We must give one more anecdote, and take leave of this interesting and truly valuable book. "An artist was once maintaining that in natural appearances and in pictures, up and down, and high and low, were fixed, indubitable realities; but Faraday told him that they were merely conventional acceptations, based on standards often arbitrary. The disputant could not be convinced that ideas which he had hitherto never doubted had such shifting foundations. 'Well,' said Faraday, 'hold a walking-stick between your chin and your great toe; look along it and say which is the upper end.' The experiment was tried and the artist found his idea of perspective at complete variance with his sense of reality; either end of the stick might be called upper—pictorially it was one, physically it was the other."

The life of Faraday should be as familiar to our youth as "household words," for he was an ornament and a benefactor to the whole human race—not the hero of one nation and the scourge of another.

FOCAL LENGTH AND MAGNIFYING POWER OF OBJECT-GLASSES.

THE following paper was read by Dr. Royston-Pigott before the members of the Quekett Club and is extracted from their journal:—

Though strange, it is nevertheless true, that two observers, with the same eyepiece and objective, do not always see an object magnified to the same amplitude. A change of focus may be necessary. A short sighted person sees the virtual image of the magnified object at a distance of perhaps 6in.; the long-sighted adjusts it perhaps at 12in or even 18in.; the distinct plane of vision, called the field of view, is variably placed according to the focal length of the eye of the observer, and therefore at distances of considerable variety. Under these circumstances, if two observers, the one very short, and the other very long-sighted, both agree to observe together, their powers of vision proportionally vary. It is necessary, then, to fix a standard for estimation. Most persons can see distinctly at 10in. distance. In this case the power of any lens at this distance is found by dividing ten by the focal length f or

$$\text{Magnifying power} = 10 \div \text{focal length } f$$

$$\text{or} = \frac{10}{f} \text{ or } 10 \div f$$

To persons unread in optical principles, there appears some little difficulty in understanding the variable foci of a lens, and I may, perhaps, be excused for introducing the following illustration, known, I believe, to very few working opticians:—

If we take a lens (say 3in. focus), and form the image of a candle (or much better, the image of a small perforation in a brass plate placed before it) upon a sheet of white paper, it is well-known that if you move the candle from the lens you must move up the paper towards it, in order to obtain a clear image. Now, the special point which I wish to bring out is this, that exactly at the position where the image is formed clearly at the same distance from the paper as the candle is, the distance between the candle and image is the least possible, or a minimum. A most useful result is now obtained; in every case this minimum distance is exactly four times the focal length of the lens. In the case of a 3in. lens this minimum image distance will be found to be exactly 12in.

We will now suppose that instead of the 3in. lens a 2in. objective is used in precisely the same way. The minimum image distance between a candle and its image will be found much less than 8in., so that the real focal length* is 14/36 or rather less than 1½in. There are two or three preliminary points which may not be uninteresting. To find the focal length of a plano-convex lens, turn the flat side to the sun, and measure the exact distance from the sharpest image on a card to the convex surface. If the lens be equiconvex, half the thickness must be added. If the lens be used as a convexo-plane, and the plane side is towards the image, when the aberration is reduced, two-thirds of the thickness must be added. The minimum image-distance avoids these inconveniences of measurement altogether. In every case the true focal length will be more accurately determined by using only a small central aperture applied to the lens in question.

I have designed an instrument of considerable accuracy for measuring the focal length of ordinary lenses, consisting of a perforated metal plate, and a white screen, or piece of ground glass, with a carrier for the object-glass or lens. By means of a long screw, tapped with similar right-handed and left-handed dies, the perforated plate and lamp and the screen are simultaneously made to approach or recede from the lens, which is thus kept always exactly equidistant from the plate and from the screen. The lens to be measured being fixed, the screw is turned, until an exact image is formed upon the screen, of the perforations; one-fourth of the distance between them is exactly the focal length required. I term this instrument a Focimeter. But in the case of very minute lenses, considerable difficulty is experienced in finding their exact focal length by measurement of their curves. In this case, the focal length can be obtained most readily by the following artifice:—If the magnifying power be great, a stage micrometer is to be placed exactly at 10in. distance from the ground-glass screen. If a microscope be used, by taking out the field and eye-glasses of the eyepieces, an ordinary circular 1-100th micrometer may be inserted; then replacing the eye lens only, the image of the stage micrometer must be accurately observed, and the magnitude of a 1-100th nicely determined in the divisions of the eyepiece micrometer. Suppose this to be (m), the actual focal length of the lens in question will be found for small lenses as follows:

Divide ten by this number (m), increased by two. Larger lenses will required a correction to be hereafter explained.

Example.—A small lens is found to magnify a hundredth of an inch upon the stage to measure thirty-five hundredths at 10in. distance from the stage, within the field of an eyepiece, deprived of its field lens. Find the focal length; also for a plano convex find the curvature of the tool to grind the lens.

$$N = 35. \quad f = 10 \div (M + 2) = 10 \div 37$$
$$= 0''\cdot 27027 \text{ nearly.}$$

In a plano-convex lens radius of curvature for flint—

$$= \tfrac{1}{2} \text{ focal length} = 0''\cdot 13513\text{in.}$$

Example 2.—A compound lens forming an object-glass of great power enlarges the thousandth of an inch to 158 divisions in 1000ths, as before at 10in. Find the approximate focal length. Here

$$f = 10 \div (158 + 2) = 10 \div 160 = \frac{1}{61}$$

From this it appears that an exact sixteenth should produce an image precisely 158 times as large when the object is exactly 10in. from the field of the eye-lens at the stop of the eyepiece.

For practical purposes, therefore, an eye-lens magnifying ten times would enlarge the object in this case 1,580 times. Now a C eyepiece of Powell and Lealand is just equivalent to an 1in. lens; therefore, when these makers announce their sixteenth to magnify 1,600 times with a C eyepiece, this objective is nearly the one-sixteenth of an inch focal length within a small decimal.

The magnifying power employed at any moment is often so great a desideratum, and yet so unattainable (when one is closely engaged in some delicate investigation, and using a variety of objectives), without great loss of time, that the following observations upon a simple method exhibited at a meeting of the Fellows of the Royal Microscopical Society recently may, it is hoped, prove acceptable. Having met with many persons and some opticians who experienced a difficulty in understanding the reason of the thing, I trust that the preceding remarks will clear the difficulty away.

If we settle it as an axiom for very high powers, such as the one-eighth and one-sixteenth, that at 10in. distance of the stop of an eyepiece, without the field-glass, the enlargement of thousandths on the stage will give the focal length simply by dividing ten by the amplification increased by two, then it is evident that by using a single lens of 1in. focal length magnifying ten times, if we count how many hundredths of an inch in the stop correspond to a hundredth on the stage micrometer, ten times that amount with an inch or C eyepiece is the magnifying power. Now replace the field-lens (usually of 3in. focus) for an eyepiece of 2in. focal length, having an eye-lens of 1in., the magnifying power will be reduced considerably in the proportion shown by the new reading. Whatever object-glass is now used, and whatever length of tube happens to be in use, so long as the eye-lens is 1in. focal length, ten times the apparent amplification of the stage micrometer will give the power under employment.

I keep an eyepiece (2in.) with 1in. eye-lens, armed with a glass micrometer, ready for use. Every microscopist should demand that the optician mark the focal length of each of his eyepieces. Powell and Lealand's C eyepiece is exactly 1in. focal length; and at the usual distance of 10in. the power of any object-glass with it is at once found by multiplying the reciprocal of the focal length (eight is the reciprocal of one-eighth) by one hundred.

The standard rule by which nominal "inches," "quarters," "eighths," "sixteenths," and "twentieths" are constructed is, therefore, most properly taken, so that with a C eyepiece of 1in. focal length and the stop of the eyepiece being exactly 10in. from the stage, their respective magnifying powers shall be:—

(Objectives)	Inch	Quarter	Eighth	Sixteenth	Twentieth
(Powers)....	100	400	800	1,600	2,000

I have found Nobert's lines to form very beautiful stage micrometers; but as they are fractions of the Paris line, observations with them require laborious reduction to the English standard. But I wish to acknowledge here the kindness of Mr. Baker, the optician, in placing at my disposal Jackson's own beautifully ruled micrometer lines, 2,000 to the inch. With the aid of this, and a micrometer in the stop of the eyepiece, I found the power of Powell and Lealand's new ¼in., with a 1in. Kellner of Browning's make and searcher (with a fine definition), to be 5,250 diameters.

Without searcher and 1in. eye-piece:—

			nearly.
Andrew Ross..	1851..	"quarter"..	power, 540 = one-fifth.
Wray........	1870..	one-fifth ..	power, 540*

Resume.

1.—The focal length of a lens is one-fourth the least distance between image and object at which it can be distinctly formed.

2.—If a distance of 10in. between object and image be taken (to simplify the calculation), and the amplification measured for a division, then in the case of small lenses, the focal length is found by dividing ten by the divisor increased by two.

3.—The magnifying power of an object-glass for any length of tube can be ascertained by using an eye-lens of 1in. focal length, with or without a field-lens, by measuring the amplification of a stage micrometer upon another placed in the stop of the eyepiece, and then multiplying it by ten.

4.—Different eyepieces being compared by the Camera Lucida, or marked in focal length, by the maker, all other powers are immediately ascertained by the simple rule of proportion.†

* Focal point of a lens is generally known to be the focus of parallel rays.

* The actual focal length = 10 ÷ (54 + 2 + 1-54th) = 10 ÷ (56·0185); or a power of 540 represents a focal length about 2-100ths of an inch less than a true one-fifth.

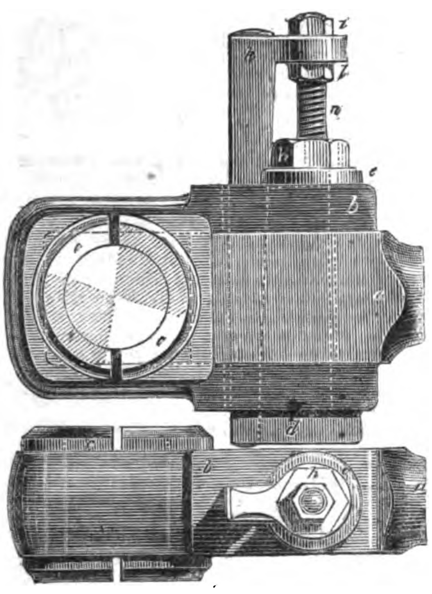
† A ½in. eyepiece will, of course, be twice the power of the inch, and so forth.

POOR MAN'S PROVENDER.

A MARKED, but unfortunate trait, in the character of the average Briton, consists, says the *Food Journal*, in the fact that he unhesitatingly rejects and repudiates every unaccustomed article of food introduced to his notice, if it happens to be cheap; and the lower in the social scale the individual happens to be, the more strenuous is his opposition. Although preserved Australian beef and mutton have been before the public now for a considerable time, and have even gained admittance into one of the leading West-end clubs, we wonder on how many working men's tables they appear. If such is the slow progress of a really delicious and cheap preparation, we fear our advocacy of an inexpensive and nourishing German viand can scarcely hope for more favour. Nevertheless, as food journalists, it seems to be our duty to make known everything likely to benefit the son of toil as well as his master. Sauer-kraut, an efficacious preservative against scurvy, is thus prepared:—When cabbage has arrived at maturity, and is compact and hard, it is divested of its outer leaves, the stalk cut away, and the remainder shred finely and packed in layers in large earthenware pots or barrels. Between each layer salt is sprinkled, along with carraway seeds and juniper berries. When full, the vessels are covered each with a heavy weight, and in a month the contents are fit, after four hours' boiling, for use. After the Sauer-kraut is ready for cooking, it will keep sound for years if the stock is always covered with brine. With Australian beef as a basis, this as a vegetable, and a little brown bread or potatoes, as accessories, we venture to think that even the poorest might extemporise a good dinner within his means.

STUB-END FOR CONNECTING ROD.

THE annexed illustration of a method of strengthening stub-ends of connecting rods is extracted from the *Journal of the Franklin Institute*, and may be found useful in some cases. In this stub the block *a*, strap *b*, and boxes *c c*, are made in the usual way. The key *k*, has a lug, through which the bolt *n*, an extension of the gib, passes, a slot hole being provided to allow for draft of key, and nuts *i i*, to hold key securely in place. The head *d* of gib holds the strap in the usual way, but on the other end a nut *h* is placed, resting on a circular washer *e*, notched at the key. The diameter of this part of the gib is made more than the thickness of the gib, to gain strength, but the extension *n* may



be made less. This plan may be resorted to with advantage to strengthen existing stubs, giving the bolt to the strap and screw adjustment and holding to the key.

THE BARRON STEEL PROCESS.

THE Barron Steel Process is attracting considerable attention in the United States, and judging by the results which are said to be obtained, it must be a very satisfactory method of making steel as well as the most economical. According to the *Iron Age* it was invented by Mr. Thomas J. Barron, in 1868, who associated himself with others, and a company was formed to introduce tools of steel made by this process. After devoting two years to careful experiments and study of the conditions of success, the manufactory began operations on the 1st of March last, and now employs forty hands. Thus far the success is reported to be very encouraging, and enlargement of the establishment is in contemplation. From an article in the Louisville *Commercial*, we obtain the following particulars respecting the process:—Tools, such as axes, hatchets, hoes, and adzes, to the manufacture of which chief attention has been paid, are first fashioned of iron by the usual methods. They are then placed in revolving drums, where the roughness and foreign substances which belong to them when they come from the moulds are worn off by attrition. They are then packed in layers in iron boxes, closely covered with clay, and subjected to the action of oxide of iron and chemical substances, which decarbonise the iron of which they are composed. Herein is the secret of the process. In these boxes the tools are subjected to an annealing process, which lasts for from three to six days, when, being decarbonised, purified, and malleable, they are ready to be changed into steel. A retort holding about a ton of the tools, occupies the centre of a large oven, which is kept at a temperature just below the point of fusion. In this they absorb gasoline, introduced from a tank near by, and pure charcoal gas, generated in a retort on the top of the furnace. The iron becomes steel in from eight to ten minutes, when the tools are removed to be tempered, ground, and polished for the market. It is claimed that this process is the quickest and the best yet discovered. The company is now melting about a ton and a half of iron a day, and as soon as proper facilities are provided will begin the manufacture of steel rails. Professor Newberry, of Columbia College, New York, makes the following report of a practical test of the steel produced in this way:—"With tailor's shears cast in shape, made malleable, and then converted by the Barron process, I have cut Florence silk so nicely as to prove the edge perfect; then, with the same shears, have cut up sheets of tin and untempered steel; and returning to the silk, have found the edge wholly unimpaired, and this after a repetition of more than twenty times." Arrangements are making to start a large establishment at Pittsburg for the manufacture of tools by this process.

LOCK NUTS AND WASHERS.

A NEW arrangement of locking nut and washer, with a spanner adapted to the special requirements of the arrangement, has been patented by Messrs. Blakemore, Sherring, and Horstman. The invention consists essentially in the employment of a washer, having a cut or slit in it whereby the washer or a portion thereof is caused to act as a spring. This washer fits over the bolt, which is grooved or cut away longitudinally throughout the screwed portion thereof, the hole in the washer being formed correspondingly to prevent it from turning; the underside of the nut is notched or made with ratchet teeth, so that when the nut is screwed down, the slotted cut or slit portion of the washer springs up and takes into one or other of the notches or ratchet teeth. These notches or teeth may be over the whole or only partially across the face of the underside of the nut; and the slit or cut in the washer may be made in any desired direction, as practice may suggest. By another arrangement, and when using a nut with a plain inside face, the washer may be cut or a slit made therein at one side thereof so as to form a tongue; the washer being placed over the bolt, as the nut is screwed home the cut or tongue portion of the washer springs up and stops against one of the sides, or in succession against two or more of the sides of the nut, thus preventing the latter from unscrewing. Another form likewise used with a plain faced nut is where the cut portion of the washer is turned up at right angles to the face of the washer, and so springs against the edges of the nut, thus offering a certain amount of resistance to unscrewing. The washer may be of any irregular or other form suitable for preventing it from turning; in many cases this may be accomplished by turning a portion of the same over the edge of the work to be fixed to prevent its turning on the bolt. The inventors prefer, however, to make the nuts bevilled on their edges and to use a spanner bevilled on its edges to adapt itself and to correspond with the bevil or bevils on the nut, and thereby to press down the spring portion of the washer when it is required to unscrew the nut. The nut may be made with a projecting collar at or near its outside surface; but in that case the inventors use a spanner of a tapering thickness, so that when the spanner is fully inserted between the collar and the washer the spring tongue or tongues of the latter are pressed down, and the nut is released from the washer and may be unscrewed. For fish plates and other purposes where the bolt holes are sufficiently close together, they employ a double or compound washer having two or several holes therein with cuts in the metal to secure the several bolts as before described.

FIG. 1

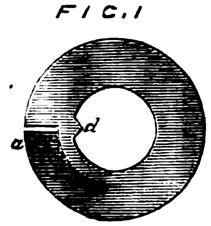


FIG. 2

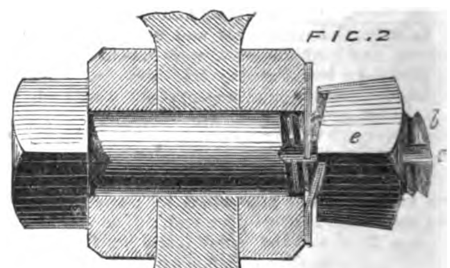

Fig. 1 is a plan of the form of washer which the patentees prefer, and Fig. 2 exhibits so much of a rail in section with nut and washer applied as may be required to comprehend the construction. In these figures *a* is the slit or cut in the washer, *b* is the bolt, *c* is the groove or cut therein, and *d* is the corresponding projection on the washer which takes into the groove *c* to prevent the washer from turning on its bolt; *e* is the nut bevilled on its sides and notched on the underside, as seen at Fig. 2. To secure the nut place the washer on the bolt *b* with the projection *d*, taking into the groove *a*, screw the nut down on the washer, when the spring portion formed by the slit *a* rises and takes into one or other of the notches, and thereby prevents the nut *e* from becoming loose. In order to unscrew the nut, a spanner made to correspond with the bevil of the nut is pushed on, forcing down the spring-portion of the washer and releasing the nut.

TEST FOR ALUM IN BREAD.

WHAT is known as the logwood test is now generally accepted as the best method of detecting alum in bread. It was communicated by the author, Mr. Horsley, to the *Chemical News*, and is as follows:—

1. Make a tincture of logwood by digesting for eight hours 2 drachms of freshly-cut logwood chips in 5oz. of methylated spirit in a wide-mouthed phial, and filter.

2. Make a saturated solution of carbonate of ammonia in distilled water.

A teaspoonful of each solution mixed with a wine-glassful of water in a white-ware dish forms a pink-coloured liquid. Bread containing alum immersed in it for five minutes or so, and stood upon a plate to drain, will in an hour or two go blue on drying; but, if no alum is present, the pink colour fades away. If, on drying, a greenish tinge appears, that is an indication of copper, as carbonate of ammonia produces that colour, but never a blue. As a counter-check for iron, a piece of the moist blue-coloured bread may be drenched with a few drops of glacial acetic acid, when that containing iron will be bleached of a dirty-white colour, but with alum a rose-pink or slight buff colour will be observed.

Or it may be tried another way, thus:—Take a piece of the bread in its plain state, and having digested it in dilute acetic acid for an hour or so, press out the liquor and filter; then put in a lump of carbonate of ammonia, and, when all effervescence ceases, add to the clear liquor a few drops of solution of sulphide of potassium or sodium. If iron is present, it will be indicated by a dark colour, there being no colour produced with alum; but the addition of a little tincture of logwood immediately reveals it. I might even go further, and say that, if necessary, you may quantitatively estimate the alumina thus:—Take (say) ½lb., of crumb bread, digest it in a clean basin with some dilute acetic acid, and allow it to stand a few hours; then break up the mass and pass the liquor through a glass percolator, the rim being covered with calico, repeating the percolation two or three times until the liquor is clear. Throw in carbonate of ammonia to saturation, and add tincture of logwood in excess, when, if alum is present, a dark blue colour will be produced, with a flocculent blue precipitate on standing awhile. Collect this precipitate on a filter, wash it off into a dish with dilute nitric acid, and evaporate the red liquor to dryness. Collect the residue in a small Berlin crucible and ignite it at a red heat, when a white powder will be obtained, consisting of alumina, with possibly a little lime; treat this with liquor potassæ to dissolve out the alumina, mix with a little water, filter, and boil with carbonate of ammonia to obtain the pure alumina.

Our Coal Stores.—Professor Ramsay, F.G.S., member of the Coal Commission, in a recent address to the Dudley Geological Society, expressed a strong and encouraging opinion as to the presence of coal beneath the New Red and Permian. He believes that the majority of the coal-fields of this country have been joined together in one large area, and that by downthrow and other faults, the fields separated; but that the intervening spaces covered the coal, which, still further buried by the forces, brought about the separation. Some had, no doubt, been too deeply buried to pay for getting, and some was too thin for remunerative results, though at workable depths. He calculated that more coal lay at workable depths than appeared in the fields. The South Staffordshire field was supposed to contain 3,201,672,216 tons of coal, but beneath the Permian attached were 10,880,000,000 tons; the Warwickshire field contained 458,652,714 tons, but that concealed should be put down at 2,494,000,000 tons; and the Leicestershire coal-field contained 836,799,734 tons, but beneath the Permian were 1,790,000,000 tons of coal.

MECHANISM.*

(Continued from p. 429.)

ALL machinery can be reduced to a classified list of elementary combinations in mechanism, the character of any portion being assigned to it from its general features, and not from any minute detail. For instance, all those pieces of mechanism in which motion is mainly communicated from piece to piece by what is called "rolling contact," where the principal moving parts are in actual contact and roll one upon another, should be classified under such division as that of "rolling."

The next division might include those contrivances by which one moving part in actual contact with another communicates motion through a process of "sliding." Cams and screws communicate motion by "sliding." The Archimedean drill, generally used for light work, is an example of this kind of communicated motion.

Another mode of communicating motion results from the wrapping or folding of cords or chains over bodies, rigid, and generally circular, although they may be of any form; straps or bands over wheels are of this class. Again, there are numbers of contrivances in which motion is transmitted from piece to piece by means of bent or straight rods and bars. Very perplexing, though very useful motions, result from these. The grouping of them is distinguished by the name of "links." There are contrivances which depend chiefly upon the folding over, again and again, of cords or straps; to the class comprehending these the name communication of motion by "reduplication" is given. It is illustrated in the case of double and treble sets of pulleys.

Another is the transmission of motion by means of an intervening fluid. Sir William Armstrong's hydraulic machine, with its accumulator, is an example. Motion communicated by an intervening fluid has been adapted to facilitate telegraphic delivery in London. Telegrams received in Telegraph-street are put into little cylindrical "carpet-bags," which are placed in tubes and moved forward by air at high pressure, and so shot to the post-office at Charing-cross, or to such places as the tubes are laid. The messages are taken out of the carpet-bags, put into envelopes, and sent to their destination. The speaking-tubes in this building and in offices are examples of motion communicated by fluids.

Under each of these, six heads there may be arranged three and even more classes of motion. A tabular view of these divisional characteristics of modes of communicating motion, and a classification in reference to the relations of direction, and the ratios of the velocities, may be useful for future reference:—

Division.	Character.	
A	Motion communicated by	Rolling.
B	"	Sliding.
C	"	Wrapping.
D	"	Links.
E	"	Reduplication.
F	"	Fluid.

Of each there are at least three classes:—

Class.	Directional relation.	Velocity ratio.
1 ..	constant ..	constant.
2 ..	constant ..	varying.
3 ..	varying ..	constant or varying.

On Monday last, after the lecture was over, a gentleman remarked, "You said that mechanicians, as distinguished from mechanics, thought nothing about plummer-blocks and anti-friction curves." He asked, what is an anti-friction curve? An anti-friction curve has nothing to do with pure mechanism, but it has to do with the workshop, and it may be permitted, although beside the exact title of these lectures, to produce an anti-friction pen for the purpose of forming an anti-friction curve. Some years ago—a great many years ago—there was a discussion in the mathematical papers respecting the curve of least friction for rotating shafts. At the lower end of a vertical shaft the friction upon the bearing is a proportional part of the pressure. The question was how should that bearing be formed, and the mode in which it should be formed is given by this pen. Any skilled mechanic may make the pen. It is a piece of brass wire 6in. long, freely movable about a pin put into a piece of wood, 2in. long, and ¾in. broad, and ¼in. thick. There is bent over the wire a small piece of steel brought down so as to allow ink to be inserted between the two jaws; the ink will therefore flow as from a pen. The mode in which the pen is used is this. Supposing a bearing to be of a certain size in the lower diameter, and of a known dimension in the upper, the question is, to ascertain the curve to be formed between those two diameters. At right angles to a straight line, set off the two radii at their proper distance apart. Parallel to this straight line place a straight edge. Against this edge, where it crosses the larger radius, place the wood, to which the wire of the pen is attached. Slide the steel pen along the wire until it is at the extremity of the radius. Then adjust the straight edge, and draw the wood along it until the pen crosses the extremity of the shorter radius. The path of the pen describes what is called an anti-friction curve, and the bearing of a shaft made with that vertical section is the one of least friction.

To return to the tabular characteristics of mechanism. It has perhaps been truly said that if there were no exceptions there need be no rules. There are before you, in illustration of this, two pieces of mechanism which cannot be arranged under the tabulated heads. One is called Atwood's machine—a machine designed about the close of the last century, and to which we are indebted for our knowledge of the influence of gravity on falling bodies. The free motion of falling bodies becomes so rapid that the velocity cannot be observed. Mr. Atwood suggested and carried out the idea that if, whilst permitting gravity to exercise its full and usual influence, that influence could be distributed through a balanced mass, then, although the velocity were retarded, yet the law of that velocity would remain, and might be ascertained.

The arrangement of mechanism by which he accomplished this is here. Two equal weights are attached to the ends of a very flexible silk cord, about twelve feet long. This cord being laid over a pulley, the weights being equal, they might be placed in any position, and would so remain. Mr. Atwood reasoned that if he could reduce to the smallest possible quantity the friction on the bearings of the pulley, he might determine the laws of falling bodies. Thus to reduce it, led to the contrivance of placing the bearings of the pulley upon the rims of four other pulleys—in fact, as far as possible, he converted a sliding into a rolling contact.

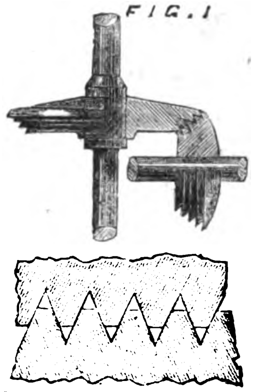
The silken cord was placed with one of the equal weights near the ground and the other near the pulley. A small and known weight being placed upon the upper one, caused a motion in the mass of the two connected weights, and dependent upon the relations of the small weight and the mass so the velocity of descent was retarded. By means of a vertical scale the rate of descent could be observed, and the laws of gravity be thence deduced.*

As a piece of mechanism, this instrument cannot well be placed under any of the heads specified in the table.

Here is another illustration of a machine which cannot be classed. It is one in which we are all interested, because by means of it coals are prepared for London free from slack. A waggon of coals, as brought out of the pit, is not ready for special sale, and the question is how are those coals to be screened and made fit for the market, such a market, at any rate, as you have in London. The manner in which the slack is to be separated is not our business at present; we have simply to do with the motion, not the separation. On the table is a model of a railway waggon into which the larger lumps will be shot. Here is another into which what we may call the first class of slack will be shot, and, here is another into which will be shot the dust, or that which is really little better than dust, out of which artificial fuel is made. This waggon of mixed coal direct from the pit is run into the apparatus. Observe the motion on the withdrawal of the hand from the break. The apparatus gently rotates—the coals are slid and not thrown on the screens, and the work being done the apparatus returns to its original position. To accomplish these reverse actions no special contrivance of mechanism is required. It is done by a change of the centre of gravity of the moving machinery, consequent upon the discharge of the coals from the pit waggon. When the coals are in the waggon, the centre of gravity is at one side of the horizontal axis, and so causes the motion by which the mixed coals are discharged. Then the centre of gravity is at the other side, and so causes the apparatus to return to its original position. Such mechanism cannot be placed in one of the tabulated divisions.

The subject of the lecture more especially intended for this evening is on the communication of motion by rolling contact. The necessity for getting shafts to rotate so that one should cause the other to move must have arisen in very early days. You remember even so recently as Jewish times we read that "Two women should be grinding at the mill," so that it seemed to need two people to cause one shaft to rotate, for the millstone was driven by two people. To fold a cord round one shaft and then round another so as to communicate a motion, would not be a difficult matter, but to bring these shafts into a relation that needed no cords at all, that would then have seemed to be the perfection of mechanism. We have an example here* of such rolling contact. On these two wheels there are no teeth, but they roll on one another only. It would be very desirable to dispense with teeth, but it is quite clear that mechanics have not yet attained to such perfection that two wheels shall truly roll with regard to each other whilst acting on shafts in fixed bearings. The one wheel here on the upper shaft drops, and so contact of the circumferences is preserved. This was one contrivance to keep up contact. It is found in the blower we have so constantly in use where one wheel is held by a spring against the other. In another case, one wheel is covered with leather in order to secure a rolling contact. Other modes, prior to the introduction of teeth, have been adopted in order to preserve this rolling contact. Perhaps none is better than that of covering each of the rollers with brushes of hair. We are thus led to the origin of teeth upon wheels. We all know that teeth are generally placed across the wheel in the way you see here, so that the contact is secured. Some persons have adopted the suggestion of what may be called teeth running in a direction parallel to the plane of the wheel. This is the case in Robertson's friction gearing, a plan much adopted for the communication of motion by means of pulleys, grooved parallel to the face of the pulley. Wheels used as described are generally called "pulleys." In ordinary cases, teeth run parallel to the shaft; in this case, at right angles to the shaft. For the purpose of throwing in and out of gear the latter are safe, and free from the objection which the ordinary teeth have—namely, the great liability to be broken if a sudden strain comes upon them. These wheels are still manufactured by the Patent Gearing Company at Glasgow, and to them we are indebted for the model before you, of which Fig. 1 is a diagram.

FIG. 1



In other cases, one pulley is put into a swing frame. The upper pulley in this model, sliding in a groove, is then merely hung upon a hinged frame, which allows weight to be borne by it, and so increase is given to the pressure upon the lower pulley. That is another contrivance for getting this motion by rolling contact. Others are formed by loading the axles with weights. These practices, however, have been abandoned where the communication of power is concerned, and toothed-wheels have taken their place. All other plans but teeth are objectionable, because they fail to communicate or keep up a true velocity ratio, and still fail where definite relations of motion must be established. If it is essential that motion should take place in the ratio of one to twelve, or one to twenty, no mode of pure rolling can accomplish it, but if it is simply essential to secure rolling contact for the purpose of high velocity, and for the purpose of converting high velocity into power, it has of late years been most successfully accomplished by Mr. Ramsbottom, at Crewe.

We are much indebted to the authorities at Crewe for the machinery now on the table. Heavy weights are at Crewe lifted by the agency of a cord travelling at a very high velocity.* Here are pieces of the cord used for that purpose. One, an old piece, has done its work, and the other, a new piece, had it not been cut off, would have had to do its work. It is a cotton cord, made very pliable, and caused to move at the rate of 5,000ft. a minute, and, as 5,280ft. are a mile, we may say it travels at the rate of a mile a minute. This speed is converted into power, and that is done by pure rolling contact. It is accom-

* By the Rev. ARTHUR RIGG, M.A., being the Cantor Lectures delivered before the Society of Arts.

* The following illustration of a mode of using Atwood's machine for the purpose named in the lecture may be of interest to some readers. Let M be the mass of one weight, M + m the other, and R the resistance, friction, &c., of the machine. Now the moving force = mass multiplied by acceleration, expressed algebraically thus: P = M.f. Therefore in the experiment—

$$(M + \overline{M + m} + R) . f = m . g \qquad (1)$$

where (g) is the required force of gravity. Again, if we take a second similar experiment with other masses. Then

$$(M^1 + \overline{M^1 + m^1} + R) f^1 = m^1 . g \qquad (2)$$

combining equations (1) and (2).

$$g = \left\{\frac{2(M - M^1) + (m - m^1)}{m . f^1 - m^1 . f}\right\} f . f^1$$

In this equation all is known except f and f^1, and by Atwood's machine these can be obtained thus:—First arrange M and M + m on the machine, and allow the heavier to fall from one point to another at a known distance from the starting-point. Observe most carefully and accurately the time occupied by its motion. Then, by a well-known law, viz.:—

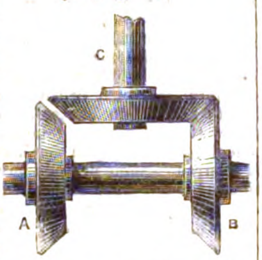
$$s = \frac{1}{2} f . t^2 \quad \text{And therefore } f = \frac{2s}{t^2}$$

Now, from this experiment, s and t are known, and therefore f can be found. Similarly, f^1 can be found, therefore in (3) all is known except (g). Therefore (g) can be found, and it is found to be = 32·2ft.

* On the table were two plain broad wheels of wood. The one was rotated in a vertical plane, by being placed on a wooden axle in a horizontal plane. The other wheel was also on a horizontal axle, which was guided in a vertical slide above the former axle, and consequently the circumference of this latter wheel was always in contact with that of the lower wheel.

plished thus. At the top of the vertical part of a crane there is a pulley on a shaft which passes down through the crane in a vertical direction, and the pulley being driven communicates motion to this vertical shaft. Let us for the present rest content with the fact that we have a vertical shaft rotating rapidly. The mode in which that motion is communicated is this. That grooved pulley on the table is at the top of the shaft. It is one of the actual pulleys. The high velocity cord does not pass round this pulley—it is simply pressed against it by means of two other grooved pulleys, one on each side, and thus is caused to bear upon a portion of the grooved circumference. You may judge, there fore, that assuming there was no loss of motion, the rim of the pulley fixed upon the vertical shaft would travel at the rate of a circumferential velocity of a mile per minute. Of course, there is a certain amount of slip which reduces this velocity. Now let us see what is done by this motion. Remember we deal with it only as a question of rolling contact, independent of the teeth of wheels, to show what can be done by rolling contact only. This shaft with the pulley at the top descends to the lower part of the crane, and there it comes upon the gearing now on the table. You have then a descending shaft. At the end of that descending shaft is a cone pulley which is made of pasteboard. It consists of two cast iron faces with pieces or sheets of pasteboard strongly clamped between them, and that is turned in a lathe to the shape required. On one casting there are two cone wheels, with such a distance between the surfaces that they only just do not touch this paste board one when it is placed as in the figure between them. Suppose that C (Fig. 2) is the vertical shaft and the bevel wheel upon it is the pasteboard one. The bevel wheels, A and B, are upon a horizontal shaft, which is capable of an end-long motion. If the wheel B be in contact with the rotating wheel, motion will be communicated to the horizontal shaft in one direction. Give now the end-long motion that shall bring A into contact, then the horizontal shaft will be caused to rotate in the other direction. There is a handle, by the motion of which either of the two cone pulleys may be brought into contact with the pasteboard one, and therefore, whatever motion is being given to the pasteboard one, can be communicated to one of the two. The actual gearing of one of these cranes was on the table. As a piece of mechanism it might have been made of wood, but as a piece of machinery it is made of cast-iron, and was sent from Crewe for the purpose of the lecture. This cardboard pulley is driven direct, being keyed upon the vertical shaft, and therefore rotating with a very high velocity. When contact is made with the pulley on one side of it, the horizontal shaft rotates, and with it a worm-wheel at the end. If the contact is made with the second cone the worm-wheel is driven in the other direction. That is sufficient for our present purpose. With the machine, of which a part is here, large driving-wheels of locomotives and heavy pieces of machinery are lifted and moved from place to place; by similar arrangements even locomotives themselves are raised.

FIG. 2



The exact velocity of these pulleys can be given. The speed of the cord passing round the top pulley is 5,000ft. per minute, and the pulley itself makes 1,958 rotations per minute. Therefore the cone below also makes 1,958 rotations, and as it is not quite of the same diameter of the other, but rather larger, upon the law of reduction of these pulleys the pulley on the horizontal shaft makes 2,238 rotations per minute. Therefore the worm at the end moves at the rate of 2,238 rotations per minute, and then by the worm arrangement a very rapid reduction takes place until the wheels, by means of which loads are raised and carried from place to place, move with a circumferential velocity of only 79ft. per minute, so that the velocity of one mile is reduced to 79ft. as a question of travelling, for the smaller class of these cranes travel along lines, and so convey from place to place the heavy weights they may have lifted. It is also reduced to about 79ft. as a question of lifting, the two motions being kept distinct. This illustration will be sufficient for an example of the communication of motion by rolling contact where there are no teeth.

Although "rolling contact" is the especial purpose of this evening, yet it will be essential to say a few words in reference to a machine, of which an elementary portion is before you. The Registrar-General, with great kindness—a kindness which has met us on every hand in reference to illustrations for these lectures—has supplied these parts of the calculating machine made by Messrs. Scheutz.

Before describing the simple and durable apparatus, it may be well to explain the objects contemplated by those who have given their minds to the construction of calculating machines.

Perhaps Mr. Babbage was the first to direct attention to a peculiar mathematical relationship existing in almost all tables of numbers in sequence. He had observed that, if a consecutive series of these numbers were taken, and each subtracted from the next higher number, a deduced table of smaller numbers could be obtained. Performing a similar operation of subtraction upon the lines in this second table, a third table of still smaller figures resulted. Proceeding thus, he found that generally there resulted a series of the same, or nearly the same, numbers. For example, take the squares of the first nine digits; these squares are:—

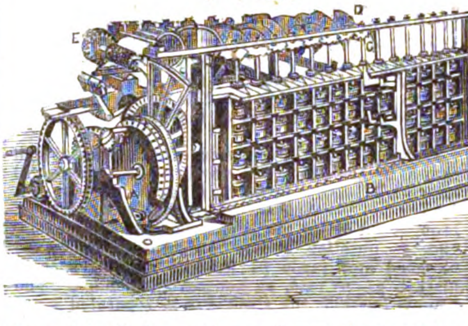
Square Numbers	1	4	9	16	25	36	49	64	81
First Differences	3	5	7	9	11	13	15	17	
Second Differences	2	2	2	2	2	2	2		

If, now, mechanism were so contrived that the lower line was constantly added to the one above, and this (the second line), so increased, were added to the first, a series of figures would be obtained which, in the illustration given, would constitute a series of square numbers.

Such was the foundation of the scheme which Mr. Babbage laid as that on which to rear the superstructure of a calculating machine. Mr. Babbage's views, so far as they have received "body, form, and fashion," are now in the Museum at South Kensington. Two gentlemen—one a Mr. Schentz, of Stockholm, the other a gentleman of England—partly from the published intentions and views of Mr. Babbage, and partly following out their own ideas, devised mechanism to do the work of calculation. Two machines on the plan of Messrs. Scheutz and his son have been made. One is at the Observatory at Albany, in America, the other at Somerset House.

The woodcut, Fig. 3, represents the general appearance of the machine. In each of the small recesses at the front is a wheel, or ring, or what may more correctly be called slice, about ½in. deep

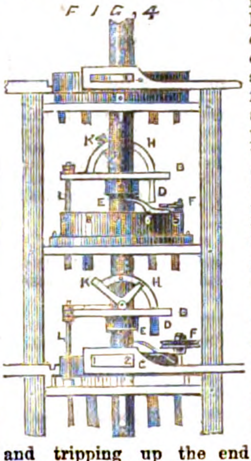
FIG. 3



of a metal cylinder, resting, as it were, in a groove, and having ten short pieces or legs projecting below. The woodcut (Fig. 4) may serve to show the general arrangement in two of the small recesses. These cylinder slices are not attached to the vertical shafts which pass through each recess. Attached, however, to the shafts are contrivances which not only are carried round with the shaft, but have upon them pins or studs capable of a vertical motion. This pin can be seen at G, between K and H, in the lower recess of Fig. 4.

It may be observed that as the shaft rotates, a projecting trigger or pin D will be tripped up by the inclined plane E, attached to the lower cylinder-slice. Thus tripped up, the pin G, previously referred to, will be lifted out of the bell-crank K H. This bell-crank is loaded at K, and that end, therefore, falls. The consequence is that the pin G is supported upon the other arm H of the bell-crank, when the trigger D has passed over the inclined plane E, and so held between what we have called the legs of the upper cylinder-slice. So long, therefore, as the shaft moves the cylinder will be moved. The rotation, however, brings the bell-crank into contact with a small inclined plane, not visible in Fig. A, and tripping up the end K of the bell-crank releases G, which falls down, and so discontinues the rotation of the cylinder-slice. This reliance upon the influence of gravity is a peculiar feature in this mechanism, and is not found in other machines dealing with calculations. It will be observed that around the cylinder slices, or rings, the figures from 0 to 9 are engraved. Any one of these figures may be brought by the hand or by the mechanism into the front vertical line, they are then

FIG. 4



regarded as the figures which are to enter into the calculations.

The lecturer, by enlarged working models, explained the action of other parts of the machine so far as related to the calculating mechanism. The combined action of these parts conveyed to the upper line of the machine, shown in Fig. 3, the various additions indicated by the laws of differences as previously illustrated.

It will be observed that hitherto no mechanism has been described for the operation of carrying. For example—if the two lines $\frac{362}{473}$ were to be added, the figures indicated would be 735 instead of 835. Messrs. Scheutz had, therefore, to provide for this carrying. In Fig. 3, it will be observed there is an upright marked B, this is called a Traveller. By a mangle wheel arrangement at the left-hand side of the figure, and a chain, acted upon by a toothed wheel, into the links of which the teeth enter, this Traveller passes in front of the recesses. It will be observed that the Traveller has two projecting arms. By means of these arms he is enabled to advance one figure on any wheel where the mechanism indicates that such an advance must be made. A similar traveller at the back does the same for the rows of wheels not operated upon by the front one. Thus, after each complete revolution of the wheel-work, the upper row of figures indicates the successive lines in the series being calculated.

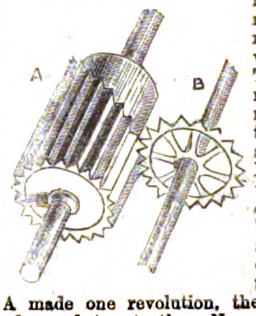
It remains to state briefly how the figures thus made apparent are to be transferred to the type wheels and so impressed, either upon stereo-metal or upon a matrix of paper pulp, from which type-metal casts may be taken.

To say that it is done by a series of stepped cams something similar to the snail cam, by which the number of strokes made by the hammer of a clock is determined, would be a brief but not very sufficient explanation. This much must, however, suffice for the present, and those who wish for further information can obtain it on reference to the patent of Messrs. Scheutz.

Now that the mechanism of calculating machines is before us, it may be well to direct attention to that of arithmetical machines. These are for performing the ordinary operations of addition, subtraction, multiplication, and division, and not for the calculations of series by a law of differences. The one now produced is simple in construction, compact in arrangement, and satisfactory in use. Similar ones are made by Mr. Thomas, of Colmar, and are used in many parts of Europe and England.

Exclusive of the progressive parts, which are similar to those of counting, or numbering, or paging machinery, there is a very ingenious and simple arrangement for committing to the machinery any number that the operator may desire. By directing small pointers to the figures on which an operation (say) of multiplication is to be performed, and turning a handle, these figures appear in the machine. The mechanism for this is what we must now look at. The pointer to which reference has been made moves a small-toothed wheel along a square bar or shaft B. In gear with this wheel are teeth on a cylinder or pinion A. Ten of such long teeth surround about half of the cylinder. If, therefore, the cylinder A made one revolution, the wheel B would be advanced ten teeth. Now, an inspection of Fig. 5 will show that a portion of each tooth is cut off, so that the position of the wheel B upon the small squared shaft determines the number of teeth it may be advanced, and therefore enables any figure to be introduced into the machine. Although between the small shafts, A and B, the communication of motion is by cylinders of circular section, yet the amount of motion communicated is variable, being dependent upon the position of the wheel on B.

FIG. 5



(*To be continued.*)

Professor Gunning claims that the Niagara river has been in existence about 200,000 years—that a barrier 30ft. high at the head of the rapids would throw the water back into Lake Michigan.

The Glenfield Patent Starch Case.—Sheriff Davidson has rejected the appeal against Sheriff Campbell's decision in the case of Wotherspoon against J. C. Anderson, grocer, Edinburgh, by which the latter was fined £21 and expenses, for selling an imitation of the Glenfield Starch, and has granted the additional expenses.

THE CONSTITUTION OF NATURE.*

(Continued from p. 429.)

THE principle of gravitation has been already described as an attraction which every particle of matter, however small, has for every other particle. With gravity there is no selection; no particular atoms choose, by preference, other particular atoms as objects of attraction; the attraction of gravitation is proportional to the quantity of the attracting matter, regardless of its quality. But in the molecular world which we have now entered matters are otherwise arranged. Here we have atoms between which a strong attraction is exercised, and also atoms between which a weak attraction is exercised. One atom can jostle another out of its place in virtue of a superior force of attraction. But though the amount of force exerted varies thus from atom to atom, it is still an attraction of the same mechanical quality, if I may use the term, as that of gravity itself. Its intensity might be measured in the same way—namely, by the amount of motion which it can impart in a certain time. Thus the attraction of gravity at the earth's surface is expressed by the number 32, because, when acting freely on a body for a second of time, it imparts to the body a velocity of 32ft. a second. In like manner the mutual attraction of oxygen and hydrogen might be measured by the velocity imparted to the atoms in their rushing together. Of course such a unit of time as a second is not here to be thought of, the whole interval required by the atoms to cross the minute spaces which separate them not amounting probably to more than an inconceivably small fraction of a second.

It has been stated that when a body falls to the earth it is warmed by the shock. Here we have what we may call a mechanical combination of the earth and the body. Suffer the falling body and the earth to dwindle in imagination to the size of atoms, and for the attraction of gravity substitute that of chemical affinity, which is the name given to the molecular attraction, we have then what is called a chemical combination. The effect of the union in this case also is the development of heat, and from the amount of heat generated we can infer the intensity of the atomic pull. Measured by ordinary mechanical standard, this is enormous. Mix 8lb. of oxygen with 1lb. of hydrogen, and pass a spark through the mixture; the gases instantly combine, their atoms rushing over the little distances between them. Take a weight of 47,000lb. to an elevation of 1,000ft. above the earth's surface, and let it fall; the energy with which it would strike the earth would not exceed that of the 8lb. of oxygen atoms as they dash against 1lb. of hydrogen atoms to form water.

It is sometimes stated that the force of gravity is distinguished from all other forces by the fact of its resisting conversion into any other. Chemical affinity, it is said, can be converted into heat and light, and these again into magnetism and electricity. But gravity refuses to be so converted; it is a force which maintains itself under all circumstances, and is not capable of disappearing to give place to another. If by this is meant that a particle of matter can never be deprived of its weight, the assertion is correct; but the law which affirms the convertibility of natural forces was never meant, in the minds of those who understood it, to affirm that such a conversion as that here implied occurs in any case whatever. As regards convertibility into heat, gravity and chemical affinity stand on precisely the same footing. The attraction in the one case is as indestructible as in the other. Nobody affirms that when a stone rests upon the surface of the earth the mutual attraction of the earth and stone is abolished; nobody means to affirm that the mutual attraction of oxygen for hydrogen ceases after the atoms have combined to form water. What is meant in the case of chemical affinity is, that the pull of that affinity, acting through a certain space, imparts a motion of translation of the one atom towards the other. This motion of translation is not heat, nor is the force that produces it heat. But when the atoms strike and recoil, the motion of translation is converted into a motion of vibration, and this latter motion is heat. But the vibration, so far from causing the extinction of the original attraction, is in part carried on by that attraction. The atoms recoil in virtue of the elastic force which opposes actual contact, and in the recoil they are driven too far back. The original attraction then triumphs over the force of recoil, and urges the atoms once more together. Thus, like a pendulum, they oscillate, until their motion is imparted to the surrounding ether; or, in other words, until their heat becomes radiant heat.

In this sense, and this sense only, is chemical affinity converted into heat. There is, first of all, the attraction between the atoms; there is, secondly, space between them. Across this space the attraction urges them. They collide, they recoil, they oscillate. There is a change in the form of the motion, but there is no real loss. It is so with the attraction of gravity. To produce motion here space must also intervene between the attracting bodies: when they strike motion is apparently destroyed, but in reality there is no destruction. Their atoms are suddenly urged together by the shock; by their own perfect elasticity these atoms recoil; and thus is set up the molecular oscillation which announces itself to the nerves as heat.

It was formerly universally supposed that by the collision of unelastic bodies force was destroyed. Men saw, for example, when two spheres of clay, or painter's putty, or lead, were urged together, that the motion possessed by the masses prior to impact was more or less annihilated. They believed in an absolute destruction of the force of impact. Until recent times, indeed, no difficulty was experienced in believing this, whereas, at present, the ideas of force and its destruction refuse to be united in most philosophic minds. In the collision of elastic bodies, on the contrary, it was observed that the motion with which they clashed together was in great part restored by the resiliency of the masses, the more perfect the elasticity the more complete being the restitution. This led to the idea of perfectly elastic bodies—bodies competent to restore by their recoil the whole of the motion which they possessed before impact.

Hence the idea of the conservation of force, as opposed to the destruction of force, which was supposed to occur when inelastic bodies met in collision.

We now know that the principle of conservation holds equally good with elastic and inelastic bodies. Perfectly elastic bodies develop no heat on collision. They retain their motion afterwards, though its direction may be changed; and it is only when sensible motion is, in whole or in part, destroyed that heat is generated. This always occurs in inelastic collision, the heat developed being the exact equivalent of the motion extinguished. This heat virtually declares that the property of elasticity, denied to the masses, exists among their atoms, and by their recoil and oscillation the principle of conservation is vindicated.

But ambiguity in the use of the term "force" has been for some time more and more creeping upon us. We called the attraction of gravity a force without any reference to motion. A body resting on a shelf is as much pulled by gravity as when, after having been pushed off the shelf, it falls towards the earth. We applied the term force also to that molecular attraction which we called chemical affinity. When, however, we spoke of the conservation of force in the case of elastic collision, we meant neither a pull nor a push, which as just indicated, might be exerted upon inert matter, but we meant the moving force, if I may use the term, of the colliding masses.

What I have called moving force has a definite mechanical measure in the amount of work that it can perform. The simplest form of work is the raising of a weight. A man walking up-hill or upstairs with a pound weight in his hand, to an elevation (say) of 16ft., performs a certain amount of work over and above the lifting of his own body. If he ascend to a height of 32ft. he does twice the work; if to a height of 48ft. he does three times the work; if to 64ft. he does four times the work, and so on. If, moreover, he carries up 2lb. instead of 1lb., other things being equal, he does twice the work; if 3lb., 4lb., or 5lb., he does three, four, or five times the work. In fact, it is plain that the work performed depends on two factors, the weight raised and the height to which it is raised. It is expressed by the product of these two factors.

But a body may be caused to reach a certain elevation in opposition to the force of gravity without being actually carried up to the elevation. If a hodman, for example, wished to land a brick at an elevation of 16ft. above the place where he stands, he would probably pitch it up to the bricklayer. He would thus impart, by a sudden effort, a velocity to the brick sufficient to raise it to the required height; the work accomplished by that effort being precisely the same as if he had slowly carried up the brick. The initial velocity which must be imparted in the case here assumed is well known. To reach a height of 16ft., the brick must quit the man's hand with a velocity of 32ft. a second. It is needless to say that a body starting with any velocity would, if wholly unopposed or unaided, continue to move for ever with the same velocity. But when, in the case before us, the body is thrown upwards, it moves in opposition to gravity, which incessantly retards its motion, and finally brings it to rest at an elevation of 16ft. If not here caught by the bricklayer, it would return to the hodman with an accelerated motion, and reach his hand with the precise velocity it possessed on quitting it.

Supposing the man competent to impart to the brick, at starting, a speed of 64ft. a second, or twice its former speed, would the amount of work performed in this effort be only twice what it was in the first instance? No; it would be four times that quantity. A body starting with twice the velocity of another, will rise to four times the height; in like manner, a three-fold velocity will give a nine-fold elevation, a four-fold velocity will give a sixteen-fold elevation, and so on. The height attained then, or the work done, is not proportional to the velocity, but to the square of the velocity. As before, the work is also proportional to the weight elevated. Hence, the work which any moving masses whatever are competent to perform, by the motion which they at any moment possess, is jointly proportional to the weight and square of the velocity. Here, then, we have a second measure of work in which we simply translate the idea of height into its equivalent idea of motion.

In mechanics, the product of the mass of a moving body into the square of its velocity expresses what is called the *vis viva*, or living force. It is also sometimes called the "mechanical effect." If, for example, we point a cannon upwards, and start a ball with twice the velocity imparted by a second cannon, the ball will rise to four times the height. The speedier ball, if directed against a target, will also do four times the execution. Hence the importance of imparting a high velocity to projectiles in war. Having thus cleared our way to a perfectly clear conception of the *vis viva* of moving masses, we are prepared for the announcement that the heat generated by the collision of a falling body against the earth is proportional to the *vis viva* annihilated. In point of fact, it is not an annihilation at all, but a transference of *vis viva* from the mass to its ultimate particles. This, as we now learn, is proportional to the square of the velocity. In the case, therefore, of two cannon balls of equal weight, if one strike a target with twice the velocity of the other, it will generate four times the heat; if with three times the velocity it will generate nine times the heat, and so on.

Dr. Joule has shown that in falling from a height of 772ft., a body will generate an amount of heat sufficient to raise its own weight of water 1° Fahr. in temperature. We have here the mechanical equivalent of heat. Now, a body falling from a height of 772ft. has, upon striking the earth, a velocity of 223ft. a second; and if this velocity were imparted to a body, by any other means, the quantity of heat generated by the stoppage of its motion would be that stated above. Six times that velocity, or 1,338ft., would be an inordinate one for a cannon ball as it quits the gun; but if animated by six times the velocity, thirty-six times the heat will be generated by the stoppage of its motion. Hence, a cannon ball moving with a velocity of 1,338ft. a second, would, by collision, generate an amount of heat competent to raise its own weight of water 36° Fahr. in temperature. If composed of iron, and if all the heat generated were concentrated in the ball itself, its temperature would be raised about 360° Fahr.; because 1° in the case of water is equivalent to about 10° in the case of iron. In artillery practice the heat generated is usually concentrated upon the front of the bolt, and on the portion of the target first struck. By this concentration the heat developed may become sufficiently intense to raise the dust of the metal to incandescence, a flash of light often accompanying collision with the target.

Let us now fix our attention for a moment on the gunpowder which urges the cannon ball. This is composed of combustible matter, which if burnt in the open air would yield a certain amount of heat. It will not yield this amount if it performs the work of urging a ball. The heat then generated by the gunpowder will fall short of that produced in the open air, by an amount equivalent to the *vis viva* of the ball; and this exact amount is restored by the ball on its collision with the target. In this perfect way are heat and mechanical motion connected.

Broadly enunciated, the principle of the conservation of force asserts that the quantity of force in the universe is as unalterable as the quantity of matter; that it is impossible to create force and to annihilate it. But in what sense are we to understand this assertion? It would be manifestly inapplicable to the force of gravity as Newton defined it; for this is a force varying inversely as the square of the distance, and to affirm the constancy of a varying force would be self-contradictory. Yet, when the question is properly understood, gravity forms no exception to the law of conservation. Following the method pursued by Helmholtz, I will here attempt an elementary exposition of this law, which, though destined in its applications to produce momentous changes in human thought, is not difficult of comprehension.

For the sake of simplicity, we will consider a particle of matter, which we may call F, and a second movable particle, D, placed at a distance from F. We will assume that these two particles attract each other according to the Newtonian law. At a certain distance the attraction is of a certain definite amount, which might be determined by means of a spring balance. At half this distance this attraction would be augmented four times; a third of the distance it would be augmented nine times; at one-fourth of the distance sixteen times, and so on. In every case the attraction might be measured by determining, with the spring balance, the amount of tension which is just sufficient to prevent D from moving towards F. Thus far we have nothing whatever to do with motion; we deal with statics, not with dynamics. We simply take into account the distance of D from F, and the pull exerted by gravity at that distance.

It is customary in mechanics to represent th[e] magnitude of a force by a line of a certain l[ength], a force of double magnitude being represent[ed by a] line of double length, and so on. Placing, t[...]

* By Professor TYNDALL.

particle D at a distance from F, we can in the imagination draw a straight line from D to F, and at D erect a perpendicular to this line, which shall represent the amount of the attraction exerted on D in this position. If D be at a very great distance from F the attraction will be very small, and the perpendicular consequently very short. Let us now suppose that at every point in the line joining F and D a perpendicular is erected proportional in length to the attraction exerted at that point; we should thus obtain an infinite number of perpendiculars of gradually increasing length as D approaches F. Uniting the ends of all these perpendiculars, we should obtain a curve, and between this curve and the straight line joining F and D we should have an area containing all the perpendiculars placed side by side. Each one of this infinite series of perpendiculars representing an attraction, or tension, as it is sometimes called, the area just referred to represents the total effort capable of being exerted by the tensions upon the particle D, during its passage from its first position up to F.

ACOUSTIC ILLUSTRATIONS OF THE METHOD BY WHICH STELLAR MOTIONS ARE DETERMINED WITH THE SPECTROSCOPE.*

THE fourth of the series of lectures known as the Mechanics' Course was recently delivered in the large hall of the Sheffield Scientific School, upon the above subject, the lecturer being Prof. A. M. Mayer, of the Stevens Institute of Technology, United States.

Prof. Mayer began by calling the attention of his audience to the character of vibrations, instancing the pendulum as one of the best examples of visible mass-vibration, and saying that the curve representing its motion was that representing all other vibratory motions of whatever kind. This curve he had obtained experimentally by means of an ingenious apparatus which he described. Besides these, there are molecular vibrations, due to elasticity, the action of which was very clearly illustrated upon the black-board. A water-wave is a mass-vibration, as is shown admirably by Prof. Lyman's wave apparatus. The progressive character of a wave was then exhibited by means of a long wire coil, along which an impulse was transmitted as a visible undulation or wave. As an example of a molecular vibration due to elasticity, the vibration of a Brown and Sharp's straight-edge, fastened firmly at one end, was given, and a series of beautiful curves drawn upon smoked glass by a wire attached to such a vibrating rod, were thrown on the screen.

The lecturer then passed to the theories of light, describing the emission theory and the undulatory theory. Certain phenomena, such as reflection, refraction, and dispersion could be equally well accounted for by either; but certain others, such as those of interference, could be explained only by a wave or undulatory theory. This latter theory supposes a trembling of the particles either of air or of the matter filling space, which trembling, so far as interference goes, may be lateral, or longitudinal, but the phenomena of polarisation of light indicate that these vibrations are transverse to the direction of propagation of the ray. In sound, the vibration is longitudinal; in heat and light, lateral. Hence, sound-waves may interfere and produce silence; light-waves may interfere and produce darkness; heat waves may interfere and produce cold. The ear is so constituted that it takes cognisance only of the longitudinal vibrations of the air, though the air vibrates in all directions; the eye takes notice only of lateral ether-vibrations, though the ether-vibrates in all directions. Interference was then described and illustrated on the board, and the phenomena of fringes shown to result from the overlapping of waves in unequal phases, which could be a consequence only of undulations. The practical use of such knowledge as this was illustrated by a description of Newton's rings, and the method by means of which these rings may be made to indicate a distance as small as a millionth of an inch. Another instance of the practical application of these facts is Arago's Differential Refractometer, which will show a difference of density in the air of one-eight thousandth part, and by which the refraction of the air has been measured, and tables constructed, by whose use the mariner may find the true altitude of the sun.

The effect of lengthening and of shortening a wave was then explained. In the case of a sound-wave—moving 1,100ft. a second whatever the wave-length—if the length be diminished more vibrations enter the ear in the same time, and the pitch rises; if it be increased, less vibrations enter, and the pitch lowers. Light-waves are strictly analogous; whenever any one of the coloured waves which form white light is lengthened, its colour changes towards the red end of the spectrum; when it is shortened, towards the violet. Hence change of pitch in the case of sound, or of colour in the case of light, is evidence of motion, either to or from the observer; which it is, depends on whether the wave is lengthened or shortened. Now, while the motion of a star at right angles to the line of sight is easily detected and measured by the telescope, motion in the direction of this line is capable of measurement only by the spectroscope; if the motion be diagonal, then by both of these instruments together. Hence the motion of a fixed star in space, or of a whirlwind on the sun, may be measured by the change in refrangibility which certain lines in the spectrum undergo.

To illustrate this point by means of sound-waves was the object of the evening. With the lantern the image of a tuning-fork beating 256 times a second—and giving the note Ut_3—was thrown on the screen. By the side of one of the prongs, and just touching it, was a carefully rounded and varnished cork ball, suspended by a filament of silk. On sounding a second fork placed on its case and tuned in accurate unison with the first (by an ingenious method devised by Prof. Mayer) anywhere in the room, even 30ft. distant, the first was thrown into vibration and the image of the cork ball was projected a foot or two away from the prong. When, however, the second fork was sounded, and the lecturer walked rapidly—at the rate of 8ft. a second—towards or from the first, touching the case only when in motion, no motion of the cork was observed; the wave being in this way shortened or lengthened by an amount sufficient to throw it out of unison with the lantern-fork. Again, a third fork, vibrating 254 times a second, produced no effect on the ball; but when sounded and placed on its case, as this was swung rapidly towards the first fork, the wave-length was thereby so shortened as to bring it into unison with this, and the ball promptly responded. A fourth fork, vibrating 258 times, showed the same phenomenon, when placed on its case as this was swung away from the first fork, the wave thus being shortened into unison. The demonstration was most complete and satisfactory. Prof. Mayer stated that he purposed making some quantitative experiments with the apparatus, which will be of the highest value to science.

The lecturer closed with an application of this sound demonstration to the phenomena of light. It was an exceedingly interesting lecture throughout, and was listened to with the closest attention.

* From the *College Courant.*

HISTORICAL NOTES ON POISONING.

THE following remarks formed a portion of the introductory lecture to the course of Forensic Medicine delivered at King's College by Dr. David Ferrier, and are abstracted from the report in the *British Medical Journal*:—

I have chosen, said Dr. Ferrier, to illustrate the development of Forensic Medicine in one of its branches more particularly, by bringing before you the results—possibly more curious than valuable—of an inquiry into the uses of poisons, and the notions that have prevailed at different periods in the history of medicine on the subject of poisoning. This has always been a matter of curiosity and interest, not more to the medical profession than to people generally; and, on account of the ideas associated with the word poison, it has always proved an attractive theme to writers of fiction.

The earliest use of poisons seems to have been for the purpose of anointing arrows; and the word which is used to denote poison (*toxikon*) derives its origin from the word signifying bow (*toxon*). This custom dates from the most remote antiquity—from the time when men earned their means of subsistence (*bíos*) by the bow (*biós*). It is almost universally prevalent at the present day among the most primitive and savage tribes; and to this custom we owe our knowledge of one of the most powerful poisons that exists. We find frequent allusions to it in the classical writers. Homer represents Ulysses as sending to Ephyra for poison wherewith to anoint his arrows. The story of Hercules dipping his arrows in the venom of the Lernæan hydra, their deadly effects, and the dreadful accidents which befel Chiron and Philoctetes, are familiar to you all. This story is an indication of the nature of the poison employed; and we have it on the authority of numerous writers that snake-poison was frequently used for this purpose. Such was the custom of the ancient Scythians, who likewise mixed the venom with human blood, of itself regarded as a virulent poison, in order to intensify the effects. Even at that early period, they had discovered the fact, though its explanation by the physiological relation between absorption and excretion is only of recent date, that, when taken naturally, the poison was innocuous, and was only fatal when directly introduced into the blood by means of a wound.

Another very ancient use of poisons was for the purpose of the ordeal—a method of judicial investigation which also obtains among many tribes at the present day. With this custom we generally associate the physostigma or ordeal bean of Old Calabar. It is supposed that it was a poison of some kind which constituted the maar, or bitter water, of which we read in the book of Numbers, and which was used as a judicial test of the honour of wives accused of infidelity by jealous husbands. Harmless to one who was innocent, the effects in the case of a guilty woman were dire enough, causing the belly to swell, and the thigh to rot. It is very doubtful whether this were really a poison. It is more likely that the dreadful invocations of the imposing preliminary ceremony were sufficient to deter any but an innocent woman from draining the contents of the cup.

One of the most curious chapters in the literature of poisoning is that which relates to the use of poisonous substances in the preparation of *philtres*, or love-potions, which were administered under the idea that the affections of the person so practised on would be gained by the individual who employed them. Though the means adopted were often ridiculous enough, and partook more of the character of sorcery and incantation, yet in many cases they were not of the same harmless nature, and the evil effects which frequently resulted assumed such an importance in the eve of the law, that, even at an early period, the administration of such philtres was looked upon in the same light as more serious attempts at poisoning, and was punished as a capital offence.

Among the Greeks and Romans, Medea was universally regarded as the greatest adept in the art of preparing philtres; and hence the term *Medeides herbæ* was used by Horace and Ovid to designate such substances generally. Next in reputation stand the Thessalian women, who may be supposed to have learnt the art from Medea, and who attained great celebrity in all that related to poisoning, sorcery, and incantation. Hence "Thessalian arts" and "Thessalian poisons" are frequently employed by the classical writers as generic terms, applicable to all forms of poisoning. Philtres are described by Ovid and others as affecting the reason and causing a phrensy which sometimes terminated fatally. Lucretius, the great philosophical poet of the Ciceronian era, is said to have written his poem "On the Nature of Things" in the intervals of delirium occasioned by a philtre or love-potion secretly administered to him by his wife or mistress, Lucilia; and Lucullus, the Roman general, is stated to have died in a state of delirium from a similar cause. The laws of the Twelve Tables contained special provisions against this form of poisoning. Though it would appear, therefore, both from the accounts we have received and from the necessity of special enactments against it, that the administration of philtres often led to results far more serious than were contemplated by those who used them, we can hardly regard otherwise than as a subject of amusement the credulity which prevailed even up to a very late period with respect to many substances held in high repute, and supposed to be possessed of marvellous properties. Most of these substances would hardly come under the head of poisons, or even noxious substances, as we understand them; but yet in most countries their administration was forbidden, as coming under the head of sorcery and witchcraft.

It is a curious circumstance, and one which we find great difficulty in accounting for, that not merely human blood, but the blood of animals in general, was universally looked upon as a poison in ancient times; and that this belief should have been shared by medical writers up to a comparatively recent period. We read in Herodotus that Psammenitus, King of Egypt, was put to death by Cambyses by being made to drink bullock's blood. Such also, according to the popular belief, was the mode in which Themistocles committed suicide. Unwilling to fight against his own countrymen, he drank a goblet of the blood of a sacrificial ox, and expired almost immediately. Even up to the time of Blumenbach, in the middle of the last century, the belief that blood was poisonous was general, and it was treated of as such in many learned works on poisons and legal medicine. Zacutus Lusitanus, writing in 1657, relates many instances of dreadful effects resulting from the drinking of blood. It is worth while quoting one of these. A student, animated by the spirit of practical joking, gave to another, instead of wine, 2oz. of the blood of a red-haired woman mixed with sugar. The victim of this joke did not experience any immediate bad effects, but after a day or two he passed into a raving state, and became ultimately a confirmed idiot. One is tempted to remark that the individual in question cannot at best have been far removed from this state, if he could mistake for wine the nauseous mixture offered to him. And, in the opinion of Andreas Cæsalpinus, who nearly anticipated Harvey in the discovery of the circulation, it is to human blood that we owe the origin of one of the most virulent contagious diseases. He traces the origin of syphilis to the fact that the Spaniards, in abandoning the small town of Somma, at the foot of Mount Vesuvius, mixed all the wine of the place with the blood of the patients in the hospital of St. Lazarus.

Blumenbach, in his lectures, recommended his students to make experiments in order to clear up all doubts as to the poisonous qualities of blood. One student experimented on himself, and drank seven ounces of warm bullock's blood without experiencing any evil effects. Another preferred to experiment on a dog, which likewise survived the experiment.

Returning from this digression on blood once more to the subject of philtres, we find that the belief in them was strong even as late as the time of Van Helmont, in the middle of the seventeenth century. Van Helmont himself was fully persuaded of their efficacy, and perhaps the most remarkable statement in regard to them occurs in one of his writings. Here is a translation of it: "I know a plant of common occurrence, which, if you rub and cherish in the hand till it becomes warm, and then take the hand of another and hold it till it also becomes warm, that person will forthwith be stimulated with love for you, and continue so for several days." There were not a few, however, even in ancient times, who were sceptical as to philtres. Ovid, who speaks so much in them, had his doubts; and, in a letter to a young lady, he recommends, as by far the most preferable prescription, "ut ameris, amabilis esto." From these and similar truths, the influence of philtres gradually ceased to be believed in, and disappeared from medical literature by the middle of the eighteenth century. Closely connected with the practice of brewing love-drinks was the still more pernicious and dangerous one of dealing in abortifacients. What we now call the crime of abortion was not in early times regarded as such. False political and social doctrines had much to do with the prevalence of the practice before the dawn of Christianity, and it was not till the time of the early Christian emperors that legislative measures were enacted to check it. The agents who pandered to the licentiousness and vice of this period [the Roman Empire] were numerous, and well skilled in the knowledge of almost all the mechanical and oxytoxic means of procuring abortion with which we are at the present day acquainted. Then, as now, the attempts were frequently followed by fatal consequences.

It is, however, with the use of poisons for the express purpose of taking away life that we more particularly associate the term poisoning and it is on this that so much has been written, and, at the same time, so much has been fabled. It was but natural that men should turn to some account the knowledge of the deadly effects of many substances with which they could not help becoming acquainted, and to employ them for ridding themselves of objects of jealousy, hate, envy, or revenge, especially as this could so often be done secretly and securely; and it was also natural that the same means should recommend themselves as a rapid and pleasant mode of suicide. Poisons were also employed for state purposes, as a means of execution. The most celebrated instance of this is the koneion or state poison of the Athenians, which has derived its chief interest in connection with the death of Socrates. The description given by Plato of its mode of action has given rise to considerable discussion as to its nature. Apart from its name, which would be no satisfactory guide, it has been generally identified with the *Conium maculatum* or hemlock. Some have doubted whether it were only a simple infusion of hemlock, and think that it must have had other ingredients. Whatever it was, it does not appear to have been very powerful or rapid in its action; for we are told that mental excitement was apt greatly to interfere with its effect, and sometimes more than a single dose was necessary. The carrying out of the sentence of capital punishment by means of poison was not, however, confined to the Athenians, and we have numerous instances in other countries where the same method was adopted. It was allowed as a special mark of favour in some cases; and in later days, when scientific men were eager to study the effects of poisons in an exact manner, it was permitted by the State, and criminals were quite willing to submit themselves to be experimented on with poisons, rather than undergo the horrors of a public execution. The mode of execution by poison was strongly advocated by many medical writers of the last century. Celtes, a German writer, thought it was a mark of very great simplicity and stupidity in his countrymen not to have adopted it; and Gruner, in a very eloquent and feeling manner, extols the comfort and tranquillity of being quietly put out of the way, without becoming, under the hands of the executioner, a horrible and bloody spectacle in the eyes of a cruel mob.

It was a strange custom that prevailed among the inhabitants of the island of Ceos. The old men, when they found that they were no longer of service to the State, and felt themselves a burden to their children, assembled together at a banquet of death, and, with their heads crowned with chaplets, joyfully drank a happy despatch in cups of hemlock. A more sensible custom obtained among the ancient inhabitants of Marseilles—one which might with advantage be revived at the present day, if only those most interested would subscribe to its provisions. Valerius Maximus relates that the inhabitants of that town kept a public poison, intended for the special use of those who wished to commit suicide. Before, however, the applicant was supplied he had to go before a jury of six hundred—the Timarchi—and satisfy them that he was miserable enough to be allowed to put an end to his troubles by poison. The kings of Persia were also in possession of a poison which caused a speedy and painless death, which they carefully preserved for their own special use against an evil day.

In times of trouble, and in ages of barbarous cruelty, men who took an important part in public affairs, and thus exposed themselves to the machinations of numerous enemies, often carried on their persons a sufficient quantity of some deadly poison, to which they resorted as a means of escape from tortures worse than death. I might cite numerous instances of this practice in various ages, but one or two well-known examples will suffice. I have already alluded to the death of Themistocles, which was popularly set down to the effects of blood, but which, in all probability, was due to some poison which he carried on his person. Demosthenes, when all hopes of escape from his enemies, the Macedonians, were gone, committed suicide by taking a dose of poison, which he is said always to have carried about with him in a quill. The story of Hannibal is likewise familiar to you all. After being hunted about from place to place by his relentless enemies, the Romans, he was obliged to sacrifice himself, in order to save his protector, Prusias. He is said to have carried the means of death in a ring which he constantly wore. Though we can admit the possibility of this, we have no means of ascertaining the nature of the poison, nor the method in which it was introduced into the system. Perhaps the most celebrated instance is the case of Mithridates, King of Pontus, who was, according to accounts, quite an adept in toxicology, and left behind him a work on that subject, which, however, has unfortunately been lost. Mithridates, like some oriental monarchs of the present day, lived in constant fear of being poisoned. To guard against this, he invented an antidote, which became so famous that the name Mithridatium was applied to antidotes generally. Of this, however, we shall have to speak by-and-by. By the use of this antidote, but more probably by the habitual use, in small doses, of the poison which he feared, he is said to have rendered his system insusceptible to the action of poison; so that, when he came to require its aid, it proved faithless to him, and he was obliged to have recourse to his sword. The story of Mithridates would seem to show that it was one poison only, or at most very few, which were known, or at least had recourse to, by poisoners of that time.

It is, however, to the secret crime of poisoning that we attach the chief interest, both in a popular and medico-legal sense. It is often difficult to arrive at the real truth in many of the narrated accounts, surrounded as it is, and mixed up with, so much that is evidently mythical. It is remarkable that this crime should have prevailed in some countries to a much greater extent than in others, and that so many women should have acquired a notoriety in this art. A great many of the accounts, however, which we have received regarding the proficiency which so many women are said to have attained, especially in the art of preparing slow and secret poisons, must be estimated at the same value as the similar tales of sorcery and witchcraft. As women were supposed to be specially addicted to these black arts, so they got a similar amount of credit for the art of secret poisoning; and, in ancient statutes, the word which signified witch was also used to signify poisoner. Most of the old statutes regardeded sorcery as a *veneficium*, and punished it with the same penalties. In the laws of the Twelve Tables already alluded to, persons who administered poisons, or uttered an incantation against the life of another, were punished with death; and, in the Institutes of Justinian, capital punishment was inflicted on those who by odious arts, whether by poison or by "magical whispers," took away the life of another.

The crime of poisoning does not appear to have been common among the ancient Egyptians or Jews, judging from the absence of any special legislation against it. The existence and character of the law against this crime afford a fair indication of its frequency, for in ancient times it was those who made the laws that had often the most reason to fear. The crime was very common among the Persians. This we have on the direct testimony of Xenophon; and certainly the punishment was such as might be expected to deter evil-doers. Those who were found guilty of poisoning were laid with their heads on a flat stone, and then beaten about the head and face with another stone till the skull was smashed in pieces. And, judging from the story of Statira, the Persians must have arrived at considerable dexterity in the art of preparing and administering secret poisons. It is related that Parysatis, wife of Darius, wishing to get rid of Statira, the wife of Artaxerxes, smeared with poison one side of the knife with which she carved a fowl. She sent the poisoned side to Statira, while she ate the other herself; so that Statira died apparently from causes which left no room for suspicion.

The crime was not common among the Greeks. When it did occur, the malefactors were condemned to death by the Areopagus. The Romans are said to have learnt the art of poisoning from the Persians. In this they soon excelled their masters, and indeed almost every other nation. The first great outbreak of the crime is reported by Livy, which occurred about the year B.C. 330. At this period, the morals of the upper classes of society had become so scandalous that the more virtuous and honourable members of the Senate set themselves to stem the torrent of vice. Soon afterwards, the frequent occurrence of sudden death among the illustrious senators filled the city with alarm, and led to an investigation. By the evidence of a slave, who had been privy to their councils, a secret society of patrician women was discovered, whose avowed object was to get rid of the obnoxious senators by means of poison. They vehemently denied the charge; asserting that their preparations, which were found, were only medicines for the poor. As a test, they were compelled to drink their medicines, which proved fatal to them all. Their accomplices, to the number of one hundred and seventy, were thrown into prison, where they perished. Two hundred years after this occurrence, secret poisoning again became extremely frequent, and led to the passing of the famous law "de veneficiis et sicariis" by the dictator L. Cornelius Sulla. This law is still preserved in the Institutes of Justinian. By it the crime of poisoning is held as more heinous than any other form of homicide, and was punished with corresponding severity. Under the Roman emperors, particularly about the time of Nero, poisoning was so frightfully common that few of any note were safe. The chief instrument in the perpetration of the numerous villanies which characterised the life and times of Nero was the famous Locusta. So necessary did this woman appear to the success of the schemes of Nero, that she was maintained by him as an *instrumentum regni*, and had pupils intrusted to her, that the valuable art should not become lost. It was Locusta who prepared the poison by which Agrippina despatched her husband, the Emperor Claudius, and by which, among others, Nero despatched his brother Britannicus. In the writings of Tacitus, Suetonius, and other writers of that epoch, there is much curious and interesting information regarding the experiments of Locusta, the nature of the poisons used, and what were considered at that time as the symptoms and signs of their administration. The poisons were chiefly derived from the vegetable and animal world, mineral poisons not having become known till a later period. Aconite seems to have been frequently employed.

It is also probable that aconite or some equally powerful poison formed the really active ingredient in many of the compounds which were by popular rumour supposed to owe their deadliness to substances which we now know to be wholly or almost wholly inactive. It was the popular belief that the poison which carried off Claudius was prepared from and administered to him in a dish of mushrooms. We could more readily credit the account, if it had been stated that he was poisoned by toadstools, the poisonous properties of which were well known. It has, however, long been a vulgar belief that toads are poisonous—an idea probably originating from their repulsive appearance, and from the fact that they do secrete an acrid fluid in their cutaneous glands. Modern research has not, however, confirmed this notion; and there is reason to believe that as many toads as frogs are eaten by epicures. That toads are poisonous, will in all likelihood continue to be believed as long as Shakespeare is read. Probably the same method of reasoning led to the belief in the poisonous nature of the *aplysia*, or sea-hare. Further than having a disgusting appearance and fetid odour, and having the power of emitting a coloured liquid when irritated, it does not seem to possess any specially poisonous qualities, though the subject might perhaps be worthy of further investigation. Nero is said to have frequently used this as a poison, and it is with this that Domitian is said to have poisoned his brother Titus.

(*To be concluded.*)

A Valuable Telescope.—An equatorial telescope was sold by auction, by Mr. J. C. Stevens, on Friday, and realised £745 10s., Mr. Henley being the purchaser. It is thus described in the catalogue: Equatorial telescope, complete, by T. Cooke and Sons, York; object-glass, 10in. clear aperture, and about 12ft. focal length; finder, with object-glass 2¼in. aperture; nine Huyghenian eyepieces, powers from 55 to 800; four sunshades, neutral tint; first surface reflecting prism, for viewing the sun; transit eyepiece; double parallel wire micrometer, with six eyepieces and four sunshades, in polished mahogany box; new prismatic illuminating apparatus, with Iris diaphragm for regulating the intensity of the light, and discs of coloured glass for changing its colour; sensitive level, swinging on pivots attached to the telescope tube, for determining the horizontal of the declination axis, in order that the line of collimation may sweep the plane of the meridian, enabling transits to be taken; large position circle at the eye-end of the tube, graduated upon silver, and read with two verniers and microscopes; large declination circle on the axis, graduated upon silver, and read with two verniers and microscopes; also a small supplementary declination circle, with levels, at the eye-end of the tube for quick setting; hour circle graduated upon silver, having two sets of divisions and verniers, and reading microscopes; equatorial motion communicated by clockwork, and additional tangent screw motions in right ascension and declination by means of rods and handles brought down the tube and axis.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

AXIS OF VENUS.

[4535.]—I QUITE share the opinion of "F.R.A.S." (let. 4491, p. 480) that no alleged determination of the precise inclination of Venus's axis can be accepted with confidence. But it seemed to me that his use of the word "imagined" might mislead, as not suggesting that De Vico's estimate was in any way based on observation. Before throwing out my suggestion, I looked up Webb, and though I noticed the passage quoted by "F.R.A.S." *from* p. 50, it did not seem to invalidate Webb's remarks at p. 49, that Bianchini "did his work *well*," but that "the *most effective* results" were those obtained by De Vico. (The italics are mine. Better than well seems at least not bad. The note quoted by "F.R.A.S." appears to refer to De Vico's style of writing, and to inexperience about other matters; for surely Webb knew his own mind when he was writing, and did not contradict flatly on p. 50 what he said on p. 49. I lay no stress on this point, however.

"F. R. A. S." will, I know, excuse my raising the question, since our common wish is to get as near the truth in these matters as may be. What seems pretty fairly established is a rotation period of about 23¼ hours and a great axial tilt. As to believing in De Vico's minutes and seconds of tilt, I can as well believe in his seconds, tenths of seconds, and hundredths of seconds of rotation-period, which imply that he was sure of every rotation since Bianchini's time, and that Bianchini's *observations* and De Vico's *timed* the arrival of the spots in certain positions, within a few minutes—which is absurd.

Can any one give me De Vico's estimate of the position of Venus's vernal equinox? The way in which our text-books neglect such points is simply discreditable. So far as observation is concerned, to give the axial tilt without the place of vernal equinox is as reasonable as it would be to give a planet's diameter without mentioning its distance. RICHARD A. PROCTOR.

AXES OF THE PLANETS.

[4536.]—IN answer to Mr Proctor (letter 4449, p. 406), Schröter estimated the angle which the equator of Mercury makes with the plane of his orbit at about 20°. W. T. R.

SPINNING-TOPS AND GYROSCOPES.

[4537.]—I AM quite unable to spare the time necessary for the proper discussion of this subject. I wrote only to point out the undoubted fact that mathematical analysis affords a complete account of all the phenomena of the gyroscope. What I remarked further on the subject of popular explanation was said altogether *en passant*, and should be taken in connection with what I said on the insufficiency of such explanation. But though I wrote *currente calamo*, I did not think it was in the power of any reader so thoroughly to misapprehend my remarks as J. M. Taylor and "E. H." (let. 4510 and 4511, p. 435) have done, each in his particular way. The possibilities of misapprehension are not easily gauged, however.

As to "E. H.," I shall be very brief. His remark that *whatever I may say* my ideas are extremely like "A.'s," is, of course, very ill-mannered; but he probably thinks it justified by facts: therefore, I take no exception to it. I should have thought he could perceive, however, that whereas "A." applied a mistaken idea about the bullet to illustrate the motion of a top, I applied a known fact to illustrate the same matter, the fact, namely, that the direction of motion of a swiftly moving body changes slowly under the influence of gravity. "E. H." asserts very confidently that "the question most certainly is *not*, at what rate?" It is particularly kind of him to tell me what question I was considering, but I must repeat that I *had* the rate in view. It is an undoubted fact that the shift of pose of an inclined top takes place more or less quickly according as the rotation is less or more rapid.

"E. H." proposes to give a popular explanation of gyroscope motions with several explanatory diagrams, when you, Mr. Editor, think fit. My advice to him is even as the advice of Mr. Punch to persons about to marry—*don't*. We had enough on the subject, and a good deal to spare (especially in the way of explanatory diagrams), some two or three years ago, from a gentleman anxious to enlighten the world with new ideas about the gyroscope; ideas, unfortunately, rather more new than true. If my recollection serves me aright, that gentleman used the initials "E. H.," but I am not sure. Perhaps the "E. H." of letter 4411 can tell us whether he ever favoured these columns with letters about the gyroscope.

"E. H." is obviously in labour, or eager to be in labour, with a new theory about nutation. I fear our wishes for a "safe delivery" should be limited to ourselves.

J. M. Taylor's supposition that "the centrifugal force lifts the body of the top itself," would hardly have resulted from his discussion of centrifugal motions, if he had not been *quite* so careful to avoid "entering into the mechanical analysis of the resolution and composition of the forces." The rising of a governor ball, or of a weight swinging as a conical pendulum when the velocity is increased, is in perfect accordance with those accepted laws of motion which Mr. Taylor seems so eager to invalidate (mistaking his failure to understand them, I imagine, for new lights). He would do well to remember the law (though it labours under the disadvantage of being an accepted one) that "action and reaction are equal and opposite."

Mr. Taylor "could hardly credit his senses," when he found me broadly stating that the weight of the top is insufficient to change the direction in a brief interval. Passing over the fact that his reference to his senses is not particularly polite, let me be permitted to point out that the weight of the top is the weight of its particles; that its particles are moving in different directions; that the time during which a particle moves in a given direction is a very brief interval indeed, being "no time at all;" that if one considers the motion of a given particle at any moment, one must not forget that that particle is not the whole top, *nor free to move without the top;* and that though the motion of this particle under the action of gravity would tend (*if the particle were free*) to shift the plane of the particle's rotation in one particular way, the motion of the particle directly opposite (*i.e.*, the particle so placed that the line joining the two is bisected by and perpendicular to the axis of rotation) would tend to shift the same plane of rotation in precisely the opposite way. The consideration of a few such facts as these, combined with a recollection of the circumstance that I was professedly only sketching out a certain method of reasoning, may perhaps enable Mr. Taylor to recover the reliance which he has been accustomed to place in his senses.

"Puzzled" (query 12377) may be satisfied that the height of the tower has nothing to do with the fact which puzzles him. RICHARD A. PROCTOR.

[4538.]—I THINK the suggestion of "F.R.A.S." as to the advisability of certain of our correspondents studying "fourpenny catechisms" is a good one. "A." (let. 4487) cannot understand how a cannon ball, fired horizontally, should strike the ground at the same time as if it had been dropped perpendicularly from the muzzle of the gun. He seems to imagine that the ball would travel for some distance in a horizontal direction. This is where he is in error. The ball would not travel in a strictly horizontal direction for the space of a single inch. The moment it leaves the mouth of the gun gravity begins to act, and draws it downwards. I would advise "A." to procure an elementary treatise on mechanics, and study the "parallelogram of forces." He will then see that a body acted on by two forces, represented by two sides of a parallelogram, will take a direction answering to the diagonal of the parallelogram, and that it will arrive at the end of the diag. in precisely the same time as it would have arrived at the extremity of either of the sides, if acted on only by the corresponding single force. Example.—If a cannon be trained horizontally, with the muzzle 16ft. from the ground, and a shot be fired from it—say, at the rate of 1,400ft. per second, then, leaving out the resistance of the air, the sides of the parallelogram will be 16ft. and 1,400ft. respectively, and the ball will strike the ground at the end of one second, and at the distance of 1,400ft. from the vertical line to the mouth of the gun. Owing, however, to the fact that gravity is a continuously acting force, the ball will not pass in a straight line over the diagonal of the parallelogram, its course will be a curve; but it will arrive at the other extremity in the same time as if it had described the diagonal. "A." is right in saying that a swiftly moving body offers resistance to any force seeking to change the direction of its motion. The faster the ball is propelled from the mouth of the gun, the greater resistance it offers to the deflecting force of gravity, consequently the angle which is formed at the mouth of the cannon by the line of fire, and the direction the ball takes, is less in the case of the more swiftly moving ball. In other words, the ball goes farther before striking the ground, but the time of flight is the same. If "A." cannot understand this, I hope he will follow the advice given above.

The case of "A." differs from that in which "F.R.A.S." recommended the "fourpenny," inasmuch as the querist in the latter case merely asked for information on a certain point, while "A." makes assertions which show his extreme ignorance of the subjects about which he writes, and at the same time declines to receive the information given him by better-informed correspondents.

Looe. G. M.

[4539.]—I WOULD suggest to "A." (let. 4487, p. 412), to prove the incorrectness of my assertions and correctness of his own, rather than ask me to stop stating obvious and recognised truths. I did not misrepresent him about "particles rotating in a plane, and unable to get out of it." My letter referred to other correspondents besides him, and if he will read the other letters carefully, he will perhaps see what I alluded to. He assumes it to be admitted that the ball travels for some portion of its flight in a horizontal direction, but that is just what is not admitted, for the ball begins to deviate from the horizontal the instant it is free for gravity to act on it. It is quite clear that if gravity does not act the first instant, it is not any more likely to do so at any subsequent instant. Whatever can "A." mean by such expressions as "turned in a direction contrary to the plane of its motion," or "moved in any direction contrary to a straight line"? The expression so commonly used, "resistance to change in direction of motion," is inaccurate. Such a resistance is erroneously imagined to exist, because, from want of consideration, a wrong expectation is formed of the effect of an impulse, tending to produce change of direction. In the case of rectilinear motions or moving forces, it is well known that we must apply the "parallelogram of forces" to obtain the new direction a body will move in when two forces, acting in different directions, are combined. The body offers no resistance whatever to motion in the new direction, any more than it does to moving in a straight line under the influence of a single force. And it is just the same with a rotating body like a top or gyroscope. The "parallelogram of forces" applies equally to this case, and in a more direct and simple manner than is commonly supposed.

"Epsilon" (let. 4488, p. 412) seems to be unaware that a top will gyrate without falling and without wobbling, even when its axis has a considerable inclination; when, in fact, his proposed process of cutting the peg level would not apply. He seems also to be unaware in what sense the term gyrating is applied to a top or gyroscope. A top has a motion of rotation about its own axis, but if not perfectly vertical its axis has also a motion called gyration, when, its point of support being stationary, its outer end moves in a circle. "Epsilon" introduces an entirely new view into the matter when he says "the top ceases to gyrate, and consequently falls, but not through gravitation"!

Glasgow, July 6. E. H.

THE NEGRO.

[4540.]—THE darkness of Jews long settled in certain countries, as India, China, Abyssinia, and Waregla, is as "H. J. C." notes (let. 4528), our chief warrant for any effect of climate on human colour; but a far more curious and less accountable fact, if true, is that noted by the late Dr. Wolff (himself a Jew), that all his brethren in the Levant, including Syria, were fair, light-haired and blue-eyed, or the most frequently so of any race in those regions, while here, in western Europe, a light-haired Jew is hardly known. As for the resemblance of the eastern "black Jews" to Negroes, it can be no nearer in colour than that Hindoos, and in form not at all, the latter being far nearer to ourselves in every respect than to the Negro. "Fiddler" (let. 4529) repeats his very gratuitous puzzles about Josephus, as if the latter were the most ancient authority on these matters, or as if we had not the chief documents used by him (which is not the case with any other ancient). Those documents uniformly throughout the Old Testament, name Cushites (or in Greek, Ethiopians) as remarkable for dark skin. "Can the Cushite change his skin, or the leopard his spots?" And they enumerate Cush as one of the sons of Cham, whose name, according to most Orientalists, meant black, being the root of one old name of Egypt as the land of black soil, and of our words *alchemy* and *chemistry*, as "black art," or Egyptian art. It is incorrect then to say with "Fiddler," we have no suggestion of there being any Negro in Noah's Ark. It is nearly as much implied as so brief a narrative could imply, that Ham, or his son Cush, or both (and if so, then his wife and other children) were nearly black, and yet not necessarily of the darkest race known even to the Hebrews. For while Cush and two other sons are declared to have become notoriously dark races (and one, Cush, geographically, bordering on Negroland), a fourth son, Phut, is never again named, he or his posterity, after the genealogy, until, I believe, that single verse of Nahum, where they appear only in connection with the southernmost city, and nearest to Negroland of any ever named in the Bible, and which is itself named but that once. As for the antediluvian Nephilim, there was no reason to describe their colours more than any other of their qualities, and not a word to imply they were all (or any of them) white; nor that Adam or Noah were as white as Japhet, Shem, or ourselves; but in Adam's case rather the reverse. As for Adam's son Seth (who is nowise implied to be his "third son" rather than his thirtieth) he is clearly made an ancestor through Noah, not merely of Negroes, but of all the modern world. None of us can claim less or more de cent from *this* Seth. The name, of course, as Sethos, Sethi, Sesostris, &c., became common, but the confusion of him with any Egyptian is absurd. Moreover, of all Africans, the ancient Egyptians were the least like Negroes, either in colour or anything else, though, doubtless, nearer than any Asiatic or European, but not so near as Melanesians and Australians. There is not a trace of any one "palming off Seth" (*any* Seth that I can hear of) as "father of the black race," or any wise black himself. There is this connection of the name with Cham or Khem, that both became names of an obscene idol, the same as Baal-Peor, Peor-Apis, or Priapus; and this is the "Sheth" named in Balaam's prophecy, whose worship the Messiah was to annihilate.

As for the proofs "Fiddler" asks for, "of the great antiquity of man (one hundred thousand years)", he will find, by searching Lyell's "Antiquity of Man," that there is no shadow of ground, as yet, for any such estimate. The only valid geo-chronometers are those furnished by delta deposition, peat-growth, waterfall recession, and débris of precipices, all discovered by De Luc (the first coiner, by the way, of the term "geology"); but he added, mistakenly, one from the growth of glaciers and mountain snow, which has been proved unsound, as these advance and recede for some years, even half a century at a time, advancing in wet years, and receding in dry ones. One more chronometer than his, however, occurs in such caves as that of Settle, described (p. 323), where the chips, detached by frost from the roof, had made a 2ft. covering in 12½ centuries, over the Roman Welchmen's relics, and just thrice as much between the flint folk's time and theirs, thus carrying back the sudden end of the flint workers to exactly the recorded century of Noah. So it is with all these independent chronometers, in every continent alike, the 50 centuries, neither more nor less, are uniformly attested since the great change; and men had been before it, on the whole globe, with the mammoth and mastodon; but whether for one, or two, or three thousand years, there is nothing as yet to show. The deltas of the Ganges and Mississippi seem far older, perhaps ten times; but they each have a gravel stratum at the exact depth, according to Lyell's data, corresponding to the Noachian interruption, and the sudden extinction of great animals and inferior men everywhere attested. As for his new-fangled and utterly fallacious pretence of a chronometer, the *only* one ever mentioned in his "Antiquity of Man," based on the idea that land rises so many inches in so many centuries, one really cannot stoop to refute it seriously when all readers have his own accounts before them, if not in the very same volumes, of Chili and New Zealand being thrust up 10ft. with a jerk, and the new Aleutian Isle rising 3,000ft. in a year. All writers and publishers of big books must necessarily make for their market. What they themselves believe may be nowadays a very different matter. E. L. G.

[4541.]—I HAVE read "E. L. G.'s" letter (4456, p. 407) with great attention, but has he not overlooked the almost conclusive evidence in Gen. vi. 1, 2, that the descendants of Adam were negroes, and the daughters of men children of a white race; for if the reverse, surely a white man would not consider a negress as *fair?* Then, again, with reference to the genealogy of the patriarchs in chap. v, what period of time is there described as a year? Considering their ignorance of astronomy, I think the patriarchs would reckon time by the day and lunar month, which gives seventy-eight as the age of Methuselah, a more probable length of life than nine hundred and sixty-nine of our years. As to the genealogy of Shem in chap. xi., I consider here is evidence of a change in the mode of reckoning; probably, instead of lunar, seasonal changes, such as seed-time and harvest, are the periods there given. It will be understood that the first argument in this letter is founded upon "E. L. G.'s" supposition that the Adamite and Nephilim races are of different origin.

T. A.

CONDENSATION OF STEAM IN PIPES.

[4542.]—As I have had practical experience in a similar case to that of "A. W. E." (let. 4467, p. 410), I think that perhaps the most satisfactory way of answering his seven queries relative to the condensation of steam, &c., will be to state what I have already accomplished.

About fifteen years ago I took steam down a pit through a total length of pipe of 310 yards. The boiler pressure was 45lb. per square inch, and the total loss of pressure, as near as I could ascertain, about 1lb. per square inch merely. The pipes were 2in., and were well covered with two wraps of hay-band through their entire length, and this plastered with cement, and then covered with tarpaulin to keep out the wet, as the pit was damp and continually dripping. The engine had an 8½in. cylinder, 260ft. per minute piston speed, and ran for four minutes at a time with intervals between. Close to the engine I placed a steam reservoir, also well lagged, of ten times the cubic capacity of the cylinder, and all the system of pipes was made to slope towards it in order to separate the condensed water. This vessel had a cock at the bottom to draw off the water when required, and I found that leaving the steam in the pipes for ten hours, with the engine standing still, only produced half a bucket of condensed water, showing the great value of well clothing the pipes, and the great economy resulting therefrom. What the difference would have been with naked pipes I do not know, but they would have formed a huge condenser; and seeing how cheaply and easily they may be protected, it can never be worth while to neglect doing so. By treating the exhaust pipes in the same way for a certain distance, the mine will not be appreciably heated. There is no doubt that this system presents great advantages for draining purposes, avoiding heavy cranks, spear-rods, &c., providing the pumps are properly designed to maintain a uniform flow, so as not to have to stop and start a heavy column of water at each stroke. With respect to the employment of compressed air for conveying power, I may add that all methods hitherto employed are expensive, both in first cost and in subsequent working, the only exception being in those cases where there is sufficient water-power available for driving the pumps. The problem is to convert high pressure steam into high pressure air with the least possible loss by friction of machinery, and the least possible complication of parts. An ordinary compression pump does next to nothing for at least half its stroke, and this defect is inherent in every form.

It has occurred to me lately that possibly the principle of the injector might solve the difficulty satisfactorily, and I will endeavour to explain how without the aid of a diagram. Suppose we have a large boiler, or air reservoir, under water to keep it cool, and a high pressure steam boiler near to, would not a jet of steam blowing into a long trumpet-shaped pipe, whose small end communicated with the reservoir, sweep a quantity of air along with it into the reservoir, which air would accumulate till it nearly, if not quite, equalled the pressure of the steam itself? The steam would, of course, condense on the sides, and leave only air, and this separation of the two could also be facilitated by taking off the air wherever it is required through a coil of pipes under water, such pipes to slope towards the reservoir, which would have to be blown off occasionally from the bottom. This experiment is very easily tried, and the results, if favourable, are so important and applicable to "A. W. E.'s" requirements that I suggest it may be worth his while to construct a small apparatus to test the principle, some existing steam boiler being used. A 9in. pipe closed at each end, and pressure gauge attached, would do for the air vessel, and care should be taken after the index has moved as far as it will go to shut a cock to keep in the air, as the gauge might deceive as to the real quantity of air present while the steam was actually blowing in. There is nothing contrary to mechanical law in one force resolving itself into another of equal degree, and theoretically any given number of cubic feet of steam should produce precisely the same number of cubic feet of air at the same pressure. It should be remembered that the principle of expansion in a cylinder can be utilised to a far greater extent with compressed air than with steam, even when it is superheated, and this circumstance will no doubt compensate to a great degree for any little extra expenditure of steam necessary to obtain it.

If "A. W. E." should experiment in this direction, I hope he will communicate full particulars to the ENGLISH MECHANIC.

Bath, July 9. HENRY TURTON, Engineer.

"OUR" LIFEBOAT.

[4543.]—I BEG leave to propose for discussion what ought to be the principle of construction of the vessel which is to be called "The ENGLISH MECHANIC Lifeboat," which we all, of course, wish to be a model of excellence, and I commence it by offering my guinea towards its completion, whatever the final decision as to its form may be. This is, I submit, a far more useful question to settle rightly than that of the Deluge, which has lately occupied so large a portion of your pages, and I trust it will be conducted with as much ability and animation; but without resort to insulting expressions, which, however suitable to quasi-theological disputation, would be quite out of place when seeking to learn the best mode of saving life in dire peril.

A good vessel for saving life in storm must possess in a high degree several qualities not easy to combine. She should draw very little water, and be very steady under sail; she should be very light, but very strong; she should have all the speed of a very narrow boat, and all the roominess and safety of a wide one: so must be as tight as a bottle, and as easy to enter as a barge; she must be impossible to sink or upset or break; quick to sail; easy to row; handy to steer. It is easy enough to get a vessel that will fulfil one or two of these conditions; but to contrive one that will combine them all is very difficult, and unless all of them be fulfilled to a very considerable degree "our" boat will not be one to be proud of. The most promising attempt I have heard of was made by a Mr. Richardson, of Manchester, who, about twenty years ago, patented a lifeboat he called the *Challenger*, because he challenged any other lifeboat to beat her. This boat was, perhaps, not strictly speaking an invention; it seems rather an adaptation of the principle of the double canoe, which has been in immemorial use in the Pacific, but was far more strongly constructed. It consisted of two long air-tight iron pontoons (divided and strengthened by plates into air-tight compartments) floating parallel to each other, and supporting above and between them a deck protected by a gunwale for the crew, a very ample grating being provided for the immediate escape of any water shipped. It is evident that such a vessel need draw very little water, and if provided with a dropping keel would make but little lee way; that if the tubes were constructed with fine waterlines, each in form like the half of a long vessel, she would make nearly as good headway as one such vessel would, while the two halves being held a considerable distance apart would be very steady, just as a man standing on two feet is more steady than he who stands on one. It is also clear that such a vessel would need no ballast, and could hardly capsize. Neither could she sink, for no water can enter her closed tubes, and if one were damaged, it would only slightly derange her trim, for each tube being divided into water-tight compartments a part of it only could fill. I do not know either the weight or the size of Mr Richardson's boat (or raft, as some may prefer to call it), but think it might be made very light in proportion to its size and strength, especially if made of steel, with trussed beams for thwarts to hold the tubes in position and support the gunwales. It may be rowed and steered and sailed like another boat, except that she could safely carry far more sail than one of her weight of common build.

I do not know Mr. Richardson, or whether he be still alive; but his patent, which was taken out in or before 1852, has, I presume, expired. Indeed, a means for saving life is hardly fit for a monopoly; but we cannot justly blame an inventor for resorting to the only means for obtaining repayment of the costs he must incur in experiments and construction, but must regret that no other way of repaying and rewarding such benefactors is provided. PHILO.

MONOLITHIC BUILDINGS.—To "KHODA BUX."

[4544.]—THERE is no novelty in employing the tensile strength of metal (say iron or steel) for supporting floors and roofs. We do it when we use an iron tie to truss a beam. Many years ago I had the pleasure of hearing that amiable musical enthusiast, Mr. J. Hullah, lecture on his plan for supporting the roof of a monster music hall, I don't know how many feet long and wide, without internal pillars. Not being acquainted with monolithic building, Mr. Hullah proposed to build it with bricks and mortar, and attach the tie-rods, which supported the great weight of its vast roof, to the corners of its walls. This is, no doubt, the way to avail ourselves of their greatest power to resist a horizontal pull; but being only an ignorant blacksmith, and not at all a scientific person, I failed to perceive any advantage Mr. Hullah's method of supporting a roof had over allowing it to rest on the walls, which would, if the beams of the roof be completely trussed by tie-rods, then act as columns without interstices, supporting only its weight, for no horizontal thrust could then exist.

I believe Mr. Brannan—whose address is 8, Bouverie-street, E C.—will send "Khoda Bux," or any other person who desires information, full particulars of his patent wire concrete on application. Of course, like all inventors—we are a sanguine race—Mr. Brannan considers it the preferable material for all buildings, from labourers' cottages to mansions, breakwaters, piers, and even military fortifications. It certainly does seem to possess the advantages of a maximum of strength with a minimum of incombustible material. If not exactly papier-mâché, seeing it contains nothing of which paper could be made; it is eminently "fibrous." Practically, it would seem of little importance whether the "fibre" be round or flat, and at present rolled iron or steel ribands, alias hoop iron, may be cheaper than wire; but considering that cold-drawing imparts wonderful tenacity to steel, I can't help thinking a much less weight of wire than of hoop iron would suffice to afford the required power of resistance; besides, hard drawn steel wire is much less capable of permanent extension than hoop iron, consequently floors strengthened by it would be much less liable to "sag"—*i.e.*, sink in the middle. Which of the two may be found to be cheapest is only to be determined by trial.

THE HARMONIOUS BLACKSMITH.

[4545.]—THANKS to "Khoda Bux" for his letter (4461). I trust the subject will have full discussion in your pages I am interested in. Would like to adopt the method by the process referred to. Would "Khoda Bux" permit inspection of his buildings, if they are within reach, and give details of working?

J. T. HOLEHOUSE.

"J. C." AND DARWIN.

[4546.]—THE ordinary idea of creation, is existence produced by the sole will of the creator, and is entirely distinct from the idea of origination from development. If "E. L. G." means us to suppose that Darwin insists that the oceanic islands are ancient enough to have allowed of mammalia being developed upon them, I should like to know where he does so. The more ancient lands, indeed, according as they are more or less separated by barriers, are inhabited by their peculiar races of animals and plants, and to judge by the remains found in the earth, predecessors to these can frequently be traced, having a similarity of conformation. Islands of comparatively recent date, on the contrary, according as their communication with other land is cut off, are found deficient, sufficient time not having elapsed to allow of independent development to have taken place. H.

THE ROBIN HOOD SEWING MACHINE.

[4547.]—IN answer to R. Tansley (let. 4378, p. 355), allow me to inform him that ten years since, when skirt quilting was all the rage, I made a machine that would work with from one to twelve needles, at any distance apart, and, so far as the machine went, it worked most satisfactorily at either quilting or tucking, making a lockstitch. I have the machine by me now; but there are several reasons for not using a machine with so many needles which make it answer better to use the ordinary machines, that present themselves in practice, and are not noticed in theory. My machine would feed either at right angle or diagonal to the needles. Will R. Tansley describe his machine more fully? if so, I will answer any question put to me.

"G. W. K. L.," (let. 4471, p. 410) knows little about this subject, or he would not make such remarks as are contained in his letter. He should know that the feed would not be in a line with the needles, as no good could arise from it; therefore, it must be at right angle or diagonal to the needles, and if he knows anything about sewing-machines he will know that such a machine would not be of any use in the domestic circle, but in the manufactory. H. J. S.

DOUBLE STARS.

[4548.]—On July 5th from 10h. to 12h. p.m., the air being pretty good, I examined the following stars:—1. μ^2 Boötis was at once separated with power 550, and on increasing the power up to about 700 with a Barlow lens, it was well open, but the sight less pleasing, on account of the loss of light, and the defects of the atmosphere, which, of course, were more visible. I estimated the position of the companion to be between 170° and 180°. Doubtless, this double is beyond the reach of Mr. Knott's instrument, but perhaps Mr. Key may have obtained some recent measures, and if so, I would feel much obliged if he would give them. 2. ζ Hercules. The companion of this double was well seen with power 350. I find it bulges about two-thirds of its diameter outside the first ring of the primary. 3. δ Cygni. I found this double more definite even than μ^2 Boötis. I could not see the companion steadily, but only now and then, when the rays of the primary, in moving about, were leaving it for an instant. Then it was quite clean and beautiful. 4. η Coronæ. This was seen with no difficulty at all. It is certainly the most easy of the four.

Allow me to correct the last seven lines of the postscript of my letter (4450) on Gassendi, as I see, in reading it now, that it is worded in such way as to lead to the supposition that the only means we have of knowing the revolution of a star is to count the number of years that elapse between two periastrons. If so, how could we know anything about the revolution of those stars which require hundreds and thousands of years to accomplish? Every one knows that three measures taken in three different parts of the orbit are sufficient to calculate that orbit.

Jumet-Hainaut, July 6. C. GAUDIBERT.

NEW DOUBLE STARS.

[4549.]—I have found a considerable number of new double stars recently with my 6in. refractor, and select the following, to which I would call attention:—

WEISSE XVI., 785. 16h. 41m. 48s., N. 2° 58'; mags. 8, 8½. This is a rather close pair, ⅘° s, a little f 19 Ophiuchi (Σ 2096). The distance is about 1".

WEISSE XX., 1744. 20h. 56m. 48s., N. 21° 7'. About 1° from Vulpeculæ s f. A pair of 8 mag. stars will be seen in the finder; the f star is the double. The distance is about 2", and magnitudes 8 and 9½, or 10.

SCORPIO, 15h. 54m. 39s., S. 24° 18'. A moderately difficult pair, p a 7m. star (B.A.C. 5317); distance, 2"; mags., 8½, 10. Another double, a little s of this, is Lalande 29136, 15h. 55m. 8s., S. 24° 39'; easier than last; mags., 7, 11; distance, 4".

I have already called attention to the duplicity of other stars in Scorpio, found last season, among which are 2 and 12 Scorpii, the former an exquisitely beautiful pair, the components being separated about 3". There is still another pair, nearly 1° n of 12 Scorpii, the distance of which is about the same, 4". The place of this is: 16h. 3m. 51s., S. 27° 18'. Some of these southern objects may have been observed before, as none of them are difficult with the aperture used. If any one is aware of earlier observations, I should be glad to have it noted.

I am sorry that among the numerous astronomical correspondents of the MECHANIC there is so little interest taken in this department of practical astronomy. It is quite common to hear telescopes (more particularly reflecting) spoken of from seven or eight to twelve inches aperture, and upwards. I have never seen an instrument of this kind, but understand that it is claimed their dividing power is equal to that of a refractor of the same aperture, and the illuminating power only a little less. If this is so, no one with an aperture of 7in. or more (if the instrument is good for anything) is likely to fail in finding at least one new double on every good night, and a much smaller glass will answer for very many objects. Notwithstanding Mr. Bird's large experience in this matter, I cannot agree with him in thinking that there is very little left to be done in the discovery of new objects. The field seems about as good as it ever was, and in one respect better, because the objects hitherto unnoticed are, for the most part, sufficiently difficult to make their detection much more interesting to the observer than finding and cataloguing the easy doubles, of which fully three-fourths of the lists are composed. I have met with but very few, in any of the catalogues, too difficult for my 6in. Alvan-Clark refractor, and some hundreds of the most difficult in the catalogues of the Struves I have re-discovered in searching for new pairs, the distance of a great many of them being less than 0·5". One found the other night was given as 0·3" by Otto Struve. I had expected to receive the advantage, to a greater extent, of the observations and notes of other observers in reference more particularly to the supposed new doubles, that being the only reason, and the only excuse, for occupying so much space with this subject. I trust this will sufficiently explain the rather numerous communications heretofore published.

Chicago, June 25. S. W. BURNHAM.

NEW DOUBLE STAR 11 SCORPII.

[4550.]—A night or two since I noticed a small companion to 11 Scorpii, which seems to have been missed by the Struves, and by other observers, so far as I can learn. The companion is, perhaps, 10½ or 11 mag., and precedes 4" or 5". This is an easy object for a 6in. aperture, and it is difficult to account for its omission from lists of double stars, if it has ever been examined with anything above 4in. This is readily found, as it is the nearest naked-eye star to the well-known triple, ξ Scorpii. The new pair is 1⅜° s, a little f ξ. Its place for 1870 is: 16h. 0m. 28s., S. 12° 24'. I should be glad to have Mr. Knott measure this pair, and particularly a closer and more difficult one, found recently, 6 Serpentis. This last is a very beautiful double.

Chicago, June 25. S. W. BURNHAM.

A CHEAP SUPER FOR COTTAGE HIVES.

[4551.]—R. SYMINGTON (letter 4501. p. 483), describes a common flower-pot, with plate of glass, as a cheap super. In a bee book I have read, we are warned not to use putty about a hive, as it is said bees are apt to eat it. Is this true? Two of these books tell us that queen bees will not pass through a narrow opening, but one says it should not exceed three-sixteenths, the other says one third, of an inch in width. Which is the right width to admit the working bees and to exclude the queen and the drones from the honey-storing place? PHILO.

ROTARY ENGINE.

[4552.]—I inclose a section, external and internal, of a rotary engine, which, from its simplicity and compactness, cannot but give satisfaction to many of your readers. It has been said that it is equal to 4 horse-power, if it is not above, and yet the cylinder is little more in size than an ordinary hat-box. No. 1 is an interior section; the steam enters through the pipe A, and is turned by the slide valve B alternately into the

FIG. 1

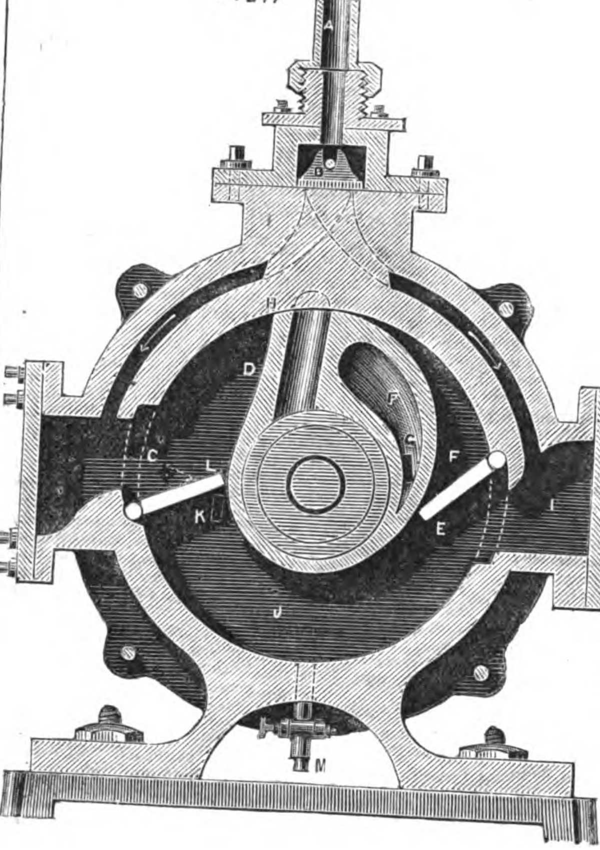

FIG. 2

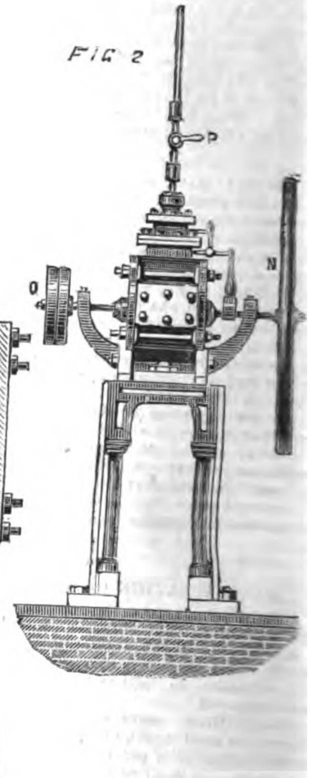


courses right and left in the direction of the arrows. We will suppose the steam to be now admitted into the chamber C; it would act upon the arm of the piston D, and force it round in the direction of the valve, at the same time the exhaustion is going on in the chamber F F, through the aperture G, but when the point of the piston H has reached the end of the valve E, that valve is closed, as shown by the dotted lines, but the instant it has passed the point of the valve E, this valve slides up the face of the piston D, and the steam being then admitted at I, renews the pressure on the surface D, at the same time the exhaustion of the chamber J is going on through the opening K, and the piston is urged on in the direction of the valve L, where the steam is again admitted. This process is repeated at either side at every revolution of the fly-wheel. The waste steam passes off through a pipe on opposite side of fly-wheel. No. 2 is a small side view showing the fly-wheel and eccentric for working slide-valve, the eccentric being between the plummer block and cylinder; N, the fly-wheel; O, driving pulleys for machinery; P, the stop cock for turning off or on the steam; M, in section No. 1, cock for draining cylinder of water or steam. JOSEPH WILLIAM FENNELL.

THE BEARING-REIN AND BLINKERS.

[4553.]—I hope the excellent and humane letter (4493) of an "Old Ploughman," at p. 384, may help to quicken the disuse of this useless and cruel contrivance, which is, I think, almost confined to what are called the educated and refined classes. I counted the other day, out of 100 horses in vehicles of various sorts, 30 only that had bearing-reins, most of them on the horses of gentlemen's carriages; but a few, I regret to say, on cart-horses, cab-drivers, costermongers, and omnibuses. Coachmen are too well educated (about horses) to use bearing-reins, which are, at the best, useless; and, if so tight as to produce any effect, hurtful and dangerous.

Every one knows, who knows anything, that he should ride or drive with a light hand, and allow his horse freedom to change the position of his head according to changing action. When a horse is pulling hard he lowers his head, when running fast he throws it forward, to get greater freedom for breathing, and when going gently he moves his head from side to side to see and, I suppose, enjoy the scenery; at least my horse looks as if he did, and I hope he does; but how can he do any of these things if his chin is pulled up nearly to his breast? As to the smart look it gives him, a horse's natural attitude both is and looks the best; it is as bad taste to alter it as it is to alter a woman's beautiful figure by squeezing up her waist till she looks like a wasp. Of course, some horses, like many men, get into loose going ways, and want training to carry themselves naturally; but this, as "F.R.A.S." properly says, may be done by the judicious use of reins, without torturing. It is not only the merciful but the wise man who is merciful to his beast.

Blinkers for horses are, I am glad to see, being given up. It is said a horse without them will be frightened by seeing the wheels following him. We do not ride horses with blinkers, and they are not frightened by the wheels they pass alongside. A horse is seldom frightened by anything he sees distinctly; it is unexpected things that startle him, and he is less likely to be startled if he has no blinkers to prevent him seeing distinctly. The only use of blinkers to a horse is to save his eyes from the whip, but a well-trained and well-used horse does not need the whip at all, or, at most, only to make him understand who is to be master, and it is generally better to conquer by gentleness than force, horses as well as men. PHILO.

TO "OUR" ENTOMOLOGICAL READERS.—NEW AND EXCELLENT FIXATIVE FOR THE DOWN OF *LEPIDOPTERA*.

[4554.]—I have some good news for all our entomologists. No doubt the majority of "our" readers have heard of the much-prized preparation for fixing drawings, known as Rouget's Fixative; for the benefit of those who have not I will describe it. A small glass flask is supplied with a miniature blowpipe, so adjusted that when the solution is poured into the vessel it can be blown out in the form of spray. The drawing is held at a distance of 12in. from the flask, and a puff or two through the latter covers it with a jet of vapour, on the almost instantaneous drying of which the drawing is perfectly fixed.

Well, it was only the other day some one—I believe a lady entomologist—had the happy thought of bathing a butterfly in the spray blown from the flask I have described. The insect looked for a few minutes drowned and spoiled. After two or three minutes in the sun the appearance of vapour had disappeared. No: so the virtue of the process. Actually the wings would bear rubbing between the thumb and finger without losing a portion of their scales. One very important advantage is at once apparent. The large space, to say nothing of expense, occupied by glass cases for the preservation of *Lepidoptera* may be saved by this process. I do not, of course, speak of cases mounted for display, but of the preservation of specimens for reference. This may readily be done with books, the leaves of which are made of cork, with slips of rather thicker cork cemented or sewn to the edges and at the back, in which the insects can be arranged directly they are captured, like artificial flies in a fisherman's pocket-book.

The value of this simplification in the mode of keeping specimens, especially abroad, to the scientific entomologist, cannot be overrated. I venture to state that there is no branch of natural history so popular, so interesting, and so accessible as entomology; none that is so generally, patiently, silently, and so enjoyably pursued. Those who take no interest in the subject are not aware of the world-spread dominance of this laudable passion. No doubt this new discovery is already widely known, and will carry joy to many collectors and many humble homes; so that it will be the means of enriching our museums with thousands of specimens of these aërial plume-bearers, so difficult to preserve in the original freshness of their rainbow hues. In offering so valuable a boon to the draughtsman M. Rouget little thought how far he was superseding the labours of the entomologist, by giving permanence to the down of *Lepidoptera*. H. B. E.

P.S.—I take this opportunity of thanking "Ento" for his interesting bits on the subject.—H. B. E.

FIDDLES.—To "FIDDLER."

[4555.]—HOMER says Jove occasionally nods. If the father of gods and men, in the elegant words of the late lamented James Crow, Esq., does "just so," we need not be "very much surprised" to find that a "Fiddler" is occasionally not quite "wide awake." When I read the statement of my friend (who has so long been accustomed to "bowing and scraping" that he has become the very pink of politeness) that Paganini produced tones "equal to a piano," I did indeed wonder, even as "Wondering Willie" once wondered what manner of man the "Blacksmith" might be. Shades of Correlli, Paganini, Sivori, and Co., to think a fiddler, a manipulator of the king of musical instruments, only producing sounds equal to those of that comparatively poor affair the piano—an instrument which all genuine fiddlers abhor for its untunableness, at least its necessity for that fiddler's horror, temperament. Of course violinists were never yet heard to play out of tune, no, not even one "comma," however many "stops" they employ.

"Fiddler" says the bow remains on the string. If he uses the word remains in the sense of continuous contact, very little tone indeed would remain. If the string never departed from the bow, how could the string vibrate "at all, at all." It would, indeed, be very "melancholy remains," for then the string would be constantly pulled in only one direction—a condition quite incompatible with vibration. I "rather guess" our bows—or rather the particles of rosin on their hairs—act just as plectra do on the string; that is to say, they communicate to the string not a continuous impulse in one direction, but a rapid succession of such impulses, just as the teeth of a saw or those of a revolving cogged wheel do, or as my rather odd fiddle-stick (which had a long row of quill plectra inserted in it) did. I feel very confident the bow no more remains in contact with the string than the hammer of a piano does which don't "block," or the repeating hammers of that very pleasing instrument, the melopiano, do. In every case of the prolonging of the vibrations of strings—whether effected by a bow applied directly to them, by a rubber which rubs some elastic material, such as silk or hair, which communicates the impulses it received to the strings, as in the case of Mott's sostinente pianoforte, and its modern rival the tetrachordon, or the melopiano, which has hammers which strike its strings at intervals of time too minute for the ear to detect, just as the eye fails to distinguish the individual spokes of a rapidly revolving carriage-wheel —the one thing needful is a rapid succession of impulses, for a really continuous impulse would produce exactly the same result as pulling your fiddle-string on one side with the finger, under which circumstances there cannot be much vibration and very little tone. Such violin practice could not offend the most refined ear, and would be more gratifying to our friends than that "bowing and scraping" abominably out of tune which, however polite, don't exactly cause the "harmonious one" to become a yet more

HARMONIOUS BLACKSMITH.

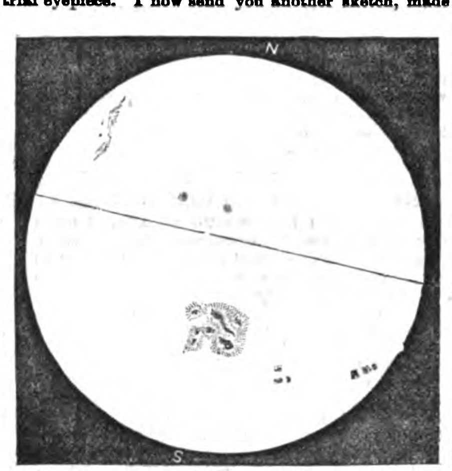
P.S.—There is nothing occult in the cause of a violin, a voice, or a piano sounding louder in an empty (of furniture) room. It is not the larger flat surfaces of the wall, floor, and ceiling (which, by the way, don't usually become much augmented by removing our "sticks"), but because the aërial waves generated by our "sweet" voices, and by the soundboards of our fiddles, &c., are not so much broken up and partially destroyed as they were by the aforesaid "sticks," which greatly obstruct their transmission. I don't think reflection from the walls, &c., can have any influence, because reflecting a sound can no more increase its intensity—unless it be reflected from a concave surface to a focus, when the increase of intensity becomes merely local, like that of light or heat—than the reflection, or rather deflection, of a billiard ball from the side of the table can increase the velocity of its motion. No doubt effects (which are not furniture) can be produced by the reflection of sounds—echoes, to wit—either in the orchestra or elsewhere (we do it in churches to the voice of the preacher), and that some of those "effects" are very surprising to those persons who are not familiar therewith, but I can conceive no pleasing musical "effect" sound reflectors behind an orchestra could produce; on the contrary, I fear we should hear a very disagreeable "echo" (not worth the halfpenny the clever newspaper of that name costs me) if the reflecting surface be distant, as it is in some concert rooms in which the concave roof acts very effectually, if not very pleasingly, as a sound reflector. The roof of the Albert Hall did so until General Scott prevented it from "publishing its reflections," which he did without infringing "the liberty of the press"—I mean the press for admittance to the People's Concerts.

ECONOMY IN USING COALS.

[4556.]—SEEING the present great advance in the price of coals, especially in London, and the probability of a still further advance, will you allow me to ask my fellow subscribers if they can (any of them) describe the methods in use on the continent and in our country places for economising coal for domestic use? I have been told that in some parts of France people use coal-dust or slack mixed with wet clay into lumps and dried in the sun or near the fire, and that the mixture burns well. I have also heard of something like this in Staffordshire. Will any of the artificial fuels do for open fireplaces? I can highly recommend the use of a wire shovel, which sifts the cinders beautifully. I burn all mine in the parlour. Of course, servants can't be made to do the same in the kitchen. W. BROWNE.

SUN SPOTS.

[4557.]—LAST week I sent you sketch of the sun as viewed through telescope, with low power and terrestrial eyepiece. I now send you another sketch, made



at 7.30 on Friday evening, July 5, with astronomical eyepiece, and power about 120. Object-glass 4in.

JAMES H. WHISTLE.

THE "ENGLISH MECHANIC" IN THE COLONIES.

[4558.]—ALLOW me to express the great pleasure I enjoy on each arrival of the Overland Mail, in perusing the monthly parts of your admirable journal, to which my son is a subscriber. It is indeed a wonder of information and instruction to all readers who feel any interest in mechanics or in science. The wide circulation of so instructive a periodical throughout distant parts of the empire must be productive in due time of valuable results.

326, George-street, Sydney. W. MACDONNELL.

THE HARP.

[4559.]—"FIDDLER" is evidently a most enthusiastic admirer of the harp, and in sounding its praises he seems altogether to overlook its imperfections. He wonders why the ancient Irish harp has gone out of fashion, and in the same breath answers himself, and gives us a very conclusive reason, viz.—that it can only be played in two keys, both of which are major, consequently, the absence of semitones precludes the possibility of producing those rich and telling harmonies which are to a melody what flesh is to a skeleton. The ballads and tunes which it can render are, though good enough in their way, of the slightest and most unscientific description, and he who plays nothing better can hardly be said to deserve the name of a musician. Even among these ballads are there not many wild and beautiful melodies in a minor key which could not be rendered at all on such an instrument as this harp? Depend upon it, no instrument goes out of fashion without good reason, for in the long run the world's verdict is always just.

I quite agree with "Fiddler" in wishing that music were more attended to in the education of youth, but I do not think with him that everybody ought to learn to sing and to play on two instruments, for if so, we should have to endure more in the way of bad music than even we do now, which is saying a great deal Let those learn that manifest a taste for the art, but for goodness sake let unmusical people alone. Playing without expression, taste or touch, singing without time, tune, or feeling:—such are the results of trying to teach music to those who are not born with a natural love for it. VERTUMNUS.

PIANOFORTE CONSTRUCTION.

[4560.]—THE "Harmonious Blacksmith" (let. 4415, p. 382) honours me by asking for my opinion on or experiments respecting corrugated soundboards. Finding, years ago, as he has done, the extension of the soundboard impracticable, and to some extent a question whether we have power enough to set it in vibration effectually if we extended it, my thoughts were naturally directed to corrugate it—*i.e.*, to construct it so as to contain a greater surface in the usual limited space. But I must confess I could never see the smallest advantage in doing so, and, therefore, made only the experiments described further on. When we depart from a straight line we gain just as much more stiffness in proportion to the greater surface so gained. This will be seen even if we make the experiment with a sheet of paper. Then we require more power in proportion to the greater surface, just as much, or more, as if the soundboard had been extended in a straight line. But, having made no experiments in that direction, I am bound to say that I do not feel inclined to throw the smallest stone at the idea. Thinking that most likely the hard grain in the pine wood is sonorous, and the soft grain between them acting partly as dampers, I did not scratch it out (as I now see some one has the patent for), but constructed two soundboards, one of beech wood and one of glass strips quarter of an inch wide, and the thirty-second part of an inch thick. These strips I glued edgeways on to pieces of wood with their extreme ends, so that they were exactly like a soundboard made of Swiss pine quarter of an inch thick, the soft grain taken out and the hard grain left only. I glued the bars behind and the bridge on the front as usual. The advantage I expected to derive from this arrangement was that the vibration should run along the hard grain more freely, not being checked by the soft grain, and having nearly double the surface (32ft. instead of 16ft.), causing the production of nearly double the quantity of tone compared with the ordinary soundboard. Well, I can put the tuning-fork almost anywhere and a certain amount of tone is always heard, but on these two soundboards I heard none. Now, I am just before my invention for which we took the patent, and without going into details I will only say this, the hard grain with nothing but the air between, produced no tone; the hard grain with material equally hard between, which would be a solid beech board, produces no tone. I conclude thus, taking the solidity of air as 0, the solidity of the hard grain = 1,000, the material between must be solidity = 500. Then I took strips of beech-wood, s. 1,000, and poplar, s. 500, glued them together alternately, and found the soundboard perfect as far as the material is concerned. By taking a piece of best Swiss pine, which it is difficult to find even one inch wide in a whole soundboard, because it grows so irregular in many respects, and the proportion of the solidity of the hard and soft grain is seldom 500 to 1,000, I found my conclusion was right, at least I gained the same practical result. I have the opinion, and it is included in the patent, that two different materials of different hardness or rigidity, specific gravity, and elasticity, may vibrate rather abruptly against each other; and I am now preparing a violin breast of three different materials, rosewood, mahogany, and Virginia pine, and will report the result. Perhaps my last experiment belongs in some respects to corrugated soundboards. I took the inside of the soundboard out, leaving only the two faces a full sixteenth of an inch thick, and supported them by glueing small strips of wood, 3in. apart, between them, but find it no good, which I expected.

J. H. SCHUCHT.

ON TUNING PIANOFORTES AND OTHER STRINGED MUSICAL INSTRUMENTS.—I.

[4561.]—PROBABLY the very earliest method of altering the tension of the strings of musical instruments for the purpose of altering their pitches, or what is termed "tuning" them, is that employed in the Nango or negro harp, a specimen of which is in South Kensington Museum, and is figured on page 13 of the illustrated catalogue of musical instruments. If I am not mistaken the Egyptian lyre in the Florence Museum, the Egyptian harp in the Museum at Berlin, and also the two Egyptian harps (copied from paintings in tombs) figured in Sir Gardener Wilkinson's great work on the "Ancient Egyptians," are all tuned by this means, as is also, perhaps, the tako goto or koto (see page 21 in catalogue). I mean by sliding the loop to which one end of each string is attached up or down an inclined bar, and thereby increasing or diminishing its tension.

Another probably very ancient method of tuning is to vary the vibrating length of a string by shifting one of its supports or bridges instead of altering the tensile force to which it is subjected. I suspect the strings of the tako goto are tuned thus, although they are so arranged that the former method also seems possible. Those of the santir or Oriental dulcimer, figured on page 32, are also examples of this method of tuning, the practice of which was probably suggested by "stopping" the strings of instruments of the lute, guitar, and viol class for producing sounds of various pitches, all such instruments being provided with a neck, and its fingerboard usually divided by transverse low bridges, technically termed "frets," which determine the length of the vibrating part of the string. (N.B.—These "pets" are exceedingly useful for determining the intonation, and the writer has often been compelled to "fret," or rather to lament, that the fiddle was deprived of them, for, if properly placed, they insure a much closer approximation to just intonation than many fiddlers' fingers—which are not invariably placed on the fingerboard—do, in practice, afford the hearer.) Sooth to say, very few fiddlers can play the diatonic scale with so near an approach to correct intonation as it is rendered by a well-tuned pianoforte, however much the aforesaid fiddlers may choose, habitually, to elevate their nasal organs at temperament notwithstanding. By the way, the varieties of stringed musical instruments provided with necks are very numerous—the Japanese biva, the Chinese pepa, the rebab, *alias* rebeck, the ujuk, the Indian tambura, the Italian chitarrone, or theorbo, the mandoline, lute, pandurina, the ancient banjo, and the modern guitar, also the whole family of viols and violins included, are examples of this class; yea, even that king of modern musical instruments, ye fiddle, which—I trust my clever friend "Fiddler" and his fellow-fiddlers won't be offended—is, after all, but a lute or guitar with its soundboard "bellied," or arched, to resist that downward pressure of its strings which necessarily results from the employment of a high arched bridge, needful for facilitating the bowing of single strings, also deprived of its frets, a deprivation occasionally to be lamented by those blessed—or cursed—with musical ears, and whose strings are bowed, *alias* "sawed," with horse-hair, instead of being "plucked" like the unsuccessful candidates are at competitive examinations by the Hon. Bob Lowe and other kind and benevolent *gentlemen* who sorrow—not as those without hope—for the customary *in*-efficiency of the said candidates.

It seems probable the simple method of altering the tension of a string by winding it round a peg must have been in use very early. I have heard the specimen of ancient Egyptian harp—not the lute—is tuned by this means, which has been employed from time immemorial by the Chinese and other eastern peoples, often in a very primitive form indeed, compared with the neatly-turned and well-finished box-wood pegs of a modern violin, or the yet more refined steel wrest-pins of a modern harp, which are turned conical in a slide lathe, probably the very highest examples of the wrest-pin family in ordinary use. I have often wished those of the pianoforte were subjected to the same process—those of some of Erard's grands made about thirty years ago, and the wrest-pins of Mr. Nosworthy's very peculiar pianos were—for then we might hope to be free from the annoyance of "jumpers." Perhaps, however, the wrest-plank and bad boring are often as much in fault as the pins.

As the weight of musical strings became increased the resisting power of their wrest-pins had to be augmented in proportion to enable them to resist the additional strain. If the reader will compare the wrest-pins of ye ancient clarichordis, ye virginals, ye spinetts, and ye harpischordis, &c., in South Kensington Museum, and elsewhere, with those of a modern concert grand piano, he will be enabled to form some idea of the change time has brought about in this matter. Large and powerful as the wrest-pins of a modern grand piano are, the writer found them insufficient to resist the strain of the strings of his experimental instrument, and was compelled to resort to the means described and figured in No. 211, p. 64 of the ENGLISH MECHANIC, to enable its wrest-pins to resist the pull of the strings, some of which (of No. 40 wire) require a straining force of nearly seven hundred pounds each.

Tuning by wrest-pins with a simple cross handle—whether that handle be the flat head of a fiddle peg, or the more powerful tuning hammer of the harp or pianoforte—is after all but a rough and primitive contrivance, whose results are unsatisfactory unless great practical skill has been acquired by long practice; it is very rapid and cheap, also nasty. Many attempts at improvement have been made, and probably the machine heads of the guitar and contrabass are among the most successful of them. Contrivances for applying the principle of the machine head to the ordinary pianoforte tuning hammer have not yet come into general use, probably more from their running counter to the prejudices of that remarkably intellectual class, ycelpt pianoforte tuners, who are remarkably conservative of evil ways, than from any inherent defect in them. I must admit every such contrivance which I have seen necessitates either the employment of two hands to the apparatus—one to hold and the other to work it—which is very inconvenient, unless you have an assistant to hold it or to strike the keys, or some contrivance, an adjustable cranked arm, for instance, which affords a fixed stop and prevents the useless rotation of the handle (see the patents of Newton, A.D. 1854, and Johnson, 1855), I have sometimes thought I could get over this difficulty by employing an endless screw on the stem of the handle at a right angle to and gearing into an oblique-toothed wheel on the pipe, in which case the stem of the handle would become at once the stop and transmitter of force. This has not, that I am aware of, been carried out, so I invite the designs of my clever fellow-readers for doing what would be a real blessing to amateur tuners.

Of course, the thicker the plank the longer the pin may be that is inserted in it; but in grand pianos, whose strings are above their wrest-planks, it would be very objectionable to increase the thickness of the latter because every such increase must compel the lowering of the hammer centres, and the further they are below the strings the more "out of the square" with the latter must the hammer's path become, at the instant it strikes them. It was probably a sense of this evil (which is of considerable practical importance, especially for obtaining clear sounds in the treble) which induced some of the earlier piano-makers to place thin strings under the wrest-plank, doing which completely gets over it, and others (Schwieso, for example—see his patent, No. 6069—who preferred continuing the usual position of the strings), to construct their wrest-planks of metal. Now it is obvious an iron wrest-plank only half-an-inch thick could not retain a wrest-pin subjected to the force of (say) three hundred pounds tending to turn it backwards, unless, indeed, it was driven into its hole much too tight to be turned with any nicety—tuning requires nicety—by any ordinary tuning hammer. A little reflection will teach us that good hard wood, probably beech, is the best kind in use—is, from its capacity of resisting compression, its elasticity, which enables it to hold the pin firmly without the necessity of driving it into its hole objectionably tight, and its non-liability to adhere dangerously to the metal pin—far preferable to metal for a wrest-plank, so long as the pins are only held by the adhesion of the surrounding material. When anything like a wrest-pin is employed in conjunction with a metal wrest-plank, some contrivance, such as the introduction of suitable elastic material between their surfaces, becomes an absolute necessity, besides which, as the metal surfaces which would be in contact with the pin in so thin a wrest-plank would be too small to resist the strain without risk of destructive adhesion, some means of increasing the surface of the parts in contact is also a practical necessity. Probably that patented by Mr. Schwieso, A.D. 1831, No. 6069, price 6d., is as good as any. As a matter of course, "in that case made and provided," as our legal friends express it, the very same thing, or at least something hardly distinguishable from it, except perhaps that it is inferior, was patented over again in A.D. 1870. Another arrangement of the metal wrest-plank was patented by Mr. Nosworthy, A.D. 1860, in which the surfaces which retain the pin are divided just as they are in the violin, but the strings, instead of being between those surfaces, as they are in the fiddle, are above both, which renders putting them on more convenient. His arrangement, however, seems open to the same objections as a moderately thick wooden wrest-plank for grands, in which the hammers strike upward, and have their strings above their wrest-planks, for the external surfaces of the two metal plates which form his wrest-plank are about as distant from each other as those of an ordinary wooden wrest-plank. I will say more on this subject next week.

THE HARMONIOUS BLACKSMITH.

EARTHQUAKES AND VOLCANOES.

[4562.]—I KNOW I have not the pleasure of being one of your most respected correspondents, but I think your love of fact and philosophy is sufficiently great to find an excuse for my drawing your attention to some little matters which are of vital importance.

You may remember that some time ago I drew the attention of your readers to a (by me) presumed connection between the attraction of planetary position (with respect to the earth) and earth disturbances—earthquakes, volcanoes, mining explosions, &c. This I did more particularly in a letter on "Astrono-Meteorology and Magnetism," in No. 215, p. 151, of the ENGLISH MECHANIC, of May 7, 1869, with several facts illustrative of such presumed influence. Like most new ideas, the principle was ridiculed, and I got a pretty good share of abuse for my pains. But there were no facts or arguments to the contrary. Lately I have been reading an article in "ours" on "Earthquakes and Volcanoes," by A. Le Plongeon, M.D., and amongst the "conclusions" he has arrived at (p. 348, June 21, 1872) I find the following nearly similar hypothesis as my own:—"4. That the sun's immense reservoir of electro-magnetism, and the other celestial bodies, which are likewise reservoirs of the same agent, increases the action of the electro-magnetic currents that traverse the earth, according to their respective positions with regard to this, and hasten the effect of the chemical operations," &c. On reading this, I think you will say the agreement in principle between us is as near as possible perfect. The only departure is, that I went beyond the learned author, and gave the exact "positions" for such disturbances. For instance, in the last MECHANIC (p. 374, June 28), he devotes his article to a long description of the "Cataclysms of the 13th and 16th August, 1868," giving most valuable and copious details of the great South American earthquakes of that period. Now, as both I and the learned author seem to agree that the positions of the other celestial bodies are the causes, it may be useful to test this period. Taking the positions from Raphael's "Ephemeris," I find them as follows:—

J	H	V	N	(×)	S	×	(Mv)
6	7	8	9	16	23	26	28

Letting the line represent the orbit of the earth during August, 1868, it will be seen that the earth was exposed, in four days, to the influence of as many planets in the same degrees of different signs, including the irregular position of the planet Venus—one so remarkable as the cause of earthquakes, shocks, inundations, &c. From the details of M. Le Plongeon, it will be seen that within three days the effects of this compound influence were in operation, though at "Jacna, for several days previously to the 13th, subterranean noises were heard, and some light shocks felt." It is also worthy of remark that this disturbance should again intensify and cease on the 14th day, when the earth came under the attractive influence of a fresh position—of Saturn. The month closed with another position of great intensity—that of Mercury in conjunction with the sun—the commencement of the period being marked by a shock at Pau, in France, on the 26th: succeeded by an "alarming shock" at Jasbereny, in Hungary, on the 28th.

Connected with rainfall, M. Le Plongeon states that shortly after the shock at Jacna, on the 13th, "it began to rain (a strange phenomenon in a country where it never rains)." In coincidence, I may add that at Bombay, on the 9th, the fall was 12in. in the twenty-four hours. In England, on the 11th, we had an excessive and general downfall, the greatest for many months previous. On the 12th, the fall at Aberdeen registered 2·58in.; Ardrossan, 2·22in.; Greenwich, 1·40in.; Nairn, 1·36in. On the 16th, fearful thunderstorms swept over France, and Italy was visited by an extraordinary whirlwind. The 28th was also the occasion of a fearful downpour of hail and rain at Natal, in Africa, which lasted two days, destroying an immense amount of property, including seven bridges, one costing £150,000.

In confirmation of the theory, I may give another singular instance of April, 1863, of intensity of influence denoted by the following diagram:—

Ma	H	[J.]	V	(Mv)	S	N
4	7	12	15	20	21	24

By this it will be seen that there were positions of Mars and Herschel on the 4—7th, followed by the earth's passage between the sun and Jupiter on the 12th, the positions of Venus, on the 15th, and, finally, the solar conjunction of Mercury on the 20th, with close positions of Saturn and Neptune. It was thus a month of extraordinary intensity of position, and was attended with remarkable phenomena, including the great earthquake of Rhodes, on the 22nd. In France, on the 11th, "a deluge of rain, mixed with hailstones of an extraordinary size, laid waste the district of Maury (E. Pyrenees), over a surface of 9,000 acres. The ground was covered with hailstones to the depth of 6in., and in some places to the depth of 18in." On the 14th a premonitory shock was felt at Rhodes; but on the 22nd, about 10.30 p.m., "a series of short undulatory movements took place, followed by a continuous shock, which quivered throughout the island for nearly a minute." One thousand houses were damaged in Rhodes, 400 nearly destroyed, 240 persons were killed, and a great many wounded, 12 out of 44 villages were utterly destroyed, and the others greatly injured. Slight shocks were repeatedly felt on the 23rd. On the 26th a violent storm of wind, hail, and rain threw down more of the partially-ruined houses, and on the 30th a further strong shock took place at noon, followed by another in an hour and a half.

Such was the fatal experience of the island of Rhodes. In England there were violent storms, and much magnetic disturbance generating, on the 23rd, one of the most remarkable and perfect appearances of "daylight aurorae" ever witnessed, thus realising another of M. Le Plongeon's "conclusions" (MECHANIC, p. 348, col. 3): "Electro-magnetic disturbances in the atmosphere suddenly taking place, and without any apparent causes, manifested by the loss of power of magnets."

I cannot follow all the numerous shocks given by M. Le Plongeon, because most of them are of too remote occurrence to get the data for the positions of the time. There is, however, quite enough for study in the details of the one of August, 1868, given. I could add such facts by dozens.

But I am glad to see the principle growing, and much more so to see so many offshoots striking out in the columns of the MECHANIC. It is satisfactory to me to know that I was not one of the least valuable of your correspondents. We shall conquer some day, and it may then, perhaps—as now—be a satisfaction to you to know that your space was not wasted and abused so much as was supposed.

July 6. FREDERIC PRATT.

[4563.]—TO-DAY'S paper furnishes me with another of these facts, of so remarkable a character in reference to what I have just written, that I am sure you will pardon my troubling you by adding it. The positions of the period—April 14, 1872—are these:—

		conj. sun.			conj. sun.
×	J. S.	(N)	×	H	(Mv)
1	11	18	15	17	24

This terrible twin-event, as you see, is the result of the combined influences of Neptune with the sun, on the 18th, falling out on the transition point. The 24th night was the sudden eruption of Vesuvius (Mercury in conjunction with the sun).

As a remarkable fact, I may state that on the 19th of March, 1861, a similar earthquake calamity fell upon the city of Mendozon, in Chili, which, in six seconds, reduced a flourishing city of 20,000 inhabitants to a heap of ruins not 6ft. high, destroying 12,000 persons. The positions then were:—

	conj. sun.	conj. sun.		
J	(Mv)	(N)	S	H
9	16	19	24	20

This is marked by two solar conjunctions within three days, and hence the greater magnetic, &c., disturbance. The storms of Europe at the time were of the greatest intensity, and were the history of the period.

You will, perhaps, tell me the immense distance of Neptune would preclude the notion of any such influence. Well, some months ago, in the ENGLISH MECHANIC, Professor Zerffi, writing on the table-turning phenomena, in answer to a similar supposed objection, was quoted as saying that a billion of Uranus distances would diminish in no wise the force of magnetic attraction.

As the utterances of a scientific man, I noticed it as a singular opposition to the negatives of "F. R. A. S.," who denied any such influence or action. "Who shall decide when doctors disagree?" When I find my opinion reiterated in the MECHANIC, can you wonder I am still obstinate enough to be a co-holder with the Professor of the doctrine?—and to apply it!

FREDERICK PRATT.

P.S.—We have some meteorology this month. The following are the positions:—

	conj. sun.		conj. sun.			conj. sun.	
×	(S)	×	(V)	N	×	(H)	×
2	10	13	16	18	21	24	28

We have three solar conjunctions, a somewhat singular and rare occurrence. I think the events will be equally so. I think you will probably hear of some severe earthquakes, &c., at the major points. At present we certainly feel that the sun has borrowed some intensity somewhere. I registered 90° in the shade yesterday, and they have it equally hot in New York, having over 200 deaths from sunstroke in the week.

Studied by planets and periods, this month ought to teach something of weather science, if its professors were not too scared by the cuckoo cry of Astro-Meteorology, and too ignorant of the true workings of Nature. F. P.

A MORNING SUNSET.

[4564.]—(Let. 4519, p. 436.)—THIS is an appearance infrequent in England, but not uncommon in the East, being caused, perhaps, in the same way as the Pillar of Fire at sunset. I once saw an evening sunrise at Wimbledon. In my "Meteorological Notes" I find the following taken from Dr. Hooker's travels in India:—"In the clear dry mornings of these regions (the Kymore Hills) a curious optical phenomenon may be observed of a sunrise in the west, and sunset in the east. In either case bright and well-defined beams rise to the zenith, often crossing to the opposite horizon. It is a beautiful feature in the firmament, and equally visible whether the horizon be cloudy or clear, the white beams being projected indifferently against a dark vapour or the blue (sky?)." In the "sunrise" I witnessed the rays crossed from west to east. It must be remembered that a glow in the East at sunset is a very common occurrence. M. PARIS.

ARTIFICIAL MANURES.

[4565.]—IN answer to "Saul Rymea" (let. 4414, p. 381), stone-coal is the popular name for the variety of coal known to scientific men as anthracite. It is generally considered as the ultimate product of the peculiar change which vegetable matter undergoes under the influence of moisture, heat, and pressure. It is pretty nearly pure carbon, containing over 90 per cent. of that element. It is very difficult of combustion, and burns without flame. It has no tendency to coke or to soil the fingers. It is worked largely in South Wales and Pennsylvania. How it could prove valuable as a manure I am at a loss to imagine, and should have been inclined to fancy with "Saul Rymea" that it was a misprint for bone-coal.

With regard to the recent invention of a manure consisting of a mixture of stone-coal and sulphate of iron, I think it was unnecessary to patent the composition, for no one would be likely to use it, at least, not a second time.

I know a district in the West of Ireland where the soil is impregnated with a small quantity of sulphate of iron (doubtless derived from the oxidation of pyrites), and the land is perfectly barren. Before "Saul Rymea" tries the effect of the proposed manure on any considerable scale, let him make a small experiment on some weed he is anxious to get rid of.

If vegetables in the open do not require more nitrogen than they can obtain from the atmospheric ammonia, how is it that manuring a crop with a nitrogeneous substance is found so greatly to increase the produce. That it does so, is a matter of fact which no farmer would think of disputing.

The cause of the present high price of ammoniacal compounds is, that they meet with such an extensive application as manures. There is no fact better authenticated than that combined nitrogen is a most valuable manurial agent. Most elaborate and accurate experiments have been made upon this subject, both in the laboratory and in the field.

As to the comparative manurial value of sulphate of ammonia and nitrate of soda, it must be remembered that 66lb. of the former contains as much nitrogen, and therefore can do as much work as 85lb. of the latter substance. This is considering both as pure, but as the sulphate of ammonia of commerce is often practically pure, while commercial nitrate of soda often contains 15 per cent. of water and impurities, it would be fairer in practice to say that 66lb. of sulphate of ammonia have the same fertilising power as 100lb. of nitrate of soda, that is, that two of the former do as much work as three of the latter. Consequently, it will be practically as cheap to use sulphate of ammonia at £24 a ton, as nitrate of soda at £16, and cheaper, if the latter manure cost £17, as assumed by "Saul Rymea."

In addition to being richer in nitrogen than nitrate of soda, the sulphate of ammonia supplies sulphate, a necessary constituent of plants, while soda is only found in very exceptional cases.

When the farmer pays £16 for a ton of the best guano, he does not give a fancy price, but merely pays the market value for the contained phosphates and nitrogen. ALFRED H. ALLEN.

M. PARIS AND PERSPECTIVE.

[4566.]—M. PARIS (let. 4427) has not quite mastered his perspective, although Mr. Proctor and other correspondents have given him very good information. Now, M. Paris says, "Why should all books upon perspective teach that the drawing should be similar to what would be seen by tracing on a sheet of glass?" Just so. In fact, the drawing ought to be the same as that seen on the sheet of glass, provided the drawing is within the cone of vision. As the cone of vision was explained by former contributors, we will not say any more about it. Now, as all books on perspective teach that the drawing ought to be the same as that on, or passing through, the glass plate, why do our artists and draughtsmen, who draw architecture, not use the glass plate under all circumstances? The answer is simple; the glass plate cannot be used in five cases out of six. When, for instance, the subject is a large or high building, the glass plate must be removed so far that the arm and hand could not reach it, in other cases it is impossible to fix a glass plate. How, then, can an artist accomplish his object? How can he draw a correct representation of his building or landscape? The only way is to learn the science of perspective, which demonstrates that all lines passing from buildings, &c., through the glass plate, can be produced upon paper, without the glass plate, by certain mathematical rules. Those rules are the deductions from the observations made upon the glass plate. All outlines of architecture and inanimate subjects ought to be drawn by mathematical rules only, otherwise they are not correct representations. One of the first rules is this: All horizontal and vertical lines behind and parallel to the glass plate remain the same in the drawing. Secondly, all other lines not parallel to the glass plate must converge to the same point, which point can be found by demonstration. M. Paris must have seen some of the latter lines, or he saw lines outside the cone of vision. We have been investigating the linear portion of perspective, but now let us go a step further and look at the aërial perspective relating to colour.

"M. A." (letter 4428) is "rather inclined to agree with M. Paris that pictures are, as to perspective, a compromise;" he also thinks, "it is agreed that the the colour need not be the same." Allow me to say "M. A." is mistaken; in fact, nothing is perhaps more difficult than to represent truthfully those objects which we see before us. It requires practice and great study to portray upon a flat surface that which is spread out in space before our eyes. The more true the artist is to nature, the less he thinks of compromise, the more perfect will be his pictures, the more they will be a source of pleasure to every one. There is an immense difference between a true pictorial representation of a landscape and a caricature; "M.A.'s" mountains "drawn two or three times their perspective height" belong to the latter class. The best advice one can give to "M. A." is simply this: Master the rudiments of linear and aërial perspective, and you will see nature to better advantage."

THE WELSH SHEPHERD.

"FIDDLER'S" VIOLIN REFLECTOR.

[4567.]—"FIDDLER," in letter 4226, p. 274, asks for my opinion respecting what he terms a sound reflector, which he thinks might be advantageously applied to a violin. I do not suppose that he means a sound reflector similar to a light reflector, which would only keep the sound out of one place and throw it into another, and, as a matter of fact, nothing can be reflected without a loss of the original quantity. I, therefore come to the conclusion that he means that when the strings vibrate the breast is set in excessive vibration to produce the fullest amount of tone possible, and over and above that a small quantity of power would still be lost. Then he wants to put a board or breast on to take up that small quantity of power and produce tone. Now, if we take it as a fact that some violins are in existence which produce the full amount of tone possible, and above that have some small power to spare, which might be transferred to another board or breast, where could we fasten it on the violin? According to a law of which I have spoken before, if we put a piece on the instrument on one place or other, it will add to the specific gravity, its centre of gravity is shifted, and, in fact, the violin vibrates in entirely new proportions, and I venture to say in most cases not for the better. J. H. SCHUCHT.

SEWING MACHINES.

[4568.]—THE Wheeler and Wilson has the defect mentioned by "G. W. K. L." in 4471, p. 410, but that is only a grievance to a learner. I do sympathise with his strictures on "A Practical Man," but surely he has never seen a practical woman driving the Wheeler and Wilson. I have one at work in my own house at present, and I beg to tell him the operator has not to leave go of the work with either hand in order to start the machine, but, employing both hands with the threads and fabric, starts the machine entirely with the feet. IRISH MECHANIC.

FRUIT PUDDINGS.

[4569.]—I WOULD like to tell you and your readers how to make a black currant or any other fruit pudding, and to have it turned out of its basin and brought to table a real success, and not a miserable afterthought, as many an ill-made heavy pudding proves itself to be. This is from experience, and I would like those wives and mothers who do not feel sure of theirs to try mine. First, gather your fruit fresh from the garden, say enough for a pint basin, take flour enough to fill that basin three parts full, use no baking powder or suet, as I believe suet to be the indigestible part of a pudding, but use instead a teacupful of the fat from the top of Australian mutton. Break this loosely into the flour, not rubbing it fine upon any account. Add just enough cold water to mix into a moderately stiff paste. Grease the basin, and lay in the paste, then the fruit, with a little sugar, cut round the basin and fit a cover. Tie a dry, clean, and floured cloth rather loose over the top, but whatever you do, do quickly. Boil in a good-sized pan with only sufficient water to rise one-third the height of the basin, keeping the water to that height. Boil one hour and a half, and see that the pan has a tight-fitting lid. The crust of the pudding will then be light and dry, with plenty of the fruit syrup inside. SARAH.

CO-OPERATIVE STORES.

[4570.]—IF "E. L. G." will go with me through the following everyday transaction in a retail store such as we have been considering (either co-operative or not), perhaps, if not himself, yet other readers of the ENGLISH MECHANIC may see a reason for the retail store charging an advance of 10 per cent. upon the wholesale price. The store buys tobacco at 3s. 8d. per pound, and the attendant, when he has time, weighs the pound of tobacco into 32 half-ounces—i.e., if he can make it hold out, which it will not do, and the last half-ounce has probably to be obtained from a fresh supply. To the first cost has now to be added the cost of a sheet of paper cut into thirty-two pieces, and the value of the half-hour's labour in weighing, and to supply the working man with his weekly half-ounce another half-hour is consumed in selling and receiving payment of the thirty-two parcels. The case now stands thus:—

	s.	d.
1 pound of tobacco cost	3	8
1 sheet of paper................................	0	0¼
1 hour's labour	0	3
Loss in weighing	0	0¾
Total cost..	4	0
Retail price at 3d. per ounce	4	0

Now each of these parcels is in the regular way of trade sold for less than half a farthing upon the first cost. With what sort of coinage would "E. L. G." pay the storekeeper for his labour upon each parcel instead of allowing him to charge an advance of 10 or 12 per cent. upon the cost price? The whole subject lies in a very small compass. The excessive competition between traders for custom has enabled the public to demand and obtain so much accommodation in the form of credit and expense in selling and delivering goods that the trader could not afford to sell at a reasonable rate of profit. The co-operative store refused to give credit, and would not incur the heavy expenses traders had submitted to in the delivery of goods, the result was that in many instances the trader was supplanted.

R. R. SMITH.

REVOLVING BRUSHES.

[4571.]—A STUDY of the woodcuts of "Allen's Patent Governor" (page 373, June 28), has given me the idea that something like the top part of Fig. 7 (only very light and portable) could be cheaply contrived to propel hairdressers' revolving brushes, if suspended from the ceiling by an indiarubber band to let it rise and fall and unhook when not in use. We see the weight, drum A, and arm W (on which the brush could be placed), and I should be thankful to be shown the best way of obtaining or fitting either spring cogwheels or bands and weight to obtain sufficient speed inside the drum. The whole need not be of any great weight, the smaller the better, and the two or three wheels multiplying each other would give plenty of speed. R. A. H.

Dugong Oil.—Attention has been recalled, by the contents of the Queensland Annexe at the International Exhibition to the medical uses of dugong oil. They have been declared by more than one medical practitioner, following Dr. Holt of Brisbane, to possess all the nutritive qualities of cod-liver oil, and to be equally useful in all the forms of tuberculous and wasting diseases which are benefited by the administration of cod-liver oil: it is alleged to possess an actually agreeable flavour, to be pleasant as an article of food, and to be acceptable to those whose stomachs reject cod-liver oil. At a recent meeting in the Annexe, the pastry was made with dugong oil, and pronounced excellent.

Temperature of the Sun.—Great difference of opinion exists as to the temperature of the sun. As an instance of this it may be said that Father Secchi maintains this temperature to be about ten million degrees Centigrade. At a recent *séance* of the French Academy, in defending his estimate against the much lower figures of Ericsson, Zöllner, and Faye, St. Claire Deville asserted that he was engaged in investigating the subject, and that his results fixed the temperature at about three or four times the melting temperature of platinum, about 6,000° to 8,000° C. Mr. Vaulle also announced an ingenious theory upon the same subject, fixing the debated figure at 10,000° C. Finally M. Fizeau stated that, having compared the solar light with that of the carbon points of the electric light, he had been able to estimate that the former was about three times as intense as the latter, and hence, assuming the relative calorific intensity to be in proportion to the luminous intensity, he had arrived at the figure of 8,000° C. as the correct one.

REPLIES TO QUERIES.

**** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[10478.]—**Pork Diet.**—Mr. Newman, at p. 413, has correctly stated some of the objectionable qualities of pork as an article of diet. He might have added others, indeed several others. Among these I may mention the following:—Persons who eat much pork are particularly liable to skin diseases, often of the most disgusting and obstinate character. Scrofula is more than usually common among them, and is generally of a very bad type. Consumption (tuberculosis) is sometimes traceable to it, and in all cases is greatly aggravated by it. Intestinal worms (round and thread) are also more than usually common among pork-eaters, besides tænia (tape-worm), mentioned by Mr. Newman. I might lengthen the list if space were no object, but the "defects" noticed by Mr. Newman, and supplemented by me (above), I regard, after a long life of professional observation, to be absolute facts. I think the prohibition of pork as an article of diet by the great Jewish and Mohammedan lawgivers shows that they were philanthropists possessing profound knowledge and wisdom. The ravages caused by a pork diet among the British troops in the Crimea a few years since will probably be remembered by many of our readers. In warm and hot weather pork is more objectionable as food than in temperate and cold weather.—ABOTES.

[11554.]—**Pedestrian Tour.** — "Avon" (p. 48) need be under no anxiety as to shoes made of No. 8 canvas standing a reasonable amount of wear; indeed, I think No. 8 canvas thicker than necessary, though it should be stout enough to carry the thick soles, well supplied with nails, needed for comfort and safety for climbing slippery mountain slopes. As the canvas wears most just above the welt, a strip of well-greased leather or of indiarubber may be fixed, reaching an inch above the sole, and over the toe. Above all things take care that the sole is cut a little longer and wider than the foot—the shoemaker will make it less if you let him. Make him understand that you want the shoes to wear, not to look fashionable. If "Avon" does not object, as I do, to the bother of lacing shoes (which should be made high), he need not have elastics, but if those are made to fit easy they cause no inconvenience. There must be no compression or confining of the foot or ankle for those who wish to walk with comfort. Remember, canvas shrinks when wet. There is much to be said in favour of "Avon's" proposal to give up any attempt to keep dry, and rely solely on the power of changing any clothes that get wet. Wet does no harm, and causes but slight discomfort to those who keep warm with exercise. If this course be decided on, instead of a repellant cloth cloak or poncho, a change of clothes must be carried, unless the pedestrian can return at night to the place from which he starts, as in the lake district he often may do without difficulty. A change of clothes need be no great weight—a pair of thin jean trowsers and an alpaca coat or a blouse are all that need be added, and they will be but little heavier than the cloak that may be left behind. Let me most earnestly warn the inexperienced never to sit so long as to get chilled in damp clothes. A severe, perhaps fatal, cold, or an attack of rheumatism, is the not unfrequent penalty of such imprudence. Let them beware also of damp sheets, not uncommon in the moist lake district, especially when the inns have more visitors than the servants can properly attend to. If the sheets feel in the slightest degree damp, take them off and sleep on the blanket. A grand protection against cold-catching is washing all over with cold water. Every bedroom of a decent inn should have its shower bath, and easily might have, and certainly would, if common-sense were not so extremely uncommon. "Avon" is quite right in preferring a satchel to a haversack, which is a terrible plague to those not used to it. I prefer a shooting jacket with capacious pockets, and if I must carry more than I can stow away in them (*e. g.*, coat and trowsers) to wrap my traps up in a large sheet of thin waterproof cloth as a pack, which can be carried in various ways as a satchel. The cloth is useful to lie down upon when the grass is not quite dry; and laid on the floor with the corners tied up it makes a capital sponge bath to be used before and after sleep. By the way, do not forget to include a large sponge amongst a pedestrian's outfit, though a towel soaked in water is a tolerably good substitute. Do not be sparing of the water. Let the inexperienced avoid hard work during the heat of the day. Start early, when the day is young, and enjoy the cool air; see the mists on the brae and the sun clearing them off, with touch as wonderful, and to many as strange, as if by magician's wand. Rest during the heat of the day, and reserve your strength and spirits for the cool of the evening. I find two good meals a day amply sufficient, not counting a bit of bread with a cup of milk on first getting up. Get a walk of six to ten miles before turning in for breakfast, with chops, or lunch, whichever you like to call it, at ten or eleven o'clock, then rest and read till the fierce heat of the day is past, and be ready for another walk, bringing you to your resting-place early in the evening. Be careful to get there early, unless you have secured a bed, as, perchance, you may have to go further than you intend. Avoid, if possible, any hard walking after your second meal, which may be dinner, tea, or supper, as you please. I prefer cocoa and chops, especially of such mutton as you get in mountain districts. I like to finish off with a glass of ale, just before going early to bed, but think it would be wiser to do without. When among lovely lakes and mountains no alcoholic stimulus is needed. A white cover over the umbrella greatly increases the protection it gives against heat, and adds very little to its weight. I have tried a great many different kinds of head-coverings, and find the common black hat the worst, and an Indian felt hat the best, of any I have tried. This is made of hard felt, is about an inch more in each diameter than the head, which is encircled by a soft band attached to strips of cork. The hat is lined with cork. It never in this climate gets hot inside. There is a passage for air between the hat and its lining, which escapes through holes at the top. I have the protection of a hard and thick hat, with the comfort of a soft one. It cost 16s., and seems, after three summers' wear, as good as new, except the band and the lining. I am told that a straw hat with a white linen cover protects sufficiently from the sun, but I have not tried one. A white handkerchief tied over the hat, and hanging down behind the neck, is good when an umbrella is not used, or when that is wanted for a stick. I do not fancy gaiters, but some like them to protect their legs from thorns, and to enable them to wear the trousers knickerbocker fashion, which they say relieves the knees. It is worth trying, but I have not tried it, though I have often wished furze, gorse, or whin thorns were not quite so sharp, or that I was better protected from them.—PHILO.

[11554.]—**Pedestrian Tour.**—"G. W. K. L." would probably find advantage in a dodge of which I have had many years' favourable experience. Since I adopted it I have never had the slightest blister or soreness of the feet. It is simply to ventilate the boot by boring two, or (say) three holes about a quarter of an inch in diameter in the upper leather—by preference in the raised parts of the wrinkles between the toe and instep. Any water that may get into the boot is then rather a comfort than otherwise, as it is soon evaporated. On coming in the stockings will usually be found dry, not soaked with condensed perspiration, and the boots may be kept comfortably soft by a daily greasing. Canvas shoes would doubtless do well for road tramping; but if "G. W. K. L." is in the habit of making the most of his trips by finding his own way over the hills with an ordnance map, he may often find himself in places where his feet would suffer without better protection than canvas, say, for instance, amongst stones overgrown with heather. To obtain the full advantage from the holes the boots should be of strong leather, an easy fit at first, with plenty of width for the toes, the more the better. A fair sprinkling of projecting nails in the soles is a great comfort on a hill side.—P. S. T.

[11589.]—**Dry Steam.**—I wish "E. L. G." would explain why he thinks that when high pressure steam escapes into the air it expands immediately, so as to fill much more space than low pressure steam does. Why should it expand instantly sixtyfold? What experiment proves that it does so expand instantly? That it would do so nearly immediately if it escaped into vacuum, and that it does gradually if it escapes into air, is no doubt true; but so far as I at present see, the pressure of the air must prevent the immediate expansion of high pressure steam beyond that of low pressure steam; and if so, its reduction of temperature by expansion alone will be the same whether it expand in air or in a cylinder so enlarged as to allow its expansion from (say) the pressure of four atmospheres at 296° to that of one at 212°. I have frequently seen in England, on a dry and warm day, the vapour of a locomotive steam jet dissolve almost immediately. The quickness of such disappearance of visible steam is a familiar indication of a coming fine day; it shows a low dew point. I expect the disappearance is still more rapid on the Suez Railway, but it is often very quick here. I believe the utility of superheating steam is to secure a reserve of heat to prevent condensation of water when part of the heat is transformed into force, and for the same reason it is advantageous to keep the cylinders of a locomotive hot, to prevent condensation in them. I do not agree with "A., Liverpool," that if a vessel be filled with steam at 1lb. and at 100lb. pressure, more water will be condensed from that at 1lb.; it will be just the reverse. But perhaps "A." has not expressed his meaning quite fully. Possibly he means steam at 1lb. increased by heat only to 100lb., if that be possible. In that case, however, the quantity of water condensed would be equal. I do not perceive what connection the rate of evaporation from an open or a closed boiler has with the question, though it is no doubt faster from an open vessel with equal fire and heated surface, the reason of which is easy to understand without supposing that each cubic foot of low pressure steam contains more or as much water as an equal bulk of that at high pressure, the quantity of water being really in proportion to the pressure if heated in contact with water. If steam be heated out of contact with water, its elasticity is increased just as that of air or gas is.—PHILO.

[11632.]—**Debility.**—To E. PARKER.—A friend in London tried to procure the bean you recommended, but dealers refuse to give it without the permit of a doctor. Can E. Parker kindly state the reason?—CORDWAINER.

[11787.]—**Electric Signal Bell.**—Allow me to correct my assertion that your magnet is incurable. I had forgotten for the moment the fact that when the armature of an electro-magnet touches its poles, a portion of its magnetism is retained for a short time. This contact may be avoided, however, by pasting a piece of paper on the side of the armature which is next to the magnet.—GLATTON.

[11792.]—**Compound Engine.**—Whilst I am much indebted to C. E. Stewart for his information on the compound engine, I must still consider my query unanswered. I wish to know the proportion the high pressure cylinder bears to the low pressure cylinder. Mr. Stewart tells me that depends on the pressure and distribution of steam. Perhaps Mr. Stewart or some other of our correspondents will be good enough to give us some more information on the subject. I should also like to see the merits and demerits of the compound engine freely discussed in these columns.—FALSTAFF.

[11874.]—**Bryant and May's Matches.**—I can assure "Saul Rymea" that my statement concerning Bryant and May's matches contains no error. Let "Saul Rymea" find a piece of hard, well-worn linoleum, then let him take hold of the match close to the head and rub it briskly, and I think he will have no difficulty in getting it to ignite. I have just succeeded in lighting six matches in succession upon a piece of linoleum which had been well warmed in the sun. Very new linoleum is too soft for the purpose. The matches I have used are obtained direct from Bryant and May's.—HIPPARCHUS.

[11874.]—**Bryant and May's Matches.**—Two days ago I tried four of Bryant and May's safety matches in succession on linoleum; all of them ignited. The linoleum was old and worn, about one foot square. I don't think it had ever formed part of a safety-box.—FREDERIC H. WARD, Surgeon.

[We have tried and failed. The linoleum, however, was comparatively new.—ED.]

[11940.]—**Waterglass as a Preservative of Natural History Subjects (U.Q.).**—Although I never tried waterglass for the above purpose, it is impossible that it will answer; it must destroy such things as wings of butterflies, and would by degrees form a white film over beetles and other subjects.—THE WELSH SHEPHERD.

[11959.]—**Vandyke Brown(U.Q.).**—This pigment is an earth found on the Continent; there it is called Cologne's earth, found near Cologne. The darker sort, Cassel earth, is found near Cassel in large quantities; it is ground in water and washed. There is also a very light and bright sort prepared by calcining green earth (terre vert). The two first sorts were formerly sold in England under their respective names, but now they are only known by the one name, vandyke brown.—THE WELSH SHEPHERD.

[11962.]—**Telegraphy in the United States (U.Q.).**—The Western Union Telegraph Company is the largest company in the United States, and most successful; offices, 145, Broadway, New York.—S. M. B.

[11970.]—**Water Regulator.**—The water regulator consists of a tube of glass, ⅜in. bore, brass-capped at both ends. The bottom cap is solid, the upper one has a hole in it into which is fitted exactly a brass rod sliding up and down. The tube should be about 8in. long, and filled with water to within about 2in. of the top. This regulator is interposed in the circuit, connections being made with the brass caps.—ALEPH.

[11973.]—**Magnetic Engine.**—In reply to "L.C.," p. 413, I have a pair of electro magnets with which I wish to make an electric engine.—GLATTON.

[12056.]—**Echo.**—Concavity is the cause of echo. Remove the cause, convert it into convexity, and the result will be the reverse—perfect freedom from echo or recurrent sound. It is lamentable what amounts are lavished on ornamentation, regardless of acoustics. If an acquaintance with science were but as appreciated and rewarded as is ornamentation skill, it would vastly more contribute to usefulness and comfort. If quite practicable, I would suggest the concavity of the vaulted roof being screened over by perforated zinc, somewhat in the form of a convex lens at front. This would divergingly disperse the sound-waves, and thus, by widening the area of dispersion, destroy all tendency to their recurrent pulsation. It might be fitted up so as to be removable for thorough cleansing of the chapel. The perforation is to aid ventilation, and would be useless without some one or more outlets to the open air above the zinc. (See "Tyndall on Sound.")—J. BARWICK.

[12070.]—**Electric Kite.**—"Ardtannes" will find, in Francis's "Electrical Experiments," p. 83, full particulars for an electric kite (from which I have succeeded several times), and full cautions, too. The last I flew some years ago so awed me (by a summer storm-cloud passing over and causing flashes, any one of which, if it accidentally had passed through the bodies of myself or friends, must have caused instant death) that I do not advise tyros to meddle with this subject.—X. M. S.

[12102.]—**Lightning.**—Fergusson says that the electric discharge—*i.e.*, lightning—travels at the rate of 288,000 miles per second; greater than the velocity of light, which is only 194,000 miles per second.—GLATTON.

[12111.]—**Hothouse Boiler.**—If "W. F." has convenience to raise his supply cistern (say) 12ft. or 14ft. above his boiler top, he may raise the boiler until the bottom of the boiler is level with his pipes; but I would warn him the safety of his apparatus depends entirely on keeping his cistern well supplied with water, as his pipes would not form a reserve in case his cistern got empty, as they would if the boiler was below the pipes.—AN ENGINEER.

[12151.]—**Concrete Engine Beds.**—I have put several concrete engine beds down, and in my opinion nothing can answer better. They are superior to any ashlar pillar that ever was made. And if your material is good you can start with safety when it is seven days old. I use a cast-iron plate for bottom, holed to receive holding down bolts. I prefer the plate in one piece; but if it is inconvenient, you can put them in separately, but mind and have one plate to take two bolts.—LUFFRA.

[12160.]—**Size of Iron Tool, &c.**—At Mr. Purkiss' request, I send you a few lines on this subject. I agree with him in all he says, with one exception—viz., the use of a duplicate speculum, or concave tool, for figuring the pitch polishing tool. This I have found to be by no means necessary, indeed I doubt if it be actually practicable. When the glass speculum is ready for polishing (having a good spherical figure), nothing more is necessary to give the pitch tool the right curve than slightly to soften it by heat, place the speculum, moistened with rouge and water, upon it, and move it about gently by hand, until each of the pitch facets is observed (looking through the glass) to be in actual, not rolling, contact with the surface of the speculum. When this is found to be the case the work may proceed, but not before. It is always well, when work is to be resumed the following day, to warm the pitch slightly before placing the speculum upon it; though I must confess I have often proceeded myself without this precaution, and with no bad consequences. I need scarcely remark that perfect contact on the polisher before work is commenced is absolutely essential to a good result. I have never found any additional refinement on the above-mentioned simple directions to be necessary in practice.—H. C. KEY.

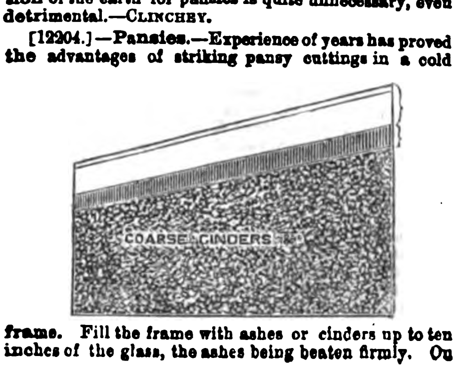
[12172.] — **Constipation.** — The communication from "J. W." (reply 12172, p. 390) is interesting and valuable, and many, I am sure, would be glad if he would give a few particulars regarding his method of curing constipation. Will he kindly state (1) if he used and still continues to use the enema daily? If not, how often should it be used, and must it always be continued after once beginning its use? (2) Has it entirely cured him of his "old friend" who returned six months after the operation? (3) What quantity of water should be injected, and does he recommend pure cold water, or would it not be better tepid and medicated? Lastly, will he kindly state the best form of apparatus for self-application, and where it can be purchased?—SAXUM.

[12192.]—**Concrete.**—To describe the whole process of concreting would be taking up more of your space than I am justified in doing; besides, it is a thing that almost any builder knows all about; at the same time I can inform "J. W. F." that I have done several stables with concrete all except the stalls, which are paved with firebrick (I was afraid it would be too slippery for the horse to get up on); the mangers were concrete too, and a more efficient and cheaper job I never saw done. They are kept sweet with little or no trouble, and they are a thing that no crib-sucker can possibly injure.—LUFFRA.

[12199.] — **Speeding Pulleys for Gut.** — E. Williams had better not make his pulleys according to the dimensions given him by "E. S. S." or "P. W. H. J." If he does he will have to alter his gut about 4in. to change fr m quickest to slowest speeds. The different angles made by the gut when running in the different gro ves have not been taken into account by "E. S. S." and "P. W. H. J." Cone pulleys to work well should be calculated and made for the distance between centres they have to work at. The following are dimensions for a pair of pulleys for a foot lathe in which the distance between centres of treadle shaft and lathe spindle is 2ft. The diameters of pulley on spindle are 10in., 8in., 6in., 4in., and the diameters on large pulley are 2ft. 6in., 2ft. 4 15/16in., 2ft. 3⅞in., 2ft. 2⅜in. The pulleys should be turned so that they measure the given diameters at the centre of the gut when tight in its place. The value of the ENGLISH MECHANIC would be very much increased if every one would be careful to see that he sends right answers or send none at all.—G. M.

[12204.]—**Pansies.** — The sifting in the preparation of the earth for pansies is quite unnecessary, even detrimental.—CLINCHEY.

[12204.]—**Pansies.**—Experience of years has proved the advantages of striking pansy cuttings in a cold



frame. Fill the frame with ashes or cinders up to ten inches of the glass, the ashes being beaten firmly. On the ashes lay four inches of carefully-sifted and worm-free turf, mixed with a little sand. In this plant the strongest ripest cuttings you can obtain, and leave six inches above for the plants to grow in. Do not let the soil be more than six inches from the glass. Keep the plants hardy, covering only with the glass, and letting in plenty of air in fine weather, water to be given occasionally and moderately. In April transfer the plants to your border, preferring a position shaded from the south and west, so far as the roots are concerned, the soil being well rotted manure mixed with loam below; and light rich soil the upper three inches. —GERARD SMITH.

[12206.] — **Geraniums and Fuchsias.** — "Phœnix" and S. Bettone in their replies seem to have overlooked the following points in the query. The geraniums were to be scarlet, the fuschias beautiful foliage, and cheap varieties produced within the last few years. In my reply I kept strictly to single scarlet zonales and variegated fuchsias. I have appended a list of good growing, free flowering, moderate-priced varieties, embracing the principal shades of colour, from which an amateur may make a fine selection without the trouble and expense it has cost me to arrive at my present stock. I may here add I should not be inclined to give a beginner the advice lately tendered in the MECHANIC—viz., to leave the selection to a nurseryman. It is not a nurseryman's interest to push the prettiest varieties, but rather those that are easily raised; and although such catalogues as those of H. Cannell, Woolwich, and G. Poulton, Edmonton, (both of whom send rooted cuttings by post—a great boon to growers far from London), are generally pretty reliable, I often find the descriptions overcoloured, and am induced to purchase new varieties indistinguishable from old ones. My plan is to obtain Hibberd's "Garden Oracle," and the catalogues of some of the best nurseries annually, and having carefully gone over these, to send to the nurseries for young plants of the best sorts. When these are in bloom I know what to retain, and what to sell, give away, or throw out. Besides the selection I now append, I shall be able in a few weeks, when new stock is better tested, to give your readers, if desired, further lists of desirable kinds. List:—Single zonales, from crimson-scarlet through the shades of salmon and rose to pure white: James Crutt, Richard Headley, Monster, Shakespeare, Mrs. Spencer, Rosamond, Beauté de Suresnes, Rose of Alandale, Purity. Doubles: Victoire de Lyon, Gloire de Nancy, Triomphe, Madame Lemoine. Golden tricolors: Sophia Dumaresque, Florence, Lady Cullum. Silver tricolors: Italia Unita or Mabel Morris. Bicolors (dark): Model, Countess of Kelli. White-edged: Silver Chain. Ivy-leaf (variegated): L'Elegate. Fuchsias (dark): Try me O! Light: Arabella. Light (very dwarf): Merry Maid. White corolla (double): Vauquer de Puebla; (single) Puritani. Double (dark): Lord of the Manor, Hercules. Not to trespass, I abridge the list of fuchsias.—IRISH MECHANIC.

[12213.]—**Coffee.**—The best machine for making good coffee is a common jug. It must be very clean, and perfectly dry. Buy the best coffee, grinding at home, and if possible just before making. Measure five teaspoonfuls to a quart of water. Let the jug stand before the fire to get hot, and be sure that the water be actually boiling before pouring over the coffee. Begin by pouring slowly; when full, slightly stir the surface, and let stand a few minutes to settle. That the water must be boiling and the jug hot is important, as this keeps the aroma from taking flight. Why this is, I cannot tell. Perhaps Mr. Bottone can. Everybody knows how essential to the enjoyment of a cup of coffee is the presence of its aroma. If the well-known fragrance is wanting (and one wonders whether it ever existed at all in some varieties of the decoction) take the railway refreshment-room kind—dark, sweet, and flabby. The highly chicorised and the weak solution—a sort of coffee broth made in a hurry without care.—SARAH.

[12217.]—**Violin Tuning.**—ERRATA (No. 380, p. 416).—The first string should be tuned to E, not C. —JOE.

[12217.]—**Violin Tuning.** — I notice several answers on violin tuning, but none of them mention the fact that in solo playing the fourth or G string is sometimes tuned to A, and even to B flat, by this means making otherwise difficult passages comparatively easy, the rest of the strings remaining perfect fifths as usual.—HONE KO TO.

[12221.]—**Brass Screws.** — The article which "J. C. L." speaks of in No. 335, p. 555, seems to me to relate to malleable iron screws, tables of which can be got in almost any mechanical book. It is universally known that there are always more threads in a brass screw than in one of malleable iron. I have never yet seen a table for brass screws, and would like very much if some of our readers could supply one.—FALSTAFF.

[12249.]—**High Pressure Fire-Box Boiler.**—I am extremely obliged to "P. W. H. J." for the information received from him through your valuable journal, and if I may trouble him further I should be pleased to know the thickness of plates for the shell and ends of boiler, and whether it would be advisable to have some of Galloway's conical tubes in each flue, and how many? As to the safety-valve, nothing but Hopkinson's patent seems to go down in this district.—495.

[12255.]—**Hair.**—"H. P. H." suggests a lotion of 1 ounce flowers of sulphur and 1 quart of water, but I cannot make the sulphur mix with the water—it floats on the top. I think he must have omitted something in the directions.—C. WATSON.

[12258.]—**Old Violin.**—No such maker as that mentioned by "A. J. L." ever attained any eminence in violin-making. I am of opinion that the label is an awkward and blundering counterfeit of the inscriptions used by the Amati family, as the date corresponds with the time at which several of the most eminent of those makers flourished. The label, however, is but a matter of minor importance, as "A. J. L." will find some of the vilest productions bearing forged labels of the finest makers. He ought to send the instrument in question to an experienced connoisseur, who would be able to inform him of its value.—P. DAVIDSON, author of "The Violin."

[12263.]—**Circular Saw Driving.**—If James Davis wishes to have 700 revolutions of saw, he will require a larger driving-wheel than 42in. The formula for such cases is this: Let A be diameter of driving-pulley in inches; B, diameter of driven pulley in inches; S, speed of driver; and V, speed of driven pulley, each in revolutions per minute. Then $A\,S = B\,V$. Thus the finding of any component with the other three given is a mere matter of substitution. In this instance A is unknown, and $B = 9$, $S = 40$, $V = 700$; $\therefore A \times 4 = 9 \times 70$; $\therefore A = \frac{630}{4}$ in., or $\frac{630}{4 \times 12}$ ft. = 13⅛ft. With the diameter of driver given the speed of driven pulley would only be 195 5-9ths per minute. If there is some insurmountable reason to prevent the driving pulley being made of greater diameter than stated, it would be advisable to use a countershaft. A good combination to effect desired purpose would be to have 44in. wheel on first driver, the belt going to 9in. wheel on countershaft. On countershaft there is to be a 32in. wheel belted to 9in. wheel on saw spindle. This would give about 700 revolutions. It would have been better if possible to have put larger than 9in. wheel on countershaft, but I have taken 44in. as the maximum for the drivers. I think that with heavy work on, with so small diameter of driven wheels, that the belt will be liable to slip.—P. W. H. J.

[12268.]—**Strength of Shafts.**—The strength of any material is estimated by the strength of its weakest part, so that in "Ixion's" example there is no need to take into consideration the diameters 2½ and 2¼, but only have to calculate for a plain shaft of 2in. diameter. It would not be any stronger if the whole of the shaft (excepting the 2in. part) were 12in. diameter. The following is the formula, in using it take the smallest diameter of the shaft out of bearings as the diameter: Let D = diameter of shaft in inches, H, the indicated horse-power, and N, the number of revolutions per minute. Then $D = \sqrt[3]{\frac{83\,H}{N}}$ in crank-shafts and prime movers, and $D = \sqrt[3]{\frac{65\,H}{N}}$ in ordinary shafting. Applying it to this case, $D = 2$in., $N = 170$; $\therefore (2)^3 = \frac{65\,H}{170}$; $\therefore 13\,H = 272$; $\therefore$ H.-P. $= 20\frac{12}{13}$ or (say) 20 horse-power.—P. W. H. J.

[12270.]—**Charcoal Furnace for Model Boiler.**—I think that three jets of the size mentioned will hardly be enough. To obtain the full power there ought to be a light every 1½in. or 2in. It would be best to have the lamp 12in. long, with six jets of diameter mentioned. Of course, without knowing what is required of the boiler, it would be impossible to determine the requisite number of jets, but I believe that this would develop the full power. The diameter of boiler is rather too small for a charcoal fire to be employed conveniently. There will be a difficulty in stoking the fire, and it will be liable to go out unless it has a good draught. The grate is to be 7in. long, supported at the back end by a bit of firebrick. It is to be 2½in. from bottom of boiler. The fire-bars are to be made of bits of ⅛in. boiler plate, and about ⅜in. wide, with three-sixteenths of an inch space between them. The boiler is to be set in a frame made of ⅛in. plate, with the chimney going up one end of boiler. The chimney is to be 3ft. long and 2in. diameter, made in 1ft. lengths for convenience of packing. In some models the chimney is square, and removed to some distance from boiler on base-board, and the smoke conducted to it beneath the bed plate through a rectangular tube. This looks well when the chimney is painted white and red in imitation of brickwork.—P. W. H. J.

[12273.]—**Water Power.** — Supposing that the length of pipe is one-tenth more than the fall, there would be 5·73 gallons supplied per minute = ·9168 cube feet. The power to be obtained by this is (.001892 × ·9168 × 80 × ·7) = ·085 horse-power = 255½lb. raised one foot high per minute. This would drive a moderate-sized machine, one that could be worked by a boy. For so small a turbine it is hardly worth while to give details, so I shall only give a few particulars. The best diameter would be (of casing inside) from 8in. to 9in. The diameter of the central wheel from outside to outside of buckets to be about 7in. The number of buckets in larger examples is 36, but I think 20 would do here, as a large number would be only useless complexity. In the manufacture, brass should be used as largely as possible to avoid being clogged up with rust.—P. W. H. J.

[12279.]—**Diminished Action of Battery.**—The nitric acid is soonest affected. Its change is a real destruction and deoxydation of the acid by the hydrogen, which in its absence would be evolved at the surface of the platinum. It cannot be purified or restored. The sulphuric acid undergoes a gradual change, being ultimately converted into sulphate of zinc.—ALFRED H. ALLEN.

[12283.]—**Food Analysis.**—Dr. Hassall's "Food and its Adulterations" is the most complete work on the subject; but, unfortunately, is out of print. If James C. Harker will wait a few weeks, he will find the information he requires in the ENGLISH MECHANIC.—ALFRED H. ALLEN.

[12285.]—**Logarithms.**—"C. P. E." has made a mistake in his query. He says that he finds log. 6·102 = ·78547 in the table. Now, he will never find the number with a decimal point to it in the table, because tables are not made with them. The points are left to be put in by the person using the tables. For instance, in a table without points, the log. of 6102 applies either to 6·102, 61·02, or 610·2, with the alteration of the characteristic. For instance, log. 6102 = 3·78547, log. 6·102 = ·78547, log. 61·02 = 1·78547, log. 610·2 = 2·78547. To find log. 6102·5 we must know log. 6102 and log. 6103. Now, log. 6102 = 3·78547, log. 6103 = 3·78554. Then the matter becomes just a matter of simple proportion, thus:

log. 6103 = 3·78554
log. 6102 = 3·78547

diff. of 1 = ·00007
∴ „ ·5 = ·00003

log. 6102 = 3·78547
∴ log. 6102·5 = 3·78547 + ·0000·3 = 3·78550

—P. W. H. J.

[12299.]—**Tar Pavement.**—I had occasion some years since to inquire as to the expediency of using gas tar in making footpaths which, as they have to be used in all weathers, should be in good condition whether it be wet or not. I was informed that when carefully made, such footpaths do not get soft either by the sun or the rain, and, if well looked after, can be kept in good condition for a very long time at very small cost. The foundation must be firm and dry, and, if not naturally, artificially drained. It is best, though not essential, to boil the tar to drive off its more volatile parts, and to thicken it with pitch; the broken stone, cinders, or gravel, must be mixed with as much tar as will just cover the surfaces of the hard material. If there is not tar enough the so-called asphalt will not bind well, and if there is too much, it will become soft in hot weather. The proper mixing of the materials is a matter of some nicety, requiring both attention and trouble, and is often badly done. When well done, the material is spread 2in. or 3in. thick upon the pathway, and rolled with a heavy roller kept wet to prevent it sticking. It improves the appearance of the work to sprinkle small fragments of sparkling spar which, imbedded in the surface of the nearly black asphalt, make it look like granite. Great care must be taken to avoid forming any hollows in which water can lodge, and every spring any hollows that may have formed must be carefully filled up. Unless this be done, and unless the foundation be good and dry, the asphalt will soon break up.—PHILO.

[12301.]—**Unequal Sizes of Cone Pulleys.**—To "JONATHAN."—I have no recollection of giving any formula for finding length of band; I don't like formulæ, as the book with them in is always left at home, like the Dutchman's anchor, just when you want it. "Derf Errac" gave one without any trigonometry on 29th October, 1869, and in Vol. IV., No. 103, there is a geomtrical calculation, both of which seem correct on trial. In Vol. VIII., No. 203, p. 460, I gave a way of making a set of pulleys to suit the band which has already been fitted to one pair of the set, and from that plan may be deduced a very easy way of calculating the length of band in this manner. The point d, which all the bands pass through, of course suits two equal as well as two unequal pulleys; therefore, if we draw a line through d parallel to A B, as is done in the diagram on p. 460, Vol. VIII., that gives you the diameter of the pulleys when equal. Now, the calculation of the band for these is simple enough, as it is only twice the length A B added to twice the half-circumference, or once the whole circumference of the pulley, which is got by multiplying the diameter by 3·1415. Now, having obtained the length of the band for equal pulleys, which also suits the pair of unequal ones first laid down, we can go on and draw other lines through d, which will give us any number of unequal ones that may be desired, all fitting the same band. If the belt has to be crossed you have only to make the sum of diameter of every pair alike, as e.g., 20 and 6, 16 and 10, 13 and 13, all equal to 26 when added together, and this holds good whatever the distance of the centres from one another. I see two answers to a query on the same subject (No. 12199, on p. 415), which show that "E. S. S." and "P. W. H. J." either don't understand the query or forgot what it was before they sat down to answer. Gut bands are never crossed, unless the pulleys are placed "in winding," as they would wear themselves out in a very short time, and it is only in the case of crossed bands that the sum of diameter remains the same as above. In my lathe a drop on the fly-wheel of 1ft. 1/16in. corresponds with a drop of 1ft. ⅞in. on the pulley, which proportion will be found to hold good for any ordinary foot-lathe, and is very different from what the above-mentioned answers put forward.—J. K. P.

[12304.]—**Phrenology.**—"Sigma" (p. 418) says that no greater mistake was ever made than to suppose, as some of our great writers do, that the mind is a blank sheet of paper on which we can write what we please, but he is as completely mistaken as it turned out he was about the electric sparks, as to what John Locke and other great writers who have followed him taught. They taught (does "Sigma" deny?) that a new-born child knows nothing, and that all it ever knows it has to learn, and that in that sense the mind is like a sheet of paper. But different minds, like different papers, are of various quality, and neither Locke nor any other great writer ever taught that we can write equally well upon any mind any more than that we can write equally easily and equally clearly upon any sort of paper. Upon some minds as upon some paper, every impression is distinct and permanent, while upon other minds every impression is like writing on blotting-paper, blurred, confused, and as uncertain as "Sigma" said my knowledge about electric sparks was, and his turned out to be. The phrenologists tell us that few minds are of equal quality throughout, that some receive and retain certain sorts of impressions better than others, and other different impressions better; that one artist, for example, will excel in drawing form, another in depicting colour, and they profess to be able to foretell in which each will most excel with equal cultivation, by observing the relative size of certain portions of the brain as indicated by the width between the eyes for form, and by a fulness over part of the eyebrow for colour, and they further allege that the size of such portions of the brain will be increased if the faculty be unusually cultivated. Whether these allegations are established by sufficient evidence is one question, but that the notion is *per se* absurd can hardly be maintained.—PHILO.

[12304.]—**Phrenology.**—In proof of the statement made in the latter part of "Sigma's" answer, I wish to state the following particulars. A friend of mine during his university career had his head examined by an eminent phrenologist. Shortly afterwards he began to read for a mathematical scholarship, and after a few months of this a marked change was visible in the shape of his forehead, and this afterwards increased by little and little till he ceased reading that particular subject.—E. JOHNSON.

[12304.]—**Phrenology.**—Phrenology may be and has been pushed too far, still there is some truth in it, but each case must be modified by the relative size of the organs, as well as by temperament, nervous, sanguine, billous, and so on, and again by early training, or inherited tendencies, all which must be taken into account. When phrenology was more in vogue it became for a time a favourite hobby, and was ridden to death. In estimating any novel doctrine or facts, it is usually well to remember that they must be taken with the counteracting weight of other facts which seem opposed; we then discover that the truth lies not in the effect of one, but in the result of both: so that if phrenology lands you in the place where men are not responsible, I shall be glad to hear when you come back how they manage matters there.—AFTERNOON.

[12309.]—**Boiled Oil.**—"G. W. C. H." should place in a glass jar some *bonâ fide* new linseed (from the oil pressing works, not the shops), pressed from fine Eastern seed, in the sunlight on the top of the house, with a piece of sheet lead scraped bright, inserted part in the oil and part in the atmosphere of the jar. Cover over with glass the mouth, so as to admit air and light freely to circulate, but not the rain to enter. In a few weeks the oil bleaches, and to the lead between wind and water a mass of mucus attaches itself, which is withdrawn by gently taking out the lead, rescraping, and again inserting until the oil becomes of the lightest sherry tint. By November it should be water white nearly, if the proportion of surface of lead has been enough in proportion to the oil used. He will find that this oil carries a power of what is called drying (to a non-cracking or blistering power, with even a dry oxide tint) without any further addition, which he is not, perhaps, aware of, though the action of the oil is not a "drying one" at all in that pure sense, but one of oxidation, which proceeds in a peculiarly increasing ratio at its finish in the constitution of the tough glass-like varnish of its complete state. He will, by this manipulation, get over the slower and primary portions of this oxidation in his jar by the help of the sunshine, leaving the latter portions to occur in his pigment under his brush by extended surface, without any addition of caustic chemicals or cooking to heat (*i.e.*, boiling), which an Italian painter of some note assured me a few years back, while travelling in that country (and being inquisitive enough to inquire into his jars of what to me looked like creatures preserved in spirits on the top of his studio), was the true secret of the staying power of the pictures of the old masters, and the cracking of modern pictures, to which, if so, "G. W. C. H." and your readers are quite welcome. If he cannot succeed, let him advertise his address, and thus obtain communication with me direct, as I have had vessels set one hard lump of transparent resin, which I dissolve in turps, and make a splendid varnish of to resist rusting on iron for experimental work.—X. M. S.

[12310.]—**Professors.**—"P. D." asks a somewhat ticklish query: "Who has the right to call himself 'Professor?'" Like the controversy about the definition of "engineer" which raged some time ago, the title can't be fixed within definite limits, or at least those who claim it as a sort of appendage to their names. We have college professors of languages, music, science, as Tyndall and Huxley, gymnasts, and a thousand other things too numerous to mention. Professor originally meant one who had gone to college or public institute and taken out certain honorary degrees; now any man may prefix or append it to his name who excels in any profession. The public, however, looks to the man who adopts it for competency to perform what he professes, and his disassociation with charlatanry.—RAT-TAT.

[12312.]—**Brick Vaulted Arches.**—Brick vaulted arches will be strongest built with the wedge-shaped brick made to follow the centre, and worked all headers. (Proved.)—W. HILL.

[12312.] — **Brick Vaulted Arches.** — Nothing can be more vicious in construction, or more sadly illustrate the vanity, for practical purposes, of any "scientific progress," while our whole industrial system is rotten and in galloping decline, than this wretched expedient for making thick arches by successive thin layers, begun in the hurry of the first railway works. It is true the Romans had occasionally made an arch in two "rings," but they were each a foot deep or more, and in large thin bricks, about equal in bulk to the mortar. It is disgraceful that, since the removal of the excise restrictions, no wedge bricks for bonded arches are to be had but by special order. All that need be wanted are about three stretchers, and four to six headers (I mean by the former those having their length wedged, and by headers those wedged in breadth). If those of each kind formed a radial layer or slice through an arch of the greatest thickness and smallest inner radius ever likely to occur, say a foot inner radius and three bricks thick, they would serve for all arches whatever, by variously alternating such a slice, or part thereof, with another part, or with a radial course of common bricks, or with two or three such courses to one wedged course. Arches of practically any inner radius, from one foot to twelve, might thus be turned, with no joint of perceptibly unequal thickness. Again, such wedges might have about half their weight saved by proper perforations in the direction of the centre battens. Only the faces of the arch (where either may be exposed) need be of solid bricks; and the key course, if perforated throughout and having its lowest stretchers not quite in contact, end to end, would receive and convey away all the foul or hot air rising to any part of the vault (of course into a kitchen chimney if at hand, or some chimney, or, what is better, a special flue inclosed between chimney-flues), and then such a vault would always be a far healthier ceiling than any flat one, or any now in use. If "Building Acts" had any reference to sanitary and public benefit instead of only to regulate risks for the promotion of the insurance trade, (the most anti-national interest possible), no stack of chimneys would be allowed to be built without one extra flue, besides those required for fireplaces, this foul-air flue extending from below the first-floor to a termination like that of all the smoke-flues, and being placed between the two warmest or most used smoke-flues; but its area need hardly, in any dwelling, exceed that of a brick at the bottom, increasing upwards by half a brick more at each story.—E. L. G.

[12315.]—**Dubroni's Photographic Apparatus.**—The great drawback in the use of Dubroni's apparatus is that after having focussed your object you have to remove the camera from the stand and go through certain manipulations before replacing it on the stand previous to exposure of the plate. In the meanwhile a hundred things may have happened to disturb your sitter or whatever you may be about to photograph, in which case you have to go all over your work again, and you may have to do this many times ere you are successful. There are other objections to this apparatus, but the one I have mentioned is insurmountable.—QUERCUS.

[12316.]—**Scale.**—The first scale described is of hundredths of a foot, ten of which are obviously = 1·2in. The ten horizontal lines crossed by nine oblique ones near each end, afford an old and good way of taking with compasses (supposing the lines very accurate, more so than they are usually on wood), any number of 200th's of an inch, up to 1,000; or of 400th's, up to 2,000, without having lines nearer together than a 20th or a 40th inch. On the other side, the scale of unequal divisions marked C means chords, and will serve to mark off any number of degrees on an arc you have struck with the chord of 60°, or distance from the 0 to 60 of the scale, as radius. Or, if you take double that length for a radius, you may regard them as sines of the corresponding numbers of half degrees, and so mark off by one step any half degree up to 45°.—E. L. G.

[12317.]—**Red Prussiate of Potash.**—Dissolve the yellow prussiate of potash in water, then pass chlorine gas through it slowly, shaking or agitating in some manner the whole time, till the liquid acquires a greenish brown colour. The end of the process may be known by taking out a few drops of the solution from time to time, and testing it with a solution of perchloride of iron, the chlorine being passed till the solution fails to produce a precipitate with this reagent. According to the equation $K_4 Fe C_6N_6 + 3Aq + Cl = K_3 Fe C_6N_6 + 3Aq + KCl$, a pound weight of the yellow prussiate would require 1·35oz. of chlorine to convert it into the red prussiate, and this weight might be obtained from either 7oz. of commercial hydrochloric acid or from 2¼oz. of common salt, nearly.—J. W. G.

[12318.]—**Artificial Oils.**—By saying that the oils of terebinth, bergamot, cloves, &c., are isomers is not meant that they can be changed absolutely into each other, so that oil of cloves shall become (say) oil of bergamot, but that on analysis each of these oils is found to contain exactly the same elements united in the same proportions—namely, $C_{10}H_{16}$, the different characters of each oil being produced by a different arrangement of the atoms of C and H in each specimen. In order to prepare oil of winter green artificially "Bob" must first procure salicine, then change this into salycylol by distilling with bichromate of potash and sulphuric acid, or he might obtain salicylic acid at once by passing carbonic acid into phenol containing small pieces of sodium, and now by distilling the salicylic acid with wood spirit and sulphuric acid he would obtain the oil of winter green or methyl salicylate. Phenol or carbolic acid may itself be made synthetically from its elements in the following way:—Pass a powerful electrical current through an atmosphere of hydrogen by means of carbon poles, acetylene is thus produced; heat this acetylene to a temperature below redness, and benzine is formed, treat benzine with nitric acid and you procure nitrobenzine; this, again, by distillation with iron filings and acetic acid produces aniline, and by treating this with nitrous acid it is possible to produce phenol or carbolic acid, so that we see the steps in the production of oil of winter green synthetically to be: Production of acetylene, C_2H_2; benzine, C_6H_6; nitro-benzine, $C_6H_5No_2$; aniline, C_6H_7N; carbolic acid, C_6HO_6; salicylic acid, $C_7H_6O_3$; oil of winter green, $C_8H_8O_3$.—J. W. G.

[12318.]—**Artificial Oils.**—"Bob" will not find the isomeric components of terebinth, bergamot, lavender, &c., to possess the saleable qualities of "taste," "appearance," or "smell," of the natural products from these sources. That (on his part) idea is "flam," but not their atomic components or chemical atoms as demonstrated by analysis. Exact isomerism of physical and chemical component never can be hoped to be arrived at except by the interposition of the process of vegetable life in the plant's cell. Though some isomerics are very near.—X. M. S.

[12319.]—**Dyeing Pulp for Sugar Paper.**—"A Paper Maker" might try a little French slate or glass blue to produce the desired colour.—RAT-TAT.

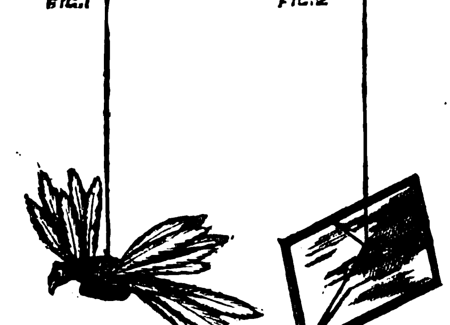
[12321.]—**Chess Player.**—The automaton chess-player is still exhibited at the Crystal Palace. There is a full description of the method of working in Brewster's "Natural Magic." "Willie Scorer" must not suppose that the visible mechanism is the source of the intelligent action.—ALFRED ALLEN.

[12321.]—**Chess Player.**—This subject is treated of at length and most fully in "Letters on Natural Magic," by the late Sir David Brewster, LL.D., F.R.S.—W. M. COLLES.

[12321.]—**Chess Player.**—I can further inform "Willie Scorer" that he will find an interesting account of the "Automaton Chess Player" in the April and May numbers of the *Chess World* for 1868.—J. W. ABBOTT.

[12323.]—**Scarecrow.**—The best scarecrow I ever made for small birds was formed of the pinion of a goose and a potato. Pull all the long pen feathers out of the pinion, and tie the remainder on to the upper side of a large potato, leaving a long string attached to suspend it; then stick the long feathers into the potato, so as to form a terrible-looking bird of prey, as shown at Fig. 1. When suspended from a high bough, or the end of a long rod, it dashes about in the wind, sweeping over or near the crops in a most threatening way, and presents such varied aspect that

FIG. 1 FIG. 2



even wingless bipeds wonder. No. 2 is a small looking-glass hung angling, and is an excellent thing for a cornfield. It flashes forth lightning all over the shop, and even rooks will not face it. When the sun does not shine, it shows everything reflected "on the move;" but the sun's rays reflected from it are a caution. Birds coming within one of its lightning flashes dodge and detour as if a ball had whistled past them. One great feature of it is that its field of refraction is always changing, so that itself seems endued with life. Its flashes may be distinctly seen for a mile.—C. N. ABBOTT.

[12325.]—**Brazing Fine Saws.**—Get a pair of tongs made with very heavy jaws. Fix the saw carefully to a board so that the ends may lie correctly and securely together, cutting away a piece of the board where the join of the saw comes, or in any other convenient manner, and prepare the place for brazing in the usual way. Have the tongs at a white heat and pinch the prepared splice with them, the brazing will be done well and neatly in a moment.—Q. YORKE.

[12328.]—**Terra Metallic Tiles.**—"Puzzled" may again renew the brightness of the tiles by dissolving alum in the water used, or hand-brush the floor, using the brush for black-leading the grates, or one formed of cut steel wires.—RAT-TAT.

[12329.]—**Practical Mechanics.**—I do not think there is any thoroughly good work which completely embraces the subject. I have often been in sore want of one myself, and have had many useful works on the subject pass through my hands but have never yet seen one that does full justice to the science of applied mechanics. If "An Irish Subscriber" has not done so, I would strongly recommend his reading the Cantor Lectures on Applied Mechanics, delivered by John Anderson, C.E., before the Society of Arts, in 1869. They appeared in the ENGLISH MECHANIC, and are also to be had in a separate form on application to the Secretary, Society of Arts, London. I beg to indorse "An Irish Subscriber's" suggestion, and think that a series of papers on applied mechanics would be gladly read by many of our subscribers, especially if they were written, as no doubt they would be, by one who is thoroughly acquainted with this interesting and pre-eminently useful subject.—CABE GLOU.

[12329.]—**Practical Mechanics.**—The three following are the best on the subject:—Goodeve's "Applied Mechanics," Rankine's "Applied Mechanics," Willis's "Principles of Mechanics."—S. M. B.

[12330.]—**Re Slide-Rests.**—In reply to "H. E.," let me ask him if he expects me to sit down and spend a whole day in writing drawings of the rests he wants. I have none by me, and they would take quite that time to make, particularly as one of them is some distance off at a friend's house. I have lately been too busy even to read the ENGLISH MECHANIC. I explained long ago why the drawings "H. E." wants had not been sent, and I will now give another reason. Some time ago a drawing of a certain instrument was requested, and I went to the trouble of making it, having previously been assured by the person asking for it that he actually wanted such an instrument and intended to fit it up for himself. A sight of the drawing choked him off at once: all he did was to return it, having carefully taken a tracing of it for himself. I don't get served so again if I know it.—J. K. P.

[12332.]—**Chemical.**—If the acid be weak, both it and the water suffer decomposition. With an acid of specific gravity 1·11 no decomposition of the water occurs, the gases consisting (when the action has continued some time) of equal measures of hydrogen and chlorine, which will slowly but completely recombine on exposure to diffuse daylight, or instantaneously if exposed to strong sunlight or burning magnesium.—ALFRED H. ALLEN.

[12332.]—**Chemical.**—The acid only will be decomposed by the action of the current; chlorine being given off at the anode or positive pole, and an equal volume of hydrogen at the cathode. In the case of sulphuric acid and water, the water is decomposed by a secondary action, owing to the liberated radical SO_4 not being able to exist in a free state, but this does not apply in the case of chlorine.—SIRIUS.

[12333.]—**Purifying Mercury.**—Your mercury must be distilled in an iron retort, at a low red heat.—DAVID W. BRAID.

[12333.]—**Purifying Mercury.**—Shake up well in a bottle with finely-powdered lump sugar. The bottle should not be more than one-quarter full. Blow air into the bottle with a pair of bellows, and shake up again, repeating the operation a few times. Then filter through a cone of smooth writing-paper with a pinhole in the apex. If this process should not remove all the impurities, redistil after having squeezed the mercury through wash-leather, and then digest in cold dilute nitric acid in a shallow dish for a day or two, stirring from time to time. The nitric acid will act but slightly on the mercury if foreign metals be present.—ALEPH.

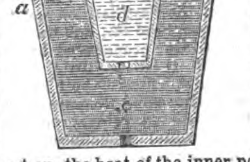
[12333.]—**Purifying Mercury.**—The mercury requires to be evaporated and condensed in distilled water.—RAT-TAT.

[12333.]—**Purifying Mercury.**—Treat the mercury with very dilute nitric acid, and then dry it; if this does not free it from the matters which "Barometer" complains of, he must redistil it, which can be readily done in an iron tube fitted with iron cap and tube screwed on, the tube from cap passing into a larger one closed at bottom, and immersed in a pail of water in order to condense the mercury.—J. W. G.

[12334.]—**Eye Query.**—When the eye loses the power of accommodating itself to near objects, such as small print at from 10in. to 12in. distance, the person is called longsighted. This change, which generally shows itself by a difficulty in reading small print by gas or candle light, commonly takes place between the ages of 30 to 50, which is called longsightness, because objects are best seen at a distance, and arises from a change in the state of the crystalline lens by which its density and refractive power, as well as its form, is altered. It frequently begins at the margin of the lens, and takes months to complete its circle, and it is often accompanied with a partial separation of the lamina, and even of the fibres of the lens. The variation of density takes place most frequently at a particular point in the margin of the lens, and at its commencement vision is considerably injured, if the human eye is not managed with peculiar care at this period. The change in the condition of the lens often runs into cataracts, or terminates in a derangement of fibres which, though not indicated with white opacity, occasions imperfections of vision that are often mistaken for amaurosis and other diseases. When the change has become symmetrical round the margin of the lens, the symmetrical action of a convex lens enables the eye to see as distinctly as before by converging upon the retina rays flowing from near objects, which the unassisted eye refracted in such a manner that they would meet at points beyond the retina. And the best advice I can give our querist will be this: Avoid excessive tea drinking, and as much as possible drinking liquors or spirits. If a smoker, give up tobacco at once, as there is nothing but regular and moderate living without excesses that will do any good. Wash the eyes in clean cold water two or three times a day, placing the face in the water with eyes open, persevere, and I have no doubt but "Spectroscope" will find great relief. If 24in. is the point at which querist can read small print, he will require a pair of convex spectacles to read in of 16in. focus, to enable him to read at the proper distance; and I would advise him to get them of smoke colour, the kind called bluish smoke, which will produce a natural effect, and they will be better to be peroscopic eyes. They may cost 10s. to 12s., and will do good service.—WILLIAM OLDFIELD, Sheffield.

[12336.]—**Vine.**—You can do both, and now is the time, heat and water both required.—OLD BOOTS.

[12337.]—**Seed.**—Some years ago, when I could not afford the luxury of a frame, or a hot-house, I raised the seeds of passion flower, canna, and some other difficult seeds in the following manner. I took a large pot a, and a smaller one b; between the two I stuffed newly-cut grass c as light as I could pack it. I sowed



the seeds in the pot d, covering it with a small piece of glass e, on the upper side of which was pasted a piece of blue tissue paper. (I had no blue glass at hand.) Then I watered and covered the larger pot with glass. I plunged the large pot in the ground. The seeds were up in no time. On removing the glasses to see how they got on, the heat of the inner pot has been so great as to be unbearable to the hand. I believe any tropical seeds might be so raised. As soon as they are up, air should be given, and when forward enough they should be planted out as wanted.—OLD BOOTS.

[12338.]—**Hyacinth Roots.**—When they have flowered let the pots be placed in a cool, dry situation, or the bulbs taken up and planted in sand, and so placed. When the leaves have withered away take up the bulbs, cut off the old roots and rootstock, loose scales and offsets (the offsets should be planted by themselves, to grow up into the flowering state), and leave the bulb in a cool dry place for a week, to harden. Then plant it in the border where it is to bloom the next year. If bulbs are purchased, plant them as soon as you obtain them, and not later than September. They will not bloom earlier for early planting, but the plant and blossoms will be much larger. The soil that answers best is composed of rotted turf mould, leaf mould, and sand, one third each, the two first ingredients being prepared long before planting time. Give six inches below and three inches of the soil above each bulb.—GERARD SMITH.

[12340.]—**Flour Paste.**—When your paste is nearly cold, add a solution of about two drachms of water in which has been dissolved 10 grs. of corrosive sublimate to each pound of paste, also about 10 drops of essential oil of lavender. Stir it well up and keep covered. You will find it a good plan to dry the paste in an oven till it is like horn, take out as much as you want at a time, and work it up with warm water.—OLD BOOTS.

[12340.]—**Flour Paste.**—All paste will get mouldy; make it in smaller quantities; it keeps best in a vessel of wood, not painted, covered over in a cool, dry place.—PAPERHANGER.

[12340.]—**Flour Paste.**—Add a little brown sugar and a few grains of corrosive sublimate to the paste; it will keep much longer, or add to it a few drops of carbolic acid.—J. W. G.

[12340.]—**Flour Paste.**—A little corrosive sublimate, or camphor, dissolved in it may keep it fresh for some time.—RAT-TAT.

[12341.]—**Moths.**—Try sprinkling the infested places with a mixture of powdered arsenic and camphor, or mix sugar with arsenic and set it in convenient places. Cover the floors and furniture with damp grass for one night, remove and thoroughly clean next morning.—RAT-TAT.

[12341.]—**Moths.**—The evil is in your sofa; your best plan is to sell it for anything you can; cure your carpet by thorough brushing and beating. If you buy another sofa keep it in constant use, and the surface well brushed, especially the parts least seen. If you only want the sofa to look at let the cover be cotton or linen, not woollen—better still, not to buy what you are afraid to use.—UPHOLSTERER.

[12343.]—**Dresser Top.**—If your sycamore top had not gone "winding" the worm would soon eat it up. There is no remedy but to have a new top of clean pine.—CABINET-MAKER.

[12343.]—**Dresser Top.**—Remove the sycamore top, steam it, and leave it under weights until it straightens and seasons. Damp cloths would not be of much use, unless at the same time constant pressure for a few hours could be applied.—RAT-TAT.

[12344.]—**Disappearance of Art.**—Ancient art, both mechanical and fine, depended mainly upon idolatry, which was by no means a cheap religion. We can hardly conceive the intense hatred of the earliest Christians to everything tainted in the least degree with idolatry—and everything was tainted with it—hence, as one prevailed the other declined, and in a few centuries Mahomedanism finished what Christianity began. I can readily believe that Christians for at least 300 years, carefully shunned for their children all that we call "art education."—E. G.

[12346.]—**Gearing Waggon Wheels.**—Bring the rule of three to bear on it thus: If dish of wheel be 2in., half the diameter 25in., length of arm or axle 10in.,

Then 25 : : 2 : 10 (arm
2

25) 200 (8in. out of straight line.
200

Bear in mind I am working from centre of arm or axle. Another way—and by far the best—is to make a full-sized drawing of wheels in their right position. Make the face of spokes in bottom part of wheels parallel to each other.—LUFFRA.

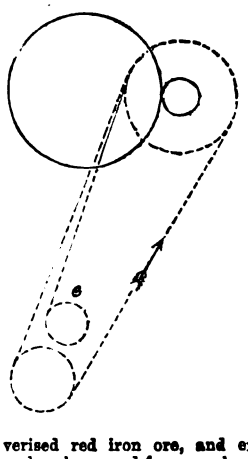
[12347.]—**Stroke.**—The stroke of an engine varies according to circumstances, which the designer must take into consideration, but the general rule is to make the stroke about twice the diameter of the cylinder. The diameter of the fly-wheel should be about four times the stroke of the engine, and the rim should weigh about 3 cwt. per horse-power.—FALSTAFF.

[12348.]—**Spanish Pronunciation.**—In answer to our learned contributor "E. L. G.," I beg to say that all good speakers of the Castilian tongue pronounce the final *z* as *theta* (the hard *th*); and the words he quotes *vez*, *paz*, *cruz*, are pronounced by good speakers *bayth*, *päth*, *crooth*, there is little, if any, difference between the Spanish *b* and *v*—both are pronounced with very nearly the same pressure of the lips as our English *b*; they write *vino* (wine) pronounced *bēno*, and they say *blancho* (white) pronounced as we should do. The final *d*, which is erroneously classed as *d* mute, is a much more difficult sound to get, it is our soft *th* very slightly. At Madrid its sound is precisely that of the *th* in our word *the* or *then*; but in Old Castile it is so nearly silent that many foreigners completely neglect it, and the words quoted by our friend "E. L. G." are pronounced by them very nearly *Berdā* and *Madri* (spelt *Verdad* and *Madrid*). The true sound, however, shows the faint presence of a final soft *th*, when heard from the mouth of a native of Old Castile. For the benefit of "Cast Steel" I wish to say that *g* before *e* and *i*, and *j*, whether initial, medial, or final, have the invariable sound of the hard guttural German *ch*. "Cast Steel," after he has mastered the verbs, will find Castilian one of the easiest of modern languages. If he will write to me privately I shall be happy to lend him for a time my "Estudios Filológicos," by Morentin, 1857. This contains a full examination of, and settles all knotty points in, the Castilian tongue, besides giving examples from the best Spanish authors.—WILLIAM WRAY, 1, Clifton-villas, Highgate Hill.

[12351.]—**Underground Telegraph Wires in Cities.**—Perhaps the following information from the "Electric Telegraph," by Bright, may be of service to "Dynam." "The wires are carried in iron pipes under the foot pavements, along the sides of the streets, and are thus conducted to the terminal stations of the various railways. Provisions, called testing posts, are made at intervals of a quarter of a mile along the street, by which any failure or accidental irregularity in the buried wires can be ascertained, and the place of such defect always known within a quarter of a mile. Some of the wires of the British and Irish Magnetic Telegraph Company were at first laid and protected in the following manner. Ten conducting wires are enveloped in a covering of guttapercha, so as to be completely separated from one another. Thus prepared, they are deposited in a square creosoted wooden trough, measuring three inches in the side, so that nearly a square inch of its cross section is allowed for each of the wires. This trough is deposited on the bottom of a trench cut two feet deep along the side of the common coach road. A galvanised iron lid, of about an eighth of an inch thick, is then fastened on by clamps or small tenter hooks, and the trench filled in. The method of laying the wires in the streets adopted by this company is a little different. In this case iron pipes are laid, but they are split longitudinally. The under halves are laid down in the trench, and the guttapercha covered wires being deposited, the upper halves of the pipes are laid on and secured in their places by means of screws through flanges left outside for the purpose. To deposit the rope of guttapercha covered wires in the trough, it is at first coiled upon a large drum, which being rolled along slowly and uniformly over the trench, the rope of wires is paid off easily and evenly into its bed."—C. N. W.

[12351.]—**Underground Telegraph Wires in Cities.**—In answer to "Dynam, Chicago," I beg to give him a short résumé of the best system used by telegraph engineers in running underground or "cable" wires through large cities or great centres of traffic. The wires through Cheapside, the Strand, Oxford-street, &c., are all laid on this plan. The first thing necessary is to obtain the consent of the Local Board to open up the ground. This is seldom refused, although it is sometimes obtained with great difficulty. (It is much to be regretted that the Government are so completely at the mercy of Local and Highway Board Surveyors in this respect.) Through busy streets the outside edge of the foot pavement is usually selected. Iron pipes with an inside diameter of 3in., of the same kind as used for gas or water, are laid about 18in. deep; as each pipe is put down a stout iron wire, No. 8 gauge, is threaded through it, and at distances of about 100 yards an iron flush or test-box is placed. This box is simply an oblong cast-iron box, 2ft. long, 10in. wide, 18in. deep, with movable stone lid laid flush with the pavement; the pipes are brought into each end of the box, and the iron wire terminated at each box and the ends secured. The pipes are then rammed with yarn and run in with lead to prevent gas or water leaking in, and the ground filled in as you go on. All is now ready for drawing in the cable. The wire most used is "No. 8 prepared guttapercha wire." This is a copper conductor of about No. 18 gauge, thickly covered with a coating of guttapercha, and that again covered with two coats of tape soaked in Stockholm tar (gas tar must be specially avoided for this purpose, as it injures the guttapercha). The wire and coating is now about the thickness of an ordinary lead pencil. The 3in. pipes will conveniently hold about thirty-five wires. The wires are wound side by side round a "drum barrow" and conveyed to the first flush box, the end of each wire is stripped of its guttapercha covering for about a foot, and the copper conductor carefully and firmly attached to the iron wire, the end of which is looped up and twisted round itself. Great care should be taken that each individual wire is firmly attached to the iron wire; the joint is then well wrapped with hemp or yarn made as smooth as possible, and well greased. Three or four men now go to the next box and steadily pull the iron wire (with cable attached) through. Of course, a man or two is left at the drum to see that the cable pays out properly and without kinking. About 6ft. should be left slack in each box to allow for testing purposes in case of faults. A box must always be put in at every set of joints or any sharp curves. The wire is usually supplied in lengths of 300 or 400 yards. If good supervision has been exercised, steady workmen employed, and every pipe thoroughly examined to see that no rough jagged pieces of iron are sticking up inside, the wires should all test as perfect when laid as before. If there is any incline in the level of the pipes it is a good plan to pour in a pail or two of water when drawing the cable through. As repairs to wires laid by this system are very difficult it is usual to run in several spare wires; if twenty-five wires are wanted thirty to thirty-five should be laid. The most fruitful causes of faults are—gas or water men smashing the pipes with a pickaxe when digging in the neighbourhood, and so cutting into the wires; rough pipes not being rejected, and careless drawing through, and bad joints. The inductive embarassment from one current flowing into another is *nil*, or at any rate so small that no account need be taken of it. I shall be happy to give "Dynam" any further information he may wish.—TEL. ENG., Oxford.

[12352.]—**Centrifugal Pump.**—There seems to be a little complication in "Teachable's" diagram of gearing wheels: *b* in the drawing is, I presume, the pinion wheel. Why not make it smaller, or place it, with another pinion wheel between the spur-wheel and disc, so as to do away with driving chain or band? By putting the large pulley and pinion on the right side of spur wheel a longer belt is necessary, and the question is whether any belt is strong enough for a 16 horse-power engine, except one longitudinally interlaced with copper wire, a dear sort of belt, though very lasting and not liable to breakage. By the arrangement alluded to the small wheel or friction roller *e* might be removed, as the belt from the greater distance of the pulley on disc and pinion pulley would work better without. Would "Teachable" try this idea, which I think is in part original? Avoid wheels and mechanism altogether, and when steam is generated to sufficient pressure in the boiler, let it be conducted at once into pump with small feed-pipe and cut-off valve. The upper portion of the pump where the steam enters may be made of larger diameter than the lower or water portion and left uncovered. The feed pipe is to be bent and pointed upwards. This arrangement is similar to the blast pipe in locomotive, and by it water could be raised through the pump-pipe and to any reasonable height, as smoke is inducted through the boiler tubes and into the smoke box, and driven out through the chimney.—RAT-TAT.



[12352.] — **Centrifugal Pump.** — If "Teachable" has his strap driving in the direction of arrow, he will not require the pulley *e* (left-hand side of strap downwards). As he does not state what kind of centrifugal pump (that is, pitch) I cannot tell him speed required. From the data he gives, his disc-shaft will travel 126 $\times \frac{72}{30} = 302\frac{1}{15}$, instead of 375 revolutions.—G. W. S.

[12356.] — **Small Malleable Castings.** —These must be made from a hard, white, crystalline iron. They must be packed in pulverised red iron ore, and exposed to a heat rather under cherry red for a week, when they will be found to be malleable. The red ore may be used over again, mixed with one-eighth part of fresh ore.—ALEPH.

[12357.]—**Stretching Vulcanised Rubber.**—Not by any process known at present. It might be spread out in a fluid state to the required dimensions, but the rubber would remain viscid.—RAT-TAT.

[12362.]—**Formula.**—See No. 295, p. 203, first formula. The last formula (for ullage) is wrong, and corrected in No. 298, p. 283.—E. L. G.

[12363.]—**Recovering Indigo.**—Treat the mixture with a weak solution of green copperas (3 per cent.), let it boil for an hour, filter, or strain through flannel bags. After standing some time, the yellowish solution will deposit the indigo nearly pure.—S. BOTTONE.

[12373.]—**Softening Spring Water.**—The hardness of water derives from the presence either of calcic carbonate, or calcic sulphate. This latter form of hardness is irremediable. That caused by the carbonate may be removed by adding a given amount of lime to the water. But it would be useless to put it in the well. The mode of procedure to be adopted would be the following:—Having found by experiment the amount of calcic carbonate contained in the gallon of water, place the quantity of water required for daily consumption in a tank. For every part, per gallon, of carbonate, which the water contains, add three-quarters of a part of fresh slaked lime. Allow the whole to stand some time before using. The tank will require cleansing from time to time to remove the deposit of chalk which will form.—S. BOTTONE.

[12380.]—**Light.**—That outside the room will be kept out, that inside the room will be dissipated and become heat. The querist must not forget that light is not an entity but a mere "mode of motion."—H. P. H.

[12380.]—**Light.**—Light is caused by rapid vibrations; anything which lessens the rapidity of the vibrations, or stops them altogether, lowers the intensity of the light, or produces total darkness. As an exemplification, let us suppose that two adjoining tanks, full of water, communicate with one another by means of an aperture. Let the water in one tank be kept in agitation by stirring &c. The water in the other tank will also participate in the motion. Let us now close the aperture. The motion of the water in the second tank soon ceases. The same is the case with light, though, of course, as the light waves are inconceiveably shorter, so the duration of the light, after the communication has been cut off, is almost inappreciable. Still, the undulations do continue, as may be proved by the fact that on exposing a scarlet geranium to the full glare of the sun, and suddenly placing it in total darkness, it is still visible for a short space of time; id est, it still communicates vibrations to the eye.—S. BOTTONE.

[12380.]—**Light.**—If the stopper of the rays be black or dark it absorbs them, so that they become heat. If white or pale, it reflects the greater portion, and if dull or glittering, turns them in all directions, to fall on every object outside, and a proportionate quantity to the sky (if there be any clear sky) so as to pass out of our atmosphere and away for ever. Now if the stopper has a face of brilliant silver, the whole (except the little that it absorbs) will be thus sent out of our world, which will, on the whole, be so much the cooler than if these rays had fallen on any other material. See my reply to query 11809, p. 337.—E. L. G.

[12381.]—**Education.**—Let "Paterfamilias" write to the Provost, S. Nicolas College, Lancing, Sussex, for a prospectus of the schools in his scheme. I think one of them will suit him.—SACRISTAN.

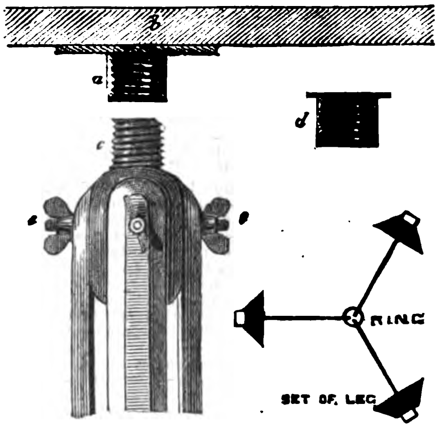
[12385.]—**Sulphur in Wall Papers.**—Ultramarine contains a considerable quantity of sulphur, hence is not adapted to colouring such papers as are to be used by jewellers, &c.—S. BOTTONE.

[12389.]—**Dirty Mercury.**—Tie the mercury into a piece of wash-leather, and force it through the pores by pressure between two boards. If the impurities come also, distil the mercury in an earthenware retort, and condense same in a flask. Pure mercury will not stain a barometer tube; a foul tube can generally be cleaned with warm hydrochloric acid.—PRIAM.

[12390.] — **Chemical.** — Roscoe's "Lessons on Elementary Chemistry" will meet "Home Student's" requirements. 1871 edition.—S. BOTTONE.

[12392.]—**Bee Management.**—The only safe way I can recommend "W. T. L." is to take the bees by stupefying them as he would do at "taking-up" time, but as the bees and not the honey seem to be the object "W. T. L." is desirous of saving, I should advise him to try chloroform and not brimstone, as the latter generally destroys life. "W. T. L." will find full instructions how to proceed with chloroform in No. 375 (answers to query 11762). After being placed in the box-hive, I should recommend constant feeding whenever it is dull or wet, as the season is getting on, and it is doubtful if they would get enough to keep them through the winter. If they are pretty strong, I should wait till end of this month, and then move about half or (say) 10lb. of comb into the box-hive with them for a winter supply; the combs may be suspended in the box by passing a stout bit of wire or small rod of iron through the middle of the box, unless it is a bar frame hive. This should, of course, be done while the bees are in a stupefied state.—BERKS FARMER.

[12393.]—**To Steady a Sketching Board.**—In answer to "Poloski," I presume that portability is the first thing to be desired. It is quite possible to get firmness if the supports to the drawing board are stout enough, such as a heavy tripod stand, like those used for levels, which, when closed, is about the thickness of a scaffold pole. Having been in a similar difficulty, I gave up the idea of perfect steadiness out-of-doors, portability being the first thing to be attained. I will describe the stand I made. It consisted of an ordinary tripod camera stand; the top portion above the leg junctions was fixed with a screw *c*, which acted with another *a*, fitted on the centre of under side of drawing-board *b*. This screw arrangement, if nicely fitted, will give all the needed firmness, supposing the board is not too large. Mine is 12in. by 16in. Then concerning the legs: the thumbscrews *e e* will, if screwed tightly before using, with the spikes at bottom, give firmness enough for all ordinary purposes. The other security that occurs to me is to have light iron wire stays to connect the legs at lower portion by screws and nuts, to take out and double up when not wanted (see small diagram), or the same purpose would be served by connecting supports by stout string.



Either of these contrivances will prevent the outward slipping. I do not believe that the camera lucida could be used with any kind of stand with much wind. An arrangement like this could be made more portable by doubling up at centre of legs by hinges, made firm for use by rings similar to those made for parasol handles.—A WORKING B.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "The Welsh Shepherd" has answered 11940, 11259; "S. M. B." 11962.

QUERIES.

[12430.]—**Automaton Chess Player.**—Will Mr. Meyer be good enough to send a copy of the article he put in the *Gentleman's Journal*, as it cannot fail to interest all "our" readers who are chess players?—WILLIE SCORER.

[12431.]—**Bees.**—Would some one be kind enough to tell me the best way to take a hive without destroying the bees? as I have, in former years, been in the habit of burning sulphur in the hive, which not only killed the bees, but gave the honey a bad taste. Also, whether I must take all the honey out of the hive, and whether a second or third swarm would be likely to live over winter?—WILLIE SCORER.

[12432.]—**Testing Beer and Spirits.**—Will some correspondent inform me how to test the strength of spirits and beers properly; and the price of the cheapest apparatus used for that purpose?—J. W. F.

[12433.]—**Pie Heater.**—I have got a tin case to make same as those used in the London pie shops. Will some kindly reader give me such instructions as will assist me, say if hot water is used, and how the steam escapes, and if the water is kept hot with a gas jet, &c.?—A COPPERSMITH.

[12434.]—**Castings.**—Has there been a heavier casting cast at Bolton than at Sheffield or Newcastle? or can some one say where the heaviest casting was cast, and where the next heaviest was cast, and what purpose they were for?—J. WATSON.

[12435.]—**The Dragon-fly.**—A few particulars concerning the natural history of the dragon-fly, in a microscopical point of view, would be of interest to the subscriber, and no doubt to many other readers. I have lately been working upon the ovipositor, which makes a beautiful object for the microscope. Besides other features worthy of notice, there are two pairs of saws, somewhat resembling those of the saw-fly, and which show very beautifully when carefully prepared and mounted in balsam. What I should like to know is, the use of these saws, seeing that the insect deposits its eggs on the surface of water. The structure of the end of the male dragon-fly's body is also very curious. Any information or reference to authors who have written on the dragon-fly would be acceptable.—J. FORD, Stamford.

[12436.]—**Chromo-Lithography.**—Can any one give the entire process, and confer a great favour on a great many subscribers?—H. B. E.

[12437.]—**Brickmaking Machine.**—In No 289 of "ours," there was an extract from an American paper describing a newly invented brickmaking machine. Will some one kindly say if the machine has been introduced to this country, and if it has come up to the merits claimed for it in the above mentioned article?—ANGLO CELT.

[12438.]—**Chess.**—Would some reader kindly give me a solution of the knight's move over the whole chessboard, beginning on one of the four centre squares?—MANTISSA.

[12439.]—**Working Plane Surfaces.**—Will some reader describe the method for grinding and polishing perfect plane surfaces? I want to construct an instrument that requires perfect surfaces for reflection. I have succeeded only partially. A reply will greatly oblige—R. ROBERTS.

[12440.]—**A New Oil Light.**—I noticed about five weeks since that a new compound oil light of intense brilliancy was introduced by a German gentleman at the Inventors' Society, London, being only inferior to the electric light. Can any of "our" readers enlighten me on the subject?—P. K. S.

[12441.]—**Ants.**—Can any of your readers inform me how I can destroy ants, which have taken up their abode under the ground floor of my house, and, like the children, they get to cupboards where any sweets are kept?—THOS. LETCHFORD.

[12442.]—**Indigestion.**—I am troubled with indigestion and, like "Aroma," I tried the Susquehanna remedy but did not derive much benefit. I also, by the advice of a doctor, tried quinine. Could any of "our" correspondents give me a remedy?—PUPIL TEACHER.

[12443.]—**The Tremolo.**—I am much obliged to "Fiddler" for his answer to query 12297 as to the tremolo on the violin; but I think he has misapprehended my question, as it was not the shake or trill I wanted information about, but the tremolo, marked by Spohr with a wavy line. It is produced by the trembling or quivering of the single finger which stops the note, not by beats of the next finger. It is, in effect, something like the "vibrato" in singing. What I want to know is how to get the finger to tremble or quiver on the note, as my fingers obstinately refuse to move in the required way.—CORELLI.

[12444.]—**Day and Night Telescope.**—What is there special in the construction of a day and night telescope, and what advantage has it over an ordinary telescope?—VIDEO.

[12445.]—**Rotten Silk.**—Being a silk smallware manufacturer, and having had a strike in the trade, I have had some looms standing some time with a little silk in. Now we begin to work them the silk is quite rotten and breaks badly, and my foreman tells me it is the dust that rots the silk, he has seen such cases before. Could you inform me if that is the case through your paper, so that in future I can guard against it. The silk is black, and was never covered, and, of course, got quite covered with dust.—ANXIOUS.

[12446.]—**Manganese Battery.**—I should feel obliged if your esteemed correspondents "Sigma" or Mr. Tonkes would give me some information as to the following:—A three cell manganese battery, which has been in action since March, 1871, suddenly stopped on Monday last. On examining the battery, I found that the binding screw attached to the carbon of the middle cell was wholly covered with a very dark green crust, which I had to file off; the others were comparatively clean; it was doubtless this which stopped the current, as when the connections were cleaned the battery tested well. Now, would the fact of the battery being put to earth at each end cause the connections to corrode in this way, as until I added another circuit to the battery (from the house to the stable in which I used the earth for the return wire) I had no trouble at all, the battery being in a dry place the connections were kept clean. The connections are made as follows:—A stout copper wire is soldered to the zincs, coated with sealing-wax varnish to within an inch of the end; the binding screw is let into a lead casting at the top of the carbon stick, and coated about an inch all round with melted rosin.—EDWARD HENRY.

[12447.]—**Employment for a Retired Tradesman.**—Having acquired about as much of the "filthy lucre" as will keep me out of the workhouse, I want something to do. Can any of your correspondents or readers assist me? The change from an active business life to one of idleness won't do, and to frustrate his satanic majesty from finding me a job, I should like a few suggestions as to what is best to amuse, instruct, and interest. My taste is just a bit scientific. Mechanics might develop by practice if I got a lathe. As I know nothing about one, which is the best? One adapted (if any) for polishing stones as well as ordinary turning, and about what should I give for one? A few joiners' tools, &c., which are most in use, in fact, if I dedicate one little room in my house as a workshop, how should I furnish it? This query will perhaps fit other poor devils in a similar plight to myself, or who may be some time—A RETIRED TRADESMAN.

[12448.]—**Wall Papers.**—In "ours" of 28th ult., there is an excellent article on poisonous wall papers, in which, I think, all colours are condemned. I should feel very greatly obliged if some one or other of our contributors would kindly let us know with what we should decorate our walls, and if all papers be poisonous what colours are the least dangerous. I am sure that many besides myself would be thankful for information on the above point.—JIGGER.

[12449.]—**Gnats.**—Any of your able correspondents will greatly oblige me by informing me through your columns what is the best remedy for gnat-bites. Also, the best preventative to being bitten at all by those noxious creatures.—CONSTANT SUBSCRIBER.

[12450.]—**Beehives.**—I think all who are interested in the management of bees are certainly very much indebted to Mr. Abbott for the timely advice and general good information he gives in your valuable columns about bees. There is a diagram of a hive in No. 350, p. 306, I want just to ask a question or two about. (1) Is this the kind of hive Mr. Abbott now uses in preference to all others, as he says he sells his old hives for a mere song? (2) Do the blocks or distance-pieces between the inner and outer case reach from bottom to top of hive, or only a block at the bottom and another at the top? (3) Are the notches at the top for the reception of the ends of bar frames cut out through both cases, or only the inner one? (4) How does he manage when he takes off the top of the hive to prevent the bees getting down between the inner and outer case?—S. R. S. B. G

[12451.]—**English Concertina.**—I have an English concertina by Prouse, brass vibrators, and screwed; three notes are gone flat. Will some clever correspondent of "ours" kindly tell me how to put it in tune? and how can I get at the inside screws?—T. W.

[12452.]—**Building on Sand.**—I should be glad to receive a suggestion as to the best mode of securing a good foundation for a house I intend building, the site on which it is to be erected being composed entirely of a bed of sand? Would it be safe to build upon the sand, or should some provision be made in the way of concrete foundation?—INQUIRER.

[12453.]—**Manganese Cell.**—I have made a manganese battery, making connections with the carbon by soldering a piece of platinum foil on the end of a piece of copper wire, and soldering the whole into a hole in the carbon, and well covering with wax, both the top of the carbon and about ½in. of the wire. I find (after four weeks) that the wire is now eaten in two. How can I remedy this? Will electro-plating a copper wire and soldering it into the carbon be sufficient as in a series solid platinum wire would be too expensive, as also would binding screws. I should be obliged by a description of a joint that could be made by an amateur, and is not too expensive? The battery is the best I have ever used? How does it answer for plating?—D. J.

[12454.]—**Southern States of America.**—Will any subscriber give me some information regarding the climate, mode, and cost of living in seaport towns of the Southern States—say in Savannah, Pensacola, or New Orleans—or name any work giving reliable information on the subject?—JAMES LARGON.

[12455.]—**Water Supply.**—Where can I find the chartered terms on which the East London Water Company supply water to consumers, if through meter to private houses as well as manufactories, price for quantities, pressure of supply, what control they (the company) may have over their water after it has passed the minute ferules they place in their street main, where the tenement branch leads out and there is no meter, and if there is any statement of uses to which such tenement's water may be applied while paying the usual household rates?—X. M. S.

[12456.]—**Fuel for Steam Engine.**—Will some reader of the ENGLISH MECHANIC inform me if the ordinary gas house coke saturated with coal tar would increase in value for heating purposes sufficiently to replace coal? It is required for a 4 horse-power steam engine. Would it be superior to equal proportions of small coal and coke? Ordinary house coals are selling here at 30s. per ton, which makes working a steam-engine rather expensive.—HORTI.

[12457.]—**Geometry.**—In a given triangle inscribe a rhombus which shall have one of its angular points coincident with a point in the base, and a side on that base.—W. M. COLLES.

[12458.]—**Blowing Apparatus.**—Wanted an apparatus for blowing air (similar to the "Bessemer" process) into a vessel 3ft. deep, and about 20in. diameter. Material, hot syrup. If any of our readers would kindly advise what is suitable, whether fan or air-pump, and what size, they will confer a very great favour upon—SIMPLEX.

[12459.]—**Bending Laths.**—Would "Jack of All Trades" or any other gentleman be kind enough to tell me the best and simplest way to bend laths 1½in. to 2in. wide × ⅛in. thick?—R. M.

[12460.]—**Four-valved Cornet.**—Will some correspondent be so kind as to give me a scale for a cornet or flugelhorn with four keys?—H.

[12461.]—**Threads in Gas-pipe.**—Will any of your correspondents inform me of the "number of threads" contained in an inch of gas-pipe from ⅛in. to 2in. diameter, and the same particulars respecting the "brass thread?"—A SUBSCRIBER.

[12462.]—**Electrotyping.**—I have several plaster-of-Paris casts, taken from medals, about a quarter of an inch thick. Will some one kindly tell me how to make guttapercha or wax moulds from them for electrotyping? They have no rim to prevent the melted wax from running off. Should the plaster be oiled before pouring the wax on? Also, I should be glad to know how to lay the blacklead on my wax and guttapercha moulds. I generally use a soft camel's-hair brush for the purpose, but it makes the blacklead stick in some places and not in others.—GLATTON.

[12463.]—**Vision.**—Can "M.R.C.S." or some other correspondent explain to me the most probable cause of the inversion of the images depicted on the retina? It is clear that after the rays pass through the crystalline an inverted image is thrown on the retina, and yet we see objects in their right position. I know of two reasons —(1), that it is by a regular education of the eye, the visual impression being corrected by touch, &c.; (2), that as we see everything inverted, nothing appears inverted, as there are no terms of comparison. I should like to know which of these theories is the best, or if there is any other.—H. SCIENCE.

[12464.]—**Aquarium.**—Can any friend say what is the cause of the water becoming white in a glass globe in which I have a goldfish? One day the water is nearly white; the next day whiter still, but just the same as if I had put water in a dirty milk-jug; on the third day I can't see the fish through the glass and water, and then I find the fish dead.—E. FOWLER.

[12465.]—**Compound Eyepieces.**—I return many thanks to "A Fellow of the Royal Astronomical Society," Mr. Proctor, Robert Thomas, and William Oldfield, for their kindness in replying to my queries. If I might trespass a little mere on their good nature, I should like to know the way to ascertain the magnifying power of compound eyepieces. I know that with a single lens eyepiece the power is as many times as the object-glass exceeds the eyepiece in focus, thus a 1in. eyepiece with a 48in. object-glass will magnify 48 times. But I do not know how to tell the power with a compound, such as the Huygenian or Ramsden that has a field-glass and eye-glass, or a terrestrial with four lenses, by what rule is their power computed?—C. B.

[12466.]—**The Harp.**—Would "Ixion" (letter 4468) through "our" journal send the length of pole and each octave string; diagram of string plate, and description of soundboard, of his wire-strung harp?—EAST-END MECHANIC.

[12467.]—**Nitrate of Soda.**—Will "Soda" be kind enough to inform me the cheapest way and best time to buy a large quantity of nitrate of soda, say a small cargo? Would now be a good time to do so? The retail price has been this season as high as 17s. 6d. per cwt., and yet at that price it is the cheapest manure which a farmer can buy.—S. BROWN.

[12468.]—**Exhibited Inventions.**—I have heard somewhere that inventions about to be exhibited for the first time at one of the International Exhibitions can, on payment of a registration fee of a few shillings, be protected for the period the exhibition lasts. Will any brother reader oblige by giving some reliable information about this?—ZURICH.

[12469.]—**Bees.—How to Get a Swarm.**—Is there any means of making bees swarm, or of separating a swarm? My bees swarmed 2nd May, and have hung out for this last month, but do not cast a second swarm. One of our friends some time ago told us (through the MECHANIC) to turn up the stock hive and place another over it and drum them up. I should like to hear Mr. Abbott's opinion on this plan before I try it, as I can't understand how the new stock thus formed gets on for a queen.—F. J. GODDEN.

[12470.]—**Separating Salts Produced from Kelp.**—Will "Analyst," Mr. S. Bottone, or any of your correspondents, inform me how I can separate the various salts produced from kelp? The salts I wish to separate are chloride of potassium, carbonate of soda, and sulphate of soda, which are produced in the first evaporisation of the kelp liquor. I believe that the sulphate of soda could be crystallised out in the cold. If caustic lime were added to the liquor, would chloride of lime be precipated, caustic potash and bicarbonate of soda be produced, and if so, could they be separated? Any information relating to the above will oblige—A TYRO.

[12471.]—**Wheels.**—Could any one of "our" readers tell me which are called the "face arms" and which the "back arms" of a wheel?—FALSTAFF.

[12472.]—**Electrical.**—Would some kind reader answer the following queries?—1. What is the reason that an ordinary "shocking coil" does not deflect a galvanometer? 2. What coil is the best to use for medical purposes, and how do they differ from the "shocking coil"? Are the "magneto-electric machines" of greater medical value than the various coils in use? 3. What kind of battery is the best to use for coils where they are required to be left for some days without alteration or pulling to pieces, that is, always ready for action?—MEDICAL.

[12473.]—**Printers' Rollers.**—I shall feel extremely obliged to any member of the printing profession who will be kind enough to inform me the best mode of casting rollers.—A TYRO.

[12474.]—**Machine for Making Aerated Drinks.**—In letter 4406, p. 380, "H. B. E." submits a sketch of a machine for making aërated drinks. I like the plan very much—the bottling and corking machine attached, also the little space which is required for its working, and the generator which is attached to it. "H. B. E." will oblige by answering the following questions:—(1) How is the machine worked—can it be worked by steam? (2) Is the water and gas pumped into the condenser together by one pump or plunge? (3) What will be the cost of the machine to make 1,500 bottles per day.—E. L. P. G.

[12475.]—**Removing Whitewash.**—Will some reader of your columns kindly inform me how to remove whitewash from the *face* of stonework and woodwork without scraping or reducing the surfaces, portions of which are carved?—S., Colombo, Ceylon.

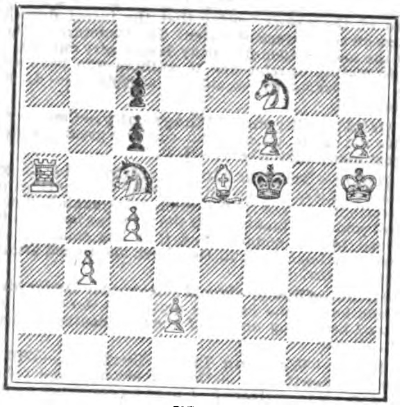
CHESS.

ALL communications intended for this department to to be addressed to J. W. ABBOTT, 7, Claremont-place, Loughborough-road, Brixton, S.W.

The feudal age appears to have been the high and palmy era of chess, which, with music, was then considered as indispensable to the formation of an accomplished knight as skill in arms. In later times, the loftiest minds of their day, including kings, statesmen, and philosophers, have not disdained to resort to it as a relaxation from grave cares. The scroll of history, rich as it is in instances, can point out no stronger or more eloquent moral to that sin by "which fell the angels," than the stern Corsican bound to his desolate rock, and playing chess for the dear life, to stun the gnawings of his twin devouring vultures—fallen pride and blasted ambition. The genius of chess, moreover, is essentially catholic and universal, taking no account of religion, politics, or country. Mankind from India to the far North—the swarthy Hindoo and the pale-faced Scandinavian—alike practise it with the same keen relish and enthusiasm. Its resources, indeed, seem to be inexhaustible; custom cannot "stale their infinite variety." Like the kaleidoscope, it continually gives out fresh forms of changing beauty; the veteran amateur, who has grown gray in the exercise of its stratagems, experiencing as much interest in the pursuit as the novice who is acquainted with barely the moves.—*Captain Kennedy.*

PROBLEM VII.—BY J. PIERCE.

Black.



White.

White to play and mate in three moves.

SOLUTION TO PROBLEM VI.

White.	*Black.*
1. Q to K 4	1. Anything
2. Mates, acc.	

TO CORRESPONDENTS.

T. J. MILLER (Faversham.)—In a problem the mate must be effected in the stipulated number of moves against the best defence Black has at his command. If it admits of a solution in a fewer number of moves, the problem is clearly faulty.

E. T. (Grays.)—Philidor's "Legacy" is a well-known position, but hardly of sufficient interest for reproduction in our columns.

R. A. PROCTOR.—The problem, as amended, is considerably improved, both in design and construction. It shall shortly appear.

G. SLATER.—In order to prevent any further mistakes, have the goodness to submit the problems with which you have favoured us on diagrams.

A. W. COOPER.—We have mislaid your address. Please forward it again, as we wish to communicate with you.

J. KLING.—The problem in four moves is an elegant composition. The remaining two we have not yet examined, but doubtless they are equally good.

ARGO (Yarmouth.)—Problem I. can be solved by 1 R to R 8, &c. Problem III. is also wrong—

$$(1)\ \frac{\text{Q to Q sq.}}{\text{P R 4}}\ (2)\ \frac{\text{Q takes P}}{\text{P Q 3}}\ (3)\ \frac{\text{P Q 3}}{\text{anything}}\ (4)\ \text{mates.}$$

Problem II. is seemingly correct, and rather a neat idea. In order that it may be further examined, forward it afresh on a diagram.

G. WHITFIELD.—A report next week.

J. NEVILLE and S. N. BARKER.—Compare the published solution.

CORRECT solutions to Problem V. (continued).—M. L. Marks (Swansea); J. H. A. H. (Chester); Wiseaf (Dulwich); S. H. H. (York).

CORRECT solutions to Problem VI. have been received from E. T. (Grays); R. A. Proctor; G. Slater; J. E. (Lincoln); Rorie; G. Keller (Warrington); W. Airey (Worsley); C. Yeo (Paignton); A. Cunnington (Devizes); B. T. G. (Accrington); Wiseaf (Dulwich); C. J. L. (Portsmouth); J. H. A. H. (Chester); Theodore Fawsett (London); William Cook (Penge); A. W. Cooper. All others are wrong.

Hatfield.—Putty.—A, Liverpool.—E. L. G.—C. B. H.—Near-sighted.—Humming Bee.—Wm. Black.—F. R. A. S.—Spinning Top.—Ed. M. Marshal.—H. Weldon.—Saul Rymea.—E. M.—O. P. Q.—Five Years' Subscriber.—R. A. Proctor.—Clinchey.—Book-Keeper.—J. T. Routh.—Mostyn.—P. H. Stacey.—Communicator.—W. H. H. Cooper.

A READER, Tonbridge, and "Lollipop."—Advertise.

VERTUMNUS.—Your letter on Noah, his predecessors, and successors, would lead us slap into a Biblical controversy. Its insertion would give "E. L. G." a reason for writing more than one letter.

O. B. M.—Rather too fantastical.

JOHN MITCHELL AND SON.—We have no terms for inserting illustrations and descriptions of patented inventions. We never made and never intend to make any charge for anything that goes into the body of the paper.

J. W. DAWSON.—Consult a physician.

CHARLES COLLINS AND G. E. L.—Your communications are advertisements.

J. SNELLGROVE expresses a hope that some papers on elementary mechanics will soon appear in the ENGLISH MECHANIC. Is J. Snellgrove aware that a series of papers on this subject appeared in the ENGLISH MECHANIC—by the Rev. E. Kernan—about eighteen months since?

J. M. B.—You advance too far on forbidden ground for our columns. Should be glad to hear from you on some more practical subject.

AMATEUR PHOTOGRAPHER, L. Newton, J. W. E., W. L. Warren, A Jones, A. S. Lewes, Orlando Hank, T. M'Gregor, Geo. Earnshaw, Johan, R. Owen, Zakynthos, and Subscriber are referred to indices to back volumes.

R. TANSLEY.—Another correspondent satisfactorily disposes of "G. W. K. D.'s" remarks, so there is no need to insert your sketch. We should be glad to receive sketch and description of the other machine you refer to.

Communications which can only appear as advertisements to hand from Private Student, T. H. (Camberwell), Zinc, A. A. F., W. Ward.

INQUIRER.—Consult a surgeon.

A PATTERNMAKER.—Wash them daily.

A MEMBER.—Both matters for a medical man.

J. W. (Leeds).—For your first query try carbolic acid soap.

S. I. G.—Thanks. See "Hints to Correspondents."

JOHN GAVIN.—Recipes for making blacking have been frequently given. The only way of competing with the large manufacturers is to be contented with less "profit," unless indeed, you discover a new process by which you can make blacking cheaper than they can. It stands to reason that its manufacture on the large scale, where all the ingredients are bought at first hand, must cost less than it would in a "moderate way." It would be useless to insert the query as you put it.

AB INITIO.—For "silk solvents" see p. 286, Vol. XI.

H. W. F.—You will find information on electro-gilding, silvering, and plating generally in Vol. XIII., pp. 342, 369, 393, 471, 496, 498, 549, &c.

PHILO.—Your letter headed "Rude Personalities" would add fuel to the fire. You accuse several well-known and highly valued correspondents of "rudeness" and "cowardice." Can you not see that if such a letter were inserted it would inevitably call up stinging retorts? You complain that we do not insert your several replies to personal attacks. If we did, the evil you complain of would be materially aggravated. You say "I have no objection to being attacked *if allowed to reply*, and would far rather be laughed at than have no laughing at all, but prefer laughing at others." Is it not best to go to the root of the matter, and, if possible, say what you have to say in such a manner as to give no one an opportunity of attacking you or laughing at you at all?

READER, Tip. O., R. A., and James White.—Your queries, &c., are advertisements.

G. W. BACON AND CO.—We have already described the Beckwith Sewing Machine, and have no more space to spare for the purpose at present. All suggestions as to being "permanent advertisers" are respectfully repudiated.

ERRATUM.—In the article on Chemical Physiology, "lymphatics" (p. 422), by a slip of the pen, was written for "lacteals."

A. W. J. C.—You will find your query about an electric kite answered on p. 364—so recently as June 21!

SPINNING TOP.—J. M. Taylor says: "The explanation I gave in the latter part of letter 4510 needs correction. The theory presented itself to me but a few hours before I noted down the reasonings in that letter. These are therefore but crudely stated, and with your permission I will forward a concise and corrected statement for next week's issue."

PLATO.—J. W. Durrad says: "In my drawing (let. 4474, p. 411) your engraver has inserted a spot in the inner shadow. I do not think I put one in my sketch, and certainly did not see one. Neither is the shading on the floor shown. I thank 'F.R.A.S.' for his excellent tests. I will examine them on the earliest opportunity, and (with your permission) send results."

JACK OF ALL TRADES.—Yours next week.

E. J. T.—Your letter is too dialectical. Why not discuss in moderate space the essence of things, and not use so many words about words.

JOHN BAYNES.—See "Notices to Correspondents," No. 6.

M. P. STUDDY.—You had better put the matter in the hands of the police, as we are constantly receiving such complaints as yours. We will not let the person you complain of advertise in our columns, but we cannot prevent him answering advertisers. Correspondents and advertisers should be more particular in parting with goods or money. We have repeatedly cautioned them.

OCEANIC CIRCULATION.

In Two Parts.

BY RICHARD A. PROCTOR, B.A., HON. SEC. R. A. S.
Author of "The Sun," "Light Science," "Essays on Astronomy," &c.

PART I.

THERE are some questions, seemingly innocent enough, which yet appear fated to rouse to unusual warmth all who take part in their discussion. One cannot, for instance, find anything obviously tending to warmth of temper in the telescopic study of a planet; yet the elder Cassini was moved to passionate invective by certain observations of Mars not perfectly according with his own; and Sir W. Herschel, usually so philosophic, was roused by Schröter's recognition of mountains in Venus to deliver himself of a criticism justly described by Arago as "fort vive, et, en apparence du moins, quelque peu passionnée." The question, again, whether the 'Eozoon Canadense" is a true "Rhizopod," though not altogether removed from the region of hard words, might appear to be unlikely to excite war-like emotions; yet there has been some very pretty fighting over it. The solar corona has in like manner given occasion for rather strong writing; and if, on the one hand, the supporters of a lately-abandoned theory said of their opponents that "they made themselves ridiculous," these, in their turn, at times used a tone reminding one of the scholar who said of a rival, "May God confound him for his theory of the Irregular Verbs:" yet the corona seems at a first view rather calculated to produce a sedative effect than to excite unphilosophic wrath. The subject of oceanic circulation would appear to belong to the class of questions here considered. The very name of the Gulf Stream is to some physical geographers as a red cloth is to a bull. Even Sir John Herschel, usually placidity itself, was moved when he spoke on this point. But, though he and Maury grew warm enough in its discussion, their warmth was ice-cold compared with the fire of more recent disputants. We have before us the latest contribution to the subject, a rather ponderous essay in one of our leading quarterlies; and herein we find pleasing references to the "stupidities" of one set of opponents, the "shallow nonsense" of a second, "the wrong-headedness" of a third, with other similar amenities. More than once during the progress of this controversy the gentle public has been reminded of Bret Harte's remarks

> . . . . . about the row
> That broke up the Society upon the Stanislow;

and has been inclined to urge with "Truthful James," that they

> Hold it is not decent for a scientific gent
> To say another is an ass,—at least to all intent;
> Nor should the individual who happens to be meant,
> Reply by heaving rocks at him to any great extent.

The controversy has not, indeed, reached this last stage of development, and we trust it never will; but it has gone so near to it as to suggest that the disputants have wished to demonstrate, by example, the justice of Darwin's theory about the human "snarling muscles." *

*"He who rejects with scorn the belief that the shape of his own canine teeth, and their occasional great development in other men, are due to our early progenitors having been provided with these formidable weapons, will probably reveal by sneering the line of his own descent. For though he no longer intends, nor has the power, to use these teeth as weapons, he will unconsciously retract his 'snarling muscles' (thus named by Sir Charles Bell), so as to expose them ready for action, like a dog prepared to fight."—Darwin's "Descent of Man," Vol. I., p. 176. We may mention, by the way, that an instance has recently occurred, in which the human teeth were used to some purpose against one of the recognised masters in the art of biting. A man, proceeding in company with several others through a wood, was attacked by a hyena (usually one of the most cowardly of beasts). His companions fled, and having no weapon he was reduced to the necessity of showing tooth for tooth, and taking a good grip of the hyena's nose, he compelled that gentleman to howl with anguish. On this, the man's companions returned, and presently beat the hyena to death.

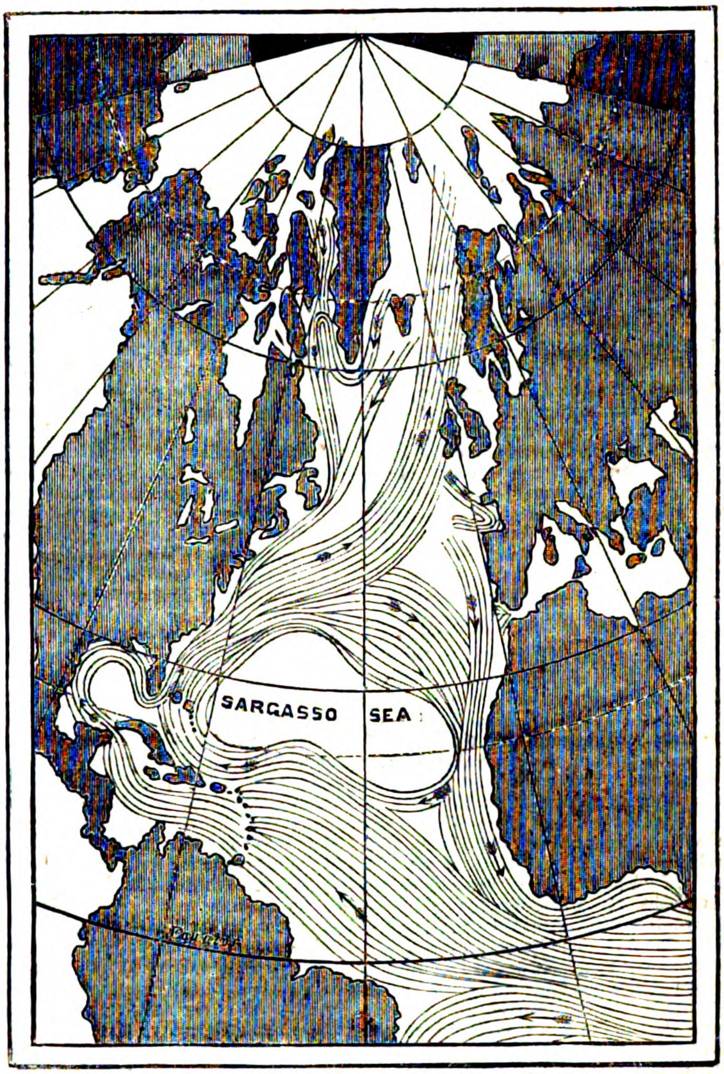
I propose to inquire into the subject which has been thus warmly discussed, trusting not to be myself inveigled by it into any warmth of expression. Indeed, but for the fate of others, I should feel no anxiety on this point, though I have myself a favourite theory to uphold respecting one branch of the subject. As it is, I share something of the feeling of the Red Cross Knight when he was approaching "Foul Error's den," and his monitress said to him "The perils of this place I better wot than thou; therefore I rede, Beware." I am not without hope, however, that I may be able to keep my snarling muscles quiescent.

I shall direct attention chiefly to the Atlantic currents, as being those whose real direction and extent are best known, and those, moreover, whose characteristics are most important to European nations.

Let us begin with the surface currents, and though the system of surface circulation can scarcely be said to have a real beginning, let us start with the great equatorial currents which flow westwards from the Gulf of Guinea,* or more correctly from the Bight of Biafra. We speak of the westwardly equatorial *currents*, because not unfrequently there is an equatorial eastward current running between two much more important *tropical* westward currents. Yet ordinarily there is one great westward current running in an unbroken stream from equatorial Africa to the shores of Brazil, and even when this great current is divided into two by an eastward current this last is only to be regarded as a sort of "backwater." The water moving westwards is relatively cold, more especially on the African side of the Atlantic.

The accompanying map exhibits the nature of the surface circulation of the North Atlantic. It is constructed on one of the forms of equal surface-projection described in my "Essays on Astronomy," and has the advantage over the ordinary Mercator's charts of exhibiting the true

* Along the *shores* of the Gulf of Guinea there flows an easterly current, several degrees warmer than the equatorial current.



dimensions of the various currents. I would, however, invite the student who wishes to familiarise himself with the true nature of the Atlantic currents to construct other maps; for instance, a polar map on the first method of equal-surface projection described in that essay, and a map of the whole Atlantic on the second plan, taking the meridian 40° west of Greenwich as the central one.

Of the water carried westwards by the great equatorial movement, the most important portion after reaching Brazil is carried northwards towards the West Indies. The reason of this is obviously to be found in the fact that Cape San Roque, forming the jutting angle of Brazil, lies several degrees south of the equator. The portion carried southward forms the Brazil Current, and after travelling along the shores of South America almost as far as the mouth of the La Plata, acquires gradually an eastwardly motion which eventually carries it back across the Atlantic towards the Cape of Good Hope, there to pass northwards and so again to traverse the Bight of Biafra. The surface-circulation in the south Atlantic is thus seen to be comparatively simple

The larger portion of the equatorial current is carried less quickly northwards, because the northern shore-line of Brazil and Guiana is inclined at a much smaller angle than the south-eastern to the westwardly course of the great equatorial currents. Thus the water which is carried towards the West Indies has time to acquire under the tropical sun a much higher temperature than it had possessed when traversing the Gulf of Guinea. It is divided into two parts by the *quasi*-barrier which the West Indian Islands (or rather the semi-submerged mountains of which they form the crests) oppose to its progress. A comparatively small portion finds its way into the Caribbean Sea, and making the circuit of the Gulf of Mexico, passes out eastwards round the peninsula of Florida. We may fairly assume that this portion *is* comparatively small; simply because this true gulf stream, passing between Cuba and Florida on an eastern course would continue so to move for at least some considerable distance, were it not in some way deflected. But it actually turns almost due northwards after passing through the Bahama Sea, traversing the Bemini narrows on this course, and so onwards towards Hatteras. This would seem to imply that the true Gulf Stream is pressed northwards by the arrival of a much larger body of water which has travelled outside the West Indies. It is true that the diversion of the Gulf Stream northwards may be really caused by the Great Bahama Bank. But this would equally establish our position; for if the Bahama Bank is thus effective in diverting the whole of this now swiftly moving current, the Windward Isles may be assumed to be correspondingly effective in diverting the greater portion of the sluggish equatorial current. Moreover, if we remember how shoals commonly take their origin, we may consider that the very existence of the Bahama Bank is probably due to the former encounter of the two important branches of the equatorial current—the part which had circled the Gulf of Mexico and the part which had travelled outside the West Indies. Thus, the northerly course finally taken by the Gulf Stream implies that the latter portion had prevailed over the former, and, therefore, that it is the most considerable portion. I must mention, however, that the Edinburgh Reviewer holds the part which enters the Caribbean Sea to be the larger.

Be this as it may, the Gulf Stream proper has acquired, during its circuit, characteristics perfectly distinct from those which it had had when entering the Caribbean Sea, or from those possessed by the remaining portion when approaching the Bahamas. In the first place, having traversed a much longer course under the same intense tropical heat, the Gulf Stream has become much warmer than the outer stream. In the second place (probably from having traversed the outlets of the Mississippi, and so carrying with it the finely-divided matter brought down by that river), the Gulf Stream has acquired a peculiar blue colour, somewhat resembling that recognised in most of the Swiss lakes.* Thirdly, its course having carried it into narrow channels, it has required a relatively rapid rate of outflow, insomuch that the surface flow of the current on its outward passage through the narrows of Bemini, takes place at a rate of from $2\frac{1}{2}$ to 4 miles per hour. Its width here is at the surface not more than about 25 miles, its maximum depth rather more than a quarter of a mile (about two-fifths of the channel's maximum depth), and its mean rate of flow probably about 3½ miles per day.

I shall not follow the Edinburgh Reviewer in considering the details of the progress of the Gulf Stream from the Narrows of Bemini to Cape Hatteras, because, though in themselves of the utmost interest and importance, these details throw no special light on the general subject of oceanic circulation. Suffice it that as far as Hatteras the Gulf Stream remains distinctly recognisable, and that even off Sandy Hook (New York) its surface temperature is little reduced, and its velocity still amounts to about one mile per hour. Off Nantucket the breadth of the current is about 410 miles, its winter surface temperature only 10° below that which it had in the Florida Channel, and its rate of flow still nearly one mile per hour. It has at this part of its course acquired a good deal of easting, a circumstance which must (unquestionably, we conceive) be ascribed to the fact that it brings from low latitudes the more rapid easterly rotation movement of the earth. The same would, of course, apply to the less characteristic but larger current which has arrived at the same latitudes *without* circuiting the Gulf of Mexico.

Now here we approach a critical part of our subject. It is admitted by all that off Newfoundland the Gulf Stream loses its special characteristics. As Dr. Hayes remarks, "its strength diminishes; the air of a higher latitude brings its temperature down to that of the North Atlantic generally" (not, however, without raising the temperature of the North Atlantic to some extent); "the water loses all its Gulf Stream character as to course, warmth, and flow (and as to colour also); and it dies away into the sluggish Atlantic drift which sets from a westerly to an easterly direction." It is not so generally noticed, but will scarcely, I suppose, be disputed, that the Gulf Stream water strengthens, and that appreciably, this sluggish Atlantic drift. Then it is reinforced by the portion which has travelled outside the West Indian Islands; and we may assume (without giving rise to objections) that the general prevalence of south-westerly winds will further strengthen the eastward motion of the combined mass. At any rate, let the causes be what they may (and presently we shall have a further cause to take into account), it is admitted by all physical geographers that a great, though slow current, or drift, *does* pass eastwards from the neighbourhood of Newfoundland. Moreover, it is admitted by all that the southern part of this current (which the Edinburgh Reviewer actually regards as identifiable with the Gulf Stream*) traverses the Atlantic until, nearing the Azores, it joins the southwardly Guinea current; while the northern part passes on a north-easterly course, which carries it between Britain and Iceland, between Sweden and Spitzbergen, onwards, even as far as the very neighbourhood of Nova Zembla. Lastly, it is admitted by all that, directly or indirectly, this great north-easterly current causes the climate of Great Britain, and of the north-western parts of Europe generally, to be milder than that of North American regions in corresponding latitudes.

It might appear, then, that all these things being admitted, no question of any importance remains so far as the actual facts of the oceanic surface-circulation are in question. We shall presently see that a question has arisen as to the *cause* of the observed facts; but as to their *nature* everything that seems worth discussing at all appears to be satisfactorily disposed of.

Let those readers who in their simplicity have adopted this notion hasten to dispossess themselves of it by reading some remarks by Dr. Hayes, the American explorer, quoted with approval by the Edinburgh Reviewer. The latter having repeated from "Lothair" "a sneer at the shallow nonsense which has been talked about the Gulf Stream, and at the exaggerated estimates of its potency which have been put forward by men (as well as women) who ought to have known better" (these are the reviewer's words, not Mr. Disraeli's) proceeds as follows: "As Dr. Hayes truly remarks, 'Weather predictors without end have launched upon it their stupidities; meteorologists have deluged the world (*sic*) with their assumptions respecting it; theorists of all kinds have floated their notions upon it. One whirls it away into the arctic regions, and opens a passage to the pole with it; another compels it to give a climate to countries where otherwise there would be no climate worth mentioning; while still another spins it round the Atlantic Ocean, and its wide-spread arms close upon a stagnant sea. . . . Through means such as these mankind has come to look upon the Gulf Stream with a certain degree of awe. It is a "breeder of storms;" the giver of heat; it might become the father of pestilence. Will it always continue to do its duty as hitherto? or will it start off suddenly with some new fancy, and, pursuing some new course, upset the physical and moral status of the world?'"

Now we have seen that the writer who thus indorses Dr. Hayes's diatribe, is among those who hold that a southern offset from the Gulf Stream circles round the Sargasso Sea to join the Guinea current. He says farther on that he "entirely accords" with the opinion of Buchan, the meteorologist, that the north-easterly current above referred to produces "an afflux of warmth brought to the British Isles by the water that laves our western coasts." He proceeds, "There is ample evidence that the cold of some parts of the north polar area is greatly mitigated by an afflux of water bringing with it the comparative warmth of temperate seas. It has long been known that cocoa-nuts, tropical seeds, trunks of tropical trees, timbers and spars of ships wrecked far to the south, and sometimes portions of their cargo, are found on the shores of the Western Hebrides, the Orkney, Shetland, and Faroe Islands, the north of Norway, and even Spitzbergen; and since their transport has taken place just in the course of the Gulf Stream if prolonged to the north-east, their arrival has been accepted almost without question as evidence of its agency. The evidence furnished by the surface-temperature of that north-eastern portion of the Atlantic Ocean which intervenes between Iceland and the North Cape, and then stretches away to the eastward between Spitzbergen and Nova Zembla, seems at first sight conclusive to the like effect. A large amount of additional thermometric evidence has been collected of late years; and this has been most ably digested by the eminent German geographer, Dr. Petermann, who has recently put forward a series of maps for different periods of the year, in which these observations are embodied, and their results made obvious to the eye by the course of the "lines of equal temperature," which in the summer pass between Iceland and the Shetland Islands, a little to the east of north towards Spitzbergen, and thence with more of an easterly bend even beyond the seventy-fifth degree of north latitude. The existence of a warm stream in this direction has been confirmed still more recently by two adventurous officers—Lieutenant Julius Payer, of the Austrian army, and Lieutenant Weyprecht, of the German army—who followed its path last summer in a small sailing vessel hired by themselves, and state that they found open water from east longitude 42° to east longitude 60°, even beyond the seventy-eighth parallel of north latitude, the highest point they reached being north latitude 79°, in east longitude 43°. A Russian expedition under Prince Alexis Alexandrovitch, of which the distinguished *savant*, Von Mildendorf, had the scientific charge, was about the same time exploring the Polar Sea between Nova Zembla and Iceland; and Von Mildendorf has stated to the Imperial Academy of St. Petersburg that "the corvette *Waja*... has proved the extension of the Gulf Stream to the west coast of Nova Zembla, and that we find it on the meridian of Banin Noss (in east longitude $43\frac{1}{2}$°) still of a width equal to two degrees of latitude, and of a temperature of fifty-four degrees Fahrenheit, cooling down only four or six degrees at depths of thirty and fifty fathoms."

As if to remove all question as to his real opinion the reviewer immediately adds that he fully accepts, not only the great body of facts so "industriously correlated by Dr. Petermann, but the inference Dr. Petermann draws from them that an attempt to penetrate the polar ice-wall to the north-east of Spitzbergen is more likely to be successful than the search for a passage in any other direction."

So that (1) Dr. Petermann, regarded by our reviewer as an eminent geographer; (2) Von Mildendorf, whom he regards as a distinguished savant; and (3) the reviewer himself, who no doubt does not regard himself as either shallow or stupid, seem all agreed as to the very points which the reviewer has spoken of as involving stupidities and shallow nonsense. Certainly they all agree as to the only points which seem in the least worthy of discussion.

What, then, the reader will ask, is the matter in dispute? Over what momentous question have the angry words quoted above been bandied?

After diligent search for the apple of discord, the student of the review will be led to the conclusion that it is neither more nor less than the *name* "Gulf Stream." We have seen that Von Mildendorf calls the warm current which passes by Nova Zembla the Gulf Stream. In this, it appears, he has shown shallowness and stupidity. Dr. Petermann has equally committed himself, or, rather, has committed a more serious offence. For Von Mildendorf might have used the offensive epithet only through inadvertence; but Dr. Petermann not only uses it, but has the hardihood (we might almost say the cruelty) to maintain that "it is a matter of no consequence." Moreover, as our reviewer sadly admits, "other physical geographers" agree with Dr. Petermann.

The reviewer is so grieved by the defection of the "distinguished savant," the "eminent geographer," and "the other physical geographers" that for a moment his confidence deserts him, and instead of applying afresh to them, directly, the lash which has indirectly reached them, he proceeds thus mildly: "In our *belief*, of which we shall presently explain the grounds, the *real* Gulf Stream has no more to do with the inflow into the polar area, than with the ripening of oranges at Naples, or the maintenance of Catholicism at Rome, so that, even if its current were to be

* This explanation of the colour of the Gulf Stream seems the best that has hitherto been offered. The *Edinburgh* reviewer thus states the matter:—"The remarkable blueness which distinguishes the water of the Gulf Stream from the oceanic water through which it flows may be due to its retaining in suspension the finest of the sedimentary particles brought down by that river, the coarser having been deposited near its [the river's] mouth; just as the intense blueness of the waters of Lake Geneva depends on its retention of the finest sedimentary particles brought down by the Rhone in the upper part of its course, while that of the waters of the Mediterranean is due to its pervasion by the like particles brought down by the Lower Rhone and other rivers, which discharge themselves into its western basin, and by the Nile in its eastern." It will be remembered that Prof. Tyndall, by researches carried on during the return of the *Urgent* from the eclipse expedition of 1870, was enabled to threw considerable light on the cause of the colour and shades of colour in water at greater or less depth. See also Dr. Carpenter's "Report of Researches in the Mediterranean," in the "Proceedings of the Royal Society," Vol. XIX., p. 200.

* He says that the great equatorial current is partly supplied "by the return of a portion of the Gulf Stream."

entirely diverted by the cutting of a wide channel through the Isthmus of Panama, not only would the climate of the British Islands suffer very little, but a north-easterly stream of warm water . . . would still mollify the severity of polar cold, and help to render Spitzbergen and Nova Zembla accessible to arctic voyagers." This belief, in which I cordially concur, would seem to afford excellent reason for rejecting the name Gulf Stream whenever the course of the stream shall thus have been diverted, but scarcely seems to justify the disuse of the name under the actual circumstances; still less would it appear to afford good grounds for using such hard words as "shallow nonsense" and "stupidity." If the course of the Danube were intercepted in Baden, it is tolerably certain that a mighty river would continue to flow past Vienna, Belgrade, and Ismail to the Black Sea; nor would the noble river which flows northward through Germany be much reduced though the Rhine were diverted in the Grisons: yet geographers are satisfied to call these rivers the Danube and the Rhine, not adopting new names at every stage where some new influx changes the size and character of either. And the title "Gulf Stream" has, in like manner, advantages in point of convenience, which are likely to prevent geographers from rejecting it yet awhile. It may mislead some few into supposing that the whole of the great north-easterly current has passed through the Gulf of Mexico, just as we can conceive that some few students of geography might imagine all the water which flows past Cologne, or Coblentz, to have come from the Grisons, or all that flows past Nikopolis to have come from Baden. Almost every convenient name however, is open to some such disadvantage; and the student of oceanic circulation who finds he has been to some degree misled by a name must not mistake the detection of his error for a great geographical discovery.

Majora canamus.

We have hitherto considered surface-currents only. We have not, indeed, considered all the surface-currents which traverse the North Atlantic; but the principal streams have been indicated. We must now direct our attention to submarine currents.

(*To be continued.*)

THE MUSEUMS OF LONDON.—I.

THE MUSEUM OF PRACTICAL GEOLOGY.

THIS institution is situated in Jermyn-street, S. James's; and incorporated with it in the same building are the Royal School of Mines, the Office of the Geological Survey, and the Mining Record Office. It originated in a suggestion made to the Government by Sir H. T. De La Beche, in 1835, that in the newly-instituted Geological Survey lay the means of collecting fossils, rock-specimens, &c., in illustration of the maps and publications of the Survey, and also the opportunity of bringing together practical illustrations of the arts and manufactures more or less connected with geology. The suggestion was adopted, and offices first set up at 6, Craig's-court, which, however, were speedily outgrown, and the present building was erected by Mr. J. Pennethorne, and opened in May, 1851, by H.R.H. the Prince Consort. The School and the Record Office are subsequent outgrowths of De La Beche's idea; it has lately been proposed by the Royal Science Commission to separate the School and Museum, but no further action has yet been taken. The institution, as well as the survey, was first placed under the direction of De La Beche, the founder, at whose death they passed to the late Sir R. Murchison. Professor Ramsay has succeeded Sir Roderick as Director General of the Geological Survey, and the post of director of this institution is attached to that office.

With regard to the School, the names of such men as Owen, Tyndall, Huxley, Frankland, Ramsay, Percy, &c., who are, or have been, professors, are sufficient proof of its high standard. The Museum aims at setting before the public the economic value of geological knowledge, the principles of obtaining and utilising those mineral productions which are so important to us, and also of affording to the student as complete an illustration as possible of the geology of the United Kingdom. Under these circumstances, it is surprising that the Museum is so little known, even among the people of London, while it is rarely found on the list of interesting places to be seen by country visitors. Many who hear of it regard it as a "dry" collection of old stones, and under this impression neglect the many objects of general interest which it contains. We recommend to all our readers who have the opportunity, and who have never yet visited it, to do so, and if useful, curious, or instructive natural objects have any interest for them they will not be disappointed. The Museum is opened gratuitously every day in the week except Sundays and Fridays; on Monday and Saturday from 10 a.m. to 10 p.m., on other days from 10 a.m. to 4 or 5 p.m., according to the season. It is also closed for a month from August 10th to September 10th.

The Museum itself may be described as consisting of one large oval room, lighted by means of a glass roof, and at night by gas-jets near the roof. The entrance leads first into a hall, connected with which is the lecture theatre, capable of seating about 600 persons. Having ascended to the principal floor, we see how the whole of the wall space is utilised by means of two narrow projecting galleries running round the greater part of the building, and having upright wall cases on the one hand and flat table-cases on the other. The palæontological specimens are, with one or two exceptions, confined to these galleries.

The building is a practical illustration of the application of geology to the arts, the materials being selected with a view to this end. The front in Piccadilly (being, however, without an entrance there) is of dolomite or magnesian limestone from Yorkshire, similar to that employed for the Houses of Parliament, but the difference in the state of preservation of the two buildings is very instructive. The front in Jermyn-street, where is the only entrance, is partly of the above stone and partly of red Suffolk bricks. The steps at the entrance are of granite, from Peterhead, and at the doorway is a slab of slate from Penrhyn. The pavement and steps leading into the hall is of Portland stone, the side walls of Derbyshire alabaster, while in the hall columns and slabs of serpentine are included in the walls. The floor in the centre of the hall is formed of a tesselated pavement surrounded by slabs of polished granite.

To the student of geology the Museum affords an opportunity (too often wanting to the town student) of seeing for himself specimens of the various rocks which form the crust of the earth, and of the fossils which they contain. Although the specimens exhibited are mainly such as are found in the British Islands, still they are so typical that they may well serve as specimens of universal geology. As a collection of British fossils this stands unrivalled, and as this department is in the hands of Professor Huxley, we may rest assured of its being arranged to the best educational advantage. The fossils are broadly classified in stratigraphical order, commencing with the Cambrian fossil in the end lower-gallery case on the left hand of the visitor as he enters the principal floor. On the floor of the room is a fine block of serpentinous limestone with remains of the Eozoön—the earliest known fossil—from the Laurentian district of Canada, and in a case near will be found a longitudinal section of the fossil, showing its arrangement in cell layers. There is a very fine collection of trilobites from the Silurian and Devonian rocks, and the carboniferous fossils (the vegetable remains being placed in the wall cases) are well represented. In each of the formational divisions there is a sub-classification into families and genera, and the majority of the specimens are marked not only with the generical and specific name, but also with the name of the bed and the locality where it occurs. In the recesses of the upper gallery will be found a fine collection of rock specimens, including an interesting collection of specimens exhibiting traces of glaciality, *e.g.*, striæ, &c., some of which, from the Permian beds, are adduced by Ramsay as proofs of the recurrence of glacial epochs. There is also a collection of volcanic products from Etna and Vesuvius, and a second collection of specimens (together with a model) from the district of the extinct volcanoes of Auvergne in France, affords an opportunity of convincing ourselves of the similarity of these products in (geologically) ancient and modern times. In this upper gallery is shown a small series of photographs of portions of the south coast of England, and we cannot but express our opinion as to the desirability of obtaining a complete series for the whole coast.

In the horseshoe series of cases on the principal floor is a splendid and showy collection of minerals arranged under the heads of the principal elements—carbon, sulphur, &c. This is, of course, not comparable for its completeness to the collection in the British Museum, but is probably, for that very reason, more likely to attract the attention of the general visitor. Extremely interesting in a metallurgical point of view is the very large collection of specimens of ores of the various metals, and in the table cases will be found numerous illustrations of the various processes connected with these, as well as the properties and uses of the products. Some articles, as swords, gun-barrels, &c., are shown in the different stages of manufacture, as are also cups and bottles in another portion of the building. One case is devoted to electrotype reproductions, including coatings of leaves, tubes of the pitcher plant, fossils, beetles, &c., with copper by this process.

But the economic value of the Museum is, perhaps, most strikingly displayed in the ceramic series. First of all there is a very complete collection of specimens of clay suitable for pottery from the various geological formations, and the manufacture in various stages of its progress is well illustrated. The series extends from the date of a Babylonish brick and Egyptian objects, through the Roman productions in our island, chiefly from Caistor, near Peterborough (where ancient kilns have been found), through the varieties of majolica and Palissy wares to the Staffordshire and Wedgwood productions of recent times. The institution is fortunate in possessing a good representative collection of Wedgwood's manufactures, including the copy of an antique vase. In two rooms at the opposite end of this floor will be found models of implements and machines used in mining and metallurgical operations.

On the floor of the hall are several cases containing cubical specimens (about 6in.) of the building stones found in this country, which were collected for the purposes of the committee appointed to select materials for the Houses of Parliament. A gigantic figure of Hercules is executed in stone from the same quarry whence was taken the stone for the Houses. Large polished pedestals of marble, and table inlaid with marbles, in various patterns are also placed here.

Such is a brief description of the main features of this Museum, and we think the aims of the projectors expressed in their address on the opening ceremony were not too high, that these collections might be made and "arranged with every reference to instruction, so that those interested might be enabled to judge how far our known mineral wealth might be rendered available for any undertaking they might be required to direct, or were anxious to promote, for the good or ornament of their country." W. H. W. T.

ASTRONOMICAL NOTES FOR AUGUST.

BY A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

THE right ascension of the Sun at Greenwich mean noon on August 1 is 8h. 47m. 37·3s., and his declination north 17° 53′ 50·7″. He will, therefore, be situated to the east-south-east of δ Cancri, and pretty near to the star in question. He rises in London on the 1st at 4h. 26m. a.m., and sets at 7h. 45m. p.m.; his rising and setting, in the same locality, taking place on the 31st at 5h. 12m. a.m. and 6h. 47m. p.m. respectively. The equation of time is additive (but rapidly diminishing) during the entire month. On the 1st, 6m. 1·14s. must be added to the time of apparent noon to obtain that which a properly regulated clock should show, and this, as we have said, decreases, so that on the 31st, mean noon is only 1·58s. in advance of apparent. The semi-diameter of the sun at the instant of his appulse to the Greenwich meridian on August 1st is 15′ 47·9″, and this will occupy 1m. 6·59s. of sidereal time (which is equivalent to 0·18s. less of mean time) in its transit. On the 31st the solar semi-diameter will have increased to 15′ 53·4″, but this will only occupy 1m. 4·42s. of sidereal time (convertible, as before, into mean time by the subtraction of 0·18s.) in its passage over the meridian. The sidereal time at Greenwich mean noon on the 1st is 8h. 41m. 36·14s.; and on the 31st, 10h. 39m. 52·79s.; the mean time at sidereal noon, or mean time of transit of the first point of Aries being 15h. 15m. 53·40s. and 13h. 17m. 56·18s. on those days respectively. Before dismissing this portion of our "Notes," we would invite attention to the curious fact that although Schwabe's period (for the present cycle) of maximum frequency of sun-spots has certainly passed, a supplementary maximum—if we may so speak—seems to be in progress just now; and groups of spots of great size, extent, and beauty reward the notice of the observer.

The Moon will be New at 9h. 45·6m. a.m. on the 4th; will enter her first quarter at 5h. 52·3m. a.m. on the 12th; be full at 8h. 53·3m. in the evening of the 18th; and enter her last quarter at 8h. 34·8m. on that of the 25th. She is 26·7 days old at Greenwich mean noon on the 1st, and 28·7 days old at the same hour on the 3rd. Then at noon on the 4th her age will be 0·1 day, and so on until the 31st, when it will, of course, be 27·1 days. At 2 o'clock in the afternoon of the 11th, Libration will bring an additional portion of her south-east quadrant into view, while at 8 in the evening of the 23rd the same cause will operate in the exhibition of more of her south-west limb. The Moon will be in conjunction with Mars at 10h. 36m. a.m. on the 2nd; with Uranus 10 minutes before noon on the 3rd; with Jupiter at 5h. 39m. a.m. the next day; with Venus at 7h. 15m. in the evening of the 4th; with Mercury at 2h. 10m. on the afternoon of the 6th; with Saturn at 3h. 50m. a.m. on the 16th; again with Uranus at 9h. 12m. on the night of the 30th; again, too, with Mars at 5h. 29m. on the early morning of the 31st; and, lastly, once more with Jupiter at 11h. 41m. the same night. Our notices of the separate planets will, however, show why these conjunctions will all be invisible.

Five actual occultations of, and four close approaches to, fixed stars by the Moon will occur during the month of August. Firstly, on the night of the 10th, at 9h. 43m., the Moon will pass quite close to 96 Virginis. Then, on that of the 12th, at 9h. 47m., λ Libræ will disappear at her dark limb, to reappear at her bright one (after the Moon has set) at 10h. 52m. On the evening of the 15th, at 7h. 50m., σ Sagittarii will disappear at the Moon's dark limb, reappearing at her bright limb at 8h. 53m. Again, on the 20th, just as 30 Piscium is rising, at 8h. 31m. p.m., it will be occulted by the bright limb of the Moon, reappearing afterwards at the dark limb at 9h. 28m. Subsequently, on the same night, at 10h. 8m., 33 Piscium will disappear at the bright limb; to reappear at the dark one at 11h. 11m. The Moon will pass quite close to B.A.C. 17 at 1h. 22m. in the early morning of the 21st. During that of the 22nd, at 2h. 5m., 26 Ceti will disappear at her bright limb, reappearing at the dark one at 3h. 1m. Lastly, at 2h. 43m. a.m. on the 24th, and 2h. 55m. a.m. on the 28th, she will be almost in contact (as viewed from Greenwich) with 38 Arietis and 5 Geminorum respectively.

Mercury is an evening star at the beginning of this month, setting on the 1st about 50 minutes after the Sun, from which he attains his greatest eastern elongation, 27° 19′, at 2h. 46m. a.m. on the 3rd, very evidently below our horizon. After this he of course approaches the Sun again, and sets sooner and sooner every evening, until he becomes invisible from his proximity to it. He will actually be in inferior conjunction with the Sun at 7h. 51m. in the evening of the 30th. His conjunction with the Moon at 2h. 10m. p.m. on the 6th has been already spoken of; and we may add that he will also be in conjunction with Venus at 2h. 53m. on the afternoon of the 23rd. His diameter will increase from about 7″ at the beginning of August, to nearly 10″ during the middle third of it; and during the commencement of the last half of the month he will be pretty favourably situated for observation in daylight. It is almost needless to add that an equatoreal is indispensable forfinding the planet under these circumstances.

Venus having (as stated last month) passed her superior conjunction on the 16th of July, is now travelling eastward, and is an evening star. She, however, only subtends an angle of some 10″, is very nearly round, and is, altogether, a very unsatisfactory telescopic object. She sets on 1st only 20 minutes after the Sun, and half an hour after him on the 31st. Her conjunction with the Moon at 7·15 p.m. on the 4th, and with Mercury at 2h. 53m. in the afternoon of the 23rd, have been noticed above.

Mars is a morning star. Rising on the 1st at about 2h. 27m. a.m., and on the 31st at 2h. 14m. He travels during August from a barren region to the north-east of δ Geminorum, to a point to the north-east of δ Cancri. His southing takes place on the 1st at 10h. 49m. a.m., and on the 31st at 10h. 3m. a.m.; and his setting, of course, in bright sunlight during the whole month. His diameter is still under 5″, and he is therefore absolutely destitute of any interest whatever for the observer with the telescope, merely presenting the aspect (of which we have spoken on former occasions) of a large red fixed star. We have noticed under another head his conjunction with the Moon at 10h. 36m. a.m. on the 2nd, and at 5h. 29m. a.m. on the 31st. He will also be in conjunction with Uranus 57 minutes after midnight on the 23rd.

Jupiter will be in conjunction with the Sun at 4h. 5m. a.m. on the 3rd, and will, consequently, be absolutely invisible during the earlier part of the month. He will, however, later, become a morning star, rising some two hours before the Sun at the end of August. He is travelling towards the east, through a particularly void region of the heavens, in the constellation Cancer. We have previously spoken of his conjunction with the Moon at 5h. 39m. a.m. on the 4th, and at 11h. 41m. on the last night of the month.

It is possible that the reappearance of satellite 4 from occultation at 3h. 17m. a.m. on the 30th, and the disappearance of satellite 1 in eclipse at 4h. 51m. 39s. a.m. on the 31st, may be caught; while at 4h. 18m. after midnight on the same day (*i.e.*, at 4h. 18m. in the early morning of September 1), the egress of the first satellite from Jupiter's face will be visible.

Saturn is now the leading object in the night sky, but is still too close to the horizon, even at its culmination, for satisfactory observation. It might be worth while, however, in observing Saturn at present, for the amateur to try the effect of the exceedingly ingenious eyepiece invented by the Astronomer Royal, for the correction of that chromatic aberration which tends, *inter alia*, to render a planet at so small an altitude indistinct. Saturn rises on the 1st of August, about half-past six o'clock in the evening, is on the meridian at 10h. 27·4m., and sets about 2h. 23m. the next morning; his rising, southing, and setting on the 31st taking place at 4h. 25m. in the afternoon, 8h. 23·4m. in the evening, and 21 minutes after midnight respectively. He remains in Sagittarius during the whole of August, and is travelling slowly towards (and a little to the south of) the star π in that constellation. The part of the sky through which he is passing is almost a blank. We have mentioned above his conjunction with the Moon at 3h. 50m. a.m. on the 16th; but this will obviously happen after he has set.

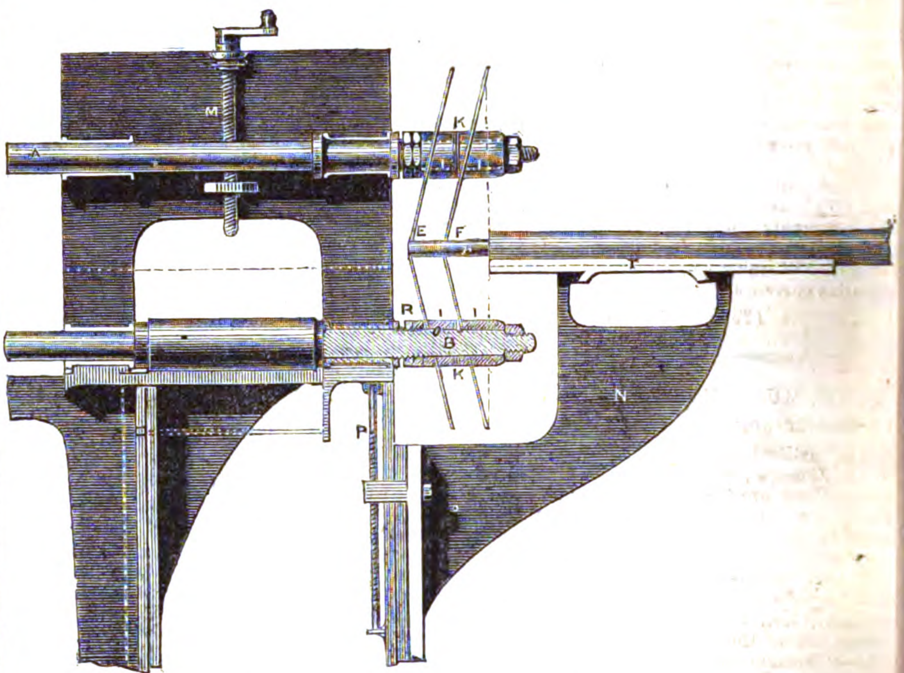
Uranus is a morning star, rising on the 1st about 3h. 39m. a.m.; and on the 31st 1h. 50m. after midnight. As he souths and sets in broad daylight during the earlier part of the month, and sets in strong twilight at the end of it, he must be looked for before sunrise. He is situated in a barren space in Cancer, and may be fished for on a line joining 20 and η in that constellation. This is, though, only a very rough direction for finding him; as, at the beginning of August, he will be slightly above such an imaginary line; and below it towards the end of it. The conjunctions of this planet with the Moon at 11h. 50m. a.m. on the 3rd, and at 9h. 12m. p.m. on the 30th; as also his conjunction with Mars at 12h. 57m. p.m. on the 23rd have been referred to under other heads.

Neptune is now coming into view in the night sky; rising on the 1st at 10h. 8m., southing the next morning about 4h. 59m., and setting, of course, in sunlight. At the end of the month he will rise a little after 8 o'clock in the evening, and be on the meridian about 3 in the early morning of the succeeding day. He may be fished for very slightly to the north-east of ο Piscium during the early part of August; just to the east of that star about the 16th; and, later in the month, to the south of east of it. It requires, as we have before intimated in these columns, a thoroughly good telescope to satisfy the young observer of the planetary nature of this distant member of our system.

The famous shower of shooting stars, annually visible on a night, or nights, from the 9th to the 11th of August (chiefly on that of the 10th, S. Lawrence's day), must be familiar to every observer who reads these lines. All, then, that is necessary is to remind the student to watch, on all three of the nights named, for a spectacle which must certainly well reward his vigils.

TENONING MACHINE.

A MACHINE for cutting tenons, by what is claimed to be an improved method, has been recently patented by Mr. C. M. Lloyd. The arrangement of the saws diagonally on the shaft is the principal peculiarity of the invention, which will be understood from the accompanying engraving. By this means the inventor claims that a clean and perfectly true tenon and shoulder is formed; that the saws are readily adjusted to cut any desire[d] thickness of tenon without loss of time, and tha[t] the saws can be sharpened whilst in position fo[r] working. Instead of placing the saws to run tru[e] on the shaft, they are attached to "run zig-zag," s[o] that their peripheries cut over the surface of th[e] tenon in widths of 3½in. more or less as may b[e] desired. The saws are kept in position by bevelle[d] collars, and are secured to the shafts by keys an[d] screw nuts. The inventor says that it is obviou[s] that a circular saw set at an angle on a shaft will [at] each revolution present all segments of its circum[-] ference to a different portion of the face of the woo[d,] and will travel the exact distance between the low[est] position of the saw, at any given moment, and a perpendicular line drawn from the uppermost edg[e] of the saw at such moment. Upon this principle the saws are applied to the shaft, fixed by coll[ars] and keys, and, according to the angle at which they are thus fixed, so will their proportionate trave[rse] for cutting the tenon be regulated.



In the figure, which is partly in section, A [B] ar[e] the upper and lower shafts set in gun metal journals, the shafts rotating at a very great speed, varying according to the character of the wood to be cu[t]. These shafts carry the four circular saws E, F, &c., set in diagonal grooves, in the collars I I, the[ir] angle being equal, although in reversed directions; the lower shaft being in section, the arrangement of fixing the saws is clearly shown, the key or feather O in dotted lines serving to keep the colla[r]s in a fi[rm] position. Provision is made for removing the collars and saws, and for substituting others as required by means of screw nuts, whereby the distance between the saws may be changed, the intermedi[ate] washers K K, or others maintaining such intervening space between them, and the position of the saws on the shafts may be altered in order to form the shoulder further from the edge of the wood or timber, or *vice versâ*, by means of the nuts seen in the engraving. The depth of tenon is regulated by shifting the position of the upper shaft A by the screw gear M, and by regulating the height of the table T corresponding.

For the feeding arrangement N is a bracket, capable of sliding vertically in guides, its elevation being regulated by the endless screw P; this bracket carries the transverse sliding table T, in the bed of which the wood is set and adjusted to the saws exactly as desired, and fixed by any means, the bed and table being made to travel in the bracket by manual or other power. The operation of the machine is as follows:—Let the part *r* of the wood be the tenon supposed to have been cut by the saws E, F, G, H, then the saw E will have cut from the point E, to the point F, and the saw F will have cut from F to the shoulder of the tenon; the teeth of the respective saws thus having travelled longitudinally along the tenon from those points exactly in accordance with the diagonals. The saws are, of course, run with great rapidity; the chief value of the machine, however, appears to be the facility with which it can be arranged to cut different sized tenons. It is not apparent on an inspection of the drawing how a "perfectly true shoulder" is obtained.

NOVEL METHOD OF DESTROYING VERMIN.

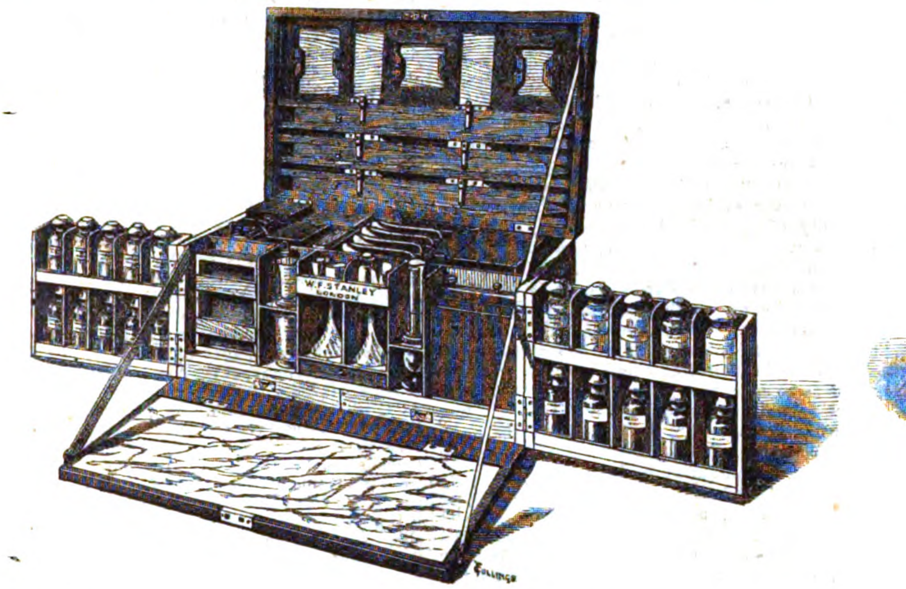
A MEETING of scientific gentlemen and others interested in farming and horticulture was recently held at South Kensington to witness some experiments with a patent vermin asphyxiator, which claims to be a disinfector, vaporiser, and universal fumigator as well. The experiments were conducted under the superintendence of Mr. Frank Buckland, who, in an introductory speech, pointed out the advantages of some reliable destroyer for the insects that infest our gardens and fields, and also the larger vermin, like rats and snakes, that in some countries are even greater pests than the insect world. The rabbit question, which Mr. Buckland jocosely stated had become a political claptrap, was shown to be effectually solved by this new machine. The process is simple, and though not new, either in its effects or means of application, is, however, so effectually concentrated and made practicable in this machine as to be to all intents a novel affair. By means of a fan, turned by hand, sulphurous acid gas can be driven through a nozzle into drains, rat, rabbit, and snake holes, and the gas either drives the vermin out, so that they can be killed outside, or it suffocates them in the holes. Some amusement was caused by a rat that was to be smoked out of a burrow made for the purpose, escaping and biting two of the bystanders who attempted to catch him. However, when caught and put into the burrow, the asphyxiator soon drove him out again. Some snakes were almost smoked and killed. A piece of stinking and maggotty meat was exposed to the action of the gas, and at once the maggots were killed, and the meat lost its bad odour. To people who have large granaries, maltsters, and others, the asphyxiator will be very valuable. An experiment with some weevils in a jar of corn killed them all in a few seconds. The pan attached to the fan can be filled either with the compound to produce sulphurous gas (merely pieces of brown paper dipped in hot sulphur), when it is required to fumigate thoroughly and destroy life, or ordinary smoke from grass can be used if it is required to drive out rabbits from their burrows. The deodorising effects of sulphurous acid gas are well known, and there is no doubt that this machine would be very valuable to disinfect houses after infectious diseases. Its application to shrubs in the open air can only be but partial, but in greenhouses it might be quite certain, and those shrubs subjected to the smoke were quickly cleared of their aphides.

PHOTOGRAPHIC LABORATORIES.

HITHERTO it is has been the custom for amateur photographers to purchase the various articles they require separately, and from time to time, or else to obtain in the first instance a box of apparatus and chemicals, neatly and closely packed in their case, but by no means conveniently arranged, if the containing box is afterwards to be used as a receptacle for the apparatus when in use.

Mr. Stanley's laboratories, as he calls them, are so arranged that every article has its place, and can be taken out or put back without displacing anything else; indeed, it is easier to return the article used to its proper compartment than to place it elsewhere. Another advantage is that when the operations are concluded, the whole affair can be closed in a minute.

Our illustration will give an idea of the general arrangement. When the lid is raised and the front turned down, the whole of the interior is exposed; the larger parts of the apparatus are contained in the back, each having its own division, while the chemicals and smaller articles appear in front, arranged just as they might be in a chemist's shop. The front, which has proper means of support when open, serves as a table to work upon.



In the larger sets of apparatus shown in the second illustration, there are two wings which turn outwards when the front is open, these contain the reserve stock of chemicals, the solutions in use for the time being occupying the central part of the case.

CONCRETE BUILDING.

THE following particulars of concrete building in Scotland, taken from the *Aberdeen Journal*, will interest several of our readers; the cottages referred to are in course of erection on the property of Mr. Lumsden of Pitcaple, a gentleman who is one of the directors of a concrete company in London:—

The whole process of building houses of concrete is so exceedingly simple that the employment of skilled labour is quite unnecessary, and indeed the four labourers who were employed in the construction of the cottages referred to had never seen anything of the kind before, and yet they performed their allotted work without the slightest difficulty. A foundation having been laid, a double framework of wood, or panelling, 9in. apart and 18in. high, is placed above the foundations round the entire building, forming a kind of box. This panelling consists of pieces of wood, varying in breadth from 3in. or 4in. to over 1ft., with a bead on the upper edge having an aperture by which the pieces are slid on to an iron rod. Being thus telescopic in construction, the pieces of wood can be lengthened or shortened according to the extent of the building. At intervals between the panels are placed upright bars, called separating posts, several feet high, through which the iron rods supporting the panels pass and are secured. At equal distances of 18in., ascending upwards, there are apertures in the posts for the insertion of the iron rods, and the panelling round the entire structure can be raised with great ease as the building advances. When operations are to be commenced, a quantity of packing, which may consist of rough stones of any shape, the more ragged the better, which forms the first layer of the building is thrown in, care being taken to keep the packing 1in. from the face of the work, so that it may not show through it. When the 18in. of packing are filled up, the concrete, which is in a semi-liquid state, like mud, is poured into the box, and percolates down through the stones, thoroughly filling all cavities, and binding the stones and rubble together so tightly that the whole forms one solid mass. For a day the portion of wall thus made lies encased within the panelling. By that time it has become quite dry, and the panelling or frame is taken off and lifted up other 18in., the bottom of the frame resting where the top was before. Thus another box is formed above the piece of finished wall, and identically the same process which we have described is repeated, stones and rubble being thrown in, and the liquid cement being poured over them. In this way 18in. of building are finished each day if the weather be good, so that in the course of a week the walls of a cottage 8ft. or 9ft. high are strongly and firmly built.

When the panelling is screwed together to the separating posts, it is so mathematically exact, owing to its careful structure, that the wall is built as straight as if tested with a plumb line. Indeed, it cannot fail to be so, and it is interesting to note that the whole building is finished without the aid of a plumb line, which is quite unnecessary.

A noteworthy feature in connection with the building of these concrete houses is that the usual cumbrous and often dangerous scaffoldings which are used in erecting ordinary buildings is superseded by a much better, more secure, and much less unwieldy arrangement, by which ropes are entirely dispensed with. Little hollow iron tubes, called cores, are placed in the walls, through which iron rods are inserted, connected with brackets, which are securely attached to the wall, being firmly screwed through the building with nuts. The brackets are just similar in form to supports used for shelving, and on the top of the brackets are laid the planks for the scaffolding, forming altogether a neat and strong support.

The two cottages, which are built as one, are 32ft., in length, by 22ft., and 8ft. high. In each cottage there are three rooms, those in the front being about 12ft. square, and the back rooms measuring about 7ft. by 12ft. The cottages are lighted by two windows in the front and four in the back. The flooring is of concrete, which, being thoroughly impervious to moisture, makes the apartments very dry and comfortable. It is intended to have the roof built in the ordinary way with rafters and slating, but it is not uncommon for concrete to be used as a roofing material, for which purpose it answers very well. The outside walls, when built, are finished with a coating of concrete, about a quarter of an inch thick, a little finer in the quality than that used for the ordinary building, which gives a smooth finished appearance to the structure. No supports are requisite for the lintels of the doors or windows, because after the concrete is hardened it is stronger than any support of wood or stone. When the building is in progress, spaces are left for the joists, and are temporarily filled with sand, which is easily removable at any time with a trowel. The spaces for the joists are made, alternately, 3in. and 6in. in depth on each side of the building, which diminishes the pressure on the walls considerably.

Houses finished in the way we have described are much cheaper than those built in the ordinary way, the saving being from 35 to 40 per cent. The buildings, at the same time, are more comfortable because being impervious to moisture and heat, they are warm and dry in winter, and cool during the summer. The rooms can be papered over the bare walls, no lath or plaster being required, though a coating of plaster in no way affects the concrete, if it is preferred.

THE "FOSSIL" MAN.

THE discovery of the so-called "fossil" man in one of the larger caverns near Mentone, on the Italian frontier, is likely to give rise to an animated discussion in scientific circles. The fossil man, or more correctly, perhaps, we should say the skeleton, was found buried several yards below the floor of a cavern overlooking the railway cutting from Mentone to Vintimille. Owing partly to the nature of the earth and partly to the dryness of the elevated cavern the skeleton is in very fine preservation, and with the exception of the ribs, probably broken by the weight of the overlying materials, is said to be complete. An illustration of the "Troglodite de Menton" was published in the *Courier* of that town in the month of April, shortly after the discovery, and has been reproduced in a recent issue of the *Geological Magazine.* It represents the skeleton as lying in a position which might have been expected if it had been known that the body had been interred in the ordinary way, the legs being crossed and bent at the knees, and the arms folded about the head, as if the man had died sleeping, and had been carefully covered over with earth. A number of shells similar to those found on living animals in the sea around the neighbourhood were discovered close to the skull, together with a quantity of deer's teeth, all of which were pierced with a hole, as if they had formed part of a necklace or head-dress. Stone implements, which appear to have been worked into shape by rubbing—such as chisels, axes, and scrapers—as well as bone needles, were found in abundance, together with the bones of animals, notable amongst which were the lower jawbones of several "herb-eating" species.

The discoverer of these remains, which may or may not be of much importance in forming a correct estimate of geological time, is a Dr. Rivière, a gentleman holding an appointment from the French Government to examine and report on the palæontology of the neighbourhood, in which he has brought to light a large collection of bones and teeth of various animals, principally of hyænas, rhinoceroses, bears, and gigantic stags, obtained chiefly from quarries. Having worked up the quarries tolerably completely he has now turned his attention to the caves, and a first result is the finding of this skeleton. We believe that Mr. Pengelly, who has had great experience in unravelling the secrets of caves, and who has for some years directed the explorations at Kent's Hole undertaken by the British Association for the Advancement of Science, has gone to the site of the discovery, and his report, together with that of Dr. Rivière, will be read by geologists with much interest. In the mean time, two gentlemen tolerably well known in the scientific world have furnished more detailed particulars, and expressed their opinions on the matter. From these we learn that the rock in which the cave is situated is Oolitic or Jurassic limestone, which is naturally full of caverns. The cave in question is narrow and lofty, as well as deep; the floor at the entrance being some 9ft. above the bottom, while in the interior the depth is considerably greater. No remains of extinct animals such as the cave bear (*Ursus spelæus*) were found *above* the skeleton; and the appearance of the place, taken with the surrounding characteristic facts, leads to the belief that it was a case of interment during the stone age, but not early in that period—the skeleton being, probably, that of a person of some position in those times. Mr. Nicholl, who has also examined the cavern, corroborates this opinion, and says that to him it appears to be a case of burial, the stones at the back and front of the skeleton clearly proving this, for they were evidently placed by design as if to mark the place of sepulture. M. Rivière, however, does not seem to have thought much of this fact, for he removed all the stones before the skeleton was photographed. If the man was buried, then, he might or might not have been co-existent with the extinct animals so many of whose bones were found in the cave-earth near the skeleton. Close by, in front of the cave, there was, Mr. Nicholl thinks, irresistible evidence that man lived in these caves at the same time that animals *now extinct* were living in the neighbourhood. For in front of the cave is a *talus*, formed of breccia fallen from the cliff above. The stones forming this breccia are as sharp and angular as when they fell from the cliff, and are cemented by lime and oxide of iron into a hard conglomerate. It appears that two years ago this conglomerate was cut into to some depth for the railway works, and numerous flint implements, such as knives, spear and arrow heads, and bones of extinct and existing animals, were brought to light. These facts, considering that the stones forming the conglomerate are so very sharp and angular, seem to Mr. Nicholl to afford very conclusive evidence that not only are the stones lying where they fell, but that the bones and flints are also just where they were thrown by inhabitants of the caves above.

It will be readily understood that discoveries of this kind, and the conclusions to be drawn from them, throw considerable light on a subject that has been matter of dispute for some years—viz., the antiquity of man. Formerly it was generally believed that man appeared on the face of the earth only after the disappearance of what are called the extinct mammalia, and consequently after those physical changes — catastrophes, cataclysms, or whatever else they may be termed, which, in times gone by, certainly affected the surface of our planet. In more recent days, however, the belief has gradually gained ground that man is a far more ancient inhabitant of the earth than was previously imagined, this belief having arisen from the discovery of his remains and works intimately associated with those of extinct animals. The presence of flint implements, which are believed to exhibit undoubted evidence of the handiwork of man, in heaps of bones of extinct animals is common enough, but the instances in which human remains have been found in similar deposits are far more rare: consequently, the finding of this "fossil" man is an important point, and whatever evidence it may afford as to the antiquity of man will be extensively discussed and severely criticised. So long back as 1824 Dr. Buckland discovered a large portion of the skeleton of a woman in the Paviland cave, Glamorgan, commonly known as the Red Lady of Paviland, but as it was only thinly covered, and ivory ornaments made from the tusks of the antediluvian elephant and rhinoceros, whose bones were found in the same cave, were discovered in contact with it, there could be little doubt that this lady was not contemporary with the hyæna and the bear, whose bones had also found a resting-place in the same spot. About one mile from this cave, however, is another known as Long Hole, in which flint implements, unquestionably fashioned by human hands, were found along with the fossil remains of the cave bear and hyæna, &c. Another instance of the antiquity of these implements was discovered by the Rev. W. S. Symonds in King Arthur's cave, near Whitchurch, Ross, and this would appear to afford indubitable evidence of the antiquity of the flint flakes and cores of chert found in connection with the bones of the usual cave mammals; for in one part of the cave beneath a thick layer of stalagmites which was itself covered by what is believed to be a portion of an old river-bed, flint implements were found mingled with the bones and teeth of the same species of extinct animals. Similar evidence has been obtained from caves in various parts of Belgium and France, as well as in America. Dr. Schmerling found in the Engi and Engihoul caves the bones of man, worked flints, and bone implements, indiscriminately mixed with the remains of the rhinoceros, horse, elephant, bear, and hyæna; while M. Lartet, who examined the celebrated Aurignac cave, concludes that not only was man contemporary with the mammoth, but that he actually used the rhinoceros as food.

We have said enough to show that the finding of this "fossil" man, from the bearing which it may have on received theories, is of some importance, and further discoveries in the same neighbourhood may be fairly anticipated, and will be doubtless eagerly expected. The evidence presented by the explorations of caves, however, requires the greatest circumspection in the unravelling of the rather tangled skein of facts, for the mere statement that bones of man have been found mingled with those of extinct animals does not necessarily require a belief in the contemporaneity of the living beings to whom the bones belonged—rather the contrary indeed, for man can hardly have been tenant of a cavern which was at the same time inhabited by the cave bear, hyæna, and lion—but the surrounding circumstances and the characteristic features of the earth in which they were buried are points which cannot be neglected in solving the problem. It is certain that very great changes have taken place in the climate of these islands since the cave-mammals lived and flourished in them, and these different periods are well marked in the deposits found in the caves; for, as Mr. Boyd Dawkins has shown, out of forty-eight well-ascertained species living in the Palæolithic or "ancient stone" period only thirty-one were enabled to live on into the Neolithic, "new stone," or Prehistoric period, while of these thirty-one all but six are still living in Britain; there can be no doubt, too, that the climate during the Neolithic period was certainly "less severe" than the Palæolithic. But all these considerations cannot be brought within the compass of one article, and must be postponed till the report of Dr. Rivière on his so-called "fossil" man is in the hands of geologists.

THE CONSTITUTION OF NATURE.*

(*Concluded from p. 458.*)

UP to the present point we have been dealing with tensions, and not with motion. Thus far *vis viva* has been entirely foreign to our contemplation of D and F. Let us now suppose D placed at a practically infinite distance from F; here the pull of gravity would be nothing, and the perpendicular representing it would dwindle to a point. In this position the sum of the tensions capable of being exerted on D would be a maximum. Let D now begin to move in obedience to the attraction exerted upon it. Motion being once set up, the idea of *vis viva* arises. In moving towards F the particle D consumes, as it were, the tensions. Let us fix our attention on D at any point of the path over which it is moving. Between that point and F there is a quantity of unused tensions; beyond that point the tensions have been all consumed, but we have in their place an equivalent quantity of *vis viva*. After D has passed any point, the tension previously in store at that point disappears, but not without having added, during the infinitely small duration of its action, a due amount of motion to that previously possessed by D. The nearer D approaches to F, the smaller is the sum of the tensions remaining, but the greater is the living force; the farther D is from F, the greater is the sum of the unconsumed tensions, and the less is the living force. Now the principle of conservation affirms not the constancy of the value of the tensions of gravity, nor yet the constancy of the *vis viva* taken separately, but the absolute constancy of the value of the sum of both. At the beginning the *vis viva* was zero and the tension area was a maximum; close to F the *vis viva* is a maximum, while the tension area is zero. At every other point the work-producing power of the particle D consists in part of *vis viva* and in part of tensions.

If gravity, instead of being attraction, were repulsion, when the particles are in contact, the sum of the tensions between two material particles D and F would be a maximum, and the *vis viva* zero. If D in obedience to the repulsion, moved away from F, *vis viva* would be generated; and the farther D retreated from F the greater would be its *vis viva*, and the less the amount of tension still available for producing motion. Taking repulsion into account as well as attraction, the principle of the conservation of force affirms that the mechanical value of the tensions and *vires vivæ* of the material universe is a constant quantity. The universe, in short, possesses two kinds of property which are mutually convertible at an unvarying rate. The diminution of either carries with it the enhancement of the other, the total value of the property remaining unchanged.

The considerations that we have here applied to gravity apply equally to chemical affinity. In a mixture of oxygen and hydrogen the atoms exist apart, but by the application of proper means they may be caused to rush together across the space that separates them. While this space exists, and as long as the atoms have not begun to move towards each other, we have tensions and nothing else. During their motion towards each other the tensions, as in the case of gravity, are converted into *vis viva*. After they clash we have still *vis viva*, but in another form. It was translation, it is vibration. It was molecular transfer, it is heat. The same considerations apply to a mixture of hydrogen and chlorine. When these gases are mingled in the dark they remain separate, but if a sunbeam fall upon the mixture the atoms rush together with detonation. Here also we have tension converted into molecular translation, and molecular translation into heat and sound.

It is possible to reverse these processes, to unlock the embrace of the atoms and replace them in their first positions. But to acomplish this as much heat

* By Prof. TYNDALL, reprinted from the *Journal* of the London Association of Foremen Engineers.

ald be required as was generated by their union. ch reversals occur daily and hourly in nature. the solar waves, the oxygen of water is divorced m its hydrogen in the leaves of plants. As lecular *vis viva* the waves disappear, but in so ng they re-endow the atoms of oxygen and hydro- ı with tension. The atoms are thus enabled to ombine, and when they do so they restore the ecise amount of heat consumed in their separation. e same remarks apply to the compound of carbon l oxygen, called carbonic acid, which is exhaled m our lungs, produced by our fires, and found ıringly diffused everywhere throughout the air. the leaves of plants the sunbeams also wrench ese atoms asunder, and sacrifice themselves in ı act: but when the plants are burnt the amount heat consumed in their production is restored.

This, then, is the rhythmic play of nature as gards her forces. Throughout all her regions she cillates from tension to *vis viva*, from *vis viva* to ısion. We have the same play in the planetary stem. The earth's orbit is an ellipse, one of the i of which is occupied by the sun. Imagine the rth at the most distant part of the orbit. Her tion, and consequently her *vis viva*, is then a nimum. The planet rounds the curve, and begins approach the sun. In front it has a store of ten- ons, which is gradually consumed, an equivalent ıount of *vis viva* being generated. When nearest the sun the motion, and consequently the *vis va*, is a maximum. But here the available tensions ve been used up. The earth rounds this portion the curve and retreats from the sun. Tensions e now stored up, but *vis viva* is lost, to be again stored at the expense of the complementary force the opposite side of the curve. Thus beats the art of the universe, but without increase or minution of its total stock of force.

I have thus far tried to steer clear amid confusion fixing the mind of the reader upon things rather an upon names. But good names are essential; d here, as yet, we are not provided with such. e have had the force of gravity and living force— o utterly distinct things. We have had pulls and nsions; and we might have had the force of heat, e force of light, the force of magnetism, or the rce of electricity—all of which terms have been nployed more or less loosely by writers on physics. is confusion is happily avoided by the introduc- on of the term "energy," embracing under it both nsion and *vis viva*. Energy is possessed by bodies ready in motion; it is then actual, and we agree call it actual or dynamic energy. It is our old *s viva*. On the other hand, energy is possible to odies not in motion, but which, in virtue of attrac- on or repulsion, possess a power of motion which ould realise itself if all hindrances were removed. ooking, for example, at gravity, a body on the rth's surface in a position from which it cannot ll to a lower one possesses no energy. It has either motion nor power of motion. But the same ody suspended at a height above the earth has a ower of motion though it may not have exercised . Energy is possible to such a body, and we agree call this potential energy. It embraces our old nsions. We, moreover, speak of the conservation energy instead of the conservation of force; and y that the sum of the potential and dynamic ergies of the material universe is a constant antity.

A body cast upwards consumes the actual energy projection, and lays up potential energy. When reaches its utmost height all its actual energy is nsumed, its potential energy being then a maxi- um. When it returns, there is a reconversion of e potential into the actual. A pendulum at the mit of its swing possesses potential energy; at the west point of its arc its energy is all actual. A atch of snow resting on a mountain slope has otential energy; loosened, and shooting down as avalanche, it possesses dynamic energy. The ne-trees growing on the Alps have potential ergy; but rushing down the Holzrinne of the oodcutters they possess actual energy. The same true of the mountains themselves. As long as e rocks which compose them can fall to a lower vel, they possess potential energy, which is con- erted into actual when the frost ruptures their hesion and hands them over to the action of avity. The hammer of the great bell of West- inster, when raised before striking, possesses otential energy; when it falls, the energy becomes ynamic; and after the stroke, we have the rhythmic play of potential and dynamic in the vibrations of the bell. The same holds good for the molecular oscillations of a heated body. An atom is pressed against its neighbour, and recoils. But the ultimate amplitude of the recoil is soon attained, the motion of the atom in that direction is checked, and for an instant its energy is all potential. It is then drawn towards its neighbour with accelerated speed, thus, by attraction, converting its potential into dynamic energy. Its motion in this direction is also finally checked, and, for an instant, again its energy is all potential. It again retreats, converting, by repul- sion, its potential into dynamic energy, till the latter attains a maximum, after which it is again changed into potential energy. Thus, what is true of the earth, as she swings to and fro in her yearly journey round the sun, is also true of her minutest atom. We have wheels within wheels, and rhythm within rhythm.

When a body is heated, a change of molecular arrangement always occurs, and to produce this change heat is consumed. Hence, a portion only of the heat communicated to the body remains as dynamic energy. Looking back on some of the statements made at the beginning of this article, now that our knowledge is more extensive, we see the necessity of qualifying them. When, for example, two bodies clash, heat is generated; but the heat, or molecular dynamic energy, developed at the moment of collision, is not the equivalent of the sensible dynamic energy destroyed. The true equivalent is this heat, plus the potential energy conferred upon the molecules by the placing of greater distances between them. This molecular potential energy is afterwards, on the cooling of the body, converted into heat.

Wherever two atoms capable of uniting together by their mutual attractions exist separately, they form a store of potential energy. Thus our woods, forests, and coal-fields on the one hand, and our atmospheric oxygen on the other, constitute a vast store of energy of this kind—vast, but far from infinite. We have, besides our coal-fields, bodies in the metallic condition more or less sparsely dis- tributed in the earth's crust. These bodies can be oxidised, and hence are, so far as they go, stores of potential energy. But the attractions of the great mass of the earth's crust are already satisfied, and from them no further energy can possibly be obtained. Ages ago the elementary constituents of our rocks clashed together and produced the motion of heat, which was taken up by the ether and carried away through stellar space. It is lost for ever as far as we are concerned. In those ages the hot conflict of carbon, oxygen, and calcium produced the chalk and limestone hills which are now cold; and from this carbon, oxygen, and calcium, no further energy can be derived. And so it is with almost all the other constituents of the earth's crust. They took their present form in obedience to mole- cular force; they turned their potential energy into dynamic, and gave it to the universe ages before man appeared upon this planet. For him a residue of potential energy remains, vast truly in relation to the life and wants of an individual, but exceedingly minute in comparison with the earth's primitive store.

To sum up. The whole stock of energy or work- ing-power in the world consists of attractions, repulsions, and motions. If the attractions and repulsions are so circumstanced as to be able to produce motion they are sources of working-power, but not otherwise. As stated a moment ago, the attraction exerted between the earth and a body at a distance from the earth's surface is a source of working-power; because the body can be moved by the attraction, and in falling to the earth can per- form work. When it rests upon the earth's surface it is not a source of power or energy, because it can fall no further. But though it has ceased to be a source of energy, the attraction of gravity still acts as a force, which holds the earth and weight together.

The same remarks apply to attracting atoms and molecules. As long as distance separates them, they can move across it in obedience to the attrac- tion, and the motion thus produced may, by proper appliances, be caused to perform mechanical work. When, for example, two atoms of hydrogen unite with one of oxygen to form water, the atoms are first drawn towards each other—they move, they clash, and then by virtue of their resiliency, they recoil and quiver. To this quivering motion we give the name of heat. Now this atomic vibration is merely the redistribution of the motion produced by the chemical affinity; and this is the only sense in which chemical affinity can be said to be con- verted into heat. We must not imagine the chemical attraction destroyed, or converted into anything else. For the atoms when mutually clasped to form a molecule of water, are held together by the very attraction which first drew them towards each other. That which has really been expended is the pull exerted through the space by which the distance between the atoms has been diminished.

If this be understood it will be at once seen that gravity may in this sense be said to be convertible into heat; that it is in reality no more an outstand- ing and inconvertible agent, as it is sometimes stated to be, than chemical affinity. By the exer- tion of a certain pull through a certain space a body is caused to clash with a certain definite velocity against the earth. Heat is thereby developed, and this is the only sense in which gravity can be said to be converted into heat. In no case is the force which produces the motion annihilated or changed into anything else. The mutual attraction of the earth and weight exists when they are in contact as when they were separate; but the ability of that attraction to em- ploy itself in the production of motion does not exist.

The transformation, in this case, is easily followed by the mind's eye. First, the weight as a whole is set in motion by the attraction of gravity. This motion of the mass is arrested by collision with the earth, being broken up into molecular tremors, to which we give the name of heat.

And when we reverse the process, and employ those tremors of heat to raise a weight, as is done through the intermediation of an elastic fluid in the steam-engine, a certain definite portion of the molecular motion is destroyed in raising the weight. In this sense, and this sense only, can the heat be said to be converted into gravity, or more correctly, into potential energy of gravity. It is not that the destruction of the heat has created any new attrac- tion, but simply that the old attraction has now a power conferred upon it, of exerting a certain definite pull in the interval between the starting- point of the falling weight and its collision with the earth.

When, therefore, writers on the conservation of energy speak of tensions being "consumed" and "generated," they do not mean thereby that old attractions have been annihilated, and new ones brought into existence, but that, in the one case, the power of the attraction to produce motion has been diminished by the shortening of the distance between the attracting bodies, and that in the other case the power of producing motion has been augmented by the increase of the distance. These remarks apply to all bodies, whether they be sensible masses or molecules.

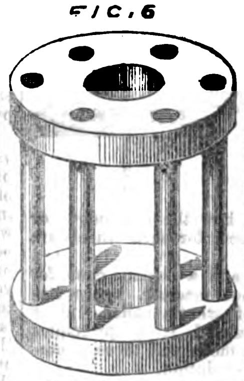
Of the inner quality that enables matter to attract matter we know nothing; and the law of conservation makes no statement regarding that quality. It takes the facts of attraction as they stand, and affirms only the constancy of working- power. That power may exist in the form of motion; or it may exist in the form of force, with distance to act through. The former is dynamic energy, the latter is potential energy, the con- stancy of the sum of both being affirmed by the law of conservation. The convertibility of natural forces consists solely in transformations of dynamic into potential, and of potential into dynamic energy, which are incessantly going on. In no other sense has the convertibility of force, at present, any scientific meaning.

MECHANISM.*

(Continued from p. 456.)

WE now return to the question of rolling curves. If one curve is to cause another to rotate, it is easy to see that the curves must have corresponding surfaces. Early mechanicians adopted a plan of which there is an example here—viz., driving pins round the edge of the wheel, and these pins worked between pins on the face of the other wheel, and thus continuous motion was obtained in shafts at right angles to each other. That motion was required because it was needful in early days to utilise the power of water for the purpose of grinding corn. The water fell vertically, and the water-wheel, therefore, moved vertically, but the millstones were required to rotate hori- zontally. The question, therefore, was, how can we with a vertical fall of water get a horizontal motion. It was got by pins driven into the face of the wheels; such wheels exist to this day in Dutch clocks. They were much increased, extended, and enlarged as machinery advanced. Ultimately they formed what are called trundle or lantern-wheels. Fig. 6 is an example of a trundle or lantern-wheel. In mill machinery the round staves are made of a tough hard wood, firmly fixed at each end. In light machinery the staves are of steel wire, and fixed only at one end.

FIG. 6

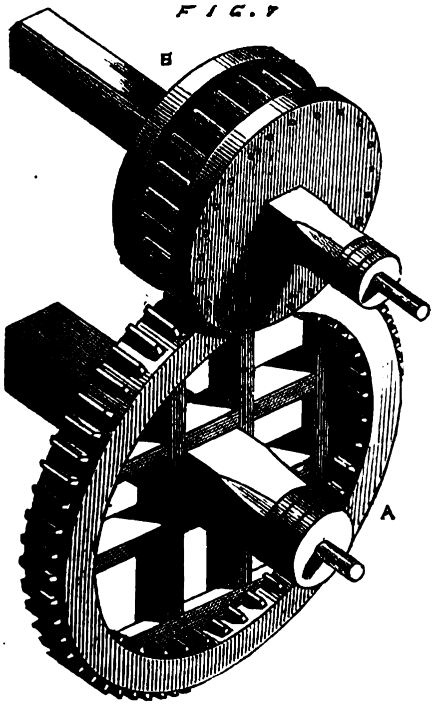


The reason why wheels in mill machinery were made so broad, in all respects so heavy, and to our eyes so inconvenient and clumsy, arose from the fact that the shafts were wooden ones, generally square—capped at the end with an iron hoop—an iron pin being driven into the wood for a bearing. Millwrights then had not means for completing these wooden shafts with that care which an Eng- lish development of the "tool-making" faculty has given us, and which we so successfully apply to iron shafts. There are drawings here of one of these earlier wheels, with its shaft and wedges, and of a modern wheel, with its turned wrought-iron shaft and key-way, from which you will at once see the difficulties which beset mechanics in the last century. It was needful that the wheels should re- volve truly with one another, but this was very diffi- cult with wooden wheels, wooden shafts, and wooden pin-teeth. Remember that it was not until Smea- ton's time (A.D. 1769) that cast-iron teeth were used for wheels.

* By the Rev. ARTHUR RIGG, M.A., being the Cantor Lectures delivered before the Society of Arts.

Another difficulty with a square wooden shaft was to make the wheel "run" truly. About sixteen wedges were used, driven in on opposite sides, but, with all the driving, the wheel could not be made to run true. An inspection of Fig. 7 will satisfy

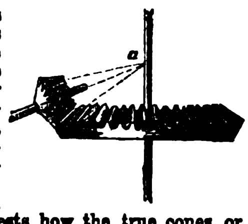
FIG. 7



any one of the difficulties alluded to. Now, however, with Mr. Whitworth's gauges for shafts, wheels can be fixed so as to run true. That was one of the earlier difficulties, and when removed there was no difficulty in disposing of these thick heavy lantern-wheels, and machinists began to adopt mathematically correct teeth, as well as true circular shafts and circular holes. There is no difficulty in making clear, without the aid of mathematics, the principles upon which these teeth should be constructed. There are diagrams on the wall intended for the purpose, but the subject belongs more properly to the next lecture.

But it was not only to shafts rotating at right angles to each other, as in the grinding of corn by water-wheels, that motion had to be communicated through rolling contact. As machinery extended, the directions of shafts to be thus driven became more and more varied. Hence for two shafts neither parallel nor at right-angles, but meeting, mechanicians were required to provide a contrivance. Fig. 8 will explain how they did this, and it also suggests how the true cones, or "bevels" as they are called, for such wheels are deduced.

FIG. 8



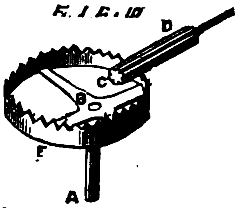
Much will have more, and a demand came for shafts not parallel and not meeting, hence has resulted a large class of wheels called "skew bevels." These are deduced from principles illustrated by this working mode and these photographs of hyperboloids of revolution.

The teeth, then, being correctly constructed, the question was, how can varying motions be communicated from one wheel to the other, or, rather, from one shaft to the other. It can be done by taking different curves, for it is the fact that, given one curve, another can always be found that will roll by a tooth arrangement in contact with it. Lobe wheels, and wheels formed upon the rims of squares, will work in gear with other lobe and square wheels. Here is an example, and it will be found that these wheels work as truly together as if they were circular. Here is another form, a heart, or cam, or lobe-shaped tooth-wheel, for which we are indebted to the authorities at South Kensington, and these rotate as truthfully as if the teeth were formed upon the rim of a circular wheel. A variable motion, therefore, has been obtained from a uniform one, for, although one of these shafts rotates uniformly, yet the velocity of the other shaft is not uniform. There are many cases in which such variable velocity is required, in none more than in arranging the velocities with which the tool or work travels in different machines. The mechanism for accomplishing that is devised in various ways. As an example of communication by rolling contact, it has been done by elliptical wheels.

FIG. 9

The history of elliptical wheels is very curious; and if there are any here who are interested in mechanism apart from mechanics, the thoughtful study of all that is written about what is called "planetary mechanism" in Rees's "Cyclopædia" will repay the time given to it. The wonders of those orreries, contrived at the latter part of the last century, are quite sufficient to excite the astonishment of mechanicians at the present day. Here is one of the plates in Rees's "Cyclopædia"—viz., one—under "Planetary Mechanism," showing an orrery moved by a small handle, but containing an immense number of wheels, probably more than 100. These orreries are very curious indeed, and we are indebted to them for two very important constructions, one being the elliptical wheel, the other the crown wheel. Astronomers wished very much to communicate a clear idea of the motions of the heavenly bodies, and they attempted to do it by machinery, not the machinery we have, but by contrivances, although, in our eyes, clumsy, yet in those days very beautiful. The orbit of the earth being elliptical, their object was to get an elliptical motion. About the year 1695 an attempt was made by Huyghens to form what we now call crown wheels. He then called them contrate wheels, because the teeth were in the contrary position to the usual one. He attempted to get at the requisite elliptical path by taking a contrate wheel, fixing its axis out of the centre, and putting a pinion to drive it; the wheel, therefore, went round with a variable velocity. Fig. 10 illustrates this arrangement. D C is a long pinion, F the contrate wheel, A B the axis placed out of the centre of the wheel F. If, now, the pinion C D moves uniformly, the axis A B will have a variable velocity, moving most rapidly when the distance from B to the driving portion of the pinion is the least. Roemer, about 1710, thought to accomplish the same object by a very ingenious contrivance, which is to be found in the cabinets of the mechanically curious to this day. He took a cone, and knowing that an ellipse is a section of a cone, he thought he could not do better than take two cones, making one grooved, and putting teeth round the elliptical section of the other, so as to fit into the grooves. Thus he got a velocity which he took to be the best representation of the path of the earth round the sun. There is a model of it here. Then a gentleman, Dr. Desauglier, who was the first to deliver public lectures on science in London, came forward about the year 1744. He attempted to accomplish the same thing by taking two wheels of a true elliptical form, nailing a string to each, so that one pulled the other round.

FIG. 10



Then Adam Walker tried to accomplish this variable motion by using epicycloidal inclined plane wheels, for a more particular description of which see the "Encyclopædia." Joseph Priestly, in 1801, accomplished the same by a contrivance which was very ingenious, and which may now be sometimes available. He did that which no mechanic who had a character to lose would venture to do—he made wheels of which the teeth were irregular, that is to say, he made a large wheel having more teeth on one half of it than on the other, and the teeth of both the wheel and the pinion being large, they worked together, though in a somewhat loose way, and thus one half of the wheel travelled more quickly than the other. By this means a pretty faithful representation of the path of the earth round the sun was obtained.

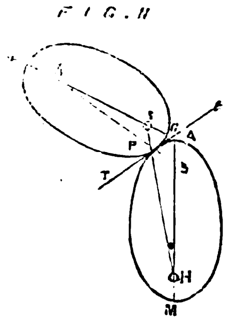
Then Pearson, about the year 1808, undertook to make, for the Royal Institution, one of the finest orreries, and one of the most extraordinary pieces of mechanism probably made in that day. He not only introduced wheels such as have been described, but attempted to get various velocities and varying distances by means of elliptical wheels; and he, for the first time, introduced an epicycloidal train, of which more in a future lecture.

Those of you who are curious in the matter of "rolling contacts" will look with interest at a clock now in the Patent Museum at South Kensington. It was made by a man named Harrison, about the year 1715, at Barrow, in Lincolnshire. It is going to this day, and keeping good time. It strikes the hour, indicates the day of the month, and with one exception, namely the escapement, all the wheels, all the teeth, and all the shafts are made of wood. The clock is well worth inspection. The same Harrison gained the reward of £20,000, which was offered by the Board of Longitude, for a nautical time-piece. The key of that clock is not a key—as we understand it—but is a pinion which drops into a wheel. The clock is made with a French-count wheel, and not a snail, such as is commonly used in modern English clocks.

Elliptical wheels are very good for rolling, so long as the driving wheel follows the driven one, but as soon as ever the reverse action takes place you will very soon see, by this specimen, that after a certain portion of the revolution is accomplished, they cease to roll in contact. Up to a certain point they roll very fairly, but as soon as the one ceases to gain on the other the rolling action ceases.

An inspection of Fig. 11 may explain this action, or what would give an experimental illustration might be more convincing. The latter may be had by cutting out two ellipses in card-board, and placing them on a drawing-board. Put pins through them at H and S, the foci. Let the ellipse A P M be the driver. It will be found that when the driven ellipse *a* P *m* is in the position in which A and (*a*) coincide, and therefore M H S and *a s h m* are in one straight line; then because the driving ellipse A P M is retiring from the driven ellipse, the rolling contact is not preserved.

FIG. 11



This difficulty was partially obviated by various devices until now, in ellipses as in the more complicated forms of cam and lobe-wheels, the rims are prepared with teeth, and the theoretical rolling action is attained.

Messrs. Muir, of Manchester, use these elliptical wheels to obtain a quick return motion in their planing machines, &c. They have kindly sent the model on which they made their calculations, and you will see from it what is the property of an elliptical wheel. Each rotates about its focus, and these axes are such that the distance from the one to the other is always the same. It is quite clear that the distance must be constant or the shafts could not be fixed. Two equal ellipses rotating as described satisfy this condition. Observe in connection with the rotation of these wheels that the driven ellipse travels with a varying velocity, although the rotation of the shaft of the driving one is constant. This varying velocity has been so arranged that when a machine is doing work the cutting instrument may be moved slowly. When the work is done, and the cutting instrument has to return in order to commence another cut, then the quick motion is imparted to it. Assume that in going forward it is doing its work, and in returning it is doing nothing. In the large model before you the cutting instrument comes back at three times the velocity with which it does its work, so that when there is nothing to do its industry is changed into running instead of labouring.

The class of rolling motions comprehended under the term "mangle wheels" must be noticed. This contrivance, illustrated in its most simple form in Fig. 12, is capable of preserving constant or variable velocity ratio with a varying directional relation. The principle alone can now be dealt with. The end of a shaft, on which is keyed a pinion, is guided in a groove, as shown in Fig. 12. It will be observed that this groove returns into the inner part of the wheel, and therefore, as the pinion is passed from the external to the internal teeth, the direction of motion of the wheel will be reversed. Now, as this groove may be of other than a true circular form, a varying velocity ratio can be communicated. These wheels sometimes fulfil very important offices in relation to the communication of motion by rolling contact.

(*To be continued.*)

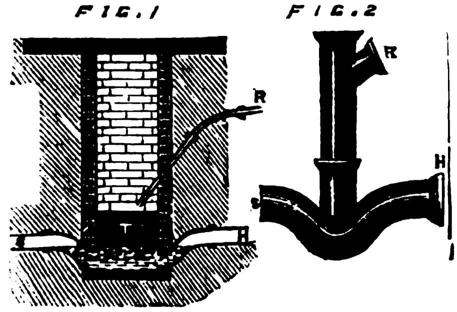
HOUSE DRAINS.*

THE literature of the sewage and drainage questions is gradually assuming gigantic proportions. Volumes have been written on the disposal and utilisation of sewage, and pamphlets innumerable have proclaimed the panaceas of their authors for all the ills of defective drains and drainage systems. The latest publication on the subject, which, however, is confined to the drainage of houses with the view of keeping gas out of them, is from the pen of Mr. Osborne Reynolds, the professor of engineering at Owen's College, Manchester, and, as might be expected, unlike the majority of the sewage brochures and letters to the dailies, contains

* Sewer Gas, and how to keep it out of Houses, by OSBORNE REYNOLDS, M.A., London: Macmillan.

a really sensible and certainly practicable plan for keeping out the sewer gas from our houses. This desirable object is not attained by employing any wonderfully constructed trap—a contrivance sundry species of which the inventors seem to think are capable of subverting the natural laws of fluids and gases, and of curing Nature of her abhorrence of a vacuum. On the contrary, Professor Reynolds abolishes all house traps, and simply places an ordinary siphon pipe between the house and the sewer, taking the precaution, however, to connect the bend in the siphon—the trap, in fact, with the external air. The object of this is, of course, to carry off any gas that may be forced through the trap before it can enter the house drains. He has applied this principle on the larger scale to his own house, and found it to answer perfectly; and in order that our readers may comprehend this simple and efficient plan, we copy the illustration of the man-hole and trap in vertical longitudinal section. All the drains in the house are connected with the pipe H, Fig. 1, which leads to a siphon trough T at the bottom of the man-hole, the latter being constructed as near the house as may be convenient. The floor of this man-hole is 2ft. above the bottom of the drain, which passes through it in the shape of an open trough T 2ft. deep and the width of the pipes, the sides being rendered in cement. This trough is so laid that the water stands half an inch above the orifice on the sewer side S, and an inch on the house side H, while to prevent scum forming on the surface, the pipe R brings rainwater from the roof and discharges it at the upper part of the trough T. Of course, in most cases a much simpler arrangement than this will suffice for the sanitary requirements of the house, for a siphon trap, Fig. 2, with a pipe communicating with the surface and connected with the rainwater pipe, will be found to prevent all influx of gas into the house. "In this way," says Professor Reynolds, "a trap is

FIG. 1 FIG. 2



formed which effectually closes both the house and the sewer from the man-hole, and *doubly closes* the house from the sewer; and if care is taken to arrange the orifices of the pipes in the man-hole as recommended, it will not be possible for the water to be sucked out of the trap [even] should the pipe run full." The little book also contains a clear exposition of some of the more common fallacies of drainage doctors together with the scientific principles which should govern this portion of the sanitary arrangements of our houses. It is a very useful book, with the contents of which every householder should make himself familiar.

THE IGNITING POINT OF EXPLOSIVES.

EXPERIMENTS have been recently made by Messrs. Leygue and Champion to ascertain the temperature at which certain explosives ignite. They used for this purpose a bar of copper, which was heated at one end only. It was provided with small grooves, placed 10 centimetres apart from each other, and provided with metallic alloys of different fusibility, so that the temperature of each part of the bar was easily ascertained. The substance under trial was then strewn upon the bar in small quantities, and the place where it ignited gave the temperature of ignition. Thus it was shown that to explode the different substances the following temperatures were required:—

	Deg. Cent.	Deg. Fahr.
Chassepot percussion-cap powder ...	191 ...	374
Fulminate of mercury....................	200 ...	392
Equal parts of sulphur and chlorate of potassium	200 ...	392
Gun-cotton..................................	220 ...	428
Nitro-glycerine..............................	257 ...	494·4
Chasse powder..............................	288 ...	550·2
Cannon powder..............................	295 ...	562·8
Picrates of mercury, lead and iron...	296 ...	564·6
Picrate powder for torpedoes	315 ...	598·8
" " musket	358 ...	676·2
" " cannon	380 ...	715·8

PROFESSOR AGASSIZ and party at last accounts were in Patagonia. They have found a "desert where even thistles will not grow," but as compensation, have also discovered "oysters a foot in diameter."

IMPROVED AUGERS.

THE improvement in augers and bits shown in the annexed illustration was patented by Mr. James Swan, of Connecticut, but the "letters" are void through neglect on his part to file a specification. He claims to have improved the well-known "Cook" bit, which was patented in this country in 1854, by a modification of the cutting edge. In that bit the cutting edge, commencing at the screw, falls back, so that the most advanced cutting point is at the extreme edge. The object of the modification is to cause the cut to commence at the centre and act as a shave from that point to the extreme edge, whereby the "tearing" often experienced in the use of the "Cook" bit is avoided. The improvement consists in starting the cut of the floor lip at nearly the opposite side of the screw point to that in which the floor lip terminates, and making the edge of a spiral form around the point to the opposite side, then reversing the curve, and carrying it forward up to the termination of the gouge lip.

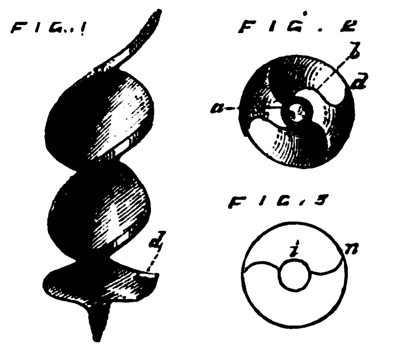


Fig. 1 is a side view of the improved bit; Fig. 2 an end view; and Fig. 3 is an end view of the "Cook" bit of the same size. The twist of the bit is formed in the usual manner. In the "Cook" bit the floor lip commences at the point *i*, on the same side and nearly in the same radial line as its termination *n*, whereby the cut is practically a square cut, the extreme edge being, if anything, a little in advance. In the Swan form the floor lip commences at the point *a*. From this point the cutter curves around to about the point *b*, or half-way from the centre to the edge, which last-named point is nearly opposite to the point of starting. From the point *b* the curve is reversed and made concave up to the completion of the gouge lip *d*, hence the cut acts as a shave to gradually cut from the point *a* towards the extreme edge, the centre being always in advance. As the letters patent are voided, it is open to any one to make augers on this plan, and test their advantages (if any) over the form in common use.

THE INCRUSTATION OF STEAM-BOILERS.*

ALL natural waters contain more or less mineral matter, consisting principally of carbonates of lime and magnesia, sulphate of lime, and chloride of sodium, in solution, and clay, sand, and vegetable matter, in suspension. The many other saline ingredients found in various waters exist in very small proportions, are generally very soluble, and have no relation to the utility of waters in boilers. Of the above-mentioned salts, the carbonates of lime and magnesia are only soluble when the water contains free carbonic acid—consequently the waters of rivers, lakes, &c., contain them in less quantities than those of wells, springs, and creeks, owing to the precipitation caused by the spontaneous evolution of the solvent on exposure to air, heat, and light. American rivers contain from 2 to 6 grains of saline matter in the gallon, in solution, and a varying quantity in suspension, generally exceeding 10 grains. Well and spring waters hold but little in suspension, but a quantity of the dissolved salts, varying from 10 to 650 grains in the gallon. When such water is boiled the carbonic acid is driven off, and the carbonates, deprived of their solvent, are rapidly precipitated in a finely crystallised form, tenaciously adherent to whatever they may first fall upon. Sulphate of lime requires 500 parts of water for its solution, and as the water evaporates supersaturation occurs, and the salt is precipitated in the same form and with the same adherent quality as the carbonates. Chloride of sodium and all the other more soluble salts are precipitated by the same process of supersaturation, but, owing to their greater solubility, much more evaporation is required. All suspended matter gradually tends to subside. This combined deposit, of which the carbonate of lime usually forms the greater part, remains adherent to the inner surface of the boiler. Gradually accumulating, it becomes harder and thicker, till it is as dense as porcelain, though tougher, and at length may obtain such a thickness as to prevent the proper heating of the water by any fire that can be placed in the

* Abstract of a paper read before the American Association for the Advancement of Science at Indianapolis, 1871, by Dr. J. G. ROGERS.

furnace. The high heats, sometimes necessary to heat water through thick scale, will sometimes convert the scale into absolute glass by combining the sand with the alkaline salts composing it; consequently more fuel is required to heat water in an incrusted boiler than in the same boiler if clean. A scale one-sixteenth of an inch thick will require the extra expenditure of 15 per cent. more fuel. This ratio increases as the scale is thicker. Thus, when it is ¼in., 60 per cent. more fuel is needed; ½in., 150 per cent., &c. To raise water in a boiler to any given heat, the fire-surface of that boiler must be heated to a temperature according with the thickness of the incrustation in an increasing ratio. Thus to raise steam to a pressure of 90lb., the water must be heated to about 320° Fahr. In a clean boiler of ¼in. iron this may be done by heating the external surface of the shell to about 325°. If ½in. of scale intervenes between the shell and the water, such is its non-conduction that it will be necessary to heat the fire-surface to about 700°, almost low red-heat. Now the higher the temperature at which iron is kept, the more rapidly it oxidises, and at any heat above 600° it very soon becomes granular and brittle, and is liable to bulge, crack, or otherwise give way to the internal pressure. This condition predisposes the boiler to explosions, and makes expensive repairs necessary. Again, it is readily seen that the presence of scale is extremely wasteful of fuel, and a hindrance to the proper working of the boiler.

Many methods have been devised to prevent and remove incrustation. Picking, scraping, cleaning, &c., are very generally resorted to. Such is its toughness and tenacity, however, that this only partially succeeds, and is moreover expensive both in time and money, since it is generally necessary to lose a working day in the operation. Various mechanical contrivances have been introduced, intended to intercept the precipitated saline matter from the supply water on its passage through the heating apparatus. They consist essentially of a series of obstructions to the flow of the water. After it has been heated almost to boiling by the exhaust steam, the carbonates are precipitated, and subside upon the shelves, straw, and other obstructions, over which the water flows. This plan, however, only partially fulfils the purpose, since it only intercepts a portion of the carbonates and suspended matter. The soluble salts all pass into the boiler, and a great portion of the dissolved carbonates also, which cannot be precipitated during the short passage through the heater. The scales, it is true, form more slowly, but as surely. It is impossible to make such contrivances completely efficacious; no merely mechanical arrangement will suffice. To chemistry alone must we look for the desired means. For a long time simple chemical means have been used in an empirical way with some success. The *modus operandi* of some of these I will notice. Starchy matters—such as Indian corn, potatoes, oil-cake, &c.—prevent scale only by enveloping the precipitates with gelatinous matter, thus lessening their weight, causing them to float, and obviating their agglutination into solid masses. This application, however, tends to cause foaming or frothing of the water, making it impossible to determine the quantity in the boiler, and hence is objectionable.

Molasses, fruits, cider, slops, vinegar, cane-juice, and a variety of other things, containing more or less acetic acid, placed in the boiler, convert the carbonates into soluble acetates. The sulphate of lime remains unaltered, however, and the iron being as much open to the attacks of the acid as the saline matter, the boiler is slowly, but, surely, damaged.

Oak, hemlock, and other barks and woods operate by means of the tannic acid therein. Various extracts, such as catechu, logwood, &c., very rich in tannin, are also used. Tannic acid decomposes the carbonates, but, unlike the acetates, the resulting tannates are insoluble. Their specific gravity, however, is low; they float in the currents of ebullition, and, having no tendency to adhere, do not agglutinate into a mass, and cannot form a scale. The sulphates and chlorides are not acted upon at all by the tannic acid, and will incrustate notwithstanding its presence. Tannin, as offered in the above-named agents, is left free to act upon the iron, and will, after a time, exhibit its damaging effects on the boiler.

The fixed alkalies are much used for this purpose, in the various forms of lye, ashes, carbonate of soda, caustic soda, potash, &c. These agents decompose the sulphate of lime, sulphate of soda or potash, and carbonate of lime being the results. The first is held in solution, the latter is precipitated, but in larger crystals, which do not form so refractory a scale as ordinarily. The carbonates of lime and magnesia are also precipitated by these agents, the free carbonic acid being taken to form carbonates or bicarbonates of soda or potash; the chlorides are not affected. This method simply modifies the form of the precipitate, and consequently the quality of the scale, without affording any means for its prevention, and therefore deserves but little attention. Ammonia and its carbonate have a precisely similar action, and the same objection stands against them. These alkalies have no chemical action on the boiler, but rather tend to preserve it, inasmuch as they prevent the free carbonic acid from combining with the insoluble crust of oxide of iron (formed by con tact with the water) to form a soluble carbonate of iron, which, being dissolved away from the iron, would leave a surface constantly exposed to fresh action. Chloride of ammonium is another means employed. This has its action only on the carbonates of lime and magnesia. The reaction produces carbonate of ammonia, which, being volatile, passes off with the steam, and chlorides of calcium and magnesium, both very soluble. This is an efficient way of removing old scale. Its only objection is the ammoniacal odour of the escaped steam.

The foregoing are methods in which a single agent is used. They are frequently combined with a view of obviating the mentioned objections. Starch, tannin, and soda, constitute the basis of most of these combinations. Crude petroleum is also used with reported partial success. The *rationale* of its action is not well understood, owing to the complexity of its chemical constitution. There are many proprietary compounds at present in use composed essentially of these elements, generally, however, with the addition of other things, introduced for the purpose of disguising their composition. Besides these, many other preparations are before the public which have been patented, all having a general resemblance, inasmuch as tannin, starch, and soda are the principal ingredients, in some form. Gum catechu is most generally the tannin-bearing body; sal soda, the alkali; and flax-seed, oil-seed cake, bran, or coarse flour the starchy element. In most of those which I have examined these very useful agents have been simply mixed empirically, without regard to chemical laws, and they generally contain more or less free tannic acid, and a considerable amount of inert, insoluble vegetable matter, which tends to produce foaming, besides being useless. Besides these methods, in which the chemical agents are introduced directly into the boiler, others have been devised, in which the waters are depurated, by chemical means, before entrance into the boiler. Clark's process consists in the precipitation of the carbonates with milk of lime, the free carbonic acid being taken up; the sulphate of lime remains in solution. Another method, proposed by myself, consists in converting the earthy carbonates into soluble chlorides by hydrochloric acid, and neutralising the excess of acid by filtration through carbonate of baryta (witherite) in coarse powder. The soluble chloride of barium thus formed decomposes the sulphate of lime, chloride of calcium being kept in solution, and the sulphate of baryta being deposited insoluble. This method recommends itself for railway water stations, on account of its cheapness and simplicity. Oxalic acid may be used very efficiently for the complete precipitation of all the lime salts as insoluble oxalates, but the expense might be a bar to its use. Tannic and acetic acids, the excess being properly neutralised by carbonate of soda, may also be used for tank depuration. These tank methods, however, cannot influence to any great extent the scale already formed; and as the removal of this is as needful as its prevention, it is palpable that that method is best for general application which secures the complete removal, as well as prevention, by chemical means operating inside the boiler.

Having this end in view, Dr. Rogers proposes two processes: one consists simply in the introduction into the boiler of a sufficient quantity of the oxalate of soda to cause the immediate decomposition of the scale-forming salts as they enter the boiler, converting them into insoluble oxalates, which are precipitated as a mushy sediment, which has no tendency to form scale, and which may be blown out from the mud-receiver, or otherwise voided. In the other process tannate of soda is the agent, kept constantly present in the boiler in solution; it decomposes the carbonates of lime and magnesia as they enter, tannates being precipitated in a light, flocculent, amorphous form, so that they do not subside at all in the boiler, but are retained in suspension by the boiling currents until they find their way into the same receiver, when they settle into a loose, mushy mass, which may be easily blown out from time to time. The carbonate of soda formed in the reaction is retained in solution, becoming a bicarbonate by appropriation of the free carbonic acid in the water. This decomposes the sulphate of lime, the resulting sulphate of soda being retained in solution, and the carbonate of lime being acted upon by fresh portions of the tannate of soda as above. The constant presence of the alkali protects the iron from all action, either of the carbonic or tannic acids. The same reactions take place between the tannate of soda and the already existing scale with like results, but more slowly, some weeks being generally required, in practice, in removing the deposit, if it exists in any considerable quantity.

Portions of scale are detached, from time to time, which may be removed at the usual cleanings, which should be made at short intervals, when possible, until the boiler is entirely clear of all incrustation, after which this will not be necessary. Extensive practical trial of this process for two years has demonstrated its utility for all varieties of boilers. It is economical, easy of application, and generally adaptable. It may be used in marine boilers as well as those using fresh water, since the marine scale is almost identical with that formed in boilers using ordinary waters, consisting almost entirely of the carbonates of lime and magnesia, and sulphate of lime. The chloride of sodium forms a mushy deposit, but is only incorporated in the scale to a slight extent.

USEFUL AND SCIENTIFIC NOTES.

A New Dryer.—M. Mène states that if 12 parts of best shellac and 4 of borax are dissolved in 100 parts of water by heat, and when cool, mingled with turpentine, an excellent and rapid dryer for oil paints will be produced. The solution may also, he says, be used as a varnish.

Testing Coffee.—Many adulterations in coffee can be easily detected, even if the taste is not a sure index. If a teaspoonful of genuine ground coffee be thrown into a tumblerful of cold water, it will float upon the surface. Some substances used in adulterating coffee will sink at once.

Spontaneous Combustion of Silk.—We learn from Dingler's *Journal* that it has been found that silk goods containing picrate of lead frequently catch fire in transit by railway. Experiments made in consequence show that a very slight amount of friction is sufficient to ignite samples of such silk fabrics.

Proposed Large Steamship.—It is stated that specifications are at present in the hands of several Clyde shipbuilders for a new vessel for the National Steamship Company. She is to run between Liverpool and New York, and is to be of gigantic proportions, second only to those of the Great Eastern. The dimensions are to be: length over all, 576ft.; breadth of beam, 50ft.; depth of hold, 35ft. It is expected that this great steamship will make the voyage from port to port in seven days.

Aluminium Coinage.—It has been a question in Paris of replacing the present bronze money by an alloy of aluminium. The adoption was supported by M. Sainte-Claire-Deville, but opposed by MM. de Marcotte de Quivières, the director of the Mint, and Peligand, chemist and assayer of coin. The reasons *pro* and *con.* are not yet made public, but the Government is recommended by the commission of the Mint to continue the experiments with aluminium.

Cleaning Greasy Wool.—A large number of manufacturers and scientific gentlemen assembled on Wednesday week at Clegg Hall Mills, near Rochdale, to witness a new process of cleansing wool by a cold method and without the use of alkali. The liquid employed is fusel oil, and a large bale of wool, greasy and dirty as possible, was submitted to experiment. We understand that the opinions expressed were favourable to the process, which is that of Messrs. Paul Toepler and Co.

Utilisation of a Waste Material.—It appears that large quantities of grease find their way into the sewers of Bermondsey. Seven years ago the Board of Works permitted its sewer men to explore the underground channels in the neighbourhood, and the result was the collection of grease or fat, which, when sold, and after paying liberally for expenses of collection, left a balance of £104. This sum is to be devoted to public improvements. This is another instance of the value of what are generally termed "waste products."

The Cholera.—Authentic numerical returns of the progress of cholera in Russia lie before us (*British Medical Journal*). They show that most imminent danger may be anticipated. In the Government of Ekaterinoslaw there had been, on June 12th, in the town of Ekaterinoslaw, 316 cases, with 195 recoveries and 109 deaths. In the Government of Kiew there had been, in the town of Kiew, on June 21st, 2105 cases, with 714 recoveries and 1001 deaths; and in Oumane, on June 10th, 196 cases, with 74 recoveries and 43 deaths. In Odessa, on June 23rd, there had been 173 cases, with 60 deaths; and in Kherson there had been, on June 21st, 301 cases, with 70 recoveries and 60 deaths. In Kamenets (Podolia) on June 10th, there had been 319 cases with 46 deaths. Cholera has also broken out in Moscow.

London Association of Foremen Engineers.—The meeting on Saturday, the 6th inst., Mr. Joseph Newton, President, in the chair, was a half-yearly meeting. The auditors' report showed the balance sheet correct, which left some cash and some not inconsiderable claims in the hands of the treasurer. The total value of ordinary funds amounts to £477 12s. 11d., the superannuation fund to £1,294 17s. 1d., stock (Three per Cents.); the widow and orphan fund also leaves a small sum in the hands of the treasurer. The report is signed by Messrs. W. H. Sissons and Robert Hedley, auditors; by Mr. Joseph Newton, president; and by Mr. Meredith Jones, treasurer. The association counts altogether 137 ordinary and 74 honorary members, 12 of the former and six of the latter class having been added to the list since January. At the last meeting Mr. Charles Leager was elected a member, and Mr. Alphonse Lafare an honorary member; Mr. James Halket was put into nomination. On the retiring of three senior members (Messrs. Reid, Coates, and Salmon), according to the statute three junior members (Messrs. Haughton, Gibbon, and Bulleugh) stepped into their places. The three new members of committee elected were, Messrs. Virtue, Carnaby, and Grantham. Mr. Scott was elected junior auditor. The meeting resolved to have a summer outing on the last Saturday in the month to Epping Forest, the detail arrangements to be left in the hands of the committee.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the English Mechanic, 81, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. Passmore Edwards.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

**** In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

AXES OF THE PLANETS.

[4572.]—I am obliged to "W. T. R." for his answer (let. 4356, p. 460) to my question on this subject. He does not, however, say whether he takes his information directly from Schröter. I have good reason for believing that "W. T. R.'s" information is correct; but if only taken from some work on astronomy it does not remove the doubts I expressed. In Klein's "Sonnensystem," the only German work I have which refers to the matter, it is stated plainly enough, "Nach Schröter soll der Æquator des Merkur mit der Ebene der Bahn einen Winkel von 20° bilden." But I have two text-books stating as plainly, "the axis of Mercury is inclined 20° to the plane of the ecliptic." That is why I ask for some information so definitely referred to Schröter's own account as to remove all doubt. I could, of course, hunt out the truth at the British Museum, or, probably, at the rooms of the Astronomical Society, but just now I am particularly busy.

Richard A. Proctor.

A GIANT PLANET.

[4573.]—I am glad to find that Mr. Proctor thinks me such a pleasing critic (let. 4446, p. 405). He thinks I acted unfairly in quoting only a part of a sentence of his, I can assure him I had no such intention, my only motive for the omission was the desire to save space. I used all the tangible part and sufficient to give the sense without alteration. He asks, have I never heard of a geometric mean? I have heard of such a thing, but did not see the most distant allusion to it in his article. May I ask him why, if he meant the geometric mean, he did not say so, instead of using the word "midway"? which, it now appears, makes him say something quite different to what he wanted to say. Midway means the part equally distant from the beginning and the end: 8,000 miles is the commencement in this case and 840,000 miles the end, and Jupiter's diameter of 82,000 miles when multiplied by five is then nearly equally distant from these two numbers. In his article he does not speak of the mean of any number, distance, size, or quantity, nor do I mention such a thing in my letter.* Also he asks "Do I need to be told that Jupiter's bulk is more than a thousand times greater than the earth's? or that it was the rough correspondence between this relation and the relation between the sun and Jupiter that he had in view?" I do not require the information he tenders me about the respective bulks, but I do wish he would tell me why he did not say Jupiter was as many times greater than the earth as the sun was times greater than Jupiter, if that was what he meant, instead of saying Jupiter was "midway" in size between the sun and earth? Jupiter to occupy a position "midway" between the sun and earth in size would require to be over six hundred thousand times as large as the earth, instead "of more than a thousand times." By no possible means can he make the ends of his argument meet, for if Jupiter was "midway" in diameter he could not be "midway" in bulk.

He tells us: "It is the very essence of his reasoning that the red-hot surface of the planet would be discernible, perhaps even through the cloud belts which seem to us the densest." Having given us his own definition of the pith of his argument, it is at last possible to grapple with him. Unfortunately, however, "the essence of his reasoning" consists of a supposition that an impossibility might occur. During several days past the sun has been invisible at noon day, the clouds having hid the bright summer sun from our sight. If our clouds can thus hide the almost vertical sun, which is thousands of times brighter than a red-hot body, what would the (to use his own words) "enormous masses of cloud suspended in the atmosphere of Jupiter" do with the visibility of a red-hot planet?

Mr. Proctor observes that his "theory presents the heat of Jupiter as (in the main) not obscure." In this particular, then, his theory is false, for the rays emitted by a red-hot body are chiefly obscure heat rays. On those occasions to which I have alluded, when the sun

* "Hyrab Sen's" attention is respectfully called to an answer to a note in answer to "E. T. J.," last page of last No. of English Mechanic.

was invisible, the aqueous vapour (need I say by absorption) so materially retarded the passage of his radiant heat that the temperature was fully one-third lower than it would have been had the air been free from vapour; and his heat is certainly not obscure.

If I have read his article he says, I know perfectly well that "he does not regard the cloud envelope as covering the whole of Jupiter." I am aware he does not view the whole of the planet as cloud covered; but judging from his own language, he certainly considers the red-hot portion to be in that condition. In that paragraph of his article wherein we are first introduced to his idea of a red-hot Jupiter he remarks, "Now, heat is the only form of force which could account for the enormous masses of cloud suspended in the atmosphere of Jupiter. And it seems difficult to conceive that the clouds could be maintained at a great height above the real surface of the planet, unless that surface were intensely hot, as hot, perhaps, as red-hot iron. If we supposed this to be the case, we should find at once an explanation of the ruddy aspect of the dark belts." Here, then, he says, the red-hot portion is covered by enormous masses of cloud, which require an intensely heated surface beneath them to maintain them at a great height; in fact, it is this great cloud mass and its behaviour that led him to the theory of a red-hot planet. The enormous clouds, and the peculiarity of their motions, prevent his viewing them as sun-raised—he thinks it must be the planet's own heat that has produced them—he sees portions of the planet look red, then he jumps to the conclusion that Jupiter is red hot. Unhappily he did not see that these enormous masses of cloud, the very existence of which compels him to believe Jupiter to be intensely heated, would prevent the planet being invisible however red-hot he might be. To have made his theory even slightly plausible he should have given Jupiter a bright white heat, and then he might have been visible through a very moderate thickness of cloud as a red-hot *looking* body, much the same as the sun when he first shows himself through a thick vapour screen with a red face.

Is it not clear Jupiter cannot be red hot, for if he were we should see no red belts, they would be hidden from our view by the "enormous masses of cloud"? In proof of this assertion I adduce the fact of the sun's disc being shut out by a far smaller mass of clouds. In my letter I said, "Now, if Jupiter is at a red heat [his clouds must be as dense and impervious as a Newfoundland fog bank; in fact, they must partake more of the nature of semi-condensed steam than of terrestrial clouds], *for if clouds are generated by the red-hot surface, rain must fall on it, and directly rain fell it would be sent hissing back in the form of steam.*" He gives only that part of the sentence which I have put in brackets, thus making me appear to say almost the reverse of what I actually said. I am represented by him as holding the opinion that Jupiter's clouds are like semi-condensed steam, and he managed to do this by omitting the words "if Jupiter is at a red heat," but as it is evident from my letter that I don't believe in a red-hot Jupiter, it is equally apparent I cannot believe his clouds to be of the very dense and steam-like nature I supposed they would be if he were red hot. The concluding portion of the sentence from which he quotes, and which I have now distinguished by italics, he ignores entirely; he does not even attempt to answer it; and as it is pertinent to the question at issue, I am driven to the conclusion that he was unable to refute this portion of my arguments, which is certainly directed to the intensely-heated planet part of his theory. Mr. Proctor wishes me to give an illustrative calculation in proof of my assertion that if Jupiter was as hot as red-hot iron—viz., 1,200° Fahr., his most distant satellite could only receive 2° from this source, and this statement astonishes him so greatly that he petulantly tells me I "count degrees Fahr. as a schoolboy counts marbles." If I do it as well as that I am satisfied, for schoolboys count marbles pretty correctly. The calculation he asks for I will give him with pleasure; but may I ask him if it would not have been better for him to have supplied a calculation, proving that the satellite in question could receive any considerable amount of heat from a red-hot Jupiter; and so refuting me instead of asking me so many questions. Forgetting that it is his theory which is on trial, he asks me to prove everything, whilst he hardly attempts to answer at all, and throughout the whole of his letter proves nothing. The method of calculation I employed is similar to that which Sir John Herschel used in estimating the actual heat of the sun. At the distance of his farthest moon (1,244,619 miles) Jupiter's rays are by radiation spread over a hollow sphere of the heavens, whose surface is, roughly speaking, 600 times as great as Jupiter's surface. Now, as his rays have, at that distance, to warm a surface 600 times as large as his own, their temperature will, from this cause, be reduced to the 600th part of what they had at Jupiter's surface; therefore, if Jupiter's heat is equal to red-hot iron, then $1200° \div 600 = 2°$ must be the amount of heat he would impart to his outer satellite. He is amazed at my assertion that Jupiter would be invisible to dwellers in his farthest moon, if he shone only as a red-hot body, and tells me I may take it for granted at that distance his "disc would appear just as bright as red-hot iron." Also, I am informed that I share in the common error that distance *per se* has an effect in diminishing the apparent brightness of a luminous object." With all due deference to so great an authority I decline taking his assertion for granted, and although I know it is the orthodox scientific view that distance does not diminish brilliancy, I shall still persist in believing it does. To support my views I will refer to the earth-shine on the moon which renders the darker part of the moon just visible, on a clear night, when the moon is a few days old. The earth, owing to greater size, sheds on the moon eleven times as much light as the moon sheds on us, therefore, earth-shine on the moon must be eleven times brighter than moonshine is here, and if distance does not diminish brilliancy the earth illumined part of the moon should appear to us very much brighter then the moonlit earth. Now, is this the case? I ask any of your readers if, on a clear moonlight night, a brick wall, which is not a very good reflector, does not appear many times brighter than the earth-lit moon? Of course, the depth of atmosphere through which we see the moon has considerable effect in dulling the brilliancy of the earthshine, but making all due allowance for this it is evident that distance is the cause of the great diminution of brightness we so plainly see. I should like to ask Mr. Proctor why, if distance does not reduce the apparent brightness of a luminous object, the stars—suns as bright as our own—do not appear so brilliant as the sun? there are no atmospheric effects to interfere in this case. I was afraid so great and potent an astronomer as Mr. Proctor would not be satisfied with petty terrestrial evidences, or I might have offered him many experimental proofs showing that distance does diminish brightness. He complains that I make him say, "Jupiter shines three or four times as brightly as a globe of his size should, if reflecting the sun's light only," and that I omitted the "important words" "if constituted like Mars or the moon." Then he goes on, "To remove all misapprehension, I actually added the words, 'Jupiter shines, in fact, very nearly as brightly as though he were constituted like one of our terrestrial clouds; This would, however, have ruined 'Hyrab Sen's' ingenious argument, and is, accordingly not admitted." To all this I reply: "If he will refer to my letter he will find it was Dr. Zöllner, and not him, whom I made say this; but I wrote on the assumption that he had adopted Dr. Zöllner's estimate of the planet's brilliancy, and as there is no reason for supposing Jupiter to be a better reflector of light than Mars, the words "if constituted like Mars" do not alter the case. If my ingenious (!) arguments would have been ruined by the fact of Jupiter's shining nearly as brightly as if constituted like one of our terrestrial clouds, why does he not show us how they would have been ruined? why does he not meet argument with argument instead of merely making an insidious assertion of no value? What do I mean, he asks, by saying that sunshine here is hundreds of times brighter than the light emitted from a body heated to redness? Unfortunately we have no means of accurately measuring light as we have of measuring heat—in fact, we cannot measure it at all, we can only estimate it by the impression it makes on our senses. I will give the method I used of estimating the li ht of a red-hot body and leave it to others to judge of its value. Let us take a page of printed matter (say of the same sized type as his article was printed in)—and hold it within a foot of a large red coke fire in a darkened room, we can then just see it sufficiently clear to read it, and the distance is so small there is hardly any loss by radiation; then let us take the same page into the open on a clear night when there is a full moon, and we shall find it as easy or easier to read it there than by the light of red-hot coke, however close we hold it. From this I infer that moonlight is as bright or brighter than the light emitted from a red-hot body, and sunlight is demonstrably thousands of times brighter than moonlight; therefore, if the light emitted by a red-hot body was even ten times as bright as moonlight, sunshine would still be hundreds of times as bright as the light emitted from a body heated to redness. HYRAB SEN.

THE NEPHILIM IN YORKSHIRE.

[4574.]—THE account of the Settle Cave discoveries, copied from the *Pall Mall Gazette* into p. 323 of the MECHANIC, had originally appeared in the former paper the very same day I noted, that your number of June 7 came forth, with the most contemptuous demands for *any evidence, either of the occurrence or period* of a universal flood (let. 4239, p. 303). I was about to notice the singular opportuneness of the answer, had you not saved me the trouble by reproducing it entire, and as Mr. Brookwood, the next week (let. 4356, p. 352) pointed out the diluvial bearing of the remarkable godsend, I should not write this, were there not a most unlucky misprint in your copy that puzzled me for a minute, and may therefore either puzzle or quite deprive some readers of the gist of the evidence. A little below the middle of last column (p. 323) a line begins, "But there were evidences of a very much older *Roman* occupation than this." The context would soon lead most readers to infer that "Roman" is a misprint for *human*, the argument being that as the two feet of frost chips, above the newer human relics have taken roundly 12 centuries to accumulate, the six feet of similar chips between the two classes of relics may probably have taken the previous 36 centuries. Having been almost driven, by this serious erratum, to revive the subject, I would further remark that the upper Romano-Celtic relics really date themselves more precisely than the *Pall Mall* writer ventured to fix them. He says, "there are two extremes between which the date of this occupation of the cave must [illegible] —the fifth century, as shown by the barbaric [illegible] and the first quarter of the seventh century, w[illegible]..us, kingdom of Stratholyde (or Cambria) was [illegible] n the by the Northumbrian Angles." Now coi[illegible] .quered circulated in such times (as they do now [illegible] constantly most civilised places) for a century or [illegible] in all but the were made; but surely these Rom[illegible] two after they Welshmen (the famous King Arth[illegible] .nised Britons or over-soft and falling race, wo[illegible]'s subjects), then an [illegible]ld not take to cave dwelling till their country was actually invaded by our ancestors the English, which was not the case in that very westerly part of modern Yorkshire (but ancient Cumbria) till well into the seventh century. The Angles, under Ida, had settled the eastern watershed in the middle of the sixth, but we read of no warfare by them west of the Penine chain till under Redwald A.D. 616, and Edwin of Northumbria, who, in 623, reduced Cumbria into permanent subjection; so that the quarter of that century is rightly fixed by the *Pall Mall Gazette* as the latest limit possible for the civilised Settle Cave relics, or 1250 years (rather than 1200) as their present least age. Supposing, then, the débris to be regular enough to admit so exact a measurement as stated of the ratio 1:3, between the upper and lower accumulation, and to be an accurate geo-chronometer, it gives us roundly $1250 + 3750 = 5000$; the exact "50 centuries," the "E. L. G.'s' 5000 years," about which so many of your correspondents have been making merry. Such, says the cave, is roundly the period since the "men of the drift" (or any older than Arthur's knights) occupied it; and such, say the elder versions of Genesis, the period since Nephilim were last in the earth, and "the earth was filled" (and consequently Yorkshire) "with violence through them." Of course those who read geological facts as they turn up, know that this is only the old story, a hundred times before and elsewhere, in divers ways meeting us. The comparison of the depths of peat, above and below the Roman causeway through the Peterborough fens; the depths of Nile mud, above and below the footings of dated Egyptian monuments; the pre-Roman and post-Roman deposits of Swiss lake deltas, and fifty other modes of testimony, as Cuvier, Buckland, and Mantell showed, all concur as closely as the above little sum. Neither in Europe, Asia, nor America, is there any clash of evidence. The Settle Cave brought no news; but the thing to note is, you having issued "Sigma's" call (p. 303) for "*any* evidence, either of occurrence or period," that morning of June 6, how singularly pat comes this issue of the *Pall Mall Gazette* the same afternoon. E. L. G.

EDDY'S GAS STOVE.

[4575.]—I AM at a loss to perceive the utility of this stove, unless it be so arranged as to bring fresh air into the room, not merely, as appears from the description, to warm that previously in, to be mingled with the products of combustion. The stove would warm a room more comfortably if the openings at the top were closed and the heated air made to escape at the bottom, for then the lower part of the room would be better warmed; moreover, the shell of the stove would become hotter, and therefore give off more radiant heat, which is the best and pleasantest form of heat for warming us. The total quantity of heat would be proportionate to the gas burned in either case. But it will be asked, "What, then, is the use of the rather complicated internal arrangements?" and that is exactly what I want to know. It seems that they will have no effect at all except to mix the products of combustion with air. If, indeed, those products were conveyed away out of the room altogether, those arrangements might be of some little use in providing a large surface for warming air; but the heat might be more usefully employed in warming a large surface, from which heat may be radiated, for radiant heat warms the bodies on which it shines above the temperature of the air surrounding them, and it is both pleasant and wholesome for us to be so warmed, when we need artificial warming at all; lately artificial cooling has been more needed. PHILO.

MONOLITHIC BUILDING.

[4576.]—To "W. G. C."—I am glad to see the subject of monolithic building brought forward in "ours," being myself a firm advocate of the system. Your letter (No. 4462) is a source of astonishment to me, as the statements you bring forward there are entirely at variance with facts which the "adverse critics" of the system can turn dead against you; the weak points of the "Polylithic" system (if you will accept the term) are not, as you seem to suppose, from thin mortar joints, nor yet from "smooth-tooled surfaces," being bad holders, but quite the reverse. Neither is the rough surface of the concrete the cause of better holding, and consequent strength in the monolithic system, but rather in the use of good cement newly prepared and used before the first intention of setting has taken place, together with being well compacted by ramming the material, which is thus brought into closer contact.

In all cementing processes the con[illegible]ditions of a good holding joint are close contact of the substances cemented and consequent thi[illegible]ness of the cementing material. The reason is se[illegible]f-evident, there being no after shrinkage, or comp[illegible]ratively none, whereas in the polylithic system the after shrinkage is very considerable, and when w[illegible]ndow and door frames intervene, as they must do in house building, and these cannot yield much [illegible] in the shrinkage, there is, I think, quite sufficient cause to account for ruptures and weakness. Furth[illegible]rmore, the practice of making beds of mortar th[illegible] lie for weeks before being used must be destruc[illegible]ve of its cementing properties. Another serious evil lies in the rapidly absorbing nature of dry brick. The water is absorbed before the chemical change has had time to complete itself, and though afterwards given up in part, still it can never restore it to good sound mortar; hence, in setting the arches of doors and windows the bricks are first wetted to counteract this tendency. Such parts are, therefore, invariably found to be the strongest in the building, the extreme thinness of the mortar joints notwithstanding.

EPSILON.

THE NEGRO.

[4577.]—THE pun of "T. A." (let. 4541, p. 461) upon the ambiguous English word "*fair*" in Gen. vi. 1, 2), ought really to be embalmed as a specimen of this generation's "biblical criticism"—the matter in which alone all may shine alike, even "T. A.," equally with a bishop. If he had happened to be a Greek or Russian, it might have been pointed out in his Septuagint, that in Solomon's Song, i. 5, a verse, where, *if anywhere* an actual negro (and that, a lady) is introduced, she gives herself this very same epithet! "I am *black*, but comely (καλὴ), O daughters." In Genesis, the Adamites "saw the daughters of men, that they were καλαί." But if "T. A." has the audacity to overrule Solomon, that no negroes can be καλὴ, this would not clash with my supposition that among the non-Adamite perished races was one black one. Has he not seen that I assume at least three distinct races, how many more is unknowable, but one race to afford the mother and the wife of Japhet, another those of Ham and the negroes, and a third those of Shem? I only said there *might be* reasons for Noah and his sons having no wife of their own race; without seeing that the story *does* plainly indicate a reason, that may in all probability have amounted to necessity. Consider the force of the statement that "all flesh (humanity) had corrupted his way upon the earth." In the remote savage tribes, whose relics alone we find, the "Flint-folk" or "Men of the Drift," the corruption consisted in mere "violence." In the civilised cities, and the Adamite race above all, it was more refined; and what do we now find in such races that have most corrupted their way? No guide but self-interest, hence infanticide, especially of female children (as in China), and it being no one's interest in particular to bring up daughters rather than kill them, imminent or actual dying out of the race for want of females to continue it. This then, happening now, must have happened when "*all* flesh had corrupted his way upon the earth." It would simply contradict this sentence to assume that after the Adamites had taken to marrying the inferior, short-lived "daughters of men" (as Gen. vi. implies) for some centuries; there remained any daughters of their own race unslaughtered. There could be no Adamitess brought up (especially as they were doubtless of slower growth) for Noah to marry, much less for his sons; and so, in all probability, the reduction of life was become inevitable whether any Deluge happened or not, and Noah would, in any case, had there been no Deluge, have ended the long-lived Adamites; or rather, as the same causes would have extinguished the mixed and short-lived races too, the Flood was necessary to *preserve* any human species on the earth at all! And so may future equally wide destructions (as prophesied) be, according to all present social appearances, equally necessary. Even if the females of the long-lived race were not extinct, this cause must have made them too scarce and precious to be within the means of Noah and his sons to purchase; for everything implies they were a poor and unknown family—that of a "just man," and "preacher of righteousness," in such times, could not be otherwise; and no wealthy or powerful man would have needed anything like a century for building and provisioning the Ark. A German fanatic of Luther's time, having persuaded himself of a new Deluge, built an ark of equal dimensions, we read, in a year or two, though so far from rich (or at least from well-advised in construction) that he saw it fall to pieces before the time anticipated for its use.

In connection with longevity, and especially whether, after the flood, it was as great in the women, it should be noted that the Bible gives but one female's age, Sarah's, and she lived barely two-thirds of her only *son's* life. Again, in Job (who was probably earlier), the death of a wife, mother of ten grown-up children, and taking of another, who bears ten more (as Abraham's last did six), appear matters of common course. But the facts that though Shem (and presumably his brothers) lived after marriage five centuries, his wife bore but five sons, Ham's but four, and Japhet's but seven, surely imply these women to have been of very different longevity from their husbands. If of the same race, why should they not have had (as tradition attributed to Eve and antediluvian women), fifty or more sons apiece, when they were so greatly needed?

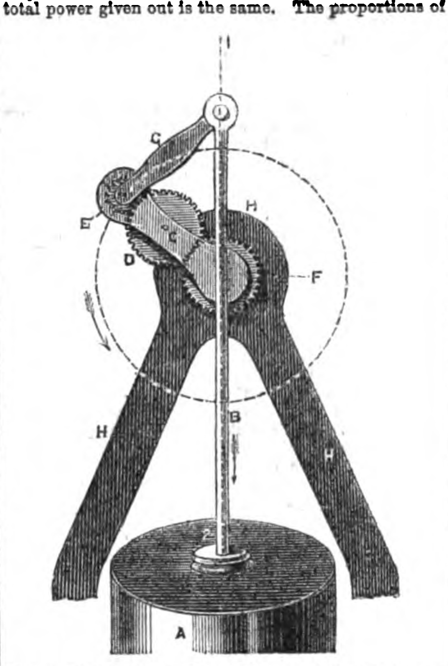
As for "T. A.'s" notion that men who, for ten generations, lived (by his own showing) the respectable age of above 900 months, never discovered the existence of a natural period *longer* than months! and called them "years" indifferently, it is really necessary he should fix distinctly *what* "change in the mode of reckoning" the genealogy of Shem gives "evidence of." At least, he or any reader equally hazy may be asked to take the small trouble (which I object to do unless forced) of copying out these verses, Gen. vii. 11, viii. 4, 5, 13, 14, 18, x. 1, xi. 10, 12, 13, 14, 15, giving to the "years" what he considers their modern meanings, and explaining at what later verse the "change in the mode" comes in. If the *longest* antediluvian life was 78 years, what does he consider the life of Abraham or Isaac to have been, longer or shorter, and for what reasons? I mean natural and admitted physiological reasons. And especially the "few and evil" years of Jacob, when he said they had not attained to those of his fathers, xlvii. 9; what were they?

The "T. A." sort of mind being commoner in this subject than in others, let me add for him that if Shem, Ham, and Japhet, or rather their three mothers and three wives, were, as I suppose, as distinct as the Mongol, Negro, and Gothic races, the angles of the triangle that includes all other modern ones, then the long-lived race, whose last pure specimen was Noah, were, of course, different from all these; and, *in colour*, may (or rather *must*) have approached what we find least like them separately at present—namely, the Red Indian—we need not suppose in any other respect than colour. Hence, Hebrew tradition would be no likelier to give them and their father any epithet than "*Adam*." We are not to suppose any of the patriarchs bore in life the names we know them by, or that Chinese, Phœnicians, Hindoos, or any nation has known them by. All these are *descriptive epithets*, made ages later; and in the Bible, rather *translations* of such epithets into the Canaanite tongue of Samuel's time. E. L. G.

A NEW METHOD OF CHANGING RECIPROCATING INTO ROTARY MOTION.

[4578.]—THE following slight sketch of a proposed means for effecting the above purpose will, I venture to think, interest some of your mechanical readers. Their opinions as to its practical utility are requested.

In the accompanying diagram A is a fixed cylinder, B the piston rod, C an arm attached to the shaft, this arm is double from E to C, and carries two toothed wheels E and D; F is a fixed tooth wheel either cast on or otherwise secured to support H H H., the shaft to which arm C is attached passes through the centre of F, and has its bearings in it and through into H; to the axle of small wheel E (indicated by dotted circles) is attached an arm G, which is connected with piston rod. The motion of piston rod is communicated by arm G to the wheel E, causing it to revolve; this sets the wheel D in motion, and this wheel being geared with the fixed one F travels round the same, carrying arm C round at same time, thus giving a rotary motion to the shaft to which C is attached The variations in power and speed at different parts of the stroke are very similar to those of the ordinary crank, and the total power given out is the same. The proportions of



the wheels are, D and F = 1, E = ½. The wheels can, of course, be used of any breadth, and sets carried on each side the piston rod, in order to distribute the work over a greater surface of teeth. This motion has been tried on a moderate scale (with two 6in. and one 3in. wheel, stroke 3ft. 6in.), and found to answer satisfactorily as regards the motion of the piston rod being maintained in a perfectly straight line, and as to the power given out equalling that given out by the ordinary crank, but it has not yet been tried in a steam-engine. It has the great disadvantage of being a combination of toothed wheels, but it has the following advantages, which may perhaps counterbalance the said disadvantage, viz.:—There is no tendency at all in this motion to throw any side thrust on the piston rod, and consequently the necessity for connecting rods, cross heads, parallel motions, slides, and guides, is done away with; it works in as little room as an oscillating engine and has a fixed cylinder. To sum up, it has none of the friction attending it usually caused in engines by machinery, used to counteract the side thrust on piston rod, which is always present in every engine turning an ordinary crank. If these advantages are sufficient to overcome the objection to the use of toothed wheels, practical men can judge. My own opinion, as a theorist, is, that for ships' use, with engines of long stroke, this motion with fixed cylinders would be preferable to either trunk, beam, or oscillating engines, and perhaps more especially for screw steam ships, as it will be observed the arm C is only one half the length of an ordinary crank for same length of stroke. I believe engines of long stroke are desiderated; if so, this motion is especially suited for them, and some of the disadvantages connected with the use of toothed wheels would be overcome by the fact that they are the parts that would be most affected by wear and tear, and are also the very parts which could be most readily renewed whenever occasion required. Drawbacks arising from weakness in the arms G and C (if any), as compared with the usual cranks and connections might be obviated by working, instead of the two cylinders as ordinarily used, four or more of the same aggregate area, and thus distributing the strain as required.

In order to take up as little space as possible the drawing is only contrived to give a general notion of the idea. If the subject should prove of sufficient interest I will gladly furnish more details in a future number, in the mean time soliciting the opinion of practical mechanics. G. PINNINGTON.

AN OPINION WANTED ON A NEW MATERIAL IN ORGAN BUILDING.

[4579.]—WILL "Harmonious Blacksmith," "J. D.," or other amateur builder kindly give their candid opinion on the adaptability of paper for organ pipes, I mean such as are circular. I do not consider myself even an amateur; but I do claim to be an enthusiast, having some slight acquaintance with the principles of organ building, and, therefore, willing to give to others the result of my thought whenever anything suggests itself. Suppose, for instance, a mandril or roller of wood, say, 2in. in diameter, and 2ft. in length, be turned perfectly straight, and a sheet of paper be coiled round it as tight as possible, putting glue or other cement all the way until the paper is of sufficient thickness, say five or six times round, being sure that glue is used first time round, so that the tube thus formed may be slipped off and put aside to set hard, after which it may have some suitably decorated paper put on the outside. Then take a piece of dry, hard wood, and turn a foot or boot in such a way as to admit of a round block or languid being put inside, and a round cap outside, leaving a passage for the speaking wind as usual. Now, take another piece of wood and turn it out so as to form a short tube of sufficient length to form that part of a pipe from the upper end of the boot to (say) two inches above the mouth, at which part a recess inside may be turned to receive the paper tube already made, and so complete the pipe. And now for what I consider the greatest difficulty, which I think may be easily overcome by those who are moderately handy at the lathe, and that is the upper lip or feather edge, which can be turned like all the rest, but in two pieces; this I will explain at another time, and, if possible, with rough drawings. My simple arguments in favour of paper are, that all the various particulars of pipe making are within the management of all amateurs, and not costly. And, again, the pipes being covered with fancy paper, may be arranged on the soundboard on the Schudamore plan, so as to have a very nice appearance, and so do without case. The largest rank may have its tallest pipe in the middle, the others decreasing to each side; the next rank smaller may have its tallest pipes at each side, the others decreasing to the middle, and so with the rest of the various stops. I believe it possible with one large and one small mandril to make all the pipes, however narrow, wide or long, increasing from one to the other with the greatest regularity needed for any scale. SUORAM.

THE BEARING REIN AND BLINKERS.

[4580.]—I INDORSE the remarks of "Philo" (let 4553) entirely, both as to bearing reins and blinkers for horses, but how are the latter to be put away when horses have been run in them for years? I use a pony without blinkers with much pleasure, but he was broken without, and the few times I ran him in blinkers gave me reason to think he would shy a good deal; without them he does not shy at all, and will bear an umbrella or parasol up behind him without taking any heed. I have a very fine mare, quiet, but high spirited, broken in blinkers, seven years old. I cannot say I should like to run the risk of now breaking her to run without; have others done so with success? While on the subject of horses, the above mare has a very flat foot and thin sole, easily hurt with sharp stones, and the sole grows very little. Will "Philo" or any of our friends advise me as to the management of her feet, the best mode of shoeing her, and whether Mr. Flemming's or the Goodenough plans of shoeing would be suitable in this case, and if so where can the *modus operandi* of these several plans be obtained? C. J. C.

SPINNING TOPS AND GYROSCOPES.

[4581.]—I HAVE always understood that when a top is spun the axis leans more and more from the perpendicular until it falls, however great the velocity; but that, at first, the increase of the inclination of the axis from the perpendicular is imperceptible, the inclination increasing more rapidly as the velocity of the top decreases. Is this so, or is the inclination of the axis constant when the velocity is great, supposing the axis to be inclined at first? Taking out of account friction and the resistance of the air, would the velocity of a top or gyroscope remain undiminished? GY.

HOPS AND SLOPS.

[4582.]—A FARMING friend, a hop grower, thinks favourably of the plan I suggested to him for getting rid of the fly from the bines—namely, syringing with soap and water. I use this remedy to get rid of the aphides from beans, &c., and it appears to me to be applicable to the hop fly. With respect to soda as a manure, he warmly recommends it for almost everything. Its *modus operandi* is, perhaps, not quite clear as manure; it is, however, a deadly enemy to wire-worm and the tribe of garden or farm plagues in general. M. PARIS.

SOUNDS OF THE MUSCLES AND THE EARS.

[4583.]—IN 1809 Dr. Wollaston called attention to the sound, or *susurrus*, produced by the muscles when in a state of contraction. The sound may be observed by putting the end of the finger gently into the ear, and bringing the muscles of the hand and forearm into strong contraction; or by applying a stethoscope to a contracted muscle. It is like that of carriages at a great distance, passing rapidly over a pavement, or, like the deep hum from a large foundry. Wollaston tried to estimate the pitch of the note by putting his thumb in his ear, while his elbow rested on a horizontal board, on which he had cut a number of equal notches, about ¼in. asunder. Against these notches he rubbed a pencil, more or less quickly, till the sound he thus produced seemed to coincide with that from the muscular contraction. Then he attempted roughly to estimate the number of notches passed in a second. They appeared to be in general between twenty and thirty in a second. Dr. Haughton has also experimented on this subject. He got a number of friends to say what they thought to be the pitch of their susurrus, by comparing this with notes in a piano. The result was that four of the observers (two of whom were ladies), found it CCC; and five (of whom three were ladies), found it DDD; these notes corresponding respectively to thirty-two and thirty-six vibrations per second. His own susurrus seemed to him to be CCC.

Considering the sound very like that of cab-wheels in London, heard in the silence of the night, when the streets being quiet, the cabmen are able to drive fast, Haughton measured the intervals of the Guernsey granite pavement, and found them to be about four inches, making therefore three knocks or impacts in a foot traversed by the cab-wheels. Supposing the cabs to drive eight miles an hour, the number of impacts per second will be

$$\frac{5280 \times 3 \times 8}{3600} = 35{\cdot}2$$

Considering the susurrus note as D D D, giving thirty-six vibrations per second, its resemblance to the sound of the cab-wheels ceases to be matter of surprise.

A phenomenon not unfrequently observed is the sudden production of sounds in the ears—sounds which cannot be attributed to an external cause, as they are generally perceived only in one ear, and, therefore, probably arise in some way from the state of the ear itself. In some parts of Germany and other countries an ethical meaning is attached to such sounds, which are interpreted as praising or accusing, according as they occur in the right or the left ear. The acoustical properties of these sounds are discussed by Mr. Oppel in a recent number of Poggendorff's *Annalen*. His own experience was that the sound began quite suddenly, was pretty strong, and of well-defined pitch, but gradually became weaker, and at last seemed very like the sound from the bell of a clock a little after the hammer has struck it. The intensity differs on different occasions. At one time the sound is very loud, at another it is soft and scarcely audible. It generally continues about from ten to twelve seconds, and is to be distinguished from a low humming sound that is sometimes perceived in illness, which is of longer continuance, and has periods of greater or less intensity.

"Having at one time," Mr. Oppel states, "perceived this tingling in the ears to recur more frequently than usual, and for several successive evenings, I found it giving, in the left ear, the note D⁴. It occurred to me to find out whether or not the note was always of the same pitch, and whether the note in the one ear was of the same pitch as that in the other." He then gives a list of 9 cases, in which the sound was in the right ear, and 18 in which it was in the left, with the pitch of the note in each case. From this, it appears that the pitch is not always the same. It ranges in these 27 examples from D^1 to B^3. In some cases two notes at the interval of an octave were perceived. In one instance (the note being G^4) he had difficulty in determining whether the sound was in the right or the left ear. It appeared to be in the middle of the head, continued an exceptionally long time (seven minutes), and was repeated about a quarter of an hour later, when it lasted five minutes. In one other case the pitch was extremely high, and he compares it to the hissing of a water drop when it falls on a heated stone.

There is another subjective phenomenon, Mr. Oppel remarks, to be distinguished from these. It is a kind of cracking in the ears, often perceived when one has cold in the head, and specially noticeable in sneezing at the beginning and end of the sneeze. It is a very high pizzicato kind of sound. Mr. Oppel observed seven cases in which it did not appear to vary much from C^5.

The above account of some of the sounds in the human body may furnish material for easy experiment to the curious. A. B. M.

THE STAR ANTARES OR ALPHA SCORPIONIS.

[4584.]—ALLOW me to call the attention of such of your readers as take an interest in matters astronomical to the present remarkable visibility of the green companion to Antares. Last night, at about 10 p.m., turning my 4¼in. achromatic (by Cooke) on this very splendid object, I saw, to my surprise, the comes as distinctly defined and brilliant as the principal star itself. With a magnifying power of 284 the discs, round and sharp, appeared to be almost in contact; whilst the colours of the two components, red and green, were positively gorgeous. Having had no previous expectation that an instrument of such very moderate aperture would be able to reveal this object at all, much less to show it with such distinctness and ease, I was quite delighted with the spectacle presented, and equal gratification, I feel assured, will be experienced by other amateurs who shall take the trouble to turn their telescopes on this most noble star.

July 21, 1872. J. L.

THE CENTRAL HILLS IN GASSENDI.

[4585.]—SEVERAL observers have of late contributed to "our" columns drawings of the great lunar walled-plain, Gassendi. On comparing these sketches with others in my possession, I was much struck by the great differences which existed between them, even with regard to the more conspicuous markings. Amongst these is the central group of hills, in which the Rev. T. Webb tells us Schröter noticed several changes. Of this group I have collected sketches from different sources, and send three, which, if placed alongside those contained in other numbers of the ENGLISH MECHANIC, will exhibit "the strange diversity of the drawings by different hands." These are such as forcibly to suggest extensive changes, even within late years; and with every allowance for differences in illumination, and for roughness or inaccuracy in sketching, I cannot but think that some great disturbing agency has recently been at work on this part of the moon's surface. The experience of the observers, and the class of instruments employed by them, appear to preclude all deception, whilst the object itself is too conspicuous to admit of mistakes, such as would serve to account for the great differences in published drawings.

The first drawing which I send is taken from the second volume of Ferguson's "Astronomy," into which it was copied from one of Schröter's plates. Ferguson remarks of it, "This mountain has three tops, one of which appears like a bright spot in the shadow of the other, when the sun is on its horizon." In this respect it agrees very well with Mr. Loder's drawings (letters 1924 and 3747), but the closeness and the relative sizes of the two western mountains (in Fig. 1) are at variance with both of Mr. Loder's figures, yet are borne out by Mr. Birmingham's sketch (let. 4241). Mädler's drawing (Fig. 2) made with the help of the Dorpat telescope, is fairly accordant with the others in these features, and all appear to agree in the situation of

FIG. 2
FIG. 1
FIG. 3

the easterly peak, which, in Schröter's drawing, is seen shining in the long black shadow thrown by its companions. It is B sigma 5, in Mr. Birt's drawing (let. 2786); Mr. Gaudibert represents it as bent in form, with the concavity facing the north (let. 4076). So much for positions.

When, however, we come to compare shapes, we find greater differences. Mädler's drawing (Fig. 2) which I have copied from plate 18 of Lardner's "Handbook of Astronomy," shows a long, slightly curved plateau, upon which three hills project. To the north of it, and below its level, is a promontory, to the east of which we see four hillocks connected together. Turning from this to Fig. 3, a marked contrast is presented to us. The drawing is copied from a beautiful sketch, made by Professor Phillips, and inserted in Vol. CLVIII. of the *Philosophical Transactions*. It was executed in 1858 with the aid of a 6¼in. refractor, by Messrs. Cooke and Sons, of York. Compared with Schmidt's plate of Gassendi, a satisfactory agreement was found to exist, amongst other points, between the two representations of the "digitated central mass." Thus, Mädler, using a superb telescope of 9⁶/₁₀in. aperture gives us a sketch totally devoid of fissures, whilst some years afterwards Professor Phillips, with the aid of a smaller instrument, was able to delineate an upheaved surface, riven and torn in an extraordinary manner, and in this he is supported by Schmidt. This, I think, points to changes which occurred between the periods at which the drawings were made.

The drawings by Messrs. Birmingham and Gaudibert next claim our attention. They represent the south central hill as penetrated by two deep fissures, and as concave at the north-west extremity. But it will be noticed that the rents occur on the western side, whilst the very reverse is shown by Professor Phillips's sketch. By what subversive process the vast heap could have been overturned so as to lie in the position given by Messrs. Birmingham and Gaudibert it is difficult to imagine. Such strange differences strongly suggest the idea of extensive volcanic action since the date of Professor Phillips's drawing. If such differences occurred merely in connection with the extent of a minute cleft, or the position of a craterlet, we could not reasonably have recourse to the alternative of "change" to account for them. But when, as in the present instance, sketches made at different epochs by experienced observers with the aid of powerful telescopes, vary as to the formation of a conspicuous group of hills, and to such an extent as to represent them in contrary ways, we cannot, I think, overcome the difficulty except on the supposition of a real change on the lunar surface. W. BROWN.

SPOTS ON THE SUN.

[4586.]—DURING the past few days I have observed the sun on several occasions with an old 4in. metallic mirror reflecting telescope, and have noticed the partial passage across the disc of a large scattered group of maculæ, which contained one spot of considerable dimensions. On July 12, at 2h., this group was situated in the north-eastern quadrant, and was constituted of twenty-seven individual spots, several of which were immersed in penumbræ. The largest spot, which was situated in the eastern portion of the group, contained three well-defined umbræ and a large irregular penumbra, which, on the east side, was very dark, and on the exterior edge pierced with a train of minute dark spots. In the other quadrants I noticed four groups, and one isolated spot surrounded with penumbra in the north-western quadrant. These groups, though small, were composed of twenty-one spots in all, so that, including the large cluster before referred to, there were forty-eight dark spots seen altogether. I should have obtained a pretty correct estimate as to the dimensions of the large spot, but clouds coming over effectually precluded the possibility of my doing so. I also observed several groups of faculæ; these were seen, as is usually the case, near or in the vicinity of the margin of the disc. At about the time of observation, cumulus clouds were continually passing over the solar surface, but it was only partially obscured.

I have thought it appropriate to forward you the foregoing particulars for publication, because much interest has, during recent years, been manifested in sun-spot observations, and many of the scientific readers of your excellent journal may be pleased to learn that the spots have again become numerous, the more especially so as we are now approaching the minimum degree of intensity of these phenomena. This appears evident from the fact that at the observatory of the British Association at Kew the number of groups (271) observed in 1871 was less than the number recorded in the preceding year, although in 1871 the sun's photosphere was considerably disturbed, and at times especially violent convulsions were noticeable.

The large and interesting group of spots to which I have called the attention of your readers will have disappeared from the western edge of the solar disc before these lines are printed, but it may be expected to reappear on the eastern side at the beginning of the ensuing month, if, indeed, it is not dissipated before that time. WILLIAM F. DENNING.

PLATO.

[4587.]—IN answer to Mr. Birt (let. 4499, p. 433, No. 381), I beg to inform him that I relied more on hearsay than on anything seen in print, that "a heap of débris was near the centre of the floor of Plato." With regard to the second part of his reply, I must say that I thought I perceived the two white spots in the hollow of the shadow, as very faint cloud-like specks, not nearly so distinct as in the sketch. But being such faint objects, I may have been mistaken, and promise Mr. Birt that for the future I will be more particular in recording what I really saw, and not what I thought I saw. And while on this subject I would ask Mr. Birt if he would kindly give me a few hints for sketching the lunar craters, &c. Because in a short time I hope to become the possessor of a larger instrument, and then intend to make the moon a special object of study. T. H. F.

TRIPLE STARS.

[4588.]—ON searching for the double star P. XVIII. 263 Aquilæ (which is designated by Smyth as a "handsome test-object"), on the data given in Webb's "Celestial Objects," p. 188, with a 4¼in. refractor, I was unable to identify it; but in the place there indicated as "following a third magnitude star, bat far south in a fine field," I found a triple star. Magnitudes of components about 9½, 10½, and 10; positions (say) 260°, 110°; distances about 6" and 14", all by estimation, as I have no micrometer; power used 185. The two closer components were difficult to observe from the strong twilight which existed, and almost as difficult as the double 9th magnitude of the triple star ψ Cassiopeia observed on the same evening —11th July. This object-glass also showed finely the closer components of P. II. 72 triple in Cassiopeia under the same atmospheric conditions. I may remark the object-glass allows the "debilissima of Herschel" between ϵ^1 and ϵ^2 Lyræ.

I would feel obliged by "our" "F.R.A.S." examining the first-named object with his 4¼in. Dallmeyer, and stating whether it is the one given by Mr. Webb as above. The position angle of the closer components does not agree with it. EPSILON.

DOUBLE STARS.

[4589.]—WILL some of our astronomical correspondents kindly say whether the following double stars have been recorded? I do not find them in Mr. Webb's "Celestial Objects, &c.," nor in Mr. Proctor's smaller atlas:—

SERPENS.—Preceding 5, about 50" of time, nearly same declination, and in the same field, with an eyepiece magnifying about 150. Seen only once, June 30, 1872, in bad weather.

OPHIUCHUS.—2° 30′ N. of E., a little following. Distance about 2″. Position about 170°, July 6, 1872.

LYRA.—About 18h. 25m. N., 28° 40′. Position between 310° to 300°. Distance about 3″, magnitude 8 or 9, and each star much about the same. Dusky yellow. There is a larger star in the same field, S. To find it, place Vega in the centre of the field and move the telescope west about 8′ and the three stars will be in the field. Seen only once, July 11, 1872.

Jumet-Hainaut. C. GAUDIBERT.

A MORNING SUNSET.

[4590.]—THE phenomenon that your two correspondents (pp. 436, 465) describe by this singular name is a mere effect of perspective, and therefore, of course, mysterious to M. Paris; but figured under the name "Converging Beams," in Brewster's "Optics" (Lardner's "Cabinet Cyclopædia") and other optical manuals. The beams, which are caused by clouds dividing the broad glare of sunlight, intercepting some and letting separate portions pass, are, of course, in fact parallel, as much so as the horizontal cornices or courses of the most regularly built street or cathedral nave. But standing in the middle of such a nave, and looking either way, M. Paris will see all these lines converge to a vanishing point or pole, eastward and also westward. So it is with the sunbeams, when they are long enough to be visible for some miles each way, towards the sun and away from him. One pole is necessarily the sun himself, and the other, being his nadir, or exact opposite, cannot be above the horizon unless he is below it, and never presents any notable appearance, the beams merely dying off towards it, like auroral streamers towards the zenith. Occasionally these beams are less visible where broadest, overhead or at 90° from the sun, than where perspective concentrates them towards his nadir; but I have commonly found the reverse the case. The phenomenon is so much commoner in morning than evening that I have only seen it by sunset once; but at perhaps a majority of the sunrises I ever watched, yet only in low latitudes. Approaching Barbadoes from the east, I have seen it on many successive mornings, and sometimes with no cloud visible, those that cast their shadows across our whole sky being below the east horizon. E. L. G.

[4591.]—NOTICING "W. W. M.'s" letter (4519, p. 488), "A Morning Sunset," forcibly brought to mind a very similar circumstance which happened to me whilst in New Zealand. One fine evening I was walking home from a neighbour's, some four miles away, and happened to reach the top of a hill just as the sun set, showing those splendid diverging rays so frequently seen in fine weather, when I noticed a precisely similar appearance in the eastern sky, and stood some time to watch it, and it had not disappeared when I reached a patch of dense bush, of a mile and a half, through which I had to pass, on emerging from which I was so low in a deep and narrow valley that I lost sight of the rays altogether.

I would also add that on the evening of Sunday, June 30, I saw the same appearance, though not nearly so bright, in the east, over the houses, as I walked down the Old Kent-road. I can't say the exact time, but people were just leaving church.

In the same hope that "W. W. M." expresses I have taken this somewhat long liberty, and but for a fear of being disbelieved should have asked for an explanation before. HONE KO IO.

THE GYROSCOPE, &c.

[4592.]—THERE is a phenomenon which I noticed some years ago which belongs to the order of things now under discussion, which ought to be considered. There is a little toy often seen and used for lottery purposes, in fact, an enlarged teetotum which spins in a central tube, and has its table divided and numbered. I found that if this is set spinning vigorously, the whole affair may be turned upside down, and the teetotum will not fall out until its motion is nearly ended. Here is something much more like gravity overcome than anything yet noticed, and the fact is one worthy of explanation. I confess I can give no satisfactory one, but I suspect friction within the central tube to have something to do with the matter.

Some of our correspondents seem to have very hazy notions of the laws of motion and of projectiles. "G. M." (let. 4538, p. 460) is right in his correction of some absurdities, but he overlooks one circumstance; a ball fired horizontally would not quite reach the ground at the same instant as it would if falling from the muzzle, because part of the force of the powder is employed in lifting the shot, for a ball fired horizontally would rise but for gravity, because its line of motion is on a tangent with the earth's surface, and therefore rises, and this prolongs the time of falling; of course. I am ignoring the resistance of the air, which is a separate element of the calculation, and by diminishing the horizontal velocity acts with the increasing vertical velocity due to gravity in converting the path of the shot into a parabolic curve. SIGMA.

[4593.]—AFTER some little consideration I fancy I have discovered the key to the curious contradictions in J. M. Taylor's letter (4510, p. 435). In criticising Mr. Proctor in his third to sixth paragraphs, inclusive, he writes for himself; whilst in other parts he must be writing for some friend with whom he is discussing the subject, and whose ideas he would rather leave to the tender mercies of others in preference to treating his friend to his own views on them. Not less amusing is the triangular combat between (or rather amongst) "A.," of Liverpool, Mr. Proctor, and myself.

To return to J. M. Taylor, let me assure him we are not "pulling down established ideas" when rejecting what "Philo" and others term the "ordinary explanation," for that explanation never was by any means "established." Is J. M. Taylor trying sarcasm, when in his second paragraph he speaks of the "impossibility of avoiding contact with the laws of mechanics and plain facts, with which it cannot harmonise?" The problem to be solved (which has been solved) is, of course, to find an explanation that does harmonise with the laws of mechanics.

Mr. J. M. Taylor is himself in criticising Mr. Proctor, and I have not much doubt Mr. Proctor will virtually admit its force and change his front to some other "one case or feature of that case," or, possibly, back to "the general features of spinning motion" (let. 4310).

As to J. M. Taylor's friend's "governor" theory, I would point out that the lifting action, in an ordinary steam-engine governor is not directly due to the centrifugal tendency. It is a secondary action, arising from the balls being connected to the vertical spindle by links or levers, which will not admit of any outward motion, excepting what is accompanied by some upward motion. A careful consideration of the conditions involved will also show that when the balls are in the act of rising the spindle must have an increased downward pressure. In the suggested explanation, it is first assumed that two particles are detached from their rigid connection, and are connected by links. Then, after describing what might happen under such circumstances, the conclusion is jumped to, that the same results must happen even with all the particles rigidly connected, and no attempt is made to show that the movable link arrangement is not essential. It is suggested that the pressure of the peg point on the table must always be positive, but it is assumed that it must vary with the velocity of the spinning motion. I really think the experiment I have more than once before referred to is conclusive on this point if fully studied. (See p. 411 of the MECHANIC for January 7, 1870.)

Many who attempt to explain the action of a top or gyroscope are not aware that the instrument can be arranged to act in many curious ways, which at first sight seem quite different from the ordinary experiment. I have formerly explained how the centre of gravity of the gyroscope may be made to trace a series of spherical epicycloids instead of a plain circle; and it is obvious that any complete theory must include these and other cases. Can "J. M. T." (or his friend), or "Philo," or "A.," show how their explanations can be rendered applicable to the case of the epicycloids?

Glasgow, June 15. E. H.

[4594.]—WITH the greatest respect for Mr. Proctor, (let. 4509), I must observe that in my opinion his answer is most unsatisfactory, and reminds one of the usual method of dealing with children when they ask us questions which we don't quite understand ourselves. Of course, he is not bound to answer any question unless agreeable to himself, and if I am to be forced to take anything for granted without having any proof shown, that would end the matter at once. The question is, "If a cannon ball be fired horizontally, how is the resistance to change of plane of motion so nullified that it becomes of no effect whatever, and the ball reaches the ground as quickly as if dropped freely from the same height?" Now surely this can be answered in language that all may understand if it is correct. As for the moon, it only strengthens my argument; she yields a certain amount to the attraction of the earth, but the superior impelling force prevents her from yielding altogether. Neither is the speed of paddle or screw sufficient to call this force into visible action. I would like an explanation of the following experiment. Take a weight and swing it round with sufficient speed and it will attain and maintain a rotatory motion in a horizontal plane as long as the power is kept up. Now, it is evident that if the cord were gradually let out and the power increased as well, this weight would not fall to the earth, but would maintain the same distance from the ground as at first; the cord has nothing to do with holding it up except that it restrains it from flying away. This can be tried by any one; whether the cord be short or long the weight maintains its position as long as the velocity is kept up, and pray how are the conditions changed, if any other force, say gunpowder, is substituted for the cord?

J. M. Taylor (let. 4510) is clearly in error when he says that "centrifugal force has not the power of retaining a particle in a horizontal plane, &c.," as he can easily prove for himself by swinging a weight attached to a cord round his head. Neither is it correct, in my opinion, to say that "centrifugal force has the power of raising," &c.; it is the lever attached to the ball which yields to its force, and in the case of the governor of an engine it necessarily raises the ball, but were the levers arranged horizontally, then they would fly out without any lifting of the balls, and it is quite fallacious to imagine that the vertical shaft would press less upon its bearing, or the top to weigh one particle lighter when in motion, because there is no tendency to move in any direction but at a tangent to the plane of motion, and were such the case then there would be a speed at which any rotating body would fly upwards. A., Liverpool.

ON TUNING PIANOFORTES AND OTHER STRINGED MUSICAL INSTRUMENTS.—II.

[4595.]—BESIDES the geared tuning-hammers before mentioned, many contrivances for tuning piano-strings with greater accuracy and convenience than it can be done by amateurs with the ordinary wrest-pin and tuning-hammer have been published. One of the earliest, applied to the strings of harpsichords, was a screw, employed a century ago by Wakefield, whose patent bears the date of 1771. I think this is the earliest employment of a screw for this purpose of which we have any record, unless, indeed, Plenius preceded him in this as he did in the employment of a separate weight to strain to the required extent each of the gut strings of his celebrated lyrichord, which in consequence (according to the handbill recently reprinted in this journal) never went of tune. In the employment of screws for tuning—I don't mean equine screws, they have been commonly employed in all ages for pulling their riders "out of tune"—Wakefield was followed by Hawkins (1800), Smith and Todd (1801), Thunder (1805), Deakin (1823), Pape (1845), Erard (1850), Gordon (1852), Greiner (1859), and others "until this day."

Hawkins, Loeschmann, Kirkman, and others applied the screw by attaching one end of the wire string to a pin or peg in a nut which travelled along the screw, just like the plate of a common slide-rest is made to travel by its screw, which is, of course, abutted endways. On the contrary, Kohlman attached his strings to hooks formed at one end of his screws, and applied the required force to them by a thick nut, which fitted the pipe of the tuning-hammer. So little muscular exertion was required that the latter, instead of the ordinary cross-handle, had only a round knob like that of the handle of a large bradawl. The same method was afterwards proposed by Moody, 1864. Not content with tuning one string at a time, some rather crotchetty folk have attempted to tune many strings at once. J. J. Hawkins, as early as 1800, proposed to make all the strings of the piano the same total length and thickness, and to vary their pitches, not only by making the lengths of their vibrating portions between the bridges differ, and after tuning them to vary the pitch of the instrument a whole octave at a time, by raising his tuning frames, one of which carried all the strings of twelve notes. Dietmar afterwards attempted the same thing in grand pianos which had Stodart's—or rather Thom and Allen's—patent tubular bracing, by means of screws at the ends of their tubes, but how he got over—if he ever did, which I greatly doubt—the difficulties which must have resulted from the total lengths of the strings of grand pianos differing I cannot conceive. Mr. F. Greener had an "exhibit" in 1851 of an odd-looking pianoforte, the sides of which had openings like the bell mouths of trumpets—probably to "let the sound out of the box." In this instrument the two strings of each note were provided with an ingenious contrivance for causing them to vibrate in unison, and they being attached to a single hitch-pin, which was fixed in a slide moved by a screw, the pitch of both might be raised or lowered simultaneously. This contrivance, however "awfully clever" it might have been, was anything but cheap, and therefore even if more useful than it appears, not very likely to come into general use. In truth, "Le jeu ne vaut pas la chandelle;" and the same may be said of Pope's contrivance for altering the pitch of six unisonous strings at once.

Probably the very best method of "fine" tuning is deflecting the string, either downwards or sideways. This was the method employed by Messrs. Wheatstone and Green for tuning the one or two flat strings of their patent musical instrument—see their patent, No. 7154, A.D. 1836—in which what I may denominate a "string reed" produces not only the ordinary reed tones of the harmonium, but also those derived from a sounding-board, with which it is connected, a very valuable contrivance, enormously augmenting the loudness and improving the timbre of the sounds. Tuning by deflection is at once the cheapest and most delicate method of fine tuning I have had experience of, and by employing it we can retain all the advantages of using wrest-pins—a practical pianoforte-maker and tuner would be sorry to part with those advantages—combined with the means of slightly, but for all practical purposes sufficiently, raising or lowering the pitch of a string without disturbing its wrest-pin or turning it backward, which is of great importance for avoiding injury to the string. Tuning by deflection was first employed in the pianoforte by Schwieso (A.D. 1826), afterwards by Stumpff (1839), Myers (1839), Pape, Burkingyoung, Brooman, and others.

I have found the cheapest and most convenient method of carrying out tuning by deflection in ordinary cottage and bichord grand pianos is to use screws which press on the wires between the wrest-plank bridge and the wrest-pins. If these screws be made with heads which fit ordinary tuning-hammers, they are most convenient in practice, because the same instrument serves for both them and the wrest-pins; but such screws are rather costly, although far from difficult to make. I have made them out of old wrest-pins, which were not drilled, by turning down the part to be screwed to about the diameter of a No. 12 wood-screw, and cutting a shallow coarse-threaded screw, about fourteen to the inch, on the reduced part. No doubt were such screws in demand, the patent wood-screw makers, or the wrest-pin makers, would make them very cheaply, considering the latter are manufactured by thousands for about half-a-crown per set of 170; but as the reader can only—if he don't make them himself—obtain them by having them made for him to special order, they will cost money. I need hardly add what is specially made must be specially paid for, yea, even through the nasal organ at times.

Although a screw with a moderately large head will serve without, it is preferable to put a metal, a hard leather, or an ebonite washer between the head of the screw and the string. This protects the latter from abrasion, especially if, when formed of metal (say brass, copper, or zinc), a groove close to, but not quite running into, its hole be formed in its under surface. This groove effectually prevents the washer from turning with the screw, and, if its ends be rounded off, also prevents any sudden bending of the wire.

As some of my very economical fellow-readers may object to the cost of a set of tuning-screws with heads to fit their tuning-hammers—N.B., that cost is by no means a "Meek" one—I can assure them a very tolerable substitute is the ordinary patent wood screw, about No. 10 or 12. Any kind of head will do if you employ a suitable washer under it; but I prefer either rose or cylindrical heads, especially the latter, technically termed "cheese" heads—probably because they are the "cheese" for our purpose; both of these heads have their under surfaces flat and square with their shanks, which is far preferable to a conical surface if the latter touches the string. Of course, if metal washers beneath the heads are employed they may be countersunk, in which case the conical form of the head becomes unimportant. It is, perhaps, preferable slightly to round the under edges of both rose and cheese heads, especially if used without washers, which I don't recommend; but when a very hard sole leather washer is interposed the wire forms a groove for itself, the ends of which are naturally rounded by the pressure, consequently no harm can ensue, even if the under edges of the screws be left quite sharp.

The greatest objection to the employment of common wood screws is the difficulty of turning them when an ordinary screwdriver is employed, without the liability of its slipping off and disfiguring the front of the wrest-plank, not to say injuring the wires. A screwdriver ⅛in. wider than the diameter of the head of the screw may have its centre filed away, leaving two prongs about one-tenth of an inch long, which receive the head between them, and greatly diminish the risk of its slipping off the screw. I find this answer admirably; but then I consider myself rather a careful person, and am apt to consider most other persons "arent," consequently something suited for the careless is almost a necessity. The best contrivance I have been able to devise is a sort of tuning-hammer with a short cross handle, or a handle like that of a graver. The pipe of this tuning-hammer is bored to receive easily—but not too loosely—the heads of the deflecting screws. It is sawn for about ⅛in. of its depth, and a steel plate, which fits the grooves in the heads of the screws, is rivetted therein. This plate does not extend within one-sixteenth of an inch of the end of pipe so that it cannot enter the grooves until almost the whole thickness of the cheese head of the screw is within the pipe. Of course, slipping off is rendered almost *impossible* with any ordinary amount of stupidity, and for anything beyond that I don't believe it to be my mission to provide, although I cannot deny such greater provision to be a great social want in this enlightened (?) age.

As the purpose of this contrivance is to slightly increase or diminish the tensions of strings, and thereby slightly alter their pitches without the necessity of turning the wrist-pin backward, which injures the wire when the latter is the thing required—provision must be made for doing both. In other words, the deflecting screws ought to be screwed in until they deflect the string about half the distance between its original position and the wrest-plank, before commencing to tune the instrument. This will enable ye tuner not only to sharpen, but also to flatten, the pitch of a string should he have the misfortune to "pull it up" too sharp with his tuning-hammer without being compelled to turn the wrest-pin back or "press the string down," by no means a desirable thing to do, although not so evil as the former. Of course, it is only us amateur tuners to which these cautions apply. It is quite notorious no professional tuner was ever known to "pull up" a string too sharp, unless, indeed, the wrest-pin was a "condemned" jumper, in which case both the act and its emphatic "condemnation" is quite excusable. The unpractical [?] blacksmith, to whom, perhaps, more than forty years' experience has taught nothing, humbly trusts professional tuners will not be offended by this attempt of his to enable amateurs to tune their pianos when they are "up the country" and out of the tuner's reach.

THE HARMONIOUS BLACKSMITH.

SOUNDBOARDS OF PIANOFORTES.—To "SCIOLIST."

[4596.]—"SCIOLIST" (let. 4419, p. 382) wishes to be informed if the removal of the long bridge and the belly-bars would improve or augment the sounds of a pianoforte, assuming its soundboard to remain equally under the influence of its strings as it is at present. I really cannot inform him, having had literally no experience of any instrument so constructed, but I will tell him what experience and observation has taught me anent this matter.

If the soundboard be very much too rigid for the strings to communicate sufficiently ample motions to it, the sounds produced are but weak. This error—which, by the way, is one on the safe side—is a very common one in pianos made by persons who very laudibly aim at great durability, and reasonably fear that deterioration of tone which almost invariably ensues when the soundboard sinks at an early period from its deficiency of strength to support the pressure caused by the down-bearings of its strings. In making their soundboards somewhat too rigid the intentions of manufacturers are honest, but like all good things—even telling the truth—it may in practice be carried further than produces pleasant results. This fault is, however, one on the right side—viz., that of safety, and may easily be remedied by removing a portion of the depth of each belly-bar with a chisel and a small thumb plane until you obtain the quality and degree of loudness of sound you want, especially in the tenor and bass, the soundboard being very seldom too rigid for the treble. N.B.—The loudness of the bass and tenor sounds of many modern pianofortes may be greatly increased by this means.

It seems very probable there must be some imperfectly ascertained proportion between the size and rigidity of a soundboard and the strings which move, and cause it to generate sounds, which induces the production of sounds of the greatest intensity combined with pleasing timbre. Perhaps some slight diminution of rigidity below this proportion increases the loudness at the cost of some deterioration of the quality of the sounds so produced; also, if the strings press on the bridge—*i.e.*, have what is termed down bearing—of durability. Whether it now is, or even will be by the employment of means superior to any now known, possible to obtain equally loud sounds by the vibrations of a soundboard whose strings do not press on it—which, by the way, was the plan proposed by the ingenious harpsichord-maker Plenius—but are simply clamped to what might then be a comparatively low and flexible bridge (either by side bearings or otherwise), I am quite unable to say, being "ignoramus." Not having any very distinct theory of the soundboard, I decline venturing to prophesy results, which, by the way, your confident theorist is usually much addicted to doing, far more so than those who possess the advantage of having had their very confident theoretical opinions corrected by many failures when they attempted to carry them out practically. I think, however, a carefully conducted course of experiments with such soundboards—which, as there would be no reason for bellying or arching them, might be made as "flat" as the writer—would be well worth the trouble of carrying out, for they seem to promise that desideratum more prolonged sounds, because the less rigid flat soundboard would probably be compelled by the strings to move sufficiently to generate audible aërial waves for a longer time than they can now move a rigid arched belly. Probably, however, this system, and most others, may have already been tried and judged by Messrs. Broadwood and other first-class old firms; for I often suspect the late "W. T." was not very far wrong when he said he believed more knowledge was hidden in their archives than he and myself would ever live to discover by experimental investigation. He added, in his sneering manner, "It would save us schemers much time, trouble, and money, if I could persuade those firms kindly to publish their failures as well as their successes," he also remarked that, as a rule, it was only those successes which afforded them pecuniary profit which they did make known by adopting them in the manufacture of their instruments.

"Sciolist" also inquires what is the reason pianofortes can't be made with both their bridges on their soundboards. I really was not aware of the fact that they could not, and, seeing that it has been done repeatedly, can't help doubting the alleged fact. As regards the bass, I know no reason why it is not commonly done, excepting that, as it is very easy to make the bass of all pianos whose strings are from 3½ft. to 4ft. long more than powerful enough for any trebles yet produced, it is not worth the small additional trouble of doing it. For very short bass strings I have already suggested its adoption. Both bridges of the piano were placed on its soundboard as early as A.D. 1827, by Dodd; but as he carried it out in the treble as well as in the bass, I "kalkalate" the tones produced must have greatly resembled the sentimental professions of some young persons "about to marry," inasmuch as it must have been "werry holler," yea, even like unto ye sounds generated in an empty tub when we drive in its bung.

THE HARMONIOUS BLACKSMITH.

ON FIDDLES, HARPS, AND MUSIC.

[4597.]—I FEEL an explanation necessary so that "our" musical readers may really know what I mean by a sound reflector. I am not certain that I have given it the right name, so it is open to any one to call it what they please; it is the result I am looking after. If you bow a violin, first under the chin, and afterwards with the back of the violin placed against a deal door with long panels, an increase of sound will be the result. Short panels show no result, but a piece of mahogany from three-quarters to an inch thick held underneath the violin while playing gives the best result. If I had never tried this, I should think it highly probable that the sound would be increased, for the same reason that a musical-box sounds much louder on a board. I agree with Mr. Schucht that it would not do to attach or fix permanently any additional weight to a violin; but I think it possible to play, with the reflector tied loosely against the back of the instrument, by its two ends if cut to fit the instrument. A piece of gut looped on the same nut as the tailpiece is on, and knotted through a hole in the reflector for one end, the other secured in like manner round the end of the neck, either end of the back may be made to touch, as a slight conjunction is all that is necessary. I am pleased to hear of the new soundboard or breast that Mr. Schucht is making, and long to hear the result. I hope he will remember the bass bar; but I would not recommend a bar between each section—perhaps, however, he will do without any bar at all after the experience he had with the supporting strips of wood. I think the centre of the breast should be at least one-eighth of an inch thick if the violin is to be strung in the usual way, as I am of opinion that the weight of the strings interferes with the tone even in the best made violins.

I can assure my friend "The Harmonious Blacksmith" that I never heard Paganini play; but I have heard that it was always an extraordinary performance, so much so that he was caricatured. Where is the fiddler that has so much notice taken of him nowadays? Where is the trumpet tone of Tartini, who composed the "Devil's Sonata" under the old gentleman's influence? But I have never heard a violin sound louder than a piano, but only as a distinct tone from it; and I have found in a general way of pleasing, that the harp and violin suit the ear of the listener best. Notice the splendid effect produced by the voice assisted by harp and violin; it is not loud, but inexpressibly charming. I wish I knew as much about the harp as "Vertumnus" infers (let. 4559); but I have never touched one, although the day may come when I shall add it to my orchestra. "We" have often asked after the construction of the soundboard of the harp with no effect: will "Ixion" oblige? I think wires would do for the short or treble end, but would be too twangy for the bass; but this depends entirely on the strength and proportion of the soundboard. Would it be able to bear the weight or pull? Perhaps Mr. Schucht's invention may do for the harp, as well as for piano or violin. With respect to the hints on musical education, I have seldom met with an ordinary amateur player who felt that music is a science. So long as they can rattle out a polka, or accompany a song in their way, that will do. Ask them to play one of Mozart's sonatas for the piano, or one of old father Hadyn's, and they will not, for they cannot. Yet there is more real music in these two alone than in all the so-called melodies of the present day. I have a word of advice to all who can play a little (as it is usually styled) on the piano. Buy Beethoven's sonatas, and learn them; especially study the masterly way in which a melody is changed or transposed from one key into another. This one principal study is lost sight of among our teachers of music, and yet once known, places the learner on the first round of that ladder that leads to perfection, as far as attainable by genius and patience. I beg leave to inform "Correlli" that if he will do as I desire, his wishes as to the tremolo will ultimately be gratified. Can he imitate the roll of a drum with five fingers (four one hand, one of the other) tattooing on a table? For this is a good exercise without a Jack Tar's assistance.

FIDDLER.

THE TREMOLO ON THE VIOLIN.—VIOLIN TUNING AND FIDDLEANA.

[4598.]—"FIDDLER" (p. 417) seems scarçely to have apprehended the scope of "Corelli's" question, and indeed, this is hardly to be wondered at, for I conceive the latter does not mean tremolo at all, this being that sort of agitation that occurs in the music accompanying the ghost scenes in the "Corsican Brothers," as performed at the Princess's Theatre, and is produced merely by very short and rapidly repeated strokes of the bow. But what is really required is, I think, the manner of producing a thrill (not trill) upon a particular note analogous to what is called expression upon the harmonium. This is not a very difficult affair, but still it requires a little attention to a few points. Firstly, the instrument must be properly held, with the neck of the fiddle resting on the left thumb, and on no account to be allowed to touch the bottom of the fork formed by the junction of the thumb with the first finger. Then the elbow must be well under the back of the violin, quite to its middle or rather beyond, th violin being, of course, held horizontally. All this wi enable the very tips of the fingers to fall perpendicularly on the strings, even on the fourth, at the top of the fingerboard if required. No more than one finger should be on a string at a time; when the second falls the first should be raised, and so on. This necessitates very firm stopping, and great dexterity of hand, and I may inform the uninitiated that the fingers do not fall at uniform distances in the production of succeeding notes, but that these distances are different for every note for the whole length of the fingerboard. Now, if "Corelli," having attended to these points, and standing upright, will stop a note with (say) the middle finger, and shake his wrist, he will find he can produce the effect he desires. The best way to tune a fiddle is to have an A tuning-fork which can be sounded on the belly of the instrument whilst the A string is plucked with the thumb, three or four inches from the nut, then the other strings can be tuned by fifths, in the usual manner. If the strings were to be tuned separately from the piano, the fiddle would be out of tune, but if the piano must be had recourse to, it is better to sound upon it a minor chord of A, rather than a single note. When a scale is played upon the piano, all the notes, relatively to each other, are out of tune, and on this account first-class singers, in practising, are guided by a violin, which, in competent hands, is always in tune, whatever may be the key. Unless very considerable improvements have been made in the organ since I devoted more attention to music than I do now, this latter instrument is still more lamentably deficient than the piano, for so little is, or was, done in the way of that shocking compromise called temperament, that it was, or is, in very few keys that it can, or could, be played without being positively and literally intolerable, in fact, excruciating. It has been mentioned in these pages that though the violin is spoken of as being in the key of G, there is no particular reason for this being so. This is an error. It is not alone in that key because the lowest note is a G, but because that scale is played in the natural first position of the hand, without any shift, when the F sharp on the first string falls naturally under the first finger, while the F natural requires either the half shift downwards on the first string, or the extension of the little finger on the second string. If "Corelli" is desirous of practising some difficult achievements on the fiddle, let him, for one, place his little finger lightly on the double high E on the first string, so as to produce a harmonic, then press the finger down in order to have the ordinary note, when he should run the little finger down the string so as to distinctly mark each note, till he arrives at the B, and finish the double octave with the remaining fingers and open string. With regard to the bow, he must begin at the point, and give it an impulse that shall make it hop so as to come down afresh on the string for each succeeding note, that it may be a staccato passage. When he can do this neatly and perfectly, say 30 or 40 times in a minute, he can begin it at the G above, and then proceed till he gets to D in the ledger lines, and proceed with the fingers on the successive strings till he comes to the end of three octaves on the open G on the fourth string. When perfect in all this he can try to do it with a drawing bow instead of a pushing one—that is to say, beginning at the heel instead of the point. Then there is another pretty exercise called Tartini's or the devil's shake. Stop a note on one of the three lower strings with the first finger, place the third finger on the next higher string on the note where it it would naturally fall, and then produce a double shake with the second and little fingers. And now a word anent the funny fiddle of our excellent "Harmonious Blacksmith," who is as felicitous in his selection of a pseudonym as he is in that of the subjects on which he writes. This instrument is of so simple a structure that it would surely have been best to have made one at once, and thus have saved us much speculation; but I cannot help remarking that I do not think it would succeed, and, to say the least, it is not wanted. Supposing all these seven soundboards to be effective, which I do not believe, where is the necessity to make so terrible a noise? No one can assert that a good violin, in proper hands, is weak or incapable of filling any reasonably sized building; and, moreover, we have here a combination of two instruments of which the fingering is essentially different, for in the violoncello it frequently becomes necessary to stop with the side of the thumb, which is brought to the front of the fingerboard for that purpose. Then there would be the very wide intervals between the fingers in stopping the notes on one part of the instrument, and the sudden transition in their great approximation on the other part; the bow requisite for the one would not do for the other. Then the manner in which this instrument would have to be held is against it, for although the fiddle can be played with the button resting on a table, nobody has ever heard anything performed in this way equal to the brilliancy that is obtainable from the old-fashioned manner of holding it, and where should we be when the thumb is brought to the front? Indeed, I am well persuaded that with all the efforts to invent a new, and improve upon the old, fiddle, we shall never hit upon anything better than we already possess; it is, as with painting and sculpture, we may, perhaps, rise to the level of the old masters, but we shall never transcend them. I have a fiddle, with a pedigree, made at Padua in 1704, by Anthony of Vicenza, that I should be very sorry to change for any modern instrument, M. Vullianme's imitations included. It is difficult to imagine what can be required when we have an instrument that admits of true legato as well as staccato playing, of the thrill above described, of gliding from one note to another without break for two octaves if necessary, of a swell and diminuendo, of the sustaining of notes to any length, of the production of chords, double notes, simultaneous octaves, and arpeggios, with a whole scale of harmonics, and a positive change of quality by means of the sourdine or damper, with a scale of a good three and a half octaves, and susceptible of being played in any key. What other instrument combines all these advantages? F.R.C.S.

THE VIOLIN.—To "SUFFOLK AMATEUR" AND "BEACON LOUGH."

[4599.]—HAVING invited criticism on my fiddle, I hail it, however unfavourable, and I thank "Suffolk Amateur" for his in letter 4421; but, with all due deference to his far greater authority, I beg to make a few remarks thereon.

"Suffolk Amateur" is quite correct in supposing I had no intention of inclosing my multitudinous soundboards in a box, the only effect of doing this with which I am acquainted being practically to reduce their number to one. The ordinary violin is said to have two soundboards—viz., its breast and back—but, if I am not greatly mistaken, only one of the surfaces of each can, in practice, generate audible aërial waves—to wit, the one surface of each which is exposed to the external atmosphere. It is quite true their inner surfaces are not quite "shut up," for apertures exist, yclept sound-holes—query holes to let out that odd kind of entity or noun substantive the sound—I suppose to establish communication between the partially inclosed and external air; but so long as these so-called sound-holes are very small, and they ordinarily have but a very minute area compared with the surfaces of the back and breast, it seems to the writer that the communication they establish must be very imperfect, so he once suggested making many sound-holes in the sides of the fiddle, for which suggestion he was duly snubbed by an expert.

My suggestion, however absurd it may seem to violinists, who usually entertain rather peculiar theories on the conditions necessary for the production of sound, was simply intended for rendering the inner surfaces of breast and back efficient for the generation of sound waves necessarily synchronous with those generated by their outer surfaces; in other words, for converting the ordinary violin into an instrument having four sound-generating surfaces instead of only two, which I then and yet believe to be, for all practical purposes, the limit of their number. I have been told there were French violins shown in the International Exhibition, A.D. 1862, which—as my Hibernian informant expressed the fact—"had no backs at all, at all, excepting their wooden back bones." I presume he meant not exactly a spinal column, but a wooden bar beneath the belly, which connected the tail-piece with the neck and resisted the tension of the strings. Such a wooden bar existed in the late Mr. J. J. Hawkins's violin without a back which I have described, also the demoralising effects thereof on one of the greatest violinists and lover of fiddles I ever knew. I really know no reason why these fiddles, although unsupported by backs, should not have been as loud as a "Strad" if, as I believe, their total areas of sound-wave generating surfaces were equally large, and for all practical purposes it would seem to be so, whether formed by outer surfaces of the lid and bottom of a box (I mean a fiddle, which, as usually constructed, is but a shallow box) or by the upper and lower surfaces of the lid of the box—in other words, the two surfaces of the fiddle's belly.

"Suffolk Amateur" thinks the resonance of a hollow box necessary to produce "power of tone." He is by no means singular in entertaining that faith in hollowness. I believe that formerly nearly all the makers of stringed musical instruments were of the sect I might take the liberty of designating "Hollowtonians." Until a comparatively recent time they, almost without exception, seemed to regard sound as a substantive, something like Jack, to be shut up, if not generated, in a box. Hence, it need not surprise us much that having, as Mrs. Glass advises, first caught their "air"—I mean their tune—in the box, that they should, if only for respiration, provide air, alias sound, holes, to let him out piecemeal. Letting him out all at once must manifestly have been impossible when we come to look at the small means of escape provided in the form of sound-holes in the soundboards of fiddles, lutes, guitars, and harpsichords. Nay, even the old grand pianoforte-makers tried hard to "box up" the sounds of that instrument, and the subsequent manufacturers of the earlier cabinet and cottage pianos made them with solid wooden back linings, until experience convinced the makers of both that a piano whose soundboard was exposed to the atmosphere on both its sides—like that of a fiddle without a back—yielded much louder sounds than it did when its soundboard formed the lid of a nearly close box. I "kalkalate" it would require a long search nowadays to find a piano, small or great, with a close back or bottom lining. Modern instruments are sometimes rather "tubby;" but their boxes or tubs are tubs with their bottoms out, consequently the box, alias tub theory, can't "hold water."

That a box is necessary to produce "power of tone" can hardly be believed when the notorious fact that the sounds of a harp are not only swelled by opening its back doors, but that those sounds generated during the whole time those doors remain open are much louder than when they are shut, is taken into consideration. Were a nearly close box necessary for the generation of loud sounds, we should indeed experience increase of loudness when the back doors of the harp are opened, but—as the box would then become one without a bottom or its equivalent—all the sounds produced after opening the swell would be weaker. Just the same thing might be expected when I open the Venetian swell of a harpsichord; but the very reverse happens.

"Suffolk Amateur" says, "Compare a tambourine with a drum." Now, tambourine is literally little tambour or drum. The French call it "tambourette," just as we call a small poker a "pokerette." Just as well might we compare a child with a man.

I am not quite sure that putting two membranes on one cylinder sensibly increases either the volume or intensity of the sound produced when one of them is struck. We don't use two membranes in a kettledrum, and yet its sounds are anything but deficient in loudness, nor can I think their power be caused by their being "boxed up." A. Saxe, who is generally supposed to know his trade "indifferent well," made them without the "kettle," and his bass drums without cylinders, alias "barrels," of any length to speak of. I am informed drums are now made with what my before-mentioned Hibernian friend terms "steel" membranes, each drum having but one. He says the quality of the tone is very fine and their power remarkably great—quite equal to sheepskin. If I am not very much mistaken, the leetle tambourette, about 7ft. diameter, which I both saw and heard at the late Alfred Mellon's promenade concerts, had but one—not sheep—skin, probably formerly the cuticular property of some distant African relative of the bereaved Mrs. 'Pottamus. Had it been born in this iron age it would have probably possessed an iron hide.

The help I requested of "Beacon Lough" was either records of the acoustic "facts"—which are found to obtain when the soundboards of musical instruments are corrugated—or the opinions of those who, like "Beacon Lough," are better acquainted than I am with theoretical acoustic science, on the probable consequences of forming them in the ways proposed by M. Pape and Mr. Robertson. I thought I made this clear when I wrote.

THE HARMONIOUS BLACKSMITH.

CTENODUS.

[4600.]—IN the ENGLISH MECHANIC, Vol. XII., No. 291, p. 112 (letter 620), I directed the attention of your readers to a curious form of bone which has been recognised as a sphenoid of *Ctenodus*. The sphenoid bones that are discovered in the Northumberland coal-measures vary very materially in size, ranging from 1in. to about 12in. in length. The average length of those discovered is about 5in., but a few days ago I had the pleasure of inspecting one of considerable magnitude. The specimen is a fragment, but the broad or anterior extremity is perfect. The length of the fragment is 7¾in., and the width of the rhomboidal extremity from angle to angle is 4in. The widths of the rhomboidal plates bear a somewhat uniform proportion to the lengths of the sphenoidal shafts, and one perfect sphenoid now before me has a plate 2in. wide, the length of the entire bone being 6¼in. I infer, therefore, that as the plate of the large sphenoid before referred to is 4in., the total length of the bone could not have been less than 12½in.

Some of the flat, ridged, palate teeth of the *Ctenodi* are 4in. long and 2in. broad, and many of the head-bones display considerable strength; it may, therefore, be fairly inferred that some of the *Ctenodi* were of great magnitude, and that their dental crushing powers were very great. Whether the carboniferous *Ctenodi*, like the modern Australian *Ceratodi*, described by Dr. Günther, were vegetable feeders has not yet been established; but whatever they fed upon, it appears to have been something not very hard and not difficult to crush, as the vast majority of the teeth found are as perfect as if they had not been used at all, or had been used only for crushing comparatively soft food.

Newcastle-on-Tyne. T. P. BARKAS, F.G.S.

THE INDUCTION COIL.

[4601.]—I HAVE met with certain difficulties in the construction of this instrument, and finding that several of my friends and some of your correspondents have met with no better success than myself, I thought I might venture to request you to insert the following, since the replies to it (if it is fortunate enough to elicit any) can hardly fail to be of use to any of your readers who may be engaged in constructing a similar machine. I have made my description as short as I could consistently with clearness:—Length between the discs, 7in., length of fasciculus 10in., diameter 1in., 22 B. W. G. Primary coil, about 50 yards of No. 18 copper wire, cotton covered and coated with a composition of pitch, resin, and guttapercha. The primary is insulated from the secondary by a thick coat of the same composition, and two or three thicknesses of paper well varnished with shellac. The secondary is divided into three spaces, of which only the central space is wound as yet. It consists of about 500 yards of No. 35 copper wire, covered with two layers of cotton (4 strands in each layer), wound on in opposite directions, and further insulated by being passed through melted paraffin, the diameter being increased by these processes to about ·06in. The layers are separated by two thicknesses of paper soaked in paraffin. The contact breaker is Ladd's improved form, placed vertically and playing on the central fasciculus. The tube on which the primary is wound is of paper, about one-sixteenth of an inch thick or a little more. The condenser consists of 18 sheets of tinfoil, 8¼in. × 10in., separated by sheets of paraffin-covered paper.

From a battery consisting of three pint Bunsens, a spark of scarcely more than one-eighth of an inch can be obtained with the condenser, and without it the sparks will scarcely pass over any appreciable interval.

The questions that I more particularly wish to ask respecting this coil, are:—1. Is there any chance of obtaining electricity of high tension without the use of silk covered wire? 2. What length of spark can I reasonably expect from a coil containing about a mile of secondary wire insulated as above described? 3. Is the wire of my primary coil (18 B. W. G.) much too fine?

I may add that I have carefully read the whole of "Sigma's" valuable papers on electricity, and I think that I have understood them pretty well. The following passage, however, puzzles me, and I cannot find any person or book that can clear up and explain the difficulty. "A current arising from the consumption of one unit of zinc will deposit exactly the same quantity of copper, viz., one unit, whether it passes directly to the coppering cell, or whether a long fine wire in which heat is developed is also interposed in the circuit; the only difference will be that it will take much longer about it." (Vol. XII., p. 77 No. 177.) It seems to me that this heated wire must radiate heat to surrounding substances and raise their temperature, thereby doing a certain number of foot pounds of work. Whence is this force derived, if the unit of zinc still deposits a unit of copper? I can understand that the mere heating of the wire would not diminish the force, provided none of the heat escaped by radiation or otherwise. I wish it, of course, to be understood that I ask this question entirely for the sake of information, and not to produce a discussion, or cast a doubt on the fact as stated by "Sigma." T. H.

REFLECTION.

[4602.]—IF we take a long belt of silvered metal, or cut a strip off a mirror, we can, by bending it, cause the reflected rays of impinging light to converge to a focus after the manner of an ordinary concave speculum. Under those circumstances a distorted image of an object will be formed at the point of convergence; is it possible so to fashion a second mirror, or grind a lens, which, receiving and transmitting the first image, will rectify its deformity, and afford a correct picture of the object? If this could be done probably we might purchase reflecting telescopes for as many pence as we now pay shillings, and for its scientific and pecuniary interest, I submit the query to the consideration of our readers. E. B. F.

PERSPECTIVE.

[4603.]—I CANNOT but think that the laws of perspective which are true for different objects in a picture apply also to the portions of individual objects, and that if what I term pictorial perspective requires a modification, for instance, in the linear perspective of distant objects, such as mountains, a good case is made out for a similar modification being requisite in the proportions of a single object. If "B. D. T." (let. 4532, will refer to my definition of perspective, he will find that the remarks I made were closely connected with the subject. "B. D. T." remarks if a picture be drawn out of (linear) perspective it will convey a false impression of its form; but in the next sentence we read, that when drawn in true perspective, mountains do not convey a correct impression of their magnitude—so that out of perspective or in perspective the mountains seem in bad case, and the only remedy proposed is the impossible one, so far as a picture is concerned, of viewing it stereoscopically. Now, it is just because a picture cannot be so viewed that pictorial perspective steps in and modifies the linear perspective, which avowedly fails in accomplishing that which it is the mission of perspective to effect.

At the risk of some repetition allow me to add: True linear perspective being the exact projection of the form of external objects on the plane of the picture cannot but place on the retina the same image that the natural object would do if its outlines were in one place parallel to that of the picture; but, as this is not the case, the images that are formed are diverse, and give rise to different impressions on the mind, one being of depth the other of flatness; the former being perceived by the stereoscopic power of binocular vision, while the latter can only be transmitted by the independent action of the eyes, and is equally well appreciated by one. It must be borne in mind that we do not see the images on the retina but by means of them; that vertical, horizontal, or parallel straight lines in a picture are not always, I might almost say seldom, vertical, horizontal, straight, or parallel in the corresponding image on the retina, though by means of these curved, divergent, &c., lines we judge with the greatest accuracy as to their straightness, parallelism, &c., so that we may readily conceive why an image, which is deficient in exact linear accuracy, may for certain "visual" reasons convey to the mind a true perception of the object to be delineated. M. A.

[4604.]—MR. PROCTOR (let. 4531, p. 439), *cum multis aliis*, seems unable to grapple with the real difficulty, which is this:—Given, a high tower of equal breadth, is the top farther from the sketcher than the base or not? If it is, it must be optically narrower, and therefore the lines defining the side viewed will not be parallel to a suspended plumb-line. Mr. Proctor, in his demonstration, simply begs the question. We are not dealing with vertical lines, and therefore the mathematical proof does not apply. The only vertical line is one exactly opposite the spectator; in the tower, therefore, one at least must incline, very little indeed, but I assert its inclination is capable of instrumental observation. M. PARIS.

[4605.]—MAY I be allowed to add yet one more letter to the copious correspondence on the subject of perspective, in answer to the "Welsh Shepherd's" last letter (4566, p. 465)? He states that the rule in perspective that all vertical lines should be drawn parallel is a deduction from observations made on the glass plate. This is not so—for if a sufficiently accurate outline could be made upon the glass plate it would give a result at variance to the rule, notwithstanding that the rule is practically correct. The real reason why artists draw all vertical objects with vertical and parallel lines, is that the convergence of vertical objects within the cone of vision is so slight as to be imperceptible, but the convergence does exist for all that. The fact being that all vertical lines do converge to a vanishing point, which is the zenith, and this convergence exists whether the object be within the cone of vision or not. But this convergence being so slight as not to be perceptible to the senses, the rule of artistic perspective which says that all vertical lines in nature are to be drawn vertical and parallel is a correct one. It appears to me that some of those writers who oppose convergency, imagine that the convergence spoken of is supposed to be equal in ratio to the convergence of horizontal lines, but the fact is, that the convergence of vertical lines within the cone of vision is only a fraction of the convergence of horizontal lines, and that fraction ever diminishing according to the increase of distance of the spectator. But that this convergence does exist even within the cone of vision can be proved as follows—Draw a horizontal line; at one end of this, and perpendicular to it, draw a shorter line; let this line represent the height of a parallel column; let A be its summit and B the base. Then on the horizontal line, fix on a spot for the spectator; let this point be sufficiently far away from the vertical line, so that a line drawn from the point to the summit will be at an angle fairly within the cone of vision. Let us call this point C; from C draw a line to A, set the compasses at C, and from the base B draw an arc cutting the line C A. The point at which the arc cuts the line gives the difference of distance from the eye of the spectator of the summit and the base; the summit is found to be slightly more distant, and must therefore optically speaking be smaller, although the senses may not be able to recognise the difference. BOBO.

[We are unable to devote any more space to this discussion.—ED.]

THE PENDULUM.

[4606.]—I HAVE recently been reading Sir J. Herschel's "Treatise on Astronomy." My attention was particularly struck with that part on geography, beginning on p. 107, where the equatorial and polar diameters of the earth are given, as the results of calculations, from meridional arcs previously measured.

Sir John says that the results, as given by him, were taken from a paper by Professor Airy, "On the Figure of the Earth." He would be considered a bold and presumptuous man to doubt or call in question the accuracy of such results, viz.:—Equatorial diameter at 7,925,648 miles; polar diameter at 7,899,170 miles. The only cause of doubt as to the accuracy of these values is the "uneven and mountainous surface of the earth." Does the measurement of meridional arcs include the uneven surface of the earth? If not, how is the case to be met? Answer, by the pendulum. Shakespeare asks the question, "How wags the time?" It is not necessary to erect a pendulum on some suitable place, such as the mouth of a coal-pit, and another some thousands of feet below the surface, and at each of those stations to watch and count the wags of the pendulum, for the purpose of ascertaining the difference of the force of gravity.

We have, by the industry, care, and precision of astronomers the exact values required—namely, the number of wags which the pendulum has made during the moon's motion round the earth, from one star to the same star again, which is termed the moon's sidereal motion, equal to logarithm 6·3730208

And 86400 s. in time log.	4·9365137
	11·3095345
5280 ÷ 16 = 330 = log. =	2·5185139
	√ 8·7910206
	4·39551030
0·4971499 ÷ 0·00072332 =	0·49642658
Equatorial diameter, 7926·54 miles =	3·89908372
	0·00144664
Polar diameter, 7900·18 miles =	3·89763708
Equatorial log. =	3·89908372
	√ 7·79672080
Mean diameter, 7913·35 miles =	3·8983604

By changing this method of calculation in the separation of the values, we shall obtain the same results. Thus:—

	4·9365137	6·3730208
	2	2
	9·8730274	12·7460416
	2·5185139	2·5185139
	√ 7·3545135	√ 10·2275277
		5·11376385
	3·67725675	3 67725675
		1·43650710
	$0·4971499^2$ =	0·9942998
		2·4308069
		10·2275277
		√ 7·7967208
	Mean diameter	3·8983604
		0·00072332
	Equatorial diameter	3·89908372
	Polar diameter	3·89763708

VERITAS.

SOUND (OR UNSOUND) THEORY.—To "F.R.A.S."

[4607.]—I FEEL highly flattered by the opinion "F.R.A.S." expresses that my acquaintance with the interior construction of some old and new stringed musical instruments may possibly be a trifle more familar than his own, also by the "handsom concession" he is pleased to make that his scientific acquirements may a *leetle* exceed my own. His opinion of the probable effect of corrugating a thick soundboard is exactly identical with my own, which, indeed, was (substantially) expressed in my letter, No. 4416, although it did not occur to me that the motion of such a soundboard's molecules might be developed in the form of heat. No doubt, corrugation is usually employed for increasing rigidity, and excess thereof can hardly conduce to the production of louder sounds; but that "theory is wholly opposed to this form of construction" does not seem to me quite self-evident, because a corrugated soundboard whose rigidity is a given quantity may be made of less weight than one whose surfaces are nearly parallel. Now the string will, *cæteris paribus*, move the lightest soundboard furthest, and thereby generate ampler aërial waves, just as it acts more powerfully on the thin soundboard of a piano whose needful amount of rigidity is obtained by gluing wooden bars on it, than it does on one whose thickness is sufficient to resist the downward pressure of the strings which rest on it. Although strongly opposed to making soundboards unnecessarily rigid, I must admit that in practice—at least in the piano—what would appear to be a very unnecessary amount of rigidity seems—so long as it is not obtained by excessive thickness of material—to be rather conducive to the production of sounds of fine timbre without sensibly diminishing their loudness when rigidity is not carried to an absurd extent. See my reply to "Sciolist."

One word about my unlucky first fiddle. Will "F.R.A.S." kindly communicate any fact which induces him to believe that aërial waves, generated by the vibrations of one or more soundboards, can have their amplitude increased, and affect us as sounds of greater loudness, when one or more of the surfaces of the said soundboards form the top and bottom of a box? So ignorant am I of theoretical acoustics that I can't even conceive how any thing in motion, or any form of energy—no, not even a sound-wave—can be made any bigger by being treated like "Jack," and "shut up" in a box any more than I can conceive the light waves, or undulations, transmitted by "F.R.A.S.'s" "aplanatic objective" can be augmented by being "shut up" within the tube of his telescope. See my reply to "Suffolk Amateur."

THE HARMONIOUS BLACKSMITH.

"ANOTHER LIQUID GLUE."

[4608.]—I HAVE tried the recipe given in p. 425 for "liquid ether glue" (No. 1: nitric ether glue and indiarubber), and if the nitric ether supplied by my chemist be the veritable article, I denounce the recipe as a delusion and a snare. As in "Another Liquid Glue" a similar solvent (?) is advised, permit me to ask some of "our" chemists to enlighten my ignorance by saying what is ether, nitric either, "ether free from alcohol," and whether either will dissolve gum (shellac), glue, and indiarubber? In the mean time these recipes will be confidently copied into newspapers as coming from a reliable source (I inclose a cutting from the *Weekly Dispatch*), and no doubt many persons, as in my case, will find their time and money thrown away in endeavouring to produce what would be a very handy article if the formula could be relied on. The circumstantiality of the details as to how this particular glue will resist hot and cold water, &c., adds to the mortification of having followed what appears to be a freak of imagination rather than the result of that experience which we expect always to find in the pages of the ENGLISH MECHANIC. F. F. C.

P.S.—My nitric ether rendered the glue and indiarubber rather more insoluble than before its application.

COPY OF CUTTING

ETHER GLUE.—An excellent liquid glue is made by dissolving glue in nitric ether. The ether will only dissolve a certain amount of glue, consequently, the solution cannot be made too thick. The glue thus made is about the thickness of treacle, and is doubly as tenacious as that made with hot water. If a few bits of indiarubber cut into scraps the size of a buckshot be added, and the solution be allowed to stand a few days, being stirred frequently, it will be all the better, and will resist the dampness twice as well as glue made with water.

WATCH REPAIRING.

[4609.]—IN the article on the above in No. 381, p. 421, by "Seconds' Practical Watchmaker," reference is made to the method of making wheels flat. Now, with the particular wheel in question—Geneva escape-wheel—"Seconds'" does not make it quite clear how to "bump it," so as to avoid a "smash."

I have found out, by experience, never to risk laying a Geneva escape-wheel entirely on to a hollow punch to bump it, but use instead an ordinary flat punch with a small hole drilled up to the centre, or a small steel-piped watch-key. Lay only the arm to be hammered across the hole in the punch, and hammer as lightly as possible, at the same time shifting the arm of the wheel a little after each blow.

If the wheel is tight, and resting equally on the shoulder of the pinion, I would certainly not advise "trueing" by the method "Seconds'" recommends, as it has a tendency to bulge the ends of the pinion leaves, which would interfere with the fourth wheel pitch. This would not happen if the pinion was hardened; but unfortunately by far the greater number of Geneva watches imported of late years have none of their pinions hard. I would suggest, with "Seconds'" kind permission, that if he would devote as much of the space in his articles as he conveniently can to "causes of stoppage" of the various "movements" upon which he treats, he will confer a boon possibly on many professionals as well as amateurs. I would also suggest that if "West Cornwall," "Yorkshire Pivot," and as many of our really able brother "pivots" as are willing, would contribute their experience as the subjects are being treated, I am sure, Mr. Editor, that subscribers would not have to complain again for some time to come—as one did a few weeks ago—that there was so little information to be derived from the ENGLISH MECHANIC in our particular branch of industry, but it would also tend very much to enlighten those who are "moving along in the dark," anent watch repairing. ABERDEEN WATCH JOBBER.

ON THE MEASUREMENTS OF THE ELECTRO-MOTIVE FORCE AND INTERNAL RESISTANCE OF A GALVANIC BATTERY.

[4610.]—(1.) THE ELECTRO-MOTIVE FORCE.—The process described by "O." (p. 411) is ingenious, capable of considerable accuracy, and, so far as I am aware, novel; but his reasoning in support of it is, I think, erroneous. His second and third equations are not generally true, but only in the particular case when the term $g\ i_3$ vanishes; and, as no *à priori* proof of their truth without that term is afforded, the whole argument fails. The general proof would be to take the equations connecting the intensities in the different portions of the conductors for each cell independently, and to equate the values of the two components of i_3. As this process is a little complicated, I offer the following simple proof. Since the resistances have, by "O.'s" hypothesis, been adjusted, so that no current flows through G, the value of g is immaterial, and may be anything, from zero to infinity, without in the least affecting the current flowing through the other parts of the arrangement. If $g = 0$, then—

$$i_1 = \frac{E_1}{x + R},$$

$$i_2 = \frac{E_2}{y + r}.$$

If $g = \infty$, $i_1 = i_2$; $\therefore$ whatever be the value of g, i_1 and i_2 are equal.

$$\therefore \frac{E_1}{x + R} = \frac{E_2}{y + r},$$

the result obtained by "O.," whose argument beyond this point is correct.

(2.) INTERNAL RESISTANCE.—With all due deference to "Sigma" (p. 301), I venture to prefer Mance's process to that of Fitzgerald for the following reasons: (*a*) The former requires only the ordinary apparatus which every electrician possesses—viz., a set of resistance coils with the bridge and multiple coils combined, a key, and a galvanometer, which last may be changed at pleasure, whereas the latter necessitates the use of a special shunt made for that purpose (and useless for any other) and always the very same galvanometer and conducting wires. (*b*) The employment of coils never less than 1 Ohm, as greater accuracy can be attained by getting a result 100 times too large, and marking off the decimal places, than by the use of fractions of an Ohm directly, and surely "Sigma" cannot consider the placing of a decimal point a "calculation," and, if not, there is none in either case. (*c*) It is far easier to see if a galvanometer is deflected when a key is depressed, than to adjust the needle to exactly the same amount of deflection in two experiments. (*d*) By the former process the result is accurate at the very moment when the reading is taken, and if a variation occurs from time to time, it can be at once measured, whereas a rapid comparison of the deflection with the two different arrangements in the latter process, even with an efficient system of switches, would, with a variable resistance, be at least very difficult. I cannot but think that "Sigma" has never tried Mance's method, because if he had he would, like myself, have been charmed with its simplicity and ease.

The plan suggested by "S. T. P." (p. 359) is a modification only of Mr. Fitzgerald's, and is open to the same objections (with the exception of the special shunt); but a new one is introduced, because the resistance of the external circuit, including the galvanometer, would not probably be expressed by whole numbers, and therefore it would be difficult to reduce the resistance by exactly one-half. Let me recommend "S. T. P." to try Mance's process, and with a proper arrangement of controlling magnets and other accessories which will doubtless suggest themselves to him, he will, I think, find it everything he can desire.

PI.

BLOWING EGGS OF SMALL BIRDS.

[4611.]—PERHAPS some of the readers of the ENGLISH MECHANIC have found it difficult to blow very small birds' eggs with a blowpipe. I always use, for wrens, titmice, and such sized eggs, a glass tube drawn to a fine point at one end, and blown about half way up its length into a bulb. I insert the fine end carefully into the hole in the egg, and, placing the larger end in my mouth, suck up the whole of the contents of the egg at once into the bulb of the tube, then inject water into the egg and suck up again with a fresh tube till all is clean. G. W. C. H.

REDUCTION OF DECLINATION.—RIGHT ASCENSION.—EQUATION OF TIME.

[4612.]—WHENEVER I have had occasion to reduce the declination, right ascension, or equation of time for required mean time I, like many observers, have resorted to the logarithm table, given in all nautical works, for the necessary aid, since they are stated to have been computed to "the nearest second." Recently, however, I have also computed these reductions according to the rule enunciated in the explanations in the *Nautical Almanac*, on its Ephemeris, in page 1, and I find their results differ by some seconds, both in time and in arc—greater when the hourly differences are large, and scarcely appreciable for ordinary requirements when the registered differences are simply decimals of a second.

To place this question clearly before your readers, I give my computations of the examples set out in pp. 539 and 540 of the *Nautical Almanac* for 1872, according to the *Nautical Almanac* rule, and by means of the logarithm table.

Required the sun's declination on January 16, 1872, at apparent noon, in longitude 60° West of Greenwich; the longitude in time is 4h.

January 16, 0h., the registered difference of declination for 1h. (increasing)	s. 28·30
January 17, 0h., the registered difference of declination for 1h.	29·29
Dividing this by $\frac{2h.}{24}$	12) 00·90
Proportion of the difference equivalent to midway time	00·0825
Which add to the registered hourly difference for 16d. 0h	28·30
	28·3825
Multiply by the given time	4
Proportional increase in declination in 4h...	1′ 53·5300″
	d. m. s.
As the declination is decreasing, subtract the above product from the registered declination on 16d. 0h	21 00 40·4
	1 53·5
The required declination for January 16, 4h.	20 58 46·9

Which corresponds with the answer in the *Nautical Almanac*.

By the Logarithm Table.

	d. m. s.
Registered declination for January 16, 0h...	21 00 40·4
" " " 17, 0h...	20 49 09·3
Difference	00 11 31·1

	d. m. s. 0 11 31	·3198
	h. m. s. 4 00 00	·7781
Proportional difference	1 57 =	1·0979

	d. m. s.
Declination on January 16, 0h., (decreasing)	21 00 40·4
Subtract proportional difference	1 57
The required declination for Jan. 16, 4h...	20 58 43·4

Required the equation of time on January 16, 3h. (apparent time), for the reduction of the latter to Greenwich mean time.

January 16, 0h., registered difference for 1h. (decreasing)	s. 0·864
January 17, 0h., registered difference for 1h.	0·834
$\frac{1·5h.}{24}$	16)0·030
	0·002
January 16, 0h., registered difference for 1h. (decreasing)	s. 0·864
Subtract the above quotient	0·002
Proportional equivalent for midway time	0·862
Multiply by the given time	3
	2·586
	m. s.
As the daily equation is increasing, add the above product to the registered equation on January 16, 0h	9 54·43
The required equation on January 16, 3h	9 57·02

By the Logarithm Table.

Jan. 16, 0h., registered equation (increasing)	9 54·43
" 17, 0h., " "	10 14·81
	0 20·38

h. m. s.	
0 00 20·4	1·8656
3 00 00	0·9031
2·5s. =	2·7687

January 16, 0h., registered equation	9 54·43
Proportional equivalent for 3h	+ 0 02·5
	9 56·9

As further illustrations, I purposed furnishing you with a set of computations of the declination for every 3m. in 1h., and for each hour in a day; but these papers would, I fear, occupy too much valuable space in the magazine. I shall, therefore, restrict myself to a few extracts from them, which will show that differences do exist in the results obtained by the *Nautical Almanac* rule, and by the logarithm table.

December 5, 1872.

h. m.	By *Nautical Almanac* Rule. d. m. s.	By Log. Table. d. m. s.	Difference of *N. A.* rule from Log. Table. m. s.
5 00	22 29 22·0	22 29 19·6	− 00 02·4
5 15	22 29 26·6	22 29 24·6	− 00 02·0
5 30	22 29 31·1	22 29 28·6	− 00 02·4
5 45	22 29 35·6	22 29 33·6	− 00 02·0
6 00	22 29 40·2	22 29 37·6	− 00 02·4
0 00	*22 27 50·6	†22 27 50·6	00 00·0
4 00	22 29 03·8	22 29 02·6	+ 00 1·2
8 00	22 30 16·3	22 30 13·6	+ 00 2·7
12 00	22 31 28·1	22 31 25·6	+ 00 2·5
16 00	22 32 39·3	22 32 36·6	+ 00 2·7
20 00	22 33 49·6	22 33 47·6	+ 00 2·0
24 00	*22 34 59·2	†22 34 59·2	00 00·0

* These quantities were computed.

† These quantities were, of course, taken from the *Nautical Almanac*.

Here it may be proper for me to note that I have tested the accuracy of the computations by rule to the 3rd differences = ·000

I put this paper forth in the hope that some of your numerous correspondents and contributors will explain which of the two methods of computation is to be esteemed as accurate—*i.e.*, to "the nearest second."

ARIES.

POWERFUL GALVANIC BATTERY.

[4613.]—THE following form of battery is very cheap and simple, and has a potential about 50 per cent. higher than a Grove or Bunsen, and more than 150 per cent. higher than a Daniell. For positive, zinc in a solution of caustic potash or soda; for negative carbon in a porous cell packed with precipitated sulphur, granulated carbon, and peroxide of manganese, and filled up with dilute sulphuric acid. The internal resistance is rather large, but if common salt be used instead of caustic potash, the resistance is much less, but the potential sinks to rather more than 10 per cent. higher than a Grove. On the whole, I think this is the cheapest and best battery that can be used for general purposes, and has no noxious fumes or other inconveniences.

2, The Cedars, Putney. H. HIGHTON.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[11554.]—**Pedestrian Tour.**—One of the greatest plagues to travellers, but especially to those on foot, is the uncertainty of obtaining sleeping accommodation at the places they desire to stop at. Often have I been obliged to go on when already tired, and to leave a more for a less interesting stopping place. It would not pay to build inns big enough to supply bedrooms for the largest number that ever want them, and so long as the numbers wanting bedrooms varies as much and as unexpectedly as it now does, this serious evil must be endured. I have often wondered that the following very simple mode of removing, or at least greatly diminishing, the evil has never, so far as I know, even been tried—namely, that of erecting large marquees, and slinging in them hammocks for travellers who may be in excess of the bedrooms provided. A tired man would far prefer sleeping in a hammock to seeking a bed half a dozen miles off, with no certainty of finding one unoccupied; indeed, I do not think it would be thought any hardship at all. The cost of providing hammocks would be very small, as in warm weather, in the tourist's season, hardly any bedding would be wanted, while the marquee would be useful in the daytime as a refreshment-room, unless the inn had ample accommodation of that sort, and if it had the hammocks might be slung in them, or under the sheds of railway stations, where there is little or no night traffic, as is generally the case at places much resorted to by tourists. A more experienced pedestrian than I am says I am quite wrong in carrying anything unusual in my pockets. He says a very light coat that will not bear heavily loaded pockets is best for walking in, and that baggage should not be carried either in pockets, or knapsack, or satchel, or a pack, but divided in two packs, which may be carried in various ways, *e. g.*, hanging by straps over the shoulders, one before the other behind, or one beneath each arm, or one in each hand, or both in one hand. He says carry no more than you will want, and do not carry yourself what you can get some one to carry for you. Often you may get your traps sent on by some conveyance to your intended sleeping-place, and secure a bed there too. The packs may be either wrapped in light waterproof cloths, or such used to shelter both them and you.—PHILO.

[11589.]—**Dry Steam.**—In saying that thirty-pound steam, escaping into air with only half-pound steam in it, would expand "instantly sixtyfold," I did not mean quite so instantly as if no air, but only the half-pound steam, were present. Does "Philo," however, imagine that if a piston rests at one end of a cylinder, the other end open to the air, and if 30lb. (or double atmosphere) steam be admitted to drive it just a quarter the cylinder's length, and then cut off, the piston will go no further than half-way? It will certainly go nearly to the other end, the steam expanding not merely twofold, but nearly fourfold, and becoming, for a moment, only 8lb. steam or thereabout, though recompressed to above 15 by the atmosphere's reaction, and again rebounding, till after some oscillations the piston rests midway. Now, with an escape into air, without the piston, the same first overshooting of the mere balance takes place, with this difference, that the air cannot react and compress it again at all, as the two dissimilar fluids interpenetrate, and cannot be brought to oppose one another, but any diffusion once gained is extended further. Indeed, the higher the steam's original pressure the quicker will it expand, not merely down to atmospheric pressure, but to far less; and the hotter its original temperature the quicker must it cool, and the greater the chance of forming snow instead of raincloud. Of course "A., Liverpool," is totally wrong about high pressure steam having less water than low. On the contrary, among all such steam as engines use—*i.e.*, wet steam between the temperatures of 200° and 300°—the quantity of water is *nearly* in proportion to the pressure, which is probably what "Philo" wrote in his last sentence but one (p. 466), and the printer has changed *nearly* into *really*, which is not true. A sixfold pressure involves only about a fivefold quantity of water.—E. L. G.

[11589.]—**Dry Steam.**—I am not sufficiently read up as to the received opinions relative to the formation of steam of various pressures, to know whether my ideas are novel or erroneous. But view it in this light, that if we have steam of any given pressure in a boiler, by the application of more heat we increase the pressure, not merely by conveying additional water into steam, but also by conveying more heat to that which is already formed, and thereby obtaining increased pressure without a proportionate increase of water converted into steam, whereas I understand "Philo" to maintain that the pressure is caused merely by the addition of a number of, shall I say, particles to those already formed. This appears to me to be the real *casus belli*, and shall be happy to be corrected if wrong. It appears to me that after perusing this last letter of "E. L. G.'s," "Caloric" must admit that the question is settled without the aid of the chemist he was so desirous to call in, and that I am correct, after all, in asserting that superheated steam is simply a higher pressure steam, containing, as admitted by "E. L. G.," more heat and less water, as he admits that it will occupy more space.—A., Liverpool.

[11778.]—**Cleaning Silk.**—I use potato-water for all colours and kinds, but I was taught to grate them into cold spring water, say a large potato to every quart of water, of which five or six will do for a couple of dresses. If for very light silk, pare the potatoes; if any way dark, merely wash them clean. The pan of water must not be stirred in the least for forty-eight hours; then, very slowly and steadily pour off the clear liquor, but not a particle of the sediment, into an open vessel—a bath, or such like—dip the pieces of silk into this liquid up and down a few times, without the least creasing them; then wipe them on a flat table with a clean towel, first one side, then the other. It is good to hang each one as dipped upon a line to allow the drops to drain off a little before wiping. Have a damp cloth to cover them in till all is done; then iron one way, on the soiled side. It astonishes one to see how stiff and nice a dress looks done in this manner. Any material, silk, woollen, mourning cottons, &c., may be so cleansed. For many years back I have never turned a dress without it.—H. O'B.

[11892.]—**Steel Combs** (U.Q.)—I beg to thank "R. H." for the very kind manner in which he has noticed my query, and I wish to inform him that I want to make the combs about 2½in. long, and containing about sixty pins or teeth.—DUSTY MILLER.

[11984.]—**Tea Testing.**—"Saul Rymea" is right so far as he goes, but he has omitted the fact that the very necessity for thus tasting teas injures the health (the nerves), and many a man has been compelled to abandon that branch of emolument from this cause, and they deserve good salaries for the risk.—B.

[12001.]—**Hair Turning White** (U. Q.).—I had my hair go red all round my head; with the use of soap my face got spots upon it. I took to washing in warm water, adding every time about six drops of pure carbolic acid; in a short time my hair went as black as a coal and curly. I never use hair oil or fat, oil and fat stop hair from being silky and curly. Finding this happen, an old gentleman with white hair, always wishing for black, used the carbolic acid. He now has jet black hair. There are two sorts of carbolic acid, pure and impure, the pure is white, the impure just the colour of bad treacle, or black red, also a crystal, all made from coal tar. Beware, and not use too much of it, it will make the skin smart and come off. A piece of cotton wool just wetted with it and put to a tooth will stop toothache in one minute.—OUTGENIOUS WHITESMITH.

[12001.]—**Hair Turning White** (U.Q.).—As "Auld Reekie" may be engaged, let me advise "J. A. A." to try pure glycerine as a strengthening lotion for the skin. After bathing the head and eyebrows with cold water and drying thoroughly, a little diluted, or in a mild form, may be applied with a piece of cloth or flesh-brush. The scalp will soon regain a healthy tone, and on the skin assuming a red and rough appearance, the glycerine may be discontinued. Cold bathing must, however, be still resorted to. No oils or "pomades," so called, are to be used, except good olive oil scented with a little rose-water or lavender occasionally. "J. A. A." may also find it necessary to remove the hair by shaving, and, as a probability, it will grow next time of a darker hue. Go into cheerful society, and if troubled with an excusable melancholy, try to forget yourself.—RAT-TAT.

[12002.]—**Aquarium.**—It is of very little consequence whether this or that water need be placed herein, or how many animals, provided only that the balance is fittingly preserved between the vegetable and the animal life. Experience will soon show this—if too much of the plants, they will overrun; if too little, they will dwindle. Sticklebacks (Jack Sharps) must not be placed with gold fish, nor with any of the similar delicate species, the "back" spines wound so fiercely. Neither be so cruel as to collect eels or other running water animals, because such will not, cannot be kept alive in still water. Neither put in large newts; a "Triton among the minnows" makes sad havoc.—H. O'B.

[12008.]—**Keeping Dust from Clocks** (U.Q.)—Fix a small fan, either of wood or tin, in a convenient place under the clock, have a weight and chain to it, and a little wheel gearing, so that you can wind up at certain times; or have a wind grinder at top of a pipe with a bell mouth, just over clock works, with a couple of inlet pipes at sides.—OUTGENIOUS WHITESMITH.

[12023.]—**Dissolving Bones** (U.Q.).—By digesting bones for several days in dilute hydrochloric acid they become gelatinous, and can be moulded into any required shape.—YOUNG SNIP.

[12053.]—**Canaries** (U.Q.).—Your canaries' eggs are rotten, because the birds did not pair soon enough. The wheezing you speak of is caused by giving them too heating food; take away the eggs and maw seed, and confine them to canary seed, which is the proper food. Maw seed is too fattening for them; hang out in the air every day and give plenty of green food; such as lettuce, endive, chickweed, watercress, or groundsell, and no doubt you will find them better.—T. B. S.

[12054.]—**The Needle Lock.**—The description of this lock by "Saul Rymea" (Vol. XV., p. 441) is very clear, but his last sentence misleading, inasmuch as he says, "It is one of the best locks ever invented, for only a key made for it will open it." I take it that it is absurd to call any lock "unpickable," for what the ingenuity of man can make that ingenuity can undo. Now, the needle lock, besides being by no means difficult to pick, is open to the fatal objection of yielding easily to force, which, I think, any burglar of note would resort to before wasting his time over the tedious operation of picking, or of manufacturing a false key. "Saul Rymea's" eulogium would have been more correct had he applied it to the Citadel lock or to Chubb's, for the needle lock has again another small defect, in readily getting out of order, and refusing to open with its own key, and whilst being very ingenious has not come up to its inventor's expectations.—Q. YORKE.

[12072.]—**Magnetic Moment.**—As far as I understand the formula for ascertaining the strength of a current by means of the tangent compass, it is independent of the strength of the needle because although the earth's magnetism exerts a greater force over a strong needle than over a weak one, yet as the power of the ring rises in the same proportion, the strength of the magnet does not enter into the final expression, which is $S = \frac{r \times T}{6 \cdot 2832} \times \tan d$. Where r = radius of the ring, T = horizontal intensity of the earth's magnetism, d = angle of deflection, and S = strength of current. The magnetic moment of the needle is in no way involved, and so I do not see how "Sigma" proposes to estimate it by "ascertaining in these units the current which produces a given deflection to each magnet in the same galvanometer." With respect to the second method mentioned, namely, measuring "the extra resistance produced by the magnet," I should be glad if "Sigma" would furnish me with details of the process, or rather the formula to be used. As regards the coil question, I may as well give the "note" from Tyndall, which runs as follows: "The primary circuit in its turn can, when complete, react upon the secondary. It is complete whenever contact is made by the automatic contact breaker. A great enfeeblement of the secondary current is the consequence. When the primary circuit is interrupted the reaction does not exist; there is no enfeeblement, the full power of the secondary being developed. It is on this account that in Rhumkorf's coil we obtain discharges in a single direction only, instead of discharges alternating in direction." The inference which I get from the above is that somehow the inverse induced current is put out by the extra current, and that, therefore, whatever be the distance between the poles of an induction coil, only the direct induced current passes; and this is, as I have before said, at variance with Ferguson; and I should like to hear more from "Sigma" on the subject, and at the same time beg to thank him for the trouble he has already taken. By the way, "Sigma" has not told me how to ascertain the position of the poles of a magnet.—BEACON LOUGH.

[12091.] — **Plums** (U.Q.).—As no one else has replied to "Derf Errac's" query—I think he will find his plums affected with disease—whether animalcular or fungoid, he should be able to discover by means of a microscope. The tree may also have more fruit than it can bring to perfection, but as he does not say so, I can only form the opinion expressed.—SAUL RYMEA.

[12093.]—**Budding or Grafting** (U.Q.).—A good work on this subject is Baltet's "L'Art de Greffer," Robinson's "Parks, Promenades, and Gardens, of Paris," contains much information on the subject; there is also a book by Glenny or edited by him, but I forget the title now. I do not grow my fruit-trees, but I know that the sorts mentioned are generally budded.—SAUL RYMEA.

[12103.]—**Staining Glass** (U.Q.).—A very fine red may be obtained from rust of iron, glass of antimony, yellow glass of lead (or litharge), each in equal quantity, to which a little sulphuret of silver is added. This composition, well ground, produces a very fine red colour on glass. Black: 8 parts of crystal glass, 2 parts of oxide of copper, and 1 of glass of antimony. Grind these ingredients together with strong vinegar. Green: 2oz. of brass calcined into an oxide, 2oz. of minium, and 8oz. of white sand. Reduce them to a fine powder, which is to be inclosed in a well luted crucible, and heated strongly in an air furnace for an hour; when the mixture is cold, grind it in a brass mortar. Green may, however, be advantageously produced by a yellow on one side, and a blue on the other. Oxide of chrome has been also employed to stain glass green. Yellow: A fine yellow by taking fine silver laminated, then dissolve in nitric acid (HNO_3), dilute with abundance of water, and precipitate with solution of sea salt. Mix this chloride of silver in a dry powder, with 3 times its weight of pipe clay, well burnt and pounded. Violet: 1 part of calcined black oxide of manganese, 1 of zaffre, 10 of white glass pounded, and 1 of red lead, mixed, fused, and ground.—CLINCHER.

[12117.]—**Restoring the Colour of Watch Plate** (U.Q.).—There are no efficient means of restoring the colour of watch plates, but regilding. The best plan is to have the plate regilt; this you can get done at any of the gilders in Clerkenwell for a very small amount.—ELECTRO.

[12156.]—**Mice Eating Peas.**—When putting in the seeds, cover them 2in. every way with fine coal ashes. Mice will not take the trouble to scratch so deep. To keep off birds from the young buds, make a network of white darning cotton, or fine twine, twisted round bits of stick a few inches high. N.B.—I have not yet discovered a plan for keeping away cats. Has any reader of "ours"? Cats may be scared, but must not be injured in the proposed plan or plans, for which I shall feel grateful.—H. O'B.

[12157.]—**Smell of Paint.**—It is true enough that a vessel of cold water left in the room will show a scum next morning, but as an intelligent workman told me that the gloss disappears from the painted surface in just equal degree, I recommend a little patience instead of any of the methods spoken of, and the smell will gradually yield to the influence of drying in a natural manner, assisted by a plentiful dose of open window.—H. O'B.

[12172.] — **Constipation.** — ("H. S. A." AND OTHERS.)—I know a great many folk of different ages and sexes cure themselves of the above troublesome symptom by drinking a tumblerful of hot water (not merely warm, but comfortably hot water) last thing going to bed for a few nights; one, two, or half a dozen, until the desired change takes place, and nature acts naturally! Kneading the flesh in any manner, so as to stir the various sluggish muscles, is an admirable assistant; but I must warn "our" readers against the delusion that "reddening the skin," which is recommended by one correspondent, will cure the malady without risking the producing of a new ailment in an irritated skin, which might prove painful and troublesome. The skin is given as a protection for the extremely delicate tissues of nerves, perspiratory pores, blood-vessels, &c., with which the Almighty has gifted his creature, man. We cannot with impunity do violence to these organs; the skin is given to man to take good care of; it needs to be daily cleansed by daily washing and wiping; but does not require irritation. Would any but a madman try to clean a fine kid glove by means of a hard brush or a coarse towel? Nay, nay; why, then, should we be told to scrub and rub till it becomes "well reddened," so marvellously beautiful a thing as our skin; finer, and more tenderly to be cared for than the most aristocratically delicate lady's glove! Sponge it, wash it, soap it, cleanse it, love it! but do it no mischief by rough usage, else you shall surely suffer. And perfect cleanliness of skin is compatible with perfect gentleness, and a gentle daily cleansing is what we require to keep our skin and ourselves in average health. The point now under consideration, constipation, often arises from too dry a state of the internal organs, and this too dry state may be produced by smoking, which causes a waste of the saliva, which is required to assist in lubricating the mucous membrane; that is, the internal skin, which lines the throat, chest, stomach, bowels, &c., and, as some learned folks assert, to also assist in the process of digestion; or, by the use of intoxicating liquors, which parch up the stomach and render all the secretions unhealthy—(to those who are unlearned I must explain that big word. The "secretions" consist of a method of nourishing our bodies by means of the circulation of the blood, conveying a renovating power to the different portions of the body as is required by each one; as, for instance, the secretion of the eyelids is called "tears," and every other "secretion" has its distinct name. The phlegm, so troublesome to those who suffer from colds or cough, is an unhealthy secretion)—or, by the non-use of vegetables at dinner and other times, because the bones and other parts of our "fleshy tabernacle" being very largely composed of water, require a large supply of watery diet to nourish them, whereas the too usual dinner of our middling and comfortable people consists too much of meat and white bread, and these wholesome articles have not in them enough of the vegetable or refusey nature. And why should mankind not eat green and root vegetables regularly as diet? Who does not relish a nice juicy beef-steak? The beast from whose carcase it is cut was most likely fed plentifully on (amongst other articles) cabbage, turnip, carrot, and such-like good things; these the cow "assimilated" and turned into meat (flesh). May I ask why we should not eat and assimilate the vegetables ourselves instead of employing the cow to do it for us? Why should not the flesh grow from the cabbage and turnip directly upon our bones instead of coming to us second-hand? And, chiefly, why should not we avail ourselves of the good gifts of Providence, bestowed for food upon the race of man? It would be wise to do so, and far fewer people would have to complain of indigestion, constipation, and kindred ailments.—AN OLD WOMAN DOCTOR.

[12184.]—**Roses.**—Pegging down roses must be resorted to early in the spring, before the buds come out, lest they be broken away in the process. A few strong forked pegs, 8in. to 12in. long, or even more, for the larger stems, so as to keep them well in place, tightening them closer down, week after week, as the stem yields to the new position. As the young shoots grow, they may be fastened down according to the taste and skill of the ruling spirit of the gardener with hair-pins. Yes! hair-pins. You buy a thousand for a few pence, any size required.—H. O'B.

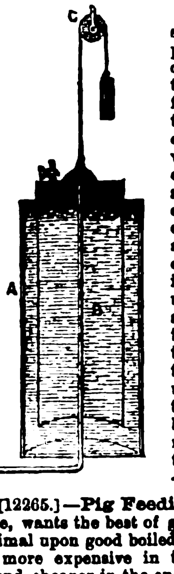
[12217.]—**Violin Tuning.**—I am very much obliged to "The Harmonious Blacksmith" for his reply on page 391 to my query on page 366. The subject of violin tuning is a complicated one, and on this account I wished to know from some one who could speak positively on it as to what violinists of high repute are in the habit of doing in respect of it. It seems that if the open stringed notes are to be made use of, the violin may be tuned in perfect fifths in the key of D, or that key which is founded on the third string as an open note, and that in the key of G the first string requires flattening by a comma. In the key of C the first string remains as in the key of G, and the second string requires flattening by a comma. In the key of F the first and second strings remain as in the key of C, and the third string requires flattening by a comma. In the key of B♭, the first, second, and third strings remain as in the key of F, and the fourth string requires flattening by a comma. It will now be seen that all the strings are flatter by a comma than when they were tuned in the key of D, and that each of the intervals from second to first string, from third to second string, and from fourth to third string, has been short of a perfect fifth by a comma. Of course, if the open stringed notes are not made use of, the equivalents to flattening the first, second, and third strings may be obtained on the second, third, and fourth strings; but if the G on the open string be required, it can only be flattened by tuning or altering the tension of the fourth string. In ascending by fourths or descending by fifths, the open notes sounded on the strings E, A, D, and G become E♭, A♭, D♭, and G♭ one after the other, and this lowering in pitch by a semitone is in addition to that by a comma spoken of above; but here, again, any alteration in the tension of the strings may be avoided excepting in the case of the open note on the fourth string, which now becomes lowered in pitch by a semitone, as well as by a comma as mentioned above. In ascending by fifths or descending by fourths, the open notes sounded on the G, D, A, and E strings become G♯, D♯, A♯, and E♯, one after the other, or are raised by a semitone; and in modulating still further, these notes become raised still more, to the extent of a comma, one after the other. It will readily be seen that when the notes become sharper through modulation, this sharpening can be accomplished on the finger-board without altering the tension or tuning of any of the strings. However, there can be no doubt but that, to obtain the full resonance of the instrument, and to obtain the best quality of notes, the instrument should be tuned for each key, according as the intervals from string to string are perfect or imperfect fifths, as the open strings will then resound of themselves if they are not sounded; and it would seem from "The Harmonious Blacksmith's" reply that Paganini altered the pitch relation of his strings sometimes to facilitate stopping in his difficult passages. By this I should understand he tuned for the key he meant to play in or modulate into. By asking the question, "how they tune in each key," I only meant to ask if violinists tune the open strings in perfect fifths for whatever key they may be playing in. Of course, between a note and its fifth there are an infinite number of notes on which to found an infinite number of major or minor scales; but when I asked the question, I supposed the modulation to be by perfect fifths.—WM. MEEK.

[12226.]—**The Portuguese Language.**—I am very much obliged to J. Gillaird for his answer to the above subject, and beg to acquaint him with that I am an optician, and used to make machinery in general. I am married, and have two children. The health of all of us is good. My means are rather limited.—CARL.

[12226.]—**The Portuguese Language.**—Grammars and dictionaries in Portuguese and English have existed for years. The best known are those by Vieyra. A Portuguese paper published in London is the *Echo Americano*, 66, Ludgate-hill.—H. MEYER, Sydenham.

[12239.]—**Soft Eggs.**—Hens may be given egg-shells, in all seasons, with great advantage to the "hen-wife," provided that the latter, after letting them dry for a few days, breaks them very small, and mixes them into the soft food.—PROVED.

[12260.]—**Cleaning Back of Teeth.**—What a beauty Miss "Beauty" must be to be actually able to write a letter to "our" journal, and not yet to have discovered that her jaws are hinged so as to open wide enough to admit of her putting a tooth-brush inside the teeth, both above and below, and scrubbing at them as long as she likes. She needs no peculiar shape of tool; and she ought (by rights) to use her brush and cold water after every meal, and at the very least, night and morning regularly. This is good sound warning and advice from—A TOOTHLESS OLD HAG.



[12261.]—**Spirometer.**—I send the description of a piece of apparatus a friend called a spirometer, to measure the amount of air discharged from the lungs at one expiration. I presume this is what our friend requires. A is a vessel containing water, inside of which is the meter B, with a stopcock at the top to discharge the air when it becomes elevated, a cord or chain with a weight attached serves as a counterpoise, and also by passing over the wheel G indicates upon the dial the amount of air in the instrument. The tube from the mouth passes through the outer vessel at the bottom, and is continued up into the little dome at the top. This prevents the bubbling noise which would be the result of the pipe ending at the bottom of the outer vessel. —JOHN HOPKINS.

[12265.]—**Pig Feeding.**—If "C. R.," or any one else, wants the best of good pig meat, let him feed the animal upon good boiled parsnips. 'Tis true this diet is more expensive in the beginning, but it will be found cheaper in the end. Test it—try it—as others have done.—A READER.

[12272.]—**Electrotyping.**—The best substances for making moulds for electrotyping are guttapercha and plaster of Paris. Guttapercha is the better one, because the outlines are sharp and well defined. If the object of which the cast is to be taken is metallic, the simplest way to form the cast is to use a fusible alloy, consisting of five parts of lead, eight of bismuth, and three of tin. The object is placed in a shallow box, and the melted alloy poured over it. A slight shock will disengage the cast from the mould. If guttapercha be used, the object should first be covered with graphite (blacklead) to prevent adhesion, and then the guttapercha, after being soaked in hot water, is pressed with the fingers against the object. This cast must be covered with graphite to make it conduct and connected with the negative pole of the battery. I am rather at a loss to know what "Zoo Andra" means by the "process of filling up at the back." Why not let the guttapercha, or whatever be used, be covered entirely with the deposit?—W. H. H. C.

[12297.]—**The Tremolo.**—See letter by "F.R.C.S." —ED.

[12301.]—**Unequal Sizes of Cone Pulleys.**—In my answer on p. 468, for 1ft. 1-16in. and 1ft. ⅞in. respectively read 1 1-16in. and 1⅞in. The "drop" means difference of radius, and in the case of my lathe-pulley the drop of 1⅞in. is from the largest to the smallest of four grooves, or three equal drops of ⅝in. each, corresponding to three equal drops of bare ⅝in. each on the fly-wheel.—J. K. P.

[12304.]—**Phrenology.**—"Philo," who appears to grumble because people laugh at him, might as well avoid giving them occasion to do so. Why cannot he content himself with giving occasional information (and occasional misinformation)? Can he not talk about what he knows or knows nothing about without snarling at others, and by misrepresenting them compelling unpleasant attention, which might not otherwise be called forth? Why should "Philo" trouble himself to tell me that I am "completely mistaken as to what John Locke and other great writers maintained?" I said nothing about John Locke, though I did use a phrase originated by him, I believe. I referred to a distinct mistake made by many, but I did not charge it to John Locke, nor do I know or much care whether he held it or no. That mistake is, that education is the chief or sole agent in forming dispositions, while I maintain that it is only capable of moulding to some extent the inherent faculties with which Nature endows us. "They taught (does "Sigma" deny ?) that a new-born child knows nothing." Well, as to mere facts, a child of course knows nothing till it lays in a stock of information by observation; but I very decidedly deny that any two children have the same powers of storing up these facts when presented to their observation. On the other hand, I say very distinctly that a child a month old manifests very decidedly the leading features of the disposition and powers it will possess through life, and that education can only mask and modify, not entirely change this disposition and powers; this is only the old and true saying, *Poeta nascitur, non fit.* Now, what the old question of electric sparks may have to do with this subject I can't see, but "Philo" chooses to drag it in—very foolishly, I think, because he only shows how incapable he is of understanding either what he reads or writes. The spark question was a mere detail, as I said at the time; he may have been right and I wrong as to whether a certain fact was established, that is nothing; but what was of consequence was that "Philo" talked authoritatively and dogmatically, and altogether erroneously, about principles. If he does not like being told this, he has only himself to thank.—SIGMA.

[12309.]—**Boiled Oil.**—Boiled oil is generally prepared by boiling a mixture of linseed oil and litharge in an open vessel until it thickens. If wanted for printers' ink it is generally set on fire towards the end of the boiling process. If it is wanted for colours which are bad dryers, it is prepared as follows:—Powdered asphaltum, litharge, or red lead, and burnt umber or manganese, each one ounce, are well stirred into one pint of linseed oil, and the mixture is gently simmered over a slow fire till the scum ceases to rise, and the fluid thickens on cooling. If the oil should be rancid, chalk or powdered talc, or magnesia may be advantageously added; it greatly assists the scum to rise, and also clears the oil by its subsidence. Gold size is generally made of boiled oil and Oxford ochre. The best vehicles for oil painting are linseed oil, poppy oil, boiled oil, and nut oil.—FREDERICA HAMILTON.

[12311.]—**Hydraulic.**—H. Meyer is incorrect, in my opinion, in stating that fluids extracted by pump, tap, or otherwise, from the lower part of a vessel descend from the surface in the first place to enter the orifice. It is the fluid immediately above the aperture which goes to supply that which is abstracted. If his view was correct, a tap or siphon inserted in the lower part of a muddy cask of beer, for instance, ought to draw the clear fluid from the surface, which clearly it does not, but if placed (say) half-way up, we shall obtain it tolerably clear; if at surface, quite so.—A., Liverpool.

[12318.]—**Gas Cooking.**—Accurate experiments to decide the real cost of cooking with gas are much wanted. The late eminent gas engineer, Samuel Clegg (often called Gas Clegg), estimated that the cost of cooking with common coal fire was about equal to the cost of cooking with gas at 4s. per 1,000 feet; but gas cooking has improved since Mr. Clegg told me this, and coal is dearer than it then was, some twenty years ago. The quantity of fuel generally wasted in cooking is enormous, and though less with gas than with coal, is with that needlessly great, as may be easily proved. I have succeeded in saving three-fifths of the coal before burnt in cooking, and have improved the cooking also by substituting a half open stove with large hot-plate for a common open fire range. The cost of fuel is, and is likely to be, so high, that it has become a duty for all, and a necessity for many, to diminish its consumption. Fortunately, that is very easy to do, by those who know how, or are not too prejudiced in favour of old ways to learn.—PHILO.

[12321.]—**Chess Player.**—For the benefit of "Willie Scorer," I send the following, and although it is not exactly what he wants, it is, I think, connected with the one mentioned:—M. Wolfgang de Kempelen, a Hungarian gentleman, and Aulic Councillor of the Royal Chamber of the domains of the Emperor in Hungary, called in that year [1769] to Vienna by the duties of his station, this gentleman was present at some experiments on magnetism, made before the Empress Maria Theresa, when he ventured to hint that he could construct for her Majesty a piece of mechanism far superior to any of those which had been exhibited. His manner of remarking this excited the attention of the Empress, who, encouraging him to make the effort, the automaton chess-player, which has since been exhibited in all the capitals of Europe, was, within six months after this period, presented at the Imperial Court. It is a presumption in favour of the pretensions of this contrivance to be a masterpiece of mere mechanism, that the original artist, after having gratified his exalted patroness and her Court with the exhibition of it, appeared for many years indifferent to its fame. He engaged himself in other mechanical pursuits with equal ardour, and is said to have so far neglected this as to have taken it partly to pieces, for the purpose of making other experiments. But the visit of the Russian Grand Duke Paul to the Court of Joseph II. again called our automaton to life. It was repaired and put in order in a few weeks; and from this period [1785] has been exhibited at intervals throughout Germany, at Paris, and in London; first by M. de Kempelen, and latterly by a purchaser of the property from his son, de Kempelen having died in 1808. I have also in my possession an account of the automaton flute-player, with a detail description of the mechanism.—ZOO ANDRA.

[12322.]—**Bees.**—"Willie Scorer" is in error in supposing that wasps destroyed his bees last year. Wasps are not aggressive, and never "attack" a hive under any conditions, but if from some cause a hive has got into a dwindling condition, and the bees are not able to defend themselves, wasps will help themselves, as will flies, ants, and earwigs. "Willie" need have no fear for his swarms, unless they be second swarms which have lost their queens or first swarms, from which maiden swarms have issued, in which case the the said first swarms, might also become queenless and dwindling, when wasps will as usual help themselves. Wasps are not enemies of bees, but they like honey and will steal it wherever opportunity offers, and will sneak about a hive for hours in the hope of obtaining entry, and often their persistency meets its reward, as by long trying at the entrance they attain the odour of the hive, and are admitted; but it is a fact, [illegible] understood perhaps from imperfect observation, that wasps never fight with bees under any conditions, and never attempt to use their stings against them. [illegible] "conscience doth make cowards of them all."—C[illegible] ABBOTT.

[12322.]—**Bees.**—Make the opening into the [illegible] narrower, the bees can then defend it better, and [illegible] keep the wasps at bay.—STRETTON.

[12330.]—**Re Slide Rest.**—My friend "J. [illegible]" requisitioned me some months ago to relieve him [illegible] task of making the promised drawings for ornam[illegible] slide rest; they have been done, but got put [illegible] consequence of my not having leisure to write the [illegible]sary description. I will, however, put my shoulder [illegible] the wheel, and send them in very shortly.—WA[illegible]

[12330.]—**Re Slide Rests.**—To "J. K. P."—I beg to thank "J. K. P." for his answer to my query, and at the same time mention that I am sorry he should think I would illuse any kindness shown me. I should not have asked for the drawings, but that, I believe, "J. K. P." has expressed his willingness to help those wishing to make their own apparatus, as in my case, and I should have certainly put them to better use than tracing them.—H. G.

[12332.]—**Chemical.**—Both.—CLINCHEY.

[12340.]—**Flour Paste.**—A little creosote or carbolic acid, mixed with paste, will preserve it from mould and maggots for a long time; very little is sufficient. A few drops of clove oil, and probably of any essential oil, have a similar but less powerful effect, as also have turpentine and camphor.—PHILO.

[12341.]—**Moths.**—I believe the best way to destroy moths and their grubs in a carpet is to stove it, and then sprinkle it with a solution of creosote in lime water. Carbolic acid is an effectual destroyer of insects, but its smell is unpleasant, at least to most persons.—PHILO.

[12360.]—**Pivots.**—To harden small drills make them red hot, cool in water, grind or rub bright, hold over bright fire, or over gas or candle, or get hold about ¼in. of end with pair of old smith's tongs, heat till point of drill is just blue, then cool in water.—OUTGENIOUS WHITESMITH.

[12360.]—**Pivots.**—"No Soft Solder" will find good staff steel best to make drills of, which can be bought at any good tool shop. Reduce steel to size, make blade of drill rather thick, harden either in oil or beeswax. I should advise him to fit new staff, which is more workmanlike and can be done in less time in many cases.—CONVERSION.

[12360.]—**Pivots.**—"No Soft Solder" must be prepared firstly with a large amount of patience to start with, because it frequently happens that when a "staff" pivot has broken off that staff must have been made from very highly tempered steel; and that a drill required for that small kind of work will seldom prove a success, even after hours of patient procedure. But to the reply. When drill is ready for hardening have a very small candle lighted, hold the blade of drill therein until just blood-red, immediately plunge it into the fat of the candle; it will then be hard, and after trimming it up upon the oil stone will be ready for use. If made a white red by heat before immersing in the tallow, the drill and steel are perished and useless. Use turpentine with the drill instead of oil.—SECONDS' PRACTICAL WATCHMAKER.

[12361.]—**Carbon or Charcoal Pipes.**—One process is to cut them from the solid carbon with a paring knife, and to mould them into required form with a peculiar kind of gouge and suitable instruments; another, to pulverize the carbon, mix with boiled linseed oil, and pass through moulds in the ordinary way. The pipes made by the latter process are not so light and porous as those made by the other. RAT-TAT.

[1236?.] — **Formula.** — To find the content of middle frustum of a circular spindle: (1) Find the distance of the centre of the middle frustum from the centre of the circle. (2) Find the area of a segment of a circle, the chord of which is equal to the length of the frustum and height half the distance between its greatest and least diameter, to which add the rectangle of the length of the frustum and half its least diameter; the result will be the generating surface. (3) From the square of the radius subtract the square of the central distance, the square root of the remainder will give half the length of the spindle. (4) From the square of half the length of the spindle take one-third of the square of half the length of the middle frustum, and multiply the remainder by the said half length. (5) Multiply the central distance by the generating surface, and subtract this product from the preceding, the remainder, multiplied by 6·2832, will give the solidity.—RAT-TAT.

[12365.]—**Elder Flower Wine.**—When the wine is just ready for bunging up, before you put the bung in just pop in a pint of best brandy to each gallon of wine (a sparkling remedy).—OUTGENIOUS WHITESMITH.

[12367.]—**Oval Turning.**—It is very possible to attach an oval chuck to any lathe whether it was ever intended or not. I have two lathes, ordinary shaped heads, with oval chucks attached by a simple arrangement, doing away with the clumsy flanges on each side of the head. If the writer will state the kind of bed I will give full information for adapting his lathe for oval-turning.—W. B. WINKLE.

[12368.] — **Imitation Bronze.** — Corrosive sublimate will dissolve readily in hot water, especially if there be a little hydrochloric acid added.—A. STONE.

[12369.]—**Water Powder.**—If "L. J. V. G." will go to any surgical instrument maker's, and ask for a spray producer, he will obtain what he requires. There are several varieties.—F.R.C.S.

[12371.]—**Truss.**—It is a great mistake to make trusses with but a single ligament. They should form a perfect support for the abdominal regions, and this can only be accomplished by forming a kind of india-rubber or canvas vessel to fit those parts, with necessary apertures, to be supported by spring or elastic pressure, or suitable bands from the shoulders. With such a truss and soft lining, which could be easily made, "Nosbor" could indulge without inconvenience in his favourite pastime of swimming, and attend his ordinary duties.—RAT-TAT.

[12372.]—**German Concertina.**—The steel is too stiff and rigid, and requires tempering or replacement by a softer metal.—RAT-TAT.

[12375.]—**Metallic Stain for Wood.**—Soaking the wood in a weak solution of nitrate of silver, and then exposing it to the light, will produce an intense black colour.—ALFRED H. ALLEN.

[12375.]—**Metallic Stain for Wood.**—I suppose you wish to stain wood black, if so, boil some chips of logwood in water for about a quarter of an hour. Then wash the piece of wood with it three or four times, allowing it to dry after each washing. Lastly, wash the wood by means of a common painting-brush, with a mixture prepared as follows:—Put one ounce of steel or iron filings into two ounces of vinegar, keep the phial near the fire so as to be gently heated for about two hours, then decant the vinegar, and keep it for use.—JOHN HOPKINS.

[12377.]—**Fall of a Bullet.**—In order to increase the range of the bullet, a rifle (on level ground) is always fired at a slight inclination upwards. We see that the sights are raised above the barrel, if fired horizontally on a horizontal plane, the elevation of the gun being 4ft. above the ground, a ball let drop from the hand will fall 4ft. in half a second, the ball fired from the rifle leaves the muzzle at a velocity of about 1,000ft. per second, but this velocity decreases rapidly from atmospheric resistance. The ball will go about 350ft., roughly estimated.—PHILANTHROPIST.

[12379.]—**Packing Piston Rings.**—In answer to "Dundalk," I beg to say that the piece of thin sheet brass must of course be inside, and fitted as per rough sketch, and as the piston head described by "X. M. S." appears unnecessarily complicated and objectionable, as liable to unscrew, Fig. 2 is a rough

FIG. 1

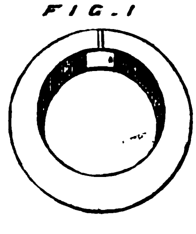


FIG. 2

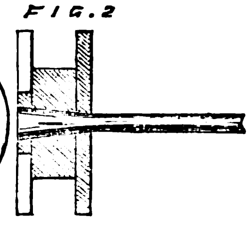


sketch of what I have found to work well. The shaded part represents the solid head into which piston rod is fitted, taper as shown, and secured by a cotter. The loose cap is secured by three sunk screws. Of course this piston head must be turned after the rod is secured in place. "Dundalk" cannot do better, in my opinion, than to make the rings of gun metal.—A., Liverpool.

[12380.]—**Light.**—The difficulty has arisen by supposing light a material substance. If the undulatory theory be adopted the answer is evident. The luminiferous ether without is thrown into vibration by the sun; these vibrations are transmitted to the ether that exists inside the room, throwing it also into motion. This motion when communicated to the optic nerve produces the sensation of light. Now, when all access ceases, what happens? Why motion within as a natural consequence also ceases (the source being cut off), there is nothing to excite the optic nerve, and darkness is the result.—CENSOR.

[12380.]—**Light.**—If we suppose "Dai Bach y Ship" to be inside his darkened room he will see the reflected rays of light from the wall opposite the hole. The rays of light from the sun travel in straight lines, and will continue in a straight course unless reflected or refracted otherwise. Thus the light travels in a straight line to the door, and is there reflected back or absorbed, all but one portion; this portion meets with no opposition at the door for the reason that a part of the door is missing. Therefore the light passes on, and it falls to the lot of the wall opposite the hole to reflect the ray. Suppose a man outside directing a jet of water against the door and hole, all the water that struck the hole would pass through and strike upon the eye of "Dai Bach," if he was peeping; he would then, I think, see it. All that did not hit the hole, but the door, would bounce off. If I might use a Hibernian expression, I would say that this is just the same only a little different.—JOHN HOPKINS.

[12380.]—**Light.** — According to the undulatory theory of the origin of light, all bodies and the celestial spaces are filled with a subtle elastic medium, called luminiferous ether. The luminosity of a body is due to a rapid vibratory motion of its molecules, which, when communicated to the ether, is propagated in all directions in the form of spherical waves, there being no progressive motion of the particles themselves, but only of the state of disturbance which was communicated by the luminous body. When, therefore, the hole through which light has been allowed to pass into a dark room, is closed, the state of disturbance is arrested, and the waves inside come into a state of rest, and darkness is the consequence.—E. B. H.

[12380.]—**Light.** — According to the undulatory theory of modern writers, light has no material existence at all, but its effects are produced by vibrations and cease with these vibrations. If "Dai Bach y Ship" is content to accept this theory, he will find his rather curious question answered.—W. H. H. C.

[12381.]—**Education.**—Much would depend on the age of the boys. Belfast is cheap to live in. There are pretty good schools. Ten scholarships are given every year to first year students, also ten to second and third year students, besides senior scholarships to fourth year students—five for classics, five for mathematics. Engineering and medicine are also encouraged. The scholarships are worth about £24 in cash, and half fees saved (£4 or £5). Cork is dearer to live in than Belfast. I like the Cork College better. Further information if desired. Many Civil Service appointments in India have been obtained by Belfast students.—PHILANTHROPIST (Ex. 1st Science Scholar, Q. C. B.)

[12384.]—**Coppering Carbon.**—Try galvanizing the carbon first in a strong battery; but I do not think Mr. Wall will succeed, as the substance is too friable to retain the coating. If this does not succeed fix the plate to it with tinman's solder, using spirits of salts, sponged in with a rag to make the melted solder and carbon assimilate. Care, however, must be taken not to saturate the junction with the acid, or no connection can be formed.—RAT-TAT.

[12385.]—**Sulphur in Wall Papers.**—It is a fact familiar to chemists that ultramarine contains sulphur, and no doubt the tarnish noticed on the silver is due to its presence. As the sulphur is an essential constituent of ultramarine, it cannot be got rid of without destroying the colour. "Ggur" had better use another paper, say a bright yellow one which turns green when wetted and held over burning sulphur. Such a paper is coloured with chrome-yellow, which has a tendency to absorb and decompose sulphuretted hydrogen, and would so keep the silver bright.—ALFRED H. ALLEN.

[12385.]—**Sulphur in Wall Papers.**—If "Ggur" does not like to remove the paper from his glass case, which is the most effectual remedy, if the paper really contains sulphur, the diffusion of the sulphurous particles can be prevented for a time by coating with size, boiled oil, water-glass, or spirit-varnish. This must be again repeated when the paper loses its glossy appearance.—RAT-TAT.

[12386.]—**The Prevention of Incrustation in Steam Boilers.**—The astringent property of the tannin contained in the timber of the oak as well as in the bark, though not in the same proportion, no doubt exercises a counter attraction on the particles held in solution. By putting a few pieces of oak, as "J. D. K." suggests in the boiler, incrustation may be partly prevented, by weakening or destroying by an opposite affinity the inherent tendency of the particles to assimilate, or rendering less tenacious their adhesion to the sides of the vessel. The dark colour of the precipitate or sediment is derived from the oak, as "J. D. K." indirectly remarks.—RAT-TAT.

[12388.] — **Onions.** — Sow "Giant Rocca" in August and transplant in the spring. I have some now (July 15) over a foot in circumference.—M. W. G.

[12389.]—**Dirty Mercury.**—Dissolve a small quantity of the mercury in hot nitric acid. Shake the rest of the metal with the solution so produced till it is quite bright; wash well. Clean the barometer tube with nitric acid, wash with water and then with alcohol and dry thoroughly.—ALFRED H. ALLEN.

[12389.]—**Dirty Mercury.**—I presume that "C., Glasgow," has not more than two or three pounds of mercury to purify. Let him do as Regnault did when he required pure mercury, viz., agitate the metal with diluted nitric acid, using one ounce and a half of acid to two of water for every two pounds of mercury. This will eliminate a goodly portion of the impurity, then pour the solution off and digest with strong nitric acid, until nine-tenths have dissolved in the acid. Take this solution, which is nitrate of mercury, evaporate it to dryness, and then heat it strongly in a retort; it thus becomes converted, first into oxide of mercury, and afterwards this becomes decomposed into oxygen, a gas, and mercury, which distils over and is condensed in the neck of the retort, and may there be collected. Traces of oxide may be removed by agitating it with sulphuric acid, and afterwards well washing with pure water repeatedly, and afterwards drying at a very gentle and moderate heat. The barometer tube may be cleaned by pouring in slightly dilute nitric acid and shaking the tube; this will remove the film, and the tube should then be carefully and repeatedly washed to remove all traces of the acid, &c., and then carefully dried; previous to filling the tube, the mercury and tube should be slightly warmed to dry them. If "C. Glasgow" requires anything more I shall be glad to help him. By the bye, lead and tin are not combustibles, save under exceptional conditions, viz., great heat in pure oxygen.—A. STONE.

[12389.]—**Dirty Mercury.** — If "C. Glasgow," puts his mercury in a cup, and pours a little aquafortis on it, he will find it turn what he terms the adulteration to a white powder. Make a funnel of writing paper, and pour through to dry it, and stand the cup on the top of his kitchen stove till he cannot bear his finger in the mercury. Pour some of the clean mercury in the tube, run it up and down a few times, clean it the same way as before, but by no means put anything wet in the tube.—Q.

[12390.]—**Chemical.**—Let "Home Student" obtain Miller's "Chemistry," 3 Vols., Longmans and Co., or if this be too much for him, try Williamson or Roscoe (Macmillan). These are really useful and standard works, and Miller's is the finest treatise on chemistry for students' use that I have ever seen. But if he wants merely to look up chemical theory for the Science and Art Department Examinations he had better read Frankland's "Lecture Notes for Chemical Students" (Van Voorst), or Valentin's "Practical Chemistry," or Buckmaster's. These contain everything likely to be asked for in the Examinations, and they will give him an advanced idea of the frantic and dazzling system (?) of notation now in vogue.—A. STONE.

[12390.]—**Chemical.**—Miller's "Chemistry for Students," Houghton's "Gill's Chemistry," Roscoe's "Elementary Chemistry," Galloway's "First Step in Chemistry."—ALFRED H. ALLEN.

[12390.]—**Chemical.**—Roscoe.—CLINCHEY.

[12390.]—**Chemical.**—"Home Student," if he is beginning his chemical studies, would do well to get Barff's "Introduction to Scientific Chemistry," Jarmain's "Chemical Tables," and Jarmain's "Qualitative Analysis," and he will have there as much as he can master in twelve months. Total cost, 6s. He should get up the definitions and formulæ in the chemical tables at the outset, and he should carefully answer the questions at the end of Barff's Chapters, on paper, or on slate. He should go through all the experiments, if possible, and commence the analysis of Group I. at once. Mr. Bottone's chapters in the back numbers of the ENGLISH MECHANIC will assist him very much in his earlier difficulties.—R. P.

[12391.]—**National Losses.**—It is evident that we must have a number of charges on the debit side of our national ledger corresponding to those put down by the manufacturer for "depreciation of buildings," "wear and tear of machinery," &c. These are the charges I mean by absolute annual national loss. As an instance, suppose a person living up to a salary of £200 per annum, very probably at the end of the year out of the £200 he has spent he will not possess what will realise £40 or £50, perhaps not £20, the remainder having been spent in food, clothes, tobacco, cigars, &c., whose ultimate, as compared with their primary, value is, if not absolutely *nil*, at all events infinitesimal. This primary value, therefore, less the ultimate value, capitalised, represents what I require. In connection with this question perhaps some reader can inform me what is the estimated annual capital production of this country, less cost of production.—EXCELSIOR.

[12391]—**National Losses.**—The only estimate which "Excelsior" might rely on as the nearest approach to an accurate estimate of absolute losses indulged in by preconcerted arrangements is the amount of taxes raised annually. When institutions are made self-supporting, and useless offices and establishments, to which these absolute losses may be directly traced, are abolished, England, as a nation, will be saved from danger and decay. Englishmen in general are brave, energetic, and intelligent; but the slough of dormant contentment with existing social arrangements, thrown around them by a puerile and interested Machiavelism, will result in inevitable ruin. It needs no dabbling politician to see this end to all bauble-satisfied and "red tape" governed countries. It can be seen in the lamentable ignorance of the lower classes and the shuffling attempts at education. With an enforced secular and military education of all classes, England can see her way to genuine legislation, and to the enlightenment and benefit of the world, through her colonies and possessions, by the unrestrained energies of her people.—RAT-TAT.

[12392.]—**Bee Management.**—The maggots or grubs which "W. T. L." found on the floors of his hive are in all probability young moths, which are about the greatest destruction to honeycombs and bees in existence. The bees can be transferred to the new hive late in the evening, which is considered the best time. There are various plans for doing this. The one generally adopted is to first stupefy the bees by chloroform. An excellent way to do this has been given lately in a back number, but I would advise "W. T. L." not to have anything to do with chloroform; its enervating effects are felt by the bees for days after its application, and some, when they sally out for honey and are returning with their loads, fall from sheer exhaustion into ponds and pools. Tobacco smoke is far better to use than this powerful drug. It can be driven in by a few puffs from an ordinary bellows, to the nozzle of which is attached a tube containing a few leaves of lighted tobacco. The bees, half smothered with the smoke, will fall almost instantly from the combs on the table or stand. All remaining stragglers can be brushed out with a feather. While lying on the table the new hive, previously rubbed round with honey and a few bits of comb attached to the top, is placed over them; they will ascend after recovering from their stupefaction; but care must be taken, by stopping up the entrance-hole, not to allow them out for a few hours, or they will immediately commence depredations. The old hive must be removed far out of their reach, to a cellar underground if possible, where its odour will not reach them, or they will torture the inmates of the house. As "W. T. L.'s" wooden hive may be bottomed, the plan recommended may not be practicable. It would, in that case, be better for him to connect the two hives by means of a tube from one entrance to the other, or the hives may stand so close together that none of the bees can escape. In either case a small pasteboard trap-door, pierced with holes, is to be fixed inside the entrance of the new hive, so that when each bee enters it falls down behind him and does not allow of his going back. "W. T. L.," by looking at a mouse-trap, may see how the trap-door is to be constructed. When all is ready, he can commence operations by beating the straw hive regularly all round from top to bottom, and the bees will immediately come out to do battle with the disturber if they can. This is, of course, to be avoided as much as possible, and "W. T. L." will have the bees, with very little trouble, in his new hive after a quarter of an hour's beating. He must, however, see beforehand that the paper, board, or leather trap-door is not too heavy to be raised by a single bee.—RAT-TAT.

[12392.]—**Bee Management.**—If W. T. L." will take two pieces of cloth (any sort) about a yard square, cut a round hole in the centre of each about 8in. in diameter, and stitch the cloths together round the edges of the hole so cut, it will answer his purpose very well, by the first cloth being tied over the bottom of the wooden box, keeping the "hole" in cloth about the centre; then turn the hive and bees upside down and place the box on it, the other cloth falling over the hive, which must be tied immediately. The bees are now secured, and a few gentle taps on the hive will drive them into the box. Should the box be smaller than the hive a couple of sticks placed across the straw hive between the cloths will support it.—NOVICE.

[12392.]—**Bee Management.**—"W. T. L." might have profited by my hints on feeding in March last. If he had followed the instructions there given (No. 365, p. 14), he need not have lost his two stocks of bees in May. My hints were for such as he, but they seem to have been wasted in his case. The maggots which have traversed his combs are the larvæ of the wax moth, which deposits its eggs in, on, or near anything waxy in or about the hive; the larvæ hatch out and feed on the said wax and attain the combs if possible. Often when hives are improperly guarded, the moth, like the wasp, will gain admission, and deposit eggs in the combs, in which case it is bad for the stock, for the larvæ encase themselves in wool, and leave a woolly tunnel or trail behind them as they proceed in their work of devastation. They love the base of the cells, and, of course, in devouring that they render useless all the cells through which they have passed on both sides of the comb, and the worst feature of all is, that the bees are unable to remove the woolly case, tunnel, or trail which the wax worms have left in their track, and consequently cannot repair the mischief. What benefit "W. T. L." expects to obtain by transferring his light stock to a wooden hive I cannot make out. I see a "Berks Farmer" gives "W. T. L." a reply, but the "Berks Farmer" evidently does not understand "W. T. L." or his bees. My advice to "W. T. L." as to transferring is—don't; his stock is weak, and the chances are that his new hive, which he says is 11in. square, but which, perhaps, means 11in. cube, is about twice the size of his straw skip, and being so, how can it be expected that his weak stock will fill it? "W. T. L." should first ascertain if his bees are healthy, and if they are not, he had better take "Berks Farmer's" advice, and "stupefy them," taking care that none recover, for as he has only the one stock, if they are diseased, it would be better for himself and neighbours if they were "with the majority," as the Yankees say. If they are healthy, and simply weak from want, "W. T. L." had better feed them where they are, so as to give them a chance, and in the meantime if he would study Langstroth's wonderful work on the "Hive and Honey Bee," he would know what to do next spring.—C. N. ABBOTT.

[12393.]—**To Steady a Sketching Board.**—A heavy weight must be suspended from the centre of "Poloski's" sketching board to which the camera lucida is firmly attached, with clamp, screws, or otherwise, by means of a hooked iron rod, or cord, so as to be weighty enough to resist the action of the wind. The weight may touch the ground, or a nail to which it is tied might be driven between the paving stones. In fact, a couple of spikes driven into the ground to which the legs are tied would hold it securely in any position.—RAT-TAT.

[12395.]—**Extracting Wax from Old Comb.**—To extract wax from comb, crush the whole into the smallest compass, and put into a canvas bag. Boil it in a large saucepan or copper, and when done, *i.e.*, when the fire is down, press it with a weight, or board and stick while under water, and the wax will float on the surface. Very old comb is seldom worth the trouble, as there is so much bulk and so little wax.—C. N. ABBOTT.

[12395.]—**Extracting Wax from Old Comb.**—Before boiling it break it up into little pieces, then boil, and the dirt and scum will float on the top, and the wax will run together.—STRETTON.

[12395.]—**Extracting Wax from Old Comb.**—If the bees never filled the cells with honey, there is no wax in the old combs to extract. This is a curious fact.—H. O'B.

[12395.]—**Extracting Wax from Old Comb.**—Try this. Put the comb into a small pan, or pie-dish will do, and let it stand in the kitchen range oven, when there is not much fire (baker's oven won't do). The wax will then gradually melt, and can be strained in the usual way. I have always found old comb "more plague than profit." You had better break it up in small pieces, and scatter it on the ground near your fall hives, and your bees will then, I should think, make use of it.—SACRISTAN.

[12395.]—**Extracting Wax from Old Comb.**—The following method, after years of testing, I have never known to fail:—Make a bag of coarse straining cloth (about 4d. per yard), and fill it as full as you can with comb, or a piece large enough to tie the comb will do without the bag—does not matter how old or dirty the comb may be—put this into a pot or copper with enough water to cover it; let it boil, and keep it boiling, and you will soon see the wax floating on the water; keep this skimmed off into a pan of cold water as long as any rises; when done, take it from the water, melt it in a saucepan carefully, and pour into a mould or pan; you will find only refuse in the cloth. I can strongly recommend this way to W. Hawkins.—BERKS FARMER.

[12396.]—**Rouge.**—Lord Rosse (in the *Philosophical Transactions*) thus describes his process of preparing his polishing powder. I prepare the peroxide of iron by precipitation with water of ammonia from a pure dilute solution of sulphate of iron. The precipitate is washed, pressed in a screw press till nearly dry, and exposed to a heat which, in the dark appears a dull low red. The only points of importance are, that the sulphate of iron should be pure, and the water of ammonia should be decidedly in excess, and the heat should not exceed that I have described. The colour will be a bright crimson inclining to yellow. Jewellers rouge is, however, frequently prepared in London by precipitating sulphate of iron with potash, well working the yellow oxide, and calcining it until it acquires a scarlet colour.—CLINCHEY.

[12396.]—**Rouge.**—Rouge is got by heating sulphate of iron first to about 540 F., afterwards to redness, in a retort of refractory material. Nordhausen sulphuric acid is given off, and the residue is rouge. Synonym Colcothar, Crocus Martis, *Caput Mortuum Vitrioli*.—A. STONE.

[12397.]—**Boat Building.**—It would take more room than the Editor would allow to describe fully the art of boat building, but it may be of some use to "W. S." to know that there are two ways of doing this—one called carvel building, in which the stem, sternpost, keel, and ribs called timbers, are first erected, and the planking afterwards applied, these timbers being usually cut to the required shape first. The other called clincher, in which method, after erecting stem, sternpost, keel, and one or more frames, as described by me in reply 12212, we proceed to fit the garboard streak, or first board to keel, stem and sternpost grooves, forcing it out gradually to the required shape by means of sticks bearing against a stout scantling extending from stem to stern; it being understood that keel is secured to a horizontal piece of timber, and stem and sternpost to a firm upright at each end. When in required shape, mark a horizontal line along the upper edge, which will be found to be a peculiar curve; cut board for opposite side exactly similar, and then nail on both; then take next ditto; fix temporarily to first by means of what are termed clams, and having drawn pencil line inside along top of first board, cut accordingly both sides always together; allow them to overlap (say) ⅜in. according to size of boat, and rivet together every 6in. with nails and roughs, always keeping upper edge of board as nearly horizontal as may be desired. I prefer a slight shear. When the top is reached, the oak timbers are steamed, and secured in their places with one or two nails while hot and pliant, and afterwards riveted when all are in place, the gunwale the same. The difference is that the clincher is much the lighter boat, as the boards may be of (say) even ½in. in thickness, whereas the carvel requires that the planking be not less than (say) 1½in. to admit of being properly caulked. If "W. S." requires any farther instructions, and the Editor can find room, as far as my information goes, it is at his service. The planking may be of any desired timber, if durability is not an object, but for steaming timbers, oak is usually employed.—A, Liverpool.

[12400.]—**Parrots.**—I have one said to be an "Australian Lory," similar to that described by "F. S. M. W." I suppose it is more properly called "Pennant's Parrakeet." They are not likely to breed.—M. W. G.

[12401.]—**House Painting.**—White lead, 4lb., patent dryers, 2 oz.; ¼ gill of boiled oil; when for outside work, linseed oil ¾ gill, and turps ¼ gill. The colour of the above is white.—F. S. M. W.

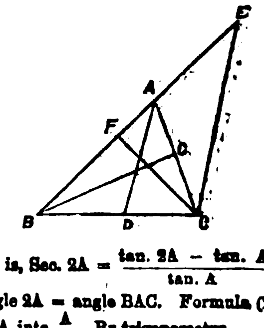
[12404.]—**Trigonometrical Theorems.**—With figure of Euclid VI., 3, draw B G, CF perpendicular to AC, AB. Then

$$FE = FA + AC \text{ and } \frac{BG}{AG} = \frac{CF}{AF} = \frac{CF}{EF} \cdot \frac{FA + AC}{AF}$$

$$= \frac{CF}{EF} \cdot \frac{AC}{AF} + \frac{CF}{EF}$$

$$\therefore \frac{CF}{EF} \cdot \frac{AC}{AF} = \frac{BG}{AG} - \frac{CF}{EF}$$

$$\therefore \frac{AC}{AF} = \frac{\frac{BG}{AG} - \frac{CF}{EF}}{\frac{CF}{EF}}$$



$$\text{That is, Sec. } 2A = \frac{\tan. 2A - \tan. A}{\tan. A} \quad (1)$$

Where angle 2A = angle BAC. Formula (2) follows by changing A into $\frac{A}{2}$. By trigonometry

$$\text{Sec. } 2A = \frac{1 + \tan.^2 A}{1 - \tan.^2 A} = \frac{2}{1 - \tan.^2 A} - 1 =$$

$$\frac{\tan. 2A}{\tan. A} - 1 = \frac{\tan. 2A - \tan. A}{\tan. A}.$$

—ALEPH.

[12404.]—**Trigometrical Theorems.**—The following is a solution to "Thetamu's" equation: With A as centre, and A C as radius, describe a circle; and draw a straight line, making an angle with A C = 2 A, and meeting the tangent C B in B. Bisect B A C by A D, cutting C B in D. Then, by Euclid VI. 3, $\frac{AB}{AC} = \frac{BD}{CD}$: but B D = B C − D C = tan. 2 A − tan. A; and C D = tan. A × A C.

$$\text{Therefore } \frac{AB}{AC} = \frac{\tan. 2A - \tan. A}{\tan. A \times AC}$$

$$\text{That is, sec. } 2A = \frac{\tan. 2A - \tan. A}{\tan. A}$$

If we now substitute A for 2 A (as this formula is perfectly general) we obtain—

$$\text{Sec. } A = \frac{\tan. A - \tan. \frac{A}{2}}{\tan. \frac{A}{2}}$$

—N. H. H. C.

[H. Mayer, G. H., Xenophon, E. W. H., and J. Sargill have also answered this query.—ED.]

[12406.]—**Worm eaten Violin.**—Use turpentine; take a little of the second string, dip in the turps, and drop in the holes. If you are no player, and the violin a very good one, give it to some one that can play and that will stop it.—E. W.

[12406.]—**Worm-eaten Violin.**—Take 1 drachm of corrosive sublimate (poison), put it into a 2oz. bottle of spirits of wine, let stand all night. Apply the solution to the interior of the violin by means of a small brush, fastened to a piece of copper wire, which can be bent and passed through the holes of the violin.—SARAH.

[12407.]—**Checkering Tool.**—The rings can be cut with a punch formed of two concentric ring cutters of hard steel, attached to suitable handle. "A Trimmer" can easily construct and arrange the rings so as to cut the dimensions given. Of course the steel must be in plates and red hot when the punch is applied.—RAT-TAT.

[12408.]—**Quill Pens.**—They are passed through hot ashes to purify them and remove the grosser fat and moisture, and render them transparent. Another method, and the one more in use, is to dip them in a solution of alum in hot water, and then place them by till they are hard.—C. P. E.

[12408.]—**Quill Pens.**—Get a baker to let you put your quills on the top of his oven for three or four weeks; be careful that there is not sufficient heat to split them; you will know when they are done by trying to make a pen with one.—SACRISTAN.

[12409.]—**Transferring Pencil Drawings on Paper to Boxwood for Engraving.**—The boxwood block must have a uniform white surface, which is got by rubbing over with flake white, wetted with water or saliva and allowed to dry. If the drawing is to be reversed for printing, it must be done upon tracing paper. A piece of paper smeared over with blacklead must be placed upon the white surface of the block, then the drawing. Go over the lines with a steel point, and the result is a clear sketch left upon the boxwood. Drawings for wood engravers are generally done upon thin white paper, and it is usual to gum them round the edges while tracing.—SARAH.

[12409.]—**Transferring Pencil Drawings on Paper to Boxwood for Engraving.** — Take a tracing of the drawing on thin paper, then scrape a little red chalk on the back of it, and rub it well all over with the fingers. Lay this on the prepared block, and go over it with a style. When this is done, you have got it on the wood in red, then pencil it over. Another way is to burnish it on to a prepared block.—XYLOGRAPHER.

[12409.]—**Transferring Pencil Drawings on Paper to Boxwood for Engraving.** — Place a sheet of black transfer paper over the face of the wood, lay upon the transfer paper the pencil drawing, then run over the pencil marks with a dull pointed instrument. I have taken copies of pencil drawings upon other sheets of paper, and I doubt not the plan will succeed in your case.—JOHN HOPKINS.

[12412.]—**Skew Bridge.**—The counterforts of all skew bridges that have come under my notice have been parallel with the face of the bridge, and this is at least a convenient arrangement, but whether in that position they react with the greatest effect against the forces brought to bear upon them depends, I imagine, upon the nature of the materials and manner in which the abutment is built, for if built so soundly that it may be acted upon as one homogeneous mass, and consequently that a thrust against it has the effect of tending to overturn it bodily on its outer footing, then the counterforts would react with the greatest effect if placed at right angles to the line of abutment; but if it is assumed that the materials of the abutment cannot be cemented together into one solid mass, then, to prevent fracture, the line of the counterforts should be at right angles to the bed joints of the arch, which is the line of face of the bridge, and is the direction in which they have been placed, as far as my experience has gone.—C. S.

[12412.]—**Skew Bridge.**—The corner buttresses ought certainly to diverge, and it is usual to make one parallel to the face of arch, the other perpendicular to its side wall, so that there may be no acute angle in the plan, but two of the jambs be right and two obtuse angles. Intermediate buttresses would be best set in an intermediate direction.—E. L. G.

[12414.]—**Cleaning Feathers.**—Use raw starch blended in cold water to the consistence of cream; cover the whole surface with this, but be careful not to lay it on so heavy as that the paste will drop off. In a week or less, in very dry weather, it will have hardened; knock it off gently, and the feathers will be clean; and "plumed," too, if you begin at the right end.—A NATURALIST.

[12415.]—**Provision for Child.**—This very important class of query, which I marvel has not occurred frequently, could hardly be answered at all, even now, but for a valuable contribution to the last number of the *Journal of Society of Actuaries* (April, p. 30), on child mortality, a branch of statistics hitherto most neglected. The following are the data necessary for "J. R.'s" calculation:—Out of 100,000 born there die in the

First year..	9,099	leaving	90,901	(discounted =	88,253)
Second	3,498	,,	87,403	,,	82,386
Third	1,791	,,	85,612	,,	78,347
Fourth	1,113	,,	84,499	,,	75,076
Fifth	927	,,	83,572	,,	72,090
Sixth......	779	,,	82,793	,,	69,338
Seventh ..	655	,,	82,138	,,	66,786
Eighth	559	,,	81,579	,,	64,399
Ninth	490	,,	81,089	,,	62,148
Tenth	446	,,	80,643	,,	60,008
Eleventh ..	430	,,	80,213	,,	57,947
Twelfth....	420	,,	79,793	,,	55,965
Thirteenth..	396	,,	79,397	,,	54,065

The numbers in the last column are those of the second, each discounted for Government interest at 3 per cent. —that is to say, the first is diminished as 103 : 100, the second in the ratio $\left(\frac{100}{103}\right)^2$, the third in the ratio $\left(\frac{100}{103}\right)^3$, and so on to $\left(\frac{100}{103}\right)^{13}$; by taking the logarithm of each number in col. 2, subtracting as many times the log. of 1·03 as the line is from the top of the table, and this leaves the log. of the number for col. 3. Thus, of 100,000 children born to-day, if we engage to pay £1 for each living this day twelvemonth, the pounds then to be paid will be 90,901, but the sum now necessary to provide this is only £88,253. Hence the numbers of col. 3 are present values of a promise of £100,000, to be paid this day year, 2 years, 3 years, &c., on condition that a child born to-day is then living. If "J. R." then adds the 13 up, he has the present value of an annuity of £100,000, the first payment this day twelvemonth, the latest possible this day thirteen years, but all contingent on the life of the child born to-day. If he omits the first line, and augments the sum of the last 12 in the ratio of 88253 : 100000, he will have the present value of similar annuity, the first payment a year hence (the child being then supposed two years old), and the last this day 12 years (all 12 contingent on life). If he omitted the last line, 54,065 and substituted the first, 88,253 (which on augmentation becomes 100,000), he would have the present value of similar annuity, the first payment certain to-day, the others contingent, and the last this day eleven years. Now, a mean between these two sums will be very nearly the value of the contingent weekly payment for these 12 years, if its annual amount were £100,000. Hence he will, by simple proportion, find its value corresponding to 5s. a week, or £13 1s. per annum. See No. 348, p. 248, especially p. 249, paragraphs numbered 9—14. P.S.—By the above data, the value for which "J. R." asks comes out £120 12s. 2½d. The "English Life-Table," calculated from the Registrar's census by the Swedish calculating engine, and published ten years ago, affords similar data; and if this query excites any interest, I will make a table of this value's variation from before birth to every three months of a child's age.—E. L. G.

[12416.]—**Spinning.**—Speed of spindle about 6000 revolutions per minute for medium counts on mules. "J. R." will find the following very useful for finding the twist per inch, for either twist or weft:—Take 50's for the standard, say 26 revolutions for twist, and 23 weft. Now we have 26 revolutions per minute for 50's twist, what shall we require for, say, 60's twist. Then we have—

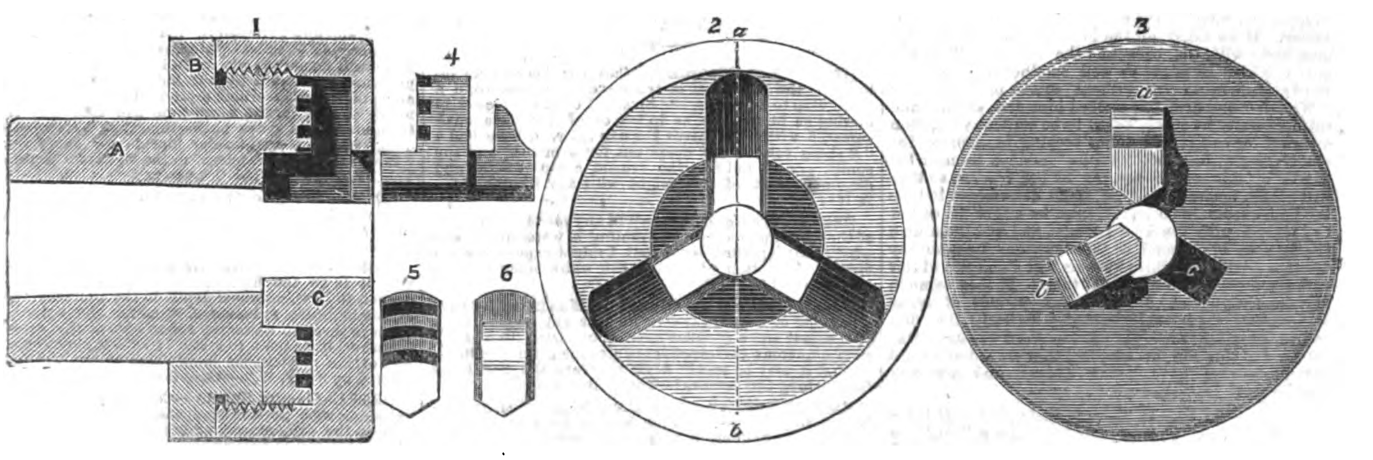
$$\frac{26^2 \times 60}{50} = \sqrt{40560} = 28{\cdot}47$$

—C. M.

[12417.]—**Hardening Spiral Springs.**—I have made hundreds of spiral springs out of 1-16in., ⅛in., and ¼in. iron, not tempered. I had straight pieces of round iron and steel which I fixed in lathe, I fixed my driver on one end, I had a small hole at the other to put end of wire through; these springs are lapped close. Some of them have worked now for about ten years and are good yet; they stand a pull and spring back; for steel springs of wire to remain open, to make them quick, you want screws for your lathe the proper pitch, with a hole at one end and driver at the other. Put wire through hole hard as you get it. Make your springs as fast as you can count them; don't do anything at them, only cut them the proper length.—OUTGENIOUS WHITESMITH.

[12419.]—**Photography.**—The fixing solution for pictures taken on gelatine and bichromate of potass is simply water slightly warmed, which removes that portion of the film which has not been acted upon by the light. The process may be briefly described as follows. Having selected a suitable paper, it is coated by means of a large flat brush with a warm solution of gelatine, in which is dissolved some pigment, of the colour required in the finished picture; the paper being coated with the coloured gelatine is put aside till dry, and is then rendered sensitive to light by being floated on a solution of bichromate of potass. When dry it may be exposed under a negative in a printing frame, as in ordinary silver printing. After exposing for a sufficient time, the paper is taken from the frame, and plunged in a drop of slightly warm water, these portions of the film unacted upon by the light being washed away, and leaving a representation of the negative in coloured gelatine. If "A." requires fuller details of the process he had better purchase "A Manual on Carbon Printing," published by Mawson and Swan, Newcastle-on-Tyne. I have omitted to state that the operations should be carried on in a yellow light as in the ordinary silver printing.—PHOTO. BRISTOLIENSIS.

[12420.]—**American Chucks.**—As an instalment in reply to this query, I send drawing in detail of the Warwick drill chuck; I shall be able to forward also the Becher, and later on the details of the Scroll chuck. The Excelsior appears from a drawing I have seen to be only an enlarged type of the Becher. Another kind, working with a key at the side, but in other respects like the Warwick, is shown in the advertising sheets of this journal, but I have never seen one of them. 1 is section through the chuck on line *a b*, Fig. 2, which is a plan of the cap piece C, Fig. 1, seen from the inside, and Fig. 3 is plan of same seen outside, showing one of the dies *a*, in position when open to fullest extent, *b*, the position of die when closed on centre, and *c* the size of gap through the front plate for the passage of dies. It will be seen that this chuck consists mainly of three pieces—the body A having the hollow at one end, and the scroll at the



other, B a collar fitting over A and screwing into the cap C, which carries the dies. This cap has a solid concentric block which is recessed out radially to guide the dies, which when in place occupy the space left unshaded in Fig. 1, 4, 5 and 6 are side view, plan as seen from inside, and plan seen from outside of one of the dies. The pitch of the scroll is one-eighth of an inch, and the thread of collar and cap left-handed, to prevent the chuck unscrewing when pulled towards you in releasing a drill.—Wakenaam.

[12421.]—**Enlarging Photographs.**—Does "Industrious Will" particularly want to use the magnesium light for enlarging, or can he be contented to work by daylight? if the latter, I can describe a small contrivance costing but a few pence, by the aid of which, with a quarter plate lens, carte negatives may be enlarged to 10 by 12, or still larger. The magnesium light is both expensive and troublesome to manage; daylight is at our command and costs nothing. If "Industrious Will" will say if daylight will do, and the Editor can insert a small engraving, I will forward drawing and description.—Photo. Bristoliensis.

[12423.]—**More Light Wanted.**—I should think the best way would be to whitewash, or paint white, the fronts of the angle houses. You don't mention what aspect they have.—Lumen.

[12423.]—**More Light Wanted.**—If there be a thick angular pier or post, it might be replaced by two thinner, with a diagonal light between them; and if the general posts be above a few inches deep from exterior to interior, lining their sides next the corner with tin or silvered glass will assist, especially if in short pieces tilted out from the post some degrees at their bottoms. If the shops have a story above them, these seem the only available resources.—E. L. G.

[12424.]—**Preserving Green Peas, Gooseberries, &c.**—Put your gooseberries in bottles (having picked off the tops and tails), then fill up the space between them with powdered lump sugar. Place these bottles in a boiler, having in it as much cold water as it will hold without floating the bottles; place the boiler on the fire and let it remain there till the sugar is dissolved by the heat. Then cork them down, and if they are air-tight they will keep for years. Be very careful that no water gets into the bottles. This is called bottling. A cheaper, and, to my mind, a nicer way is to put the fruit into bottles and then cork and seal them, and bury them about three feet in the ground. I have never tried peas, but I should think they would keep, if treated in this way. French beans may be preserved as follows:—Wash, cut, and prepare for cooking some young beans, then procure a large-mouthed glazed jar, and put a layer of salt at the bottom about an inch thick, then wipe your beans quite dry, and put a layer of them in, then some more salt, and so on. Tie your jar down and keep it in a dry place, soak them in cold water for six or eight hours before you use them, and you will be able to have fresh French beans for your Christmas dinner.—Sacristan.

[12424.]—**Preserving Green Peas and Gooseberries.**—I have always seen gooseberries, &c., preserved during the winter in bottles. Take some dry bottles and cork them down tightly, then place a seal over the cork and bury them in the earth in your garden.—Tom-Tit.

[12427.]—**Entomological.** — Will "Mimosa please to describe the "maggot" in the cabbage stem. Is it stiff and yellow? "Mimosa" speaks as if there was but one insect peculiar to decaying cabbages. How I wish it was so!—Old Amateur Gardener.

[12431.]—**Bees.**—"Willie Scorer" in trouble again; but "Willie" should give more particulars. He should say what kind of hive he wants to deprive, what it weighs, and whether the weight is made up of brood or honey. If he takes all the honey, what does he propose to do with the bees and the brood? If he has only one hive he might as well smother them at once as expect them to live without combs or honey. If "Willie's" one hive has yielded him first, second, and third swarms, he surely ought to be content with them as profit for one year, without seeking to deprive the old stock still further. "Willie" cannot transfer the combs of this year's swarms to bar frames, as they will be too tender, otherwise, if he determined to take the honey from his original hive, he might fill one or two frames with the brood combs, and add them with the bees to his second or third swarm. I cannot say whether second or third swarms will stand the winter without knowing more about them. If they came in May and were tickled with a few pounds of syrup at intervals they would probably outstrip the first swarm, provided they did not lose their queens. One reason for this lies in the fact that second and third swarms always have young queens, and are very vigorous.—C. N. Abbott.

[12441.]—**Ants.**—If Thomas Letchford will lay a few pieces of camphor in their tracts, he will find that they will cease their depredations.—Clinchey.

[12446 and 12453.] — **Manganese Battery.**— "Edward Henry's" difficulty arose from damp facilitating the capillary rise of the liquid. He must not connect both ends to earth on any account, or his battery will rapidly work itself to exhaustion, but this has nothing to do with the injury to the connection. "D. J." has made a very bad connection; no solder should be used with the platinum, but simply a piece of foil inserted at the contact. The best connection is made by depositing copper on the top and thoroughly soaking the upper part of the carbon with paraffin. The next best is put the top of the carbon in a mould and run lead over it, also saturating the upper part afterwards with paraffin to prevent the creeping up of the solution.—Sigma.

[12469.]—**Bees: How to get a Swarm.**—"G. F. Godden" does not understand the driving or drumming process evidently. When a swarm is drummed up as described by Mr. Godden, the queen should be with it, and unless it is ascertained from actual observation that the queen is there, the swarm cannot be considered perfect. The great mystery as to queens is in the mode of transforming the ordinary worker egg into a queen bee instead of a worker bee. The so-called woman's reason, "'Cos it is," is not sufficient for scientific bee-keepers; but all their research and observation have not enabled the best of them as yet to give a better, so it is still a question under discussion. It will be for the old stock to raise a new queen. Driving is simple and easy enough; but the question of its desirability at this time of year is another matter, which depends, of course, on circumstances of which the minutiæ are not given. Bees hanging out is an indication of overcrowding, but not always of intended swarming, and Mr. Godden would have been wiser, if, instead of waiting for a second swarm, he had given his bees more room. Is Mr. Godden quite sure that his bees are not queenless? Queenlessness will induce apparent laziness in bees after a short time for the simple reason that after a swarm has left the occupants of the hive fill each cell with honey as it is vacated by the young bee, and the failure of the young queen on her wedding trip renders it impossible either for the bees to take possession of the offered super, or to send out another swarm. Consequently, they fill up the cells as fast as they are vacated, and themselves are crowded out for the time being. If Mr. Godden intends to drive out a swarm, he should do it quickly, as if long delayed the swarm will not only be liable to perish in winter for want of stores, but the old stock may perish for lack of drones to fertilise the young queen. I cannot recommend driving at this late period. If Mr. Godden has lost his chance of a super while waiting for a second swarm, he had better accept the position, and be wiser next time. Perhaps he could cut out the side combs of his hive, which are almost sure to be filled with honey, and there will yet be time for his bees, if they are strong, to replace it; but for the information of all those who intend to cut out honeycomb from their stock hives, it may be well to state how that, as a rule, all new comb built now for storing purposes will be drone comb.—C. N. Abbott.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "Dusty Miller" has answered 11892; "Outgenious Whitesmith," 12001, 12008; "Rat-Tat." 12001; "Young Snip," 12023; "T. B. S.," 12053; "Saul Rymea," 12091, 12093; "Clinchey," 12103; "Electro," 12117.

QUERIES.

[12476.]—**Bee Keeping.**—Can any beekeepers inform me the best mode of transferring the bees from a straw skip to a wooden bar hive? I cannot succeed in driving or fumigation, as in two cases they have amalgamated with other hives the day after. I have had a "Myborg cabinet" in operation for a month, and the combs are all built in the second compartment, and diagonally instead of straight with the frames, &c.—B. H. J.

[12477.]—**Water-glass.**—Will any reader inform me of the best method of constructing a water-glass, and what is the greatest depth that I might expect to get a view of the bottom of the sea, the water being clear at the time?—L. Z. J. B.

[12478.]—**Sour Ale.—Heats of Mashing.**—I have a brewing of ale over twelve months old, which has an opal colour and a peculiar sweet-sour taste. Can any of your numerous correspondents give me a remedy for it, so that it may be sold? Also, what are the best heats for mashing two mashes?—Young Brewer.

[12479.]—**Scouring and Bleaching Flannels.**—Would some correspondents inform me how to scour and bleach flannels a very pure white (stating the chemicals and their quantities), and name a good modern work on the subject and its author?—Old Fuller.

[12480.]—**Silk Working.**—A portion of our silk works through small iron holes called males, attached to thread, and, by standing, it has rusted them, making them too rough for the silk. What is the best thing for taking the rust off without injuring the thread attached?—Anxious.

[12481.]—**Wax Moth.**—It would greatly oblige me if some friend or beekeeper would inform me how to destroy the egg or maggot of the wax moth in some empty combs that I wish to save, and what is the best way to keep brood combs free from this destructive little moth?—R. A.

[12482.]—**Integral and Differential Calculus.**—What is the practical scientific use of the integral and differential calculus? With what branches of mathematics is an acquaintance necessary before entering upon this one? Which is the best rudimentary treatise?—Excelsior.

[12483.]—**Rewiring Old Piano.**—I have an old square piano, 5 octaves, it has very thin wires, some of which are broken. I think of rewiring it with thicker ones. Will some brother reader kindly inform me what numbers of wire I ought to put in, stating where each number breaks off and the next begins? Also, if it will do to put plain wire for the bottom notes, instead of covered?—H. W.

[12484.]—**Inorganic Chemistry.**—Will any of your readers kindly inform me what book or books to study, in order to pass first class in the third stage for honours, in the next examinations of the Science and Art Department? I should also like to know what the honours consist of, and for what they will be given. Any information on the above will be thankfully received.—Science and Art.

[12485.]—**Electrotype Casting.**—Having a cast in lead of the Lord's Supper, and wishing to obtain an electrotype of the same in copper, I should feel much obliged if any of your readers could inform me the easiest way of doing it.—An Admirer of the Art.

[12486.]—**Machine for Cleaning Boots.**—Will some kind reader tell me if there is a machine for cleaning boots? If so, please give a description of it.—S. J. R.

[12487.] — **Annealing Spring Steel.**—Will any brother reader kindly describe a simple method of annealing spring steel, so that it may be welded as easy as iron? Also tempering elliptic springs.—Blaze.

[12488.]—**Zinc for Hot-water Tank.**—I am about to build a hot-water tank for cucumber growing. Will zinc stand hot water? I have been told that it will not. Will some kind friends give me their experience or opinion of it? I have tried galvanised iron, but that soon rusts.—F. G. C.

[12489.]—**Lacquering Brasswork.**—I have been lacquering some brasswork, the colour of which is hardly deep enough. Will any of "our" readers inform me if brass-finishers ever apply more than one coat of lacquer—if so, must the work be re-heated or how?—Electro.

[12490.]—**Grape Culture.**—Will some kind reader inform me of a good practical book of instructions on the culture of grapes and greenhouse plants of the commoner species—viz., bedding plants, &c.?—Horatio.

[12491.]—**Overgraining.**—Can any of your correspondents recommend a good substitute for beer, so largely used in overgraining? I have frequently noticed a newly grained door, even after two good coats of varnish have been applied, go quite dead on those places overgrained, while the remainder has kept bright. This, I think, shows that the beer used utterly destroys the varnish. Perhaps some of "our" practical friends will throw a light on the subject.—Harry G. Newton.

[12492.]—**Show-stand.**—I shall be obliged if some one of "our" kind readers will give me a hint or two as to the best and cheapest system of driving the above, for being placed in the window of a draper. I want to work about 3 or 4 revolutions per minute. The stand is 24in. diameter and 6ft. tall, intended to be filled with light articles.—Omnes.

[12493.] — **Grove's Gas Battery.**—Would some kind electrical correspondent to "ours" give a description of "Grove's gas battery," and tell how many square feet of platinum it would require to make 20 cubic feet of the mixed gases at the pressure of the atmosphere combine and form water; also, how many wires to conduct the electricity away would be wanted; and, if I decomposed water with the current of electricity, how much less of the mixed gases would be made than I had in the first place?—Vulcanite.

[12494.]—**Hardening Teeth.**—Last winter I had a severe attack of ticdoloreux, and I took some quinine as advised, but since then I have repeatedly had pieces of my teeth breaking off whilst eating. Would some fellow reader tell me what I could take as a remedy?—W. E.

[12495.] — **Watchmaking.**—To "Seconds' Practical Watchmaker."—Referring to the article on "The Watch, and how to Repair it," in the English Mechanic, by "Seconds' Practical Watchmaker," I wish to ask him if he will favour us with a full description of the improvements effected by our foreign neighbours in the angle of the escape-wheel tooth in the horizontal escapement. I may at the same time ask him why a fast train movement keeps better time than a slow train, in doing which I would refer him to my query on the "Trains of Lever Watches," in the English Mechanic, Vol. XV., p. 492.—West Cornwall.

[12496.]—**Stained Scarlet Tunic.**—Will some one kindly tell me what will take stains out of a scarlet tunic? The stains have been caused by the hilt of a sword rubbing against the cloth.—E. B. H.

[12497.]—**Horizontal Escapement.**—I would ask why it is in the horizontal escapement that if you deepen the escape-wheel depth in the cylinder the arc of free vibration is lessened, although the balance has to move through a greater arc to obtain the escape of the wheel from tooth to tooth. I have my own explanation of the matter, but should like to see the subject treated by "S. P. W."—West Cornwall.

[12498.]—**Green Shade.**—Can I put anything in the vat along with lime, indigo, and sulphite of iron, so as to keep the oxygen from acting upon it, and not turn blue as it always does when exposed to air? I want to keep the green shade as it is when it comes out of the vat.—Omnes.

[12499.]—**Trigonometrical.**—The hypothenuse AB of a right-angled triangle is divided at D, so that AD is to BD as CB is to CA. Show that—

$$\tan. \angle CD = \frac{a^2}{b^2}$$

$$CD = \frac{\sqrt{a^4 + b^4}}{a + b}$$

Can any one show me how this is proved, and say whether there are two solutions or not?—W. H. H. C.

[12500.]—**Land Surveyor.**—Will some reader of "ours" inform me what are the duties of a land surveyor? Also, what course of studies should an intending one go through, what books should be read, and what instruments are required?—Thomas Tomlinson.

[12501.]—**A Cheap Gas.**—I would feel much obliged to any of "our" chemists for the information as to the cheapest materials and how to use them in order to produce a gas in quantity, which need not necessarily be inflammable, but must not be heavier than air, and to state probable cost of producing any given quantity of same.—A., Liverpool.

[12502.]—**Neville's Bread.**—Will some one inform me how this kind of bread is made?—GRAMNIVOROUS.

[12503.]—**Testing Tartaric Acid.**—I am using a large quantity of tartaric acid, and I think that it is not pure, but it is adulterated with alum. If so, can any reader give me a simple test to find alum, and oblige—AERATED WATER.

[12504.]—**Sketching from Nature.**—Would some correspondent inform me of an apparatus (cheap and portable) to get in the proportions of a view from nature, or tell me how to make it? A drawing of it would greatly oblige—THOMAS KING.

[12505.]—**Plating Steelwork of Bicycles.**—Can some one tell me the process of nickel or silver plating bicycles; the apparatus required, and the cost for a 48in. ariel bicycle?—EDDY.

[12506.]—**Power of Engine.**—Would some one tell me the nominal and effective power of this engine:—Cylinder, 20in. diameter, 18in. stroke, steam cut off at two-thirds of stroke 100 revolutions per minute, 40lb. pressure of steam in boiler.—HECLA.

[12507.]—**Cricket-bat Making.**—I would feel obliged if any person would give me some particulars concerning the making of cricket-bats; also the kind of wood used.—W. B.

[12508.]—**Eloby.**—Will one acquainted with the West Coast of Africa say where a place called Eloby is, and what is the character of the climate there? I fancy it is a trading-port on one of the coast rivers.—T. SINCLAIR.

[12509.]—**Chemical.**—Will "Sigma" kindly say if there are any salts of carbolic acid which are insoluble in salt water?—T. SINCLAIR.

[12510.]—**Camera Obscura.**—I am wishful to construct a camera obscura as per the instructions given in ENGLISH MECHANIC, No. 332, p. 494. Will some kind friend oblige me with the dimensions of the necessary oblong and sliding boxes? I hardly understand the plan given with respect to the square K. L., cut away at the top of the box in which the ground-glass is inserted. Is it inserted flat or is it placed in a raised position?—G. F. FURNISS.

[12511.]—**Gas.**—Will some one kindly state about how many cubic feet of gas can be produced from a ton of ordinary gas coal?—A., Liverpool.

[12512.]—**Spotted Kid Gloves.**—Can any of your readers inform me whether any remedy is known for gloves (coloured kid) which have been spotted through exposure to damp, as I have a large stock of them and wish to avoid loss if possible?—W. S. B.

[12513.]—**Astronomical.**—Would "F. R. A. S." or some other correspondent kindly inform me what are the corresponding numbers in the B. A. catalogue to Struve's 73 Ophiuchi, 2406 Draconis, 2878 Pegasi, 26 Pegasi, and 36 Andromedæ.—C.

[12514.]—**Elder Flower Water.**—Will any one kindly give me directions how to make elder flower water as sold by chemists: also lavender water?—T. H.

[12515.]—**Mowing Machine.**—I have a mowing machine by Burgess and Key, the knives of which are constantly breaking. They are driven by a very short rod, and all other machines have a long rod; is that the cause of its breaking? The machine is very good if we could get over that difficulty.—A COUNTRYMAN.

[12516.]—**Mathematical.**—It is known that—

$$\cdot 1 = \frac{1}{10} = \frac{100}{1000}$$
$$\cdot 11 = \frac{11}{100} = \frac{110}{1000}$$
$$\cdot 111 = \frac{111}{1000}$$

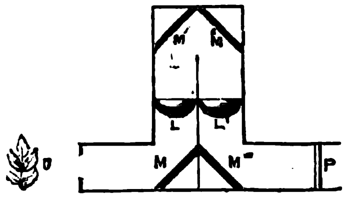
i. e., as the number of figures in the decimal is increased, the numerator of the fraction formed differs less and less from the denominator. Therefore, in the limit, which is $\cdot\dot{1}$, will not the numerator be theoretically equal to the denominator, and $\cdot\dot{1}$ equal to 1 instead of $\frac{1}{9}$?—NEANISCOS.

[12517.]—**Mathematical Machines and Tables.**—Some time since I saw Babbage's calculating machine—I think in Kensington Museum. I am at a loss to understand the exact object the inventor had in view, and although I have read several popular descriptions of it, still they do not describe it as I could wish. Perhaps some of "our" mathematical friends will kindly explain the matter, or tell me in what book a clear and full account of the machine is given. The information I am anxious for is:—1. Are the *Nautical Almanac* tables calculated by such a machine? 2. Are such tables formed in regular progressional numbers, or are they differential? 3. If differential, is the ratio regular, or do the tables consist of combinations of ratios differential or regular? 4. Did the machine in question ever realise the expectations of its inventor and become of use, or has any other machine supplanted it? An example of the tables, to illustrate them, would no doubt interest many besides—A. B. W.

[12518.]—**The Island of Hayti.**—I shall be much obliged for information about this island. What is the present form of government and who is ruler? Does Spain still possess a part of it? What language is in use, and is there any commerce carried on with Great Britain? Closely connected with the island is the name of "Toussaint L'Ouverture," the great Negro chief, who was so cruelly deceived and maltreated by Napoleon I. I should like to know how and where he died, and what became of his family?—J. L. WHITAKER.

[12519.]—**Acarus Crossii.**—Many years since the late Mr. Cross announced a series of electrical experiments continued for a lengthened period, by means of which he produced the living electrical acarus. Can any of your correspondents give me any instructions as to the details of apparatus required? These curious experiments no doubt have been repeated by others. Any information on this subject will be highly valued, and will much oblige—AUSTRALIAN SUBSCRIBER.

[12520.]—**Fluid Lens for Photography.**—Will any one tell me if it would be possible to construct a camera obscura by the following arrangement?—The rays of light flowing from the object O, are by the series of mirrors M M' M'' and M''' sent through the lenses L and L', which I propose to make of watch-glasses, L to be filled with water, and L' with sulphuric acid, in order to have them of different densities and thus make



them achromatic. P is the prepared plate on which the image would be reflected by M'''. I should also like to know how to find the focus. Suppose it found, would moving the object nearer to or further away from M alter it? Would the focal length be from L' to the plate, or only from L' to the mirror M'''?—TNETAP.

[12521.]—**Value of Locomotives.**—Can any one inform me what is the value of goods and passenger locomotives, such as the London and North Western Company are now building, according to present state of iron and labour markets?—EXCELSIOR.

[12522.]—**Length of Pendulum.**—Will some kind brother in the watch trade please give me his opinion as to the length of pendulum springs, as I find they vary from 8 to 12 turns, the more coils the less affected by change of temperature?—CONVERSION.

[12523.]—**Lacquer.**—How can I make a blue lacquer suitable for gun furniture and edge tools, and how is it applied?—WALSALL.

[12524.]—**Holtz Electrical Machine.**—Do you think it would be possible to substitute a disc of tin covered with sealing-wax varnish in the place of the smaller glass disc in the Holtz electrical machine?—TNETAP.

[12525.]—**To "F.R.A.S."**—In using "Bessel's Tables" and making the necessary corrections for refraction, how is the observer to calculate or ascertain the "apparent altitude" of a star above the horizon at the particular moment of observation, so as to determine the exact allowance to be made in setting the circles of his equatorial? A few lines in explanation of this matter would greatly oblige a puzzled—TYRO.

[12526.]—**Camera Lucida.**—Will any reader kindly give instructions for making a cheap camera lucida for the microscope?—ALF.

[12527.]—**Mounting Chalk for the Microscope.**—Will any subscriber kindly tell me the way to prepare chalk as an object for the microscope?—ALF.

[12528.]—**Hay Asthma.**—I shall feel extremely obliged to some of "our" correspondents if they could tell me of any means that I could use that would relieve my complaint. I am troubled every year for several months with what is called the hay asthma. I am under seventeen.—KATE.

[12529.]—**Improved Machine for Making Aerated Drinks.**—In the letter of "H. B. E." (4406) upon the above subject, he says the gas for aërated drinks is made from sulphuric acid and common whiting. Would he kindly let me knew the proportions, and whether it can be produced by any other compounds?—495.

[12530.]—**Name of Plant.**—Will some one tell me the name of a plant or herb that grows by the side of hedges with willow-like leaves on the ground, from whence rises up a stalk branching out into four or five branches with leaves at the bottom, and a flower spike at the top nearly a foot in length almost like agrimony, but the flowers are of a green colour, after which come four or five small green seeds.—T. B. S.

[12531.]—**Flatting.**—Having a little knowledge of house painting I have painted the walls of my room 7ft. high, and should be glad if some kind friend would let me know if there is any method of keeping the last coat called flatting alive sufficiently long, so that I may do a flank at a time by myself, and with due care have a dead colour. I have heard of a few drops of olive oil being applied, but it has gone off and part is left shiny.—PUTTY.

[12532.]—**Republican Months.**—Can any reader inform me the names of the months according to the ideas of the French Republic and their English equivalents?—J. L. WHITAKER.

[12533.]—**Magnetic Machine.**—Will "Sigma" or any reader tell me how the connections of the wires in an electro-magnetic machine are made in using different powers (say 1, 2, 3, 4 powers)? I have thought of insulating the primary coil from the secondary by gutta-percha tissue; and in winding on the secondary wire should I coil a portion of the wire, say for the first power, insulate again, wind on another portion and insulate again, and call that the second power, and wind and again insulate for the third power? A diagram of the connections will greatly assist.—CRITERION.

[12534.]—**Spring Furnace.**—Would any brother reader oblige with drawing of furnace, used to temper the leaves of bearing springs for railway trucks?—A. E.

[12535.]—**Spots on Whitechapel.**—What is the cause of water-stains on my "Whitechapel." When the man washes the trap, no matter whether dry or damp weather, the stains set as soon as water is thrown on, and no amount of drying with leather or sponge will take them out, but I have found that when it has not been used at long intervals of (say) a fortnight, they nearly fade away. I should be thankful to know the cause and prevention of this?—J. W.

[12536.]—**Speculum Grinding.**—Would Mr. Purkiss kindly answer the following queries? Suppose a 6in. speculum placed on the centre of a grinding tool does the stroke (⅓ diameter, or 2in.) mean 2in. over each side of the tool, or only 1in. over each side? and if the side motion (¼ diameter or 1½in.) means 4½in. over each side, or only ¾in. over? Does the 2in. stroke mean 2in. over one side only, and the speculum brought back again to the centre?—W. S. S.

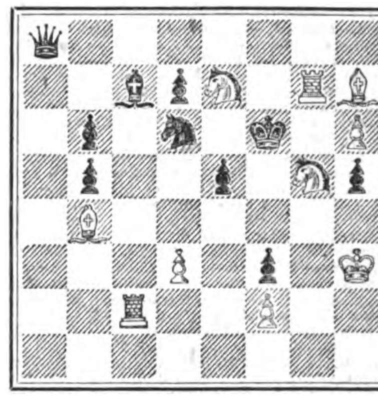
CHESS.

ALL communications intended for this department to be addressed to J. W. ABBOTT, 7, Claremont-place, Loughborough-road, Brixton, S.W.

The contest for the "Challenge Cup," open to English players only, has terminated in favour of Mr. Wisker, who, having won the cup twice in succession, is, according to the conditions of the competition, entitled to its possession. The cup was presented by the "Association" in 1866, on which occasion it was won by Mr. de Vere. In 1868 Mr. de Vere and Mr. Blackburne tied, but ultimately the latter was declared the victor. In 1870 Mr. Wisker won the cup. This year he and Mr. de Vere tied, but in playing the final game fortune favoured Mr. Wisker, who thus retains the chess championship of the country.

PROBLEM VIII.—BY R. B. WORMALD.

Black.



White.

White to play and mate in three moves

SOLUTION TO PROBLEM VII.

White.	*Black.*
1. Kt to Q 3	Black's moves are forced
2. K to K Kt 5	
3. Kt mates	

TO CORRESPONDENTS.

INDUCTORIUM AND HERMES.—The reply to the moves you suggest in Problem VI. are respectively (1.) R to Kt sq. dis. ch. and mate, and (2.) B to R 2 dis. ch. and mate.

A. L. (Dulwich).—The *Westminster Papers* can be obtained through W. Kent and Co., Paternoster-row.

M. MARKS (Swansea).—The best way of marking the position of the men on blank diagrams is by inscribing their initials: W K for white king, B Kt for black knight, &c.

W. H. WHITFIELD.—Your problem is correct, and shall appear as an enigma.

Problems received with thanks from H. Meyer, G. Heywood, and Inductorium.

Correct solutions to Problem VI. (continued).—J. Beresford (Vauxhall), T. M. T., S. H. H., York.

Correct solutions to Problem VII. have been received from A. W. Cooper, R. A. Proctor, C. J. L. (Portsmouth), H. Cherry, J. Beresford, G. Heywood (Great Torrington), and H. A. Hall, Chester. All others are wrong.

MR. H. H. CROFT, of Toronto, has discovered that the air over crystallising iodic acid becomes ozonised in a striking manner.

Embalming Bodies by Injection.—*Les Mondes* reports that the system of M. Gannal, of embalming bodies by injection, which was effected by opening the jugular vein or the carotid artery, will probably be superseded by M. Audigier's plan, in which the preserving fluid is introduced through the mouth and the larynx. About six ounces of the fluid is sufficient for the purpose, and the body should be covered with some vegetable powder soaked in the same liquid. The body is by these means completely preserved, and is entirely "mummified;" it requires a durability equal to that of wood or stone, and the facial colour remains as it was at the moment of decease. The most eminent physicians, surgeons, and anatomists in France have, it is said, testified to the efficacy of the system, which has, in addition to the advantages already mentioned that of perfect innocuousness and complete disinfection. The liquid is believed to be carbolic acid, and the mode of application is the same as that devised by Professor C. A. Seeley, of New York, and by him very successfully applied to the preservation of bodies at the hospitals there.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, July 23, and unacknowledged elsewhere:—

L. de Fontainemoreau and Co.—Wm. N. Roberts.—Major Locke.—Right Rev. James Lynch.—Irish Mechanic.—Jack of All Trades.—Wm. Coleman.—Wm. Piper.—S. Bottone.—J. J. Pyne.—Exhibitor.—W. H. P.—An English Mechanic.—Majico.—E. S. T.—Templar.—S. Trevail.—Julius Hall.—F. R. Leyden.—Charles Woodhead.—Mrs. Ethell.—Alfred W. Allen.—Wm. Brown.—R. Middleton.—Enquirer.—W. J. V. Gerard.—E. L. G.—Planette.—An Improver.—Veritas.—J. Rushwood.—Ignorant.—C. J. C.—Joseph Hudson.—P. E. M.—Administrator.—W. M. Colles.—Athelstane.—H. J. W.—F. R. C. P.—W. E. Parker.—J. R. F.—Plus.—Anxious.—Out of Pocket.—Colonist.—Rodger.—A Distressed One.—W. A. G.—S. Selwyn.—Shamrock.—Pegasus.—A Sawney.—Non Science.—Landsend.—G. Moulder.—Green Drake.—C. N. Abbott.—J. T. Culpepper.—W. R. Bird.—G. W. K. L.—Inquirer.—Gy.—J. L.—A. B. M.—H. Meyer.—Suffolk Amateur.—M. Paris.—C. J. Hindle.—A Young Astronomer.—J. Gillingham.—Delta.—W. Clarke.—W. H. Neal.—William Lea.—X. Y. Z.—A Five Years' Subscriber.—Bernardin.—Wm. Tipper.—R. K. Jones.—R. A. Proctor.—Albert S. Bradley.—James Hill.—March and Pattison.—Sigma.—J. W. Buck.—F. M. Crichton.—W. B. Hibbs.—W. Wade.—Mechanic.—A. J. Wilson.—James Cain.—J. R. Nichols and Co.—Geo. Sant.—Charles Baker.—Thomas Fletcher.—The Harmonious Blacksmith.—Seconds' Practical Watchmaker.—M. A.—Banjo.—R. N. S.—Violinist.—Analyst.—W. H. H. C.—M. A. B.—Francis Lewis.—One in a Fix.—E. Parker.—G. W. C. H.—R. M. M. S.—E. H.—E. B. Shaw.—Ohio.—Marcus Ruddle.—Old Ploughman.—Philo.—W. W.—R. P.—Linum.—Water.—A Sufferer.—Sucram.—G. A. Ames.—H. G. W.—F. F. C.—Theodolite.—A County Bookbinder.—W. Wray.—Joseph Wm. Fennell.—J. M. G. Brookwood.—Duplex.—Glatton.

W. H. H. C.—Quite in order. The query next week.

James Hill.—No stamps inclosed for "Exchange" advertisement.

Disappointed Subscriber.—It is not our fault. Try another newsagent.

C. H. Waters.—See "Hints to Correspondents," No. 6.

E. S.—No. It would be a bad precedent.

J. F. Thompson.—We know nothing more about the "graphite paint" than what was said on p. 425.

Lewes Hutchins.—See "Hints to Correspondents," No. 6.

Liver.—Much too "advanced" for discussion in these columns. Get good medical advice.

Young Mechanic, A Carpenter, L. W. L., Irwell, Sufferer, F. A. R., Gy., Young Hopeful, New Trowell, J. E. P., Mechanical Publican, are referred to indices to back volumes.

Communications which can only appear as advertisements to hand from L. W. L., M. P., J. W. S., H. D. E., A Subscriber.

W. Hewitt.—Shall be glad to receive continuation of the proposed series.

Chas. Lennox.—We do not know; suppose you write to one of them and ask him.

W. S. C.—You must be regularly apprenticed to the business.

Thomas Buchanan.—Your introductory paper on astronomy is rather too imaginative for us. You lead off in this style: "What are these brilliant scintillations? Whence and wherefore their eternal fires? Are they the distant lamps of celestial palaces, kindled on the floor of heaven (!) and showering down their nightly radiance on the soul of the sleepless gazer, for the sublime purpose of exalting his aspirations to some nobler state of being?" &c., &c. We do not know, but "F. R. A. S." would doubtless at once give the required information.

Cottager.—Your plan of laying out a garden would take a much larger engraving than we could afford space for.

W. E.—Your able letter on Linguistic Theories in answer to "E. L. G.," would inevitably launch us on a sea of theological discussion, and we therefore cannot insert it.

C. E.—The omission of the word "water" in the paragraph headed "A New Dryer," p. 439, renders it useless. We reproduce it in a corrected form this week. Thanks.

Walsall.—For information how to make emery wheels, see Vol. XIII., pp. 292, 366, 520.

Jack of All Trades.—"Suffolk Amateur" writes: "Though your subscription list seems closed, may I ask you to allot me a share in the contribution to your clever and obliging correspondent 'Jack of All Trades,' for whom I inclose my cheque for £3. I dare say it will not be a bad investment." We have forwarded the money to "Jack," and in his name thank "Suffolk Amateur."

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING JULY 16, 1872.

1989 J. Rabone, Birmingham, for improvements in spirit levels and plumb spirit levels. A communication.

1990 H. J. H. King, Glasgow, for improvements in apparatus for obtaining motive power for pumping or for measuring fluids.

1991 W. K. Birkinshaw, Derby, for improvements in machinery for cutting or holeing coal.

1992 J. Chenhall, Totness, Devonshire, for improvements in sewing machines.

1993 J. Holmes, G. T. Holmes, and F. R. Holmes, Norwich, for improvements in the construction of machinery for elevating, raising, and stacking hay, corn, straw, and other substances.

1994 A. Kay, Ince, Wigan, for a combined machine of wood and iron for ice breaking, and beveled swinging drawing paddle for boats or barges on still water.

1995 E. Davies, Liverpool, and S. Dawson, Manchester, for an improved exhaust and blast for millstones.

1996 J. M. B. Baker, Southsea, for an improved disinfecting and deodorising apparatus for water-closets and other purposes.

1997 W. E. Newton, Chancery-lane, for an improved process for surface-hardening steel. A communication.

1998 W. Evans, Willesden, and H. Cochrane, George-street, Portman-square, for improvements in table knives and forks.

1999 J. Wallace, Grove-street-road, N.E., for improvements in gas stoves and burners, and regulating apparatus to be used in connection therewith.

2000 J. Gillott and P. Copley, Barnsley, Yorkshire, for improvements in machinery or apparatus for cutting or getting coal, stone, and other minerals.

2001 J. L. de Montolson, Chancery-lane, for improvements in means and apparatus for removing the hair or fur from skins, and applying the same to various useful purposes.

2002 J. L. de Montolson, Chancery-lane, for improvements in tanning and in apparatus connected therewith.

2003 W. Thwaites, Cromwell-road, Brixton, and E. Fondeville and G. Bertin, Gaisford-street, Kentish Town, for improvements in the preparation of glaze or coating suitable for covering stone, earthenware, plaster, furniture, and other surfaces.

2004 W. Thwaites, Cromwell-road, Brixton, and E. Fendeville and G. Bertin, Gaisford-street, Kentish Town, for an improved composition or admixture for preserving walls from dampness, and for other purposes.

2005 W. Mitchell, Brandon, Suffolk, for improvements in ladders.

2006 G. Noble, Woodford-bridge, Essex, for improvements in the method of treating various kinds of fibrous materials for the manufacture of writing, printing, and other paper.

2007 J. Stones, Ulverston, Lancashire, and J. Castles, Manchester, for improvements in revolving and other shutters, and in temporary partitions, parts of which improvements are particularly applicable for preventing the transmission of sound while giving access between portions of a schoolroom, chamber, or other apartment temporarily divided.

2008 E. Le Gros, Stoke Newington, for improvements in drilling machinery. A communication.

2009 H. D. Furness, Whickham, Durham, for improvements in hydrostatic weighing and lifting machines for adjusting the weight on springs of locomotives, waggons, and carriages, and for other purposes.

2010 J. Vine, sen., J. Vine, jun., J. Brown, and J. A. Skinner, Eastbourne, for improvements in fire-arms.

2011 E. Newbold, Nottingham, for improvements in furnace bars.

2012 P. Newall and J. Barker, Warrington, for improvements in machinery or apparatus for dressing or finishing leather.

2013 R. Turnbull, Campbell-road, Bow, for an improved means of raising and lowering vessels for repairs, and for other purposes, and in the construction and arrangements of submergable pontoons and apparatus connected therewith.

2014 J. T. Parlour, Rutland-street, Pimlico, for improvements in apparatus to be used in the formation of asphalte and other pavements.

2015 S. J. Payne, Charlton, Kent, for an improvement in the manufacture of fire-bricks, crucibles, retorts, and other fire-ware goods.

2016 J. Crop, Homerton, for improvements in tobacco pipes.

2017 W. Gorman, Glasgow, for improvements in manufacturing iron and steel and in apparatus connected therewith, part or parts of such improvements being applicable to various kinds of furnaces, and for the production of gases for heating and illuminating purposes, and for coking, carbonising, or calcining other substances.

2018 G. Westinghouse, jun., Southampton buildings, for improvements in brake apparatus for railway carriages.

2019 D. Cunningham, Dundee, for improvements in the construction of breakwaters, sea walls, and other subaqueous works.

2020 J. F. Stewart and H. Defty, Middlesbrough, for improvements in and connected with puddling furnaces.

2021 W. McLaren, Glasgow, for improvements in machinery for sawing or cutting wood.

2022 P. Jensen, Chancery-lane, for improvements in charging furnaces and in the construction of furnaces and steam boilers. A communication.

2023 W. Richter, Prussia, for an improved machine for breaking bar iron.

2024 A. Sauvée, Parliament-street, Westminster, for improvements in the distribution for engines multiplying the power of the prime mover. A communication.

2025 J. Vavasseur, Southampton-street, S.E., for improvements in breech-loading ordnance.

2026 H. Uhry, Haxell's Hotel, Strand, for improvements in locomotive engines.

2027 L. P. Dore, Store-street, Bedford-square, for an improved contrivance for securing false hair on ladies' heads.

2028 W. Smith, Dublin, for improvements in railroads and in carriages to be used thereon.

2029 B. J. B. Mills, Southampton-buildings, for improvements in sizing paper, paper pulp, cotton, linen, and other fabrics and materials, and in materials to be employed therefor. A communication.

2030 Sir J. Bethune, Fifeshire, N.B., for improvements in wheels, especially applicable to traction engines.

2031 T. Clark, Aberdeen, for improvements in winnowing or seed-dressing machines.

2032 S. Alley, Glasgow, for improvement in steam boilers.

2033 J. Miller, Aberdeen, for improvements in purifying and decolourising hydrocarbons.

2034 R. H. Allen, Essex, for improvements in the construction and general arrangement of ships' passengers' berths for married couples.

2035 B. Todd, Newcastle-upon-Tyne, for improvements in the treatment of gases and fumes.

2036 E. J. L. Coillot, Barcelona, Spain, for improvements in the manufacture of lighting and heating gas, and in apparatus and burners connected therewith.

2037 W. Brunskill, Liverpool, for improvements in mechanism for forming bungs and similar tapered articles.

2038 I. Simonett and G. Roberton, jun., Bradford, for improved machinery or apparatus to be employed for removing motes and burrs from woven fabrics.

2039 E. Umbers, Leamington Spa, Warwickshire, and A. G. Fenn, Beccles, Suffolk, for improvements in and apparatus for signalling on railways.

2040 T. H. Ward, Staffordshire, for improvements in pulley blocks for raising and lowering weights or heavy bodies.

2041 A. M. Clark, Chancery-lane, for improvements in cylinder printing machines. A communication.

2042 D. Peattie, Edinburgh, for improvements in shades or blinds for windows.

2043 J. Foster, jun., Westmoreland, for improvements in machinery for manufacturing twine and other cord.

2044 W. Weldon, The Cedars, Putney, for improvements relating to the utilisation of dilute chlorine.

2045 W. W. Tonkin, Brixton-road, for improvements in the means of actuating the valves of engines, pumps, or liquid meters.

2046 E. P. H. Vaughan, F.C.S., Chancery-lane, for improvements in the mode of utilising the waste gases of metallurgical and other furnaces. A communication.

2047 J. Crofts and R. Dawson, Leeds, for improvements in apparatus employed in combing wool and other fibres.

2048 J. F. Elwell and J. Grove, Birmingham, for improvements in safes.

2049 C. F. Schlesinger, Holloway, for a new or improved apparatus for beating carpets and other fabrics. A communication.

2050 W. R. Lake, Southampton-buildings, for an improved process of welding brass or other alloy of copper upon iron or steel, applicable to the construction of journal boxes of axle bearings for railway carriages and machinery. A communication.

2051 J. Mathews, Tavistock, for improvements in jigging machinery for dressing ores. A communication.

2052 W. Holbrook, Manchester, for improvements in fasteners for sash and casement windows, shutters, and doors.

2053 W. R. Lake, Southampton-buildings, for an improved ventilating apparatus. A communication.

2054 J. H. Johnson, Lincoln's Inn-fields, for improvements in cooling air and gases and in the apparatus or means to be employed therein. A communication.

2055 R. R. Donovan, Dublin, for an improved drill-stock.

2056 J. Thomson and J. M. Thomson, Glasgow, for a new or improved radial drilling machine.

2057 H. R. Marsden, Leeds, for improvements in the jaws for stone breaking machines.

2058 C. D. Abel, Southampton-buildings, for an improved portable apparatus for impregnating air with hydrocarbon vapours or volatile oils for lighting and heating purposes. A communication.

2059 A. Prince, Trafalgar-square, Charing-cross, for a new or improved boring instrument. A communication.

2060 J. Vogan, Dockhead, Surrey, for improvements in raising or elevating corn, grain, or seed from one level to another.

2061 A. B. Barry, Crutched-friars, City, for improvements in sewing machines.

2062 J. O'Neill, Liverpool, for improvements in apparatus for signalling on railway trains.

2063 J. Gomersall and J. F. Gomersall, Dewsbury, for improvements in the manufacture of reversible twill cloth.

2064 W. Morgan-Brown, Southampton buildings, for improvements in type wheels for printing telegraphs. A communication.

2065 W. R. Lake, Southampton-buildings, for an improved compound, and method of preparing the same, for the construction of street pavements, and for other like purposes. A communication.

2066 J. Downes, Handsworth, Staffordshire, for improvements in locomotive and stationary steam-engines.

2067 W. R. Lake, Southampton-buildings, for improvements in fire-extinguishing apparatus. A communication.

2068 F. G. Marchant, North-street, Wandsworth, for improvements in wheels and apparatus connected therewith, chiefly designed for facilitating the movement of road engines and other heavy vehicles.

2069 J. Cook and H. Lafone, Liverpool, for improvements in blow-pipes and means of generating heat by the use of hydrocarbon or other volatile fluid, material, or substance.

2070 P. F. Guerin, College-street, Chelsea, for improvements in the construction of horse-shoes.

2071 C. M. Barker, Kennington-park-road, for improvements in propelling ships or vessels, and in the propellers to be employed therein.

2072 W. Clissold, Gloucester, for improved machinery for condensing and drawing fibrous substances.

2073 W. Morgan-Brown, Southampton-buildings, for improvements in printing-telegraph instruments. A communication.

1074 H. Lancaster, Lancashire, for improvements in locks or fastenings, principally intended as a substitute for ordinary padlocks.

2075 W. E. Ellson, Greywell, Southampton, for guarding and saving large and small ships from strandings and wrecks, and applicable to any present built ship.

2076 W. B. Adams, Lewisham, for improvements in locomotive engines and vehicles for railways, tramways, and common roads, parts of which are applicable to other like purposes.

2077 H. A. Bonneville, Piccadilly, for improvements in bits. A communication.

2078 F. J. Ritchie, Edinburgh, for improvements in sympathetic clocks.

2079 R. B. Starr, Finsbury-square, for an improved apparatus to be applied to omnibuses, tramway cars, or similar vehicles, to register the number of passenger carried and the various fares paid during a journey.

2080 G. Webb, Dublin, for improvements in coverings for draft horses.

2081 W. Morgan-Brown, Southampton-buildings, for an improvement in unison stops for printing-telegraphs. A communication.

2082 W. C. S. Percy, Manchester, for improvements in apparatus for protecting outside passengers on omnibuses and other carriages.

2083 H. E. Townsend, Southampton-buildings, for improvements in the standing rigging of ships and other vessels.

2084 A. M. Clark, Chancery-lane, for improvements in pads for stair and other carpets. A communication.

2085 C. A. McEvoy, Southwark, for improvements in circuit closers for torpedoes, and in connecting electric cables and conductors for use with torpedoes and for other purposes.

2086 W. Easton and F. Tattersall, Leeds, for improvements in air-compressing engines.

2087 J. H. Bass, Featherstone-street, City, for improvements in pots or vessels for making coffee.

2088 W. Fern, Cullingworth, Yorkshire, for an improved apparatus for economising fuel and effecting the consumption of smoke.

2089 G. D. Davis, Woodstock-road, Poplar, and T. Hopcraft, Mincing-lane, City, for improvements in machinery for working rudders.

2090 J. Chandler, Mile-end-road, for improvements in bath and other apparatus for the control of water and preventing waste thereof.

2091 F. Cole, Albany-road, Camberwell, and R. G. Acton, Thames-street, Greenwich, for an apparatus by means of which compressed air may be used instead of steam as a motive power for working engines.

2092 M. A. Muir and J. McIlwham, Glasgow, for improved appliances in connection with rotating shuttle boxes of looms.

2093 J. R. Casbay, Newman-street, Oxford-street, for an improved compound to be applied to the surfaces of wood or metal to preserve the same from corrosion or decay.

2094 A. F. Lagrange, Paris, for improvements in typographic presses, also applicable to lithography, autography, and metallography.

2095 S. Holdsworth, Durham, for improvements in looms for the manufacture of tufted carpets and other tufted pile fabrics.

2096 W. G. Beattie, Nine Elms, for improvements in axle boxes.

2097 H. C. Hill, Stevenage, Herts, for improvements in paving roads, streets, and footways, and in the construction and paving of tramroads.

2098 W. R. Lake, Southampton-buildings, for improvements in shirts. A communication.

2099 W. R. Lake, Southampton-buildings, for improvements in ties or fastenings for securing bales of cotton and other merchandise. A communication.

2100 W. Warnes, King's Lynn, and W. Mitchell, Brandon, Suffolk, for an improved apparatus for stacking or unstacking hay, straw, and other agricultural produce.

2101 W. H. Bennett, Parliament-street, Westminster, for improvements in apparatus for lighting and extinguishing public and other gas lamps or lights. A communication.

2102 D. Glass, High-street, Whitechapel, and D. Heslin, Phœnix-place, Clerkenwell, for improvements in the construction of Hansom cabs or that class of vehicles on two wheels and where the driver sits behind the passengers.

2103 J. W. Chambers, Manchester, for an improved means of affording additional security to safes, strong rooms, and other similar depositories.

2104 W. N. Nicholson, Newark-upon-Trent, for improvements in horse rakes, part of such invention being applicable to other machines.

2105 J. Salmon and J. Brownhill, Manchester, for improvements in machinery for bronzing or otherwise ornamenting paper and other materials.

2106 E. T. Simpson and F. Hurd, Walton, Wakefield, for a portable air compressor worked by animal or manual power.

2107 G. de Lara and M. de Salomos, Fleet-street, for keeping continually before the eyes of the public with the tremble of reference by means of an interleaved diary all descriptions of trades, businesses, all places of public resort and all requirements of the public which are or can or may be advertised.

2108 G. Smith, Brentford-road, Middlesex, for improvements in apparatus and means to be used when drawing off wine, beer, and other liquids.

2109 E. L. Owen, Bristol, and G. Underwood, Cornhill, City, for improvements in the purification of gas.

2110 C. Bray, Rochford, for an improved hair restorer.

2111 W. R. Lake, Southampton-buildings, for improvements in machinery for making and composing type for printing. A communication.

OCEANIC CIRCULATION.

In Two Parts.

BY RICHARD A. PROCTOR, B.A., Hon. Sec. R. A. S.

Author of "The Sun," "Light Science," "Essays on Astronomy," &c.

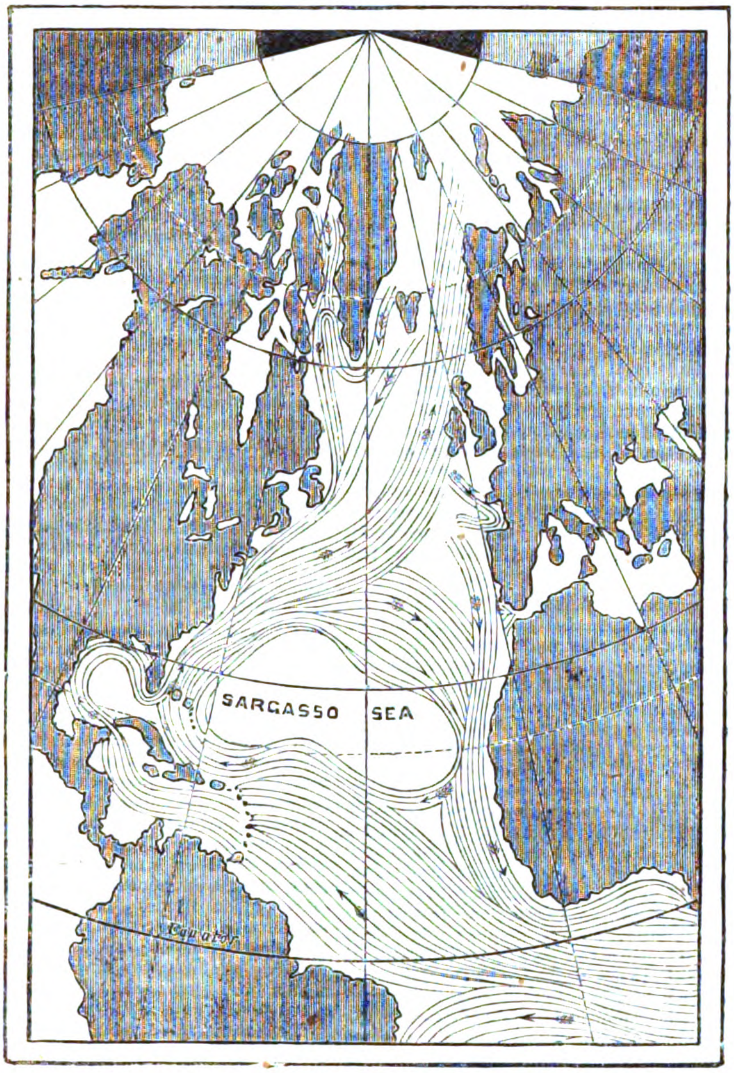
PART II.

IT is impossible to consider carefully the nature and distribution of the surface circulation without recognising the fact that there must be currents beneath the surface. It is true that one can conceive the existence of a complete system of oceanic circulation without any movement in the depths of the sea; but when we examine the actual surface-currents we find that either the commencement or the prolongation of some currents must necessarily be submarine. For instance, the quantity of water carried by the great north-easterly drift into the Arctic Ocean is very much greater than that which flows out of the Arctic Ocean, by the so-called Arctic current, past Greenland. Examining, indeed, the ordinary current charts, always drawn on Mercator's projection (seemingly because this projection is the very worst that could be devised for the purpose), we might suppose that this arctic stream was much more extensive than it really is. But what can be expected of a projection which makes Greenland (whose real area is not much greater than that of the Scandinavian peninsula) actually as large as South America. The arctic current, however, affords yet better evidence of the occurrence of submarine streams, for the extension which passes between the Gulf Stream and the United States, is in places completely lost sight of (the Gulf Stream touching the American shores), and reappears farther on. It is clear that it must have passed under the Gulf Stream in such cases.

Now, the study of the submarine currents has of late years thrown considerable light on the whole question of oceanic circulation, and has supplied the solution of some problems which had formerly appeared altogether perplexing.

We owe to Drs. Carpenter and Wyville Thomson some of the most important facts recently ascertained. Others, however, have shared in the work. I would, indeed, particularly invite attention to the fact that I do not here pretend to give anything like a complete history of recent investigations into the subject. I select only those facts which bear most significantly on the wider relations—the more marked features—of oceanic circulation.

In the first place, a result which had long perplexed physical geographers has been shown to be erroneous. It had been supposed that the temperature of sea-water below a certain depth is in all latitudes constant, and about seven degrees above the temperature at which fresh water freezes. Sir John Herschel, in his "Physical Geography," adopted this supposed discovery as well established. Now, let one consequence of such a relation be carefully noted. The surface water in the tropics is warmer than this supposed constant bottom-temperature; the surface water in arctic regions is cooler; at some intermediate latitude the surface water has the same temperature as the water at the bottom. Hence in this intermediate latitude the water is uniformly warm (according to the supposed relation) from the surface to the bottom. We may, therefore, regard the water in this latitude as constituting, in effect, a constant barrier between the tropical waters and the arctic waters. Without regarding it as absolutely immovable we should yet be compelled to regard it as so far steadfast as to negative the theory of the existence of submarine currents of an importance corresponding to that of the surface currents. Accordingly, the theory put forward by Humboldt and Pouillet to the effect tha there is an interchange of waters between polar and equatorial regions was discredited by this supposed discovery.



Drs. Carpenter and Wyville Thomson, however, have been able to show that no such relation exists. There are vast submarine regions of the Atlantic where the temperature of the water is far lower than the constant and uniform temperature believed in by Sir John Herschel. The temperature is, indeed, in places as low, or very nearly so, as the freezing point of fresh water, under a surface-temperature 20 degrees or so higher. But in other regions having the same surface-temperature the depths are 10, 12, or 14 degrees higher than that of freezing fresh water. Moreover these relations are constant, so far as the deep water is concerned.

Now, there can be only one interpretation of the circumstances here mentioned. If the depths of the ocean were unmoved by any process of submarine circulation there can be no question that a general uniformity of deep sea temperature would prevail in given latitudes. We should not find the bottom water in one region 13 or 14 degrees warmer than the water in a closely adjacent region. We have only to inquire what is the case in inland seas where no great influx of water of alien temperature can take place, to see that this must be so. Take, for instance, the Mediterranean. Here we learn from Dr. Carpenter's recent researches that "the temperature at every depth beneath 100 fathoms is found to be uniform, even down to a bottom of 1,900 fathoms; as had, indeed, been previously ascertained by Captain Spratt, although his observations, made with thermometers not protected against pressure, set this uniform temperature too high. In the western basin of the Mediterranean, as shown by the *Porcupine* observations of 1870, the uniform temperature is 54 or 55 degrees; being, in fact, the winter temperature of the entire con'ents of the basin, from the surface downwards; and being also, it would appear, the mean temperature of the crust of the earth in that region." We learn, then, two things—viz., first, that where extensive submarine motions are impossible, a constant submarine temperature may be expected to prevail in the same latitudes; and secondly, that in the latitude of the Mediterranean, the submarine temperature is about 54 or 55 degrees Fahr. Thus, it is clear, in the first place, that the varieties of temperature observed in the depths of the Atlantic must be due to the continual arrival of water of the observed temperatures, at a rate great enough to prevent the deep water from acquiring a constant temperature; and in the second place, it becomes possible to tell whence the submarine currents are flowing. If they are cooler than they should be, supposing latitude alone in question, then they are travelling from arctic towards tropical regions; and *vice versâ*. On this last point no doubt remains. In a latitude corresponding to that of the Mediterranean basin, the depths of the Atlantic are far colder, even in their warmest portions, than they would be if latitude alone were in question. "In regard to surface-temperature," says Dr. Carpenter, "there is no indication of any essential difference between the Mediterranean and the Eastern Atlantic" in the same latitudes; "and the thickness of the stratum that undergoes superheating during the summer is about the same. . . . At the depth of a hundred fathoms, in the Atlantic as in the Mediterranean, the effect of the superheating seems extinct, the thermometer standing at about 53 degrees; and beneath this" (in the Atlantic only), "there is a slow and tolerably uniform reduction at the rate of about two-thirds of a degree for every fathom, down to 700, at which depth the thermometer registers 49 degrees. But the rate of reduction then suddenly changes in the most marked manner; the thermometer showing a fall of no less than nine degrees in the next 200 fathoms, so that at 900 fathoms it stands at 40 degrees. Beneath this depth the reduction again becomes very gradual; the temperatures shown at 1,500, 2,000, and 2,435 fathoms (the last being the deepest reliable temperature-sounding yet obtained) being, respectively, 38, 37, and 36½ degrees."

Thus, there can be no possible question that the depths of the Atlantic are occupied by a vast current much colder than the deep sea temperature due to the latitude, and, therefore, necessarily flowing from the arctic towards the tropical seas.

Such are the broad facts of the Atlantic circulation. We have a surface circulation whose general features are such as have been described, and are generally admitted, though a dispute has arisen as to a question of nomenclature; and then we have a general submarine "set" of water from the arctic regions towards the tropics, the existence of which is also generally admitted.

But now we again approach a subject of controversy, and one which is certainly better worthy of discussion than that which we considered above. It relates, in fact, to the question *how* this wonderful system of oceanic circulation is brought about.

Passing over several crude theories which have long since been disposed of, we come first to the theory that the system of oceanic circulation is due to the action of the trade-winds. This theory has been maintained by Franklin and others in former times, by Sir John Herschel in our own, and is warmly advocated in the present day, by many whose opinions are not to be rashly contradicted.

Against this theory it has been urged by Captain Maury—"with singular wrongheadedness" according to the Edinburgh Reviewer, but as it seems to me with no small degree of reason—that the trade-winds are neither powerful enough nor persistent enough to account for the great equatorial currents, or therefore for the Gulf Stream. Maury says, "with the view of ascertaining the average number of days during the year that the north-east trade-winds of the Atlantic operate upon the water between the equator and 25 degrees north latitude, log-books containing no less than 380,284 observations on the force and direction of the wind in that ocean were examined. The data thus afforded were carefully compared and discussed. The results show that within these latitudes—and on the average—the wind from the north-east is in excess of the wind from the south-west only 111 days out of the 366. Now, can the north-east trades, by blowing for less than one-third of the time, cause the Gulf Stream to run all the time, and without varying its velocity either to their force or prevalence." Our reviewer not only dwells on the wrongheadedness of this argument—wholly irresistible as it appears—but asserts that "the trade-wind origin of the Gulf Stream is about as certain as the rotundity of the earth." It could have been wished that in place of abusing Captain Maury for wrongheadedness, the reviewer would have devoted a few lines to the demolition of Maury's argument.

Maury himself advanced the relative lightness of the equatorial water as the true reason of the oceanic circulation. But granting that the expansion of the equatorial water under the sun's heat, as well as the resulting buoyancy, would cause an overflow of equatorial water polewards, this overflow would be an exceedingly slow movement, and it would result in an eastwardly instead of a westwardly flow, for the very same reason that the counter trade-winds travelling polewards assume an eastwardly direction.

In the *Student* for July, 1868, I advanced another explanation. I urged that the sun's action on the equatorial and tropical regions of the Atlantic, raising immense quantities of water by evaporation, causes an influx of water from below. "There can be no question," I then wrote, "that under-currents arriving in this manner, whether from the north or from the south" (that is from arctic or from antarctic regions) "would acquire a strong westerly motion (just as the trade-winds do). Thus they would generate *from below* the great equatorial westerly current. In this upflow of cool currents having a strong westerly motion, we find the mainspring of the series of motions. The water thus pouring in towards the equator is withdrawn from beneath the temperate and arctic zones, so that room is continually being made for that north-easterly surface-stream which is the necessary consequence of the continual flow of the great western equatorial current against the barrier formed by the American current. . . Captain Maury's views seem only to require the mainspring or starting-force towards the west which has been here suggested, to supply a complete, efficient, and natural explanation of the whole series of phenomena presented by the great ocean currents."

Four or five months later, and while the results on which Dr. Carpenter subsequently based his theory of the oceanic circulation were as yet unpublished, I drew attention in the columns of the *Daily News* to the comparatively limited extent of the influences due to polar cold. This cause, I pointed out, "scarcely has any influence in latitudes lower than the parallel of 50 degrees."

In the year 1869 Dr. Carpenter was first led to advocate the theory that the continual descent of cold water in the Arctic Seas is the mainspring of the system of oceanic circulation. He reasoned that the Arctic Seas being exposed to great cold, the surface water "descends in virtue of its reduction in temperature and increase of density, its place being taken, not by the rising up of water from beneath, but by an inflow of water from the neighbouring area; and since sea-water becomes continually heavier in proportion to its reduction of temperature, this cooling action will go on without the check which is interposed in the case of fresh water."* Thus, the water becoming denser and heavier will descend, and "there will be a continual tendency to the flowing off of its deepest portion into the warmer area by which the polar basin is surrounded; producing a reduction in the level of the polar area, which must create a fresh in-draught of surface-water from the warmer area around to supply its place. This, in its turn, being subjected to the same cooling action, will descend and flow off at the bottom, producing a fresh reduction of level and a renewed in-draught at the surface."

Dr. Carpenter illustrated this theory, or rather the combined action of polar cold and equatorial heat, by an experiment, the plan of which had occurred also to myself, and been described by me in conversation somewhat earlier. "A long narrow trough having glass sides was filled with water, and a piece of ice was wedged in at one end between its side plates just beneath the top, whilst the surface of the water at the other end was warmed by a piece of metal, of which a part projected beyond the trough, and was heated by a spirit lamp placed beneath it; thus representing the relative thermal conditions of the polar and equatorial basins. A colouring liquid viscid enough to hold together in the water, while mixing with it sufficiently to move as it moves, being then introduced, the liquid as it impinged on the ice was seen to sink rapidly to the bottom, then to flow slowly along the floor of the trough towards the opposite extremity, then gradually to rise beneath the heated plate, and then to flow slowly along the surface towards the glacial end, repeating the same movement until the ice had melted."

It will be observed that in this experiment the effect of cold is not exerted alone, so that it by no means proves that the arctic cold is the chief agent in producing the system of oceanic circulation. Moreover, the conditions of the polar and equatorial basins are in one respect not accurately (or even nearly) reproduced, for the real arctic area is very much smaller, compared with the real equatorial area, than in the case of the experiment. Indeed, it appears to me that Dr. Carpenter paid far too little attention to the relative smallness of the arctic area. This may have been partly due to the erroneous ideas suggested by the ordinary maps on Mercator's Projection, in which, as I have already mentioned, the arctic regions are enormously exaggerated. It is almost impossible to study such a map as that which illustrates this paper (see part I., p. 473) without feeling that the theory presented by Dr. Carpenter will scarcely hold water, or rather—if this way of presenting the argument be permitted—that the arctic area does not hold water enough to produce the effects described by Dr. Carpenter. For in that map the whole area of the Arctic Ocean is presented;† and from out of that area, be it noted, must come the northern supply of descending water, not only for the Atlantic equatorial current, but for the much larger equatorial current of the Pacific, if Dr. Carpenter's theory be sound.

The following letter, written by Sir John Herschel only a few weeks before his lamented decease, has been very widely quoted in favour of Dr. Carpenter's theory; yet if carefully studied it will be found rather to set forth the strength of the theory advocated a year earlier by the present writer. In this letter, at least, Sir John Herschel appears to be disposed, *in so far as he concedes the efficiency of heat, cold, and evaporation*, to incline to the equatorial action as the most important. Answering Dr. Carpenter, who had addressed a letter to him on the subject, he says: "After well considering all you say, as well as the common-sense of the matter, and the experience of our hot-water circulation pipes in our green-houses, &c., there is no refusing to admit that an oceanic circulation of some sort must arise from mere heat, cold, and evaporation, as *veræ causæ*; and you have brought forward with singular emphasis* the more powerful action of the polar cold, or rather, the more *intense* action, as its maximum effect is limited to a much smaller area than that of the maximum of equatorial heat. The action of the trade and counter-trade winds, in like manner, cannot be ignored; and henceforward the question of ocean-currents will have to be considered under a two-fold point of view."

It appears to us that not only is the equatorial or rather tropical action much wider in range, but it is also more intense than the polar action. For, let us consider what happens during the heat of the day over the tropical Atlantic. Here, over an area enormously exceeding the whole Arctic basin (we are considering, be it understood, only the northern part of the system of circulation) a process of evaporation is taking place at so rapid a rate as to furnish almost the whole of that rain-supply whence the rivers of Europe and North America (east of the Rocky Mountains), take their origin. There is thus produced a continual defect of pressure, not merely along an equatorial strip, but so far as 20 or even 30 degrees of north latitude, while the downfall of rain which, taking one part with another of the temperate and sub-arctic Atlantic, may be regarded as incessant, continually adds to the pressure in these last-mentioned regions. That on the whole there must result a most effective excess of pressure over the temperate zone of the Atlantic, as compared with the tropical and equatorial portion, seems to me indisputable. Now, if we compare this with the effects of refrigeration over the relatively insignificant arctic area, which, as I have said, has to supply the North Pacific submarine circulation (if Dr. Carpenter's theory be true), as well as that of the North Atlantic, we can scarcely doubt, as it seems to me, which cause is the more effective. I would venture to predict that if Dr. Carpenter's experiment were tried first with the ice alone to produce circulation, and secondly with the heat alone, the superior efficiency of the latter cause would be at once recognised; but I much more confidently predict that if, as in the experiment I myself proposed, the relative areas of the equatorial and arctic basins were represented, there would be found to be scarcely any comparison between the effects of arctic cold and equatorial heat, so largely would the latter predominate.

It is necessary to mention, however, that the principle itself of the experiment has been objected to, on the ground that the gradation of temperature must always be much more rapid in such an experiment than in the actual case of the Atlantic Ocean. This objection, however, is, in reality, based on a misapprehension. It is sufficient that the difference of temperature at the two ends of the trough should correspond to the difference between the temperature of the Arctic and equatorial seas; and it is a matter of no importance whatever that the real rate of gradation should be represented. The case may be compared to the illustration of the descent of water to form springs or the like. Here an experiment would be valid in which the outflow of the illustrative spring was obtained by causing the vent to be so much below the level of the reservoir, though the slope from the reservoir to the vent were very much greater than in the case of any natural spring. Just as in the case of a spring it is the *difference of level*, and not the *rate of slope*, which is effective in causing the rate of outflow, so in the case of the oceanic vertical circulation, it is the actual difference of temperature, and not the rate of gradation, which produces the activity of the circulation.

Another objection has been urged against the "heat and cold theory" by a very skilful mathematician, Mr. Croll. He reasons on this wise. Since the water which is carried from the equator to the latitude of England † (say) must have partaken, when at the equator, of the earth's rotation there, which has a velocity of more than

* Fresh water expands with reduction of temperature near the freezing point, and hence, becoming lighter, the descending motion above described is interfered with in the case of fresh water.

† The bounding lines drawn from the pole on the right and left of the white space represent one and the same meridian.

* In Sir John Herschel's letters one can often recognise slight touches, we will not say of sarcasm (for he was incapable of saying aught that could be considered bitter or unpleasant), but of what may be described as a humorous suggestiveness.

† I present the general nature of Mr. Croll's reasoning, without following him in details.

1,000 miles per hour eastwards, whereas, when it reaches our latitudes, it partakes of a rotation-movement reduced to about 620 miles per hour, it follows that, neglecting the drift motions as relatively quite insignificant, friction has deprived the water which has thus travelled from the equator to our latitudes of a velocity amounting to no less than 380 miles per hour. If friction is thus effective, how utterly inconceivable is it, says Mr. Croll, that the descending currents of Dr. Carpenter's theory (or the ascending currents of the evaporation theory) should maintain their motion. Hence, Mr. Croll is an earnest advocate of the trade-wind theory.

The worst of this reasoning is that it proves too much. If friction is so effective, then when the trade-winds flag, as we have seen that they do, the ocean currents ought to be brought to a standstill. Moreover, the submarine currents exist, and the wind theory leaves them unexplained. The fact really is that Mr. Croll's reasoning has no application to a system of fluid circulation, where the advance of one part of the fluid is always made room for, so to speak, by the removal of that which it replaces. We might equally well apply Mr. Croll's reasoning to prove that a river cannot flow because of the friction along its banks, as to show that ocean currents cannot flow within their liquid banks. Indeed, many of the points in dispute in this matter of oceanic circulation may be excellently illustrated by considering the case of a river. I propose to draw this paper to a conclusion by setting forth such an illustration. My readers will not fail to recognise the opinions here severally parodied, so to speak, and so to infer the theory which I regard as affording, on the whole, the best explanation of the observed relations.

"Shallow persons," might one say, "have launched all sorts of stupidities upon the Mississippi River. Physical geographers have deluged the world with their assumptions respecting it; theorists of all kinds have floated their notions upon it. One says that it brings down, past Baton Rouge and New Orleans, the drainage of half the United States; others ascribe to it the *detritus* around the delta of that great river which flows into the Gulf of Mexico; yet others consider that it breeds the fogs infesting the path of the great stream which flows from Vicksburg to Placquemines. All this is utter nonsense. The Mississippi has no more to do with the great stream flowing through Louisiana than with the Thames at London. The real Mississippi is a stream of singular purity, and presents other characteristics clearly recognisable as far as its junction with the Missouri; but in the stream which runs past St. Louis none of the characteristics of the Mississippi can be traced. Here, to all intents and purposes, the Mississippi comes to an end. As for the cause of the motion of the great stream itself there can be little question. Some have urged that it is due to the gradual slope of the land; but in all the experimental illustrations of the effects of such slope which we have yet seen, the inclination has been monstrously exaggerated. If slope were the cause of the river's flow, then unquestionably the effective part of the action must reside in the Rocky Mountains, and not in the great reaches of the river. We admit that the chief bulk of the river lies in the great reaches; but this fact has no bearing, we assert, on the question at issue. However, it is demonstrable that no cause of this sort can be in question. For *let the following reasoning be carefully marked*. In Wisconsin, in 40 degrees north latitude, the river partakes of the earth's rotation motion, there equal in rate to about 800 miles per hour; in Louisiana, in 30 degrees north latitude, the river still partakes of the earth's rotation movement, here equal to about 900 miles per hour. Hence, were it not for the friction exerted by the banks, the water of the river in Louisiana would be flowing at the rate of 100 miles per hour westwards. If, then, friction deprives the river of this enormous velocity—as it obviously does—how much more must it deprive the river of the minute velocity of four or five miles per hour due to slope or inclination. It is certain, therefore, that the flow of the stream is due to the prevalent northerly winds of the so-called Mississippi valley. There are not wanting those, indeed, who assert that this cannot be the case, because northerly winds are *not* prevalent in this region. But the singular wrongheadedness of this reasoning renders reply unnecessary. That the flow of the great stream is caused by these winds is as certain as the rotundity of the earth."

ELECTRO-METALLURGY.—IV.

By J. T. Sprague.

7.—Sulphuric Acid.—This is the most important article used in ordinary batteries, and as it varies very much in quality and strength, it is desirable that its properties should be understood. Real O.V. oil of vitriol has a specific gravity of 1·845, and contains about 99 per cent. of the true acid HSO_4 (H_2SO_4, new notation); it is of a clear colour, and has an oily appearance: this is the acid always meant when sulphuric acid is spoken of. Brown oil of vitriol is the ordinary product of the chambers, or this boiled down in lead pans, and contains variable quantities of acid; this is a question of price only, but this acid often contains impurities of serious consequence.

Brown colour may be due to dissolved organic matter, straw, &c., and is of no moment.

Arsenic is often present, and must be strictly avoided, as it unites with the hydrogen given off, forming a deadly poison when strong, and being in any case injurious to health. It is detected by diluting the acid, and, passing a stream of sulphuretted hydrogen; arsenic forms a yellow precipitate; another plan is to put the dilute acid in a flask with scrap zinc, closing the flask with a cork in which is fitted a small glass tube bent at right angles; a Bunsen's gas-burner or spirit lamp is so placed as to make a part of this tube red hot; the gas carries off the arsenic and deposits it as a black film in the neighbourhood of this spot.

Lead is often present as sulphate and must be carefully removed, or it will deposit on the negative metal; it is only necessary to dilute the acid in a separate vessel, allow it to cool, and filter it off before use.

Nitrous acid is often present and wastes the zinc, but is otherwise of no consequence. It is detected by mixing the acid in a test tube with two or three parts water; when cool drop in a crystal of sulphate of iron, if, as it dissolves, a brown colour is produced there is nitrous acid present.

The strength of acid used in batteries may vary from one-twentieth to one-tenth by measure of acid to water.

Specific Gravity of Sulphuric Acid.

One-twentieth..	1·055	... 70·	... 1·598
One-tenth	1·100	... 80·	... 1·708
One-third	1·259	... 90·	... 1·807
50 per cent....	1·388	... 100·	... 1·846
60 „ ...	1·486		

The third line is that strength of acid which has least resistance to the passage of current, and contains one-third by *weight* of HSO_4. The following ratios are percentages by weight.

8. *Galvanometers.*—In order to obtain real definite knowledge, experiment is necessary, and to make experiment intelligently, careful measurement is essential. I therefore advise every one who makes experiments in current electricity always to have a galvanometer in circuit, and to watch its indications. Galvanometers as usually made do not convey that exact knowledge the importance of which I am pressing on my readers; they are invariably marked in degrees of the circle, and the indications of one tell nothing as to those of others. The deflection of a magnet is due wholly to the *current* passing, and for any one deflection a given and fixed chemical action occurs in each cell, &c., no matter whether one or 100 cells are generating the current, and no matter what the resistance is. It is obvious, therefore, that what we really require to know is, not the degrees deflected, but the real *current* in some definite measure, which causes this deflection. This is easy with a tangent or sine galvanometer, because we need only to obtain any constant deflection for a few hours while depositing copper or silver, and from this we can calculate the value of every other deflection on that one galvanometer. I explained this fully in No. 283, Vol. X., p. 530, and therefore need not go into it here.

Having once obtained the real value for any one instrument, it is easy to graduate others from it by including them in the same circuit; and further, if a number of instruments are made upon the same plan and with needles of the same size, all these instruments will indicate alike; at all events, sufficiently nearly so for all practical purposes. I therefore intend now to describe an instrument devised by me to suit all ordinary purposes so that readers can construct it. I have also, for the convenience of those unable to make it themselves, given the description to an instrument maker, Mr. Baker, 244, High Holborn, London, from whom it can be obtained. A few words first on general principles. If a magnetic needle be suspended *over* and parallel with a wire conveying a current entering at the north end, its north end will be turned to the *left* a certain number of degrees; if it is placed *under* the same wire, at the same distance, it will turn the same number of degrees to the *right*. If the direction of the current is reversed, so will the direction of the deflections. If now the wire is doubled back upon itself, and the needle placed between the two parts, it is evident that the direction of the current is thus reversed in the lower part, and that consequently each part acts upon the needle in the same direction, and, therefore, with doubled energy; in fact, the deflection will be doubled, not in the actual number of degrees, but in the value of the deflection itself. If we now take the effect of one complete turn of the wire as the unit, and pass another turn and then ten turns we shall increase the action on the needle double and ten fold: The distance of the wire from the needle does not affect the result, as the greater length of wire in the more distant turns compensates for the distance, exactly in circular wires and nearly so in the ordinary flat coils: thus, if we know the value of the deflections produced by different currents upon the needle in one turn and graduate the dial to this, we know that these same deflections produced by means of ten turns are caused by currents of only one-tenth in amount, but acting ten times on the needle. On this principle I have constructed what may be called a "universal galvanometer" as applicable to so many purposes, and giving its information in exact measures, not in mere degrees.

A reference to No. 287, Vol. XII., p. 1, will assist greatly in the construction. On a piece of wood or iron 2in. wide and ¼in. thick, is formed a sheath of thin copper about 5in. long, with an opening ¼in. wide cut across its upper face; this forms the chamber in which the magnet will play in the middle of the coils; a piece of hard wood ¼in. thick, 3½in. long, and 1¾in. high, with a mortice across the middle 2in. by ¼in., is fixed across the middle of the sheath, and another piece ¾in. thick on each side of it ¾in. distant, the copper ends being then turned up and cemented to the outsides; this forms two channels ¾in. wide, and deep, in which the wires are to be laid, the part of the middle piece corresponding to the opening in the face of the copper is to be removed when the instrument is completed, forming a passage through the face and body by which the magnet is placed in its chamber.

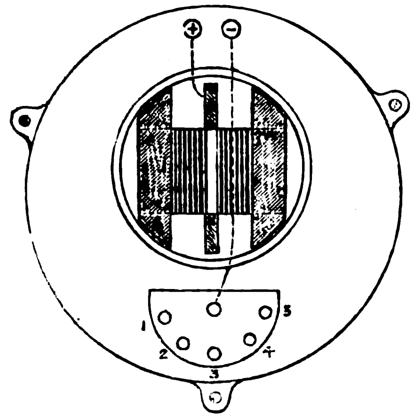
The laying on of the wire must begin in the middle, and each end must be connected so as to complete an exact turn at the middle, otherwise the indications will be inaccurate. First lay on 80 turns of No. 20 cotton covered copper wire, leaving six inches of the end for connection; the sizes given will allow exactly 10 turns to be placed in each channel, and thus four layers on each side will complete the 80 turns. Solder the end of the No. 20 (at the exact turn) to a length of No. 16, leaving [illegible]in. or 5in. of this last to come out for the connection, and lay on five turns in each channel, which is best done by two layers of 3 and 2 close up to the middle; at the tenth turn solder on a piece of the same, or stouter wire, to come out for a connection, and continue winding 8 more turns, 4 on each side, in two layers, which will fill up the space left in the outer part of the channels in the former layers. Now cut two strips ½in. wide of soft sheet copper 15in. long, and solder their ends to the 16 wire, leaving a projecting end of this for a connection; take one turn with these strips, one in each side channel, so that the current will divide itself between the two. At the exact point which completes a turn solder across the two a stout wire for a connection, and make one turn more, bringing the ends of the strips out. These last ends will be the beginning of the instrument, and when mounted are to be connected to the binding screw of the stand direct; the other wires will be connections by which the different coils can be thrown in circuit, and the effect will be thus:

Wire.	Turns.	Total turns.	Resistance.
1 ...	1 ...	1 ...	·005 Ohm.
2 ...	1 ...	2 ...	·006 „
3 ...	8 ...	10 ...	·015 „
4 ...	10 ...	20 ...	·025 „
5 ...	80 ...	100 ...	·440 „

These ends are to be led to a commutator, such as is commonly used on medical coils, a central spring traversing over five studs. I prefer to use mercury cups thus—a block of hard wood an inch thick has a central and five radial holes ⅜in.

deep by ¼in. bored in it, and when fixed on a stand, holes are bored through just large enough to pass a No. 12 copper wire, on which a head has been hammered up. These heads are well amalgamated, and a piece of wire bent twice at right angles passes from the central cup to the one desired to be used; the resistances are thus kept very small, and those of my own instrument are given above in the last column; they are so small that when used for measuring batteries, &c., they may be ignored.

The coil as described and the commutator are mounted on a stand 8in. wide, fitted with three levelling screws, and the diagram will make it plain.



The binding screws are so placed that the various currents, not forming part of the coils, balance each other, a source of error often overlooked. The ends of the two strips are to be connected direct to either + or — according to the way the coils are wound, so that the needle turns to the side to which the positive pole is connected. The other screw is joined to the centre of the commutator, and the studs, or cups, of the commutator are joined to the wires as numbered above. These connections are, of course, made below the stand. On the top of the coils is fixed a thin piece of wood, or metal, with an opening 2in. by ½in. in it, and on this is placed the dial of card to be described.

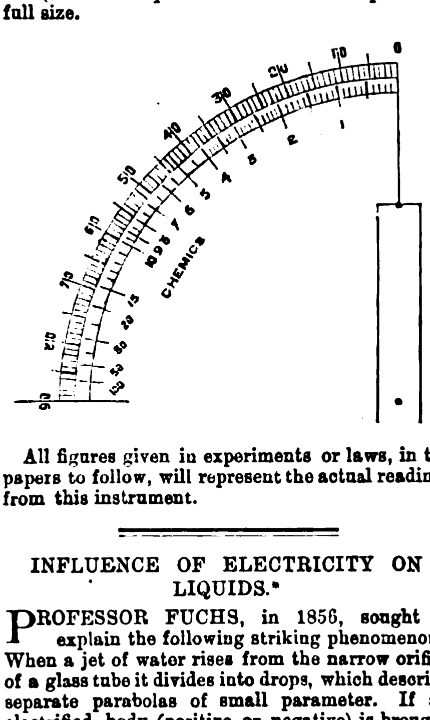
A small hole is to be bored in the middle of this opening, and into the middle wood through the bottom of the copper chamber, in which is to be inserted a steel needle, with its point rising somewhat above the dial: on this the magnetic needle turns. The needle itself is 1¾in. long; my own is made of four strips of watch spring, secured upon a piece of very fine ⅛in. tubing 1¼in. long, in the top of which is an agate centre, and on which is also secured an indicator of thin brass or aluminium, 3¼in. long, with its points exactly corresponding with those of the magnet itself, so that while the latter plays in the inner chamber the indicator marks its position on the dial. A round or square case, the top of which is glass, slips over the coil frame and protects the needle from disturbance.

9. *The Graduation.*—This is effected by placing the instrument in circuit with my tangent galvanometer, the value of which is known, with several large Daniell's cells coupled "for quantity" and a set of resistances. The dial is marked off in degrees as usual, and careful readings taken of the deflections produced when the tangent galvanometer marks the several currents required. I found that the instrument itself is roughly a tangential one, and, rather strangely, the single turn corresponds nearly in degrees of deflection with those of the four turns on the tangent instrument. The lower figures are easily marked off with No. 1 in circuit, but it is not easy to get beyond 10 Chemics. However, having done this, if we bring the tangent back to 1 Chemic and put No. 3 in circuit the instrument marks 10, while No. 5 will indicate 100. So that using this means of multiplying the readings of the tangent the whole dial is easily graduated. I thus constructed the following table, which will enable any one making an instrument on my directions to graduate it so that it will show pretty exactly the work any current is equivalent to, and if used while electrotyping, to ascertain exactly the weight of metal deposited in any time. I should think it well to mark one quadrant from this table and the opposite one, with half the values to read off for Nos. 2 and 4, and to mark the other quadrants similarly, but with Vebers, to work with the common British Association units; of course, also, it is as well to mark the ordinary degrees on an outer circle. Those who have efficient resistance instruments can readily graduate any galvanometer by the formula $C = \frac{E}{R}$, for the Daniell being 1·079 Volt, a total resistance of 1·079 marks 1 Veber, or, calling it $1{\cdot}079 \times 5{\cdot}68 = 6{\cdot}129$, and introducing that resistance in Ohm's $\frac{6{\cdot}129}{6{\cdot}129} = 1$ Chemic current, and all others are readily deduced by multiples of these figures—

Chemics.	Degrees.	Chemics.	Degrees.
1	11·3	9	58
2	22	10	60
3	31	15	69
4	38	20	73
5	43	30	79
6	47·5	50	83·5
7	52	100	86·5
8	55·5		

Thus, multiplying the figures by the equivalents of the substances, if, while coppering, the needle pointed to 79° or 30 Chemics, $31.75 \times 30 \div 10$ shows a deposit of 95 grains per hour; if it were silvering, then $108 \times 30 \div 10 = 324$ grains per hour. Galvanometers for use in practical operations could, of course, be as easily graduated to show how many ounces per hour of a metal were being deposited. As will be seen hereafter, it is quite easy to measure thus, even when several operations are going on in one vessel, and from one anode, while any irregularity which may and does frequently happen is instantly pointed out.

I give here a quadrant of the dial complete and full size.



All figures given in experiments or laws, in the papers to follow, will represent the actual readings from this instrument.

INFLUENCE OF ELECTRICITY ON LIQUIDS.*

PROFESSOR FUCHS, in 1856, sought to explain the following striking phenomenon: When a jet of water rises from the narrow orifice of a glass tube it divides into drops, which describe separate parabolas of small parameter. If an electrified body (positive or negative) is brought near, the stream contracts into a single undivided column. If the electrified body is approached still nearer, the jet again divides, and into much smaller drops, which describe wider parabolas than the former did. To explain this Professor Fuchs asked first: Why does the stream in its normal state divide into drops? and gives the quite correct answer, that it is due to the adhesion of the water to the sides of the orifice, so that the division ceased when the mouth of the tube was greased internally. He further supposed that when an electrified body is brought near, the electric tension produced in the liquid and in the mouth of the tube destroyed the adhesion, so that, as from the greased mouth, the stream rose in a coherent form. How this could happen with such slight tension was unexplained.

More recently Professor Reitlinger has taken up the subject. He found that an oil of turpentine jet, which, like water, was broken into drops, was not altered on approach of the electrified body; and that a quicksilver jet from a glass tube rose in a coherent state; while from a copper mouth it divided into drops as soon as the copper had undergone a certain amalgamation, but that then, as with oil of turpentine, the electrified body had no effect on it. He supposed that the removal of the adhesion (in the case of water) was due to the production, electrolytically, of a thin layer of gas—a somewhat bold supposition, especially where the mouthpiece is of glass, as it is not easy to see how the gas could arise in that case.

But this supposed removal of adhesion may be put aside from the question. The experiment which led Professor Fuchs to suppose that electricity produced its effect by action on the mouthpiece was, that when he surrounded the mouthpiece with another tube, he did not obtain a contraction of the jet, but when the jet was so surrounded, and the mouth-piece free, he obtained it readily. The observation is not strictly correct: it is not the mouthpiece that must be put into the electrified "shadow" (in order to prevent contraction of the stream), but the lower coherent part of the stream itself. Let the matter be brought to the test of experiment as follows:—A glass vessel filled with water is placed on an insulating stand. From its lower part proceeds a glass tube, which is bent downwards, then upwards, terminating in a fine point. A jet is in this way thrown up about 20 centimetres in height, and in a direction slightly out of the vertical. From the mouth of the tube to a height of three centimetres the stream is perfectly coherent, then it breaks up into drops, which form the parabolic "branches." For the sake of brevity we may call the coherent part the stem, the divided part the branches. (That the stem is quite coherent may be proved by means of an electroscope.) A tin plate with a circular hole in its central part (of five millimetres diameter) is placed horizontally, so that the jet passes through the hole. The falling drops pass just outside of this screen. A wire ring connected with an insulated conductor also surrounds the jet. Suppose it, once for all, negatively electrified. If, now, the screen is placed at the lower part of the stem, while the ring encircles the jet, say 12 centimetres above the orifice, the jet is contracted. Raise the screen so that the stem is quite in the electric shadow, then no contraction takes place. It recurs, however, if the ring is brought under the screen. While these things are being done let a wire connected with an electroscope be dipped into the water in the vessel, and another, connected with a second electroscope, be brought into the upper part of the jet. If the stem of the jet is shaded by the screen from the electricity of the ring the water in the vessel remains unelectrified, while the jet shows little or no negative electricity, except in the neighbourhood of the ring, where it is strongly negative; drops first attracted by the ring are then repelled, and so carry the negative electricity direct to the electroscope. If, however, the stem is not in the electric shadow, the water in the vessel becomes negative, and continues so even when the ring is discharged by being touched. The positive electricity carried away by the drops is communicated to the second electroscope, which, in this case, is charged positively. If an insulating liquid, as petroleum, be substituted for the water, the electroscopes give no indications of electricity, and the jet undergoes no alteration in form. The same insusceptibility was noticed by Professor Reitlinger in the case of oil of turpentine.

The foregoing experiment will enable us to understand what takes place when the jet is contracted. The outer part of the stem consists of particles which have received an eccentric impulse through friction at the mouth of the tube. They, therefore gradually separate from the central part of the stem to pursue their parabolic courses. When the stem is positively electrified by induction, the separated drops carry with them some of the positive electricity of the surface. The inner, unelectrified drops, are thus surrounded by electrified drops, which are thus turned back from their divergent course, and brought nearer to the axis. The jet in its further course does not become perfectly coherent; the end of the stem is only carried somewhat higher than before.

The drops describe parabolas of small parameter. If the electric influence is very strong the mutual repulsion of the drops proves superior to their attraction to the axis, and a finer and wider dispersion takes place. It appears, then, that the influence causing contraction of the jet acts at the end of the stem, not at the mouth of the tube, and the theory of adhesion being changed by electric influence may, therefore, be laid aside.

A. B. M.

* Abstract of a recent paper in *Poggendorff's Annalen*, by W. Beetz.

THE WATCH, AND HOW TO REPAIR IT.

By "'Seconds' Practical Watchmaker."

(*Continued from page* 448.)

The Verge Watch.

THERE are several kinds of watches, but there are but five at the present day in general use. We will, therefore, at once become acquainted with our old friend the verge, occasionally recall early recollections, and ultimately apply ourselves to general repairs. The first kind of watch which has to be noticed is the old-fashioned one, which may be recognised chiefly by its loud and short tick, in addition to its being thick and usually of large size. There is another kind of watch which has a tick very similar to it, yet that tick is smoother and more silent. For the amateur to be certain of the description the watch must be opened, and if a broad-rimmed wheel, with teeth perpendicular to its rim, can be seen just inside the two plates which form the framework by which the wheels and parts are kept in their places, and when looking farther inside among the works another wheel is there resembling the radial coronet-like wheel, as represented in Fig. 1, F, that is a verge watch, to describe which with any degree of clearness we must make reference again to illustration. Fig. 2 represents the old-fashioned verge watch when stopping for the want of being wound up, having the top—or upper plate, as it is technically termed—removed (see Fig. 1), so as to show all the wheels which constitute that part of the watch termed the "train." The circular plate (Fig. 2), in the holes of which all the wheels stand, is termed the pillar-plate, because in it are riveted four pillars, which support the upper plate, Fig. 1.

The parts pointed at by reference of letters, as follows, are thus known by watchmakers:—A, the barrel or box which contains the mainspring; B, fusee, on which the chain is coiled by the act of winding up the watch; C, centre-wheel; D, third-wheel; E, contrate-wheel; F, balance-wheel; G, stop-stud; H, stop; I, potence; K, follower; L, stop-spring and screw. Each part here distinguished by capital letter has to be separately described, therefore we pass at once to the engraving Fig. 2, the pillar-plate, and proceed to explain the office of the barrel, it being the prime mover. A is a cylindrical brass box, which is shown with the lid (or cover) removed, and the mainspring within it at its least tension. In the centre of this barrel will be seen a solid central axis, which is made of steel, termed the barrel-arbor; upon that the barrel revolves, being made a fixture on the other side of the pillar-plate. The mainspring is made secure at the inner end upon a small projecting hook fixed in the side of this arbor, and the outer end of the spring is fixed by another hook which is in the inside of the barrel, therefore when the barrel turns it carries with it the inclosed mainspring, which of necessity must be turned round the arbor. Now, as the mainspring is a thin and very elastic ribbon of steel, after having been compelled to follow the circular motion of the barrel it becomes coiled up into a smaller compass, and by its elasticity it has a tendency to uncoil, if left in its quiescent state; and if coiled to the utmost—which would be the case should the barrel be turned about four or five revolutions—and then suddenly let go, the barrel would have regained its original position with respect to the arbor in a few seconds, and therefore no elastic force or power would remain in action until the mainspring was again coiled round the central axis or arbor. Thus the power or force by which the whole series of wheels and parts of the watch are kept in motion lies in the barrel and mainspring; therefore, to connect the spring with the train of wheels, a steel chain is made use of, and attached to the barrel by a small hook which is inserted in a hole made on the outside, at the top of the barrel. Fig. 3 shows the peculiar construction of the chain, which is a special kind used only for watchwork, composed of small links, each part, or linking, consisting of three pieces of equal size (No. 2), having been struck from the same die. One piece being placed between two others, a rivet passes through the three pieces, so that every link has two pins or rivets in it, and when it is completed has the appearance of No. 3. By this construction the chain is rendered flexible in one plane only, and not in all directions, as is the case with chains generally. At the other end of the chain another hook is fixed, which enters a notch at the lower part of the cone, termed the "fusee," B; across this notch is a small pin on which the hook No. 4 catches. No. 1 represents the hook for the barrel. These links and hooks are very thin and small, there being in some watch-chains of old make as many as 300 pieces.

Attached to the lower part of the fusee is a wheel termed the great wheel, being that one which imparts motion to the train of wheels, and we must not omit one very important circumstance connected with the barrel and fusee prior to the description of the train itself.

The form of the fusee is seen in Fig. 2, B; its surface is cut into a spiral flat groove, wide enough to admit the chain, and deep enough to prevent it from slipping out of it. A key being applied to the squared steel arbor, the fusee by this means is turned round and round till the chain is wound on it, and thus fills the groove from bottom to top; this motion turns the barrel with it, and therefore coils up the mainspring so as to cause it to exert its greatest force. The mainspring by its elasticity produces most force when first wound up, and this force gradually diminishes as the spring uncoils; when, therefore, the watch is nearly down, and all the chain nearly off the fusee and wrapped round the barrel, the train will be turned slower and slower until quite down, because the mainspring gradually loses its power. The fusee is a means adopted to remedy this progressive diminution in the strength or power of the mainspring.

FIG. 1

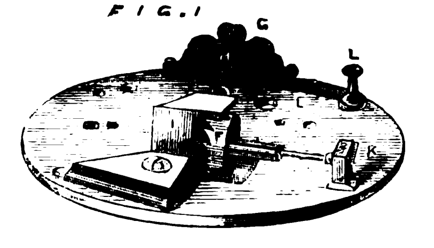


FIG. 2

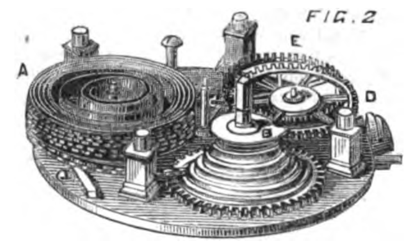

FIG. 3

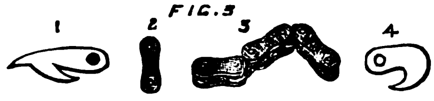


As this power gradually diminishes by the watch going down, the spiral groove of the fusee is so shaped as to cause the mainspring, when it is at its greatest force, to pull the fusee round from a point nearest to its axis. The imaginary straight line from this point, where the chain leaves the groove to the axis of the fusee is a lever, which the spiral groove causes to lengthen gradually as the spring diminishes in force; and from the well-known principle of that mechanical power, as this lever lengthens, a gradually lessening force applied at one end will produce a constant effect, or overcome a constant resistance at the other end of the lever, so that the fusee will be always turned with the same constant motion, though turned by a gradually diminishing force of the mainspring. But although general theory directs the form of the fusee it is found in practice that each watch must have its fusee adjusted to its mainspring. No two mainsprings of different watches can be relied upon to suit the fusee of another watch. To make adjustment of the mainspring and fusee correct, the outline of the fusee must not be strictly conical, for if it were the lever above alluded to would lengthen equally after equal portions of motion in the fusee; therefore, to counteract the inequality in the diminishing force of the mainspring, the leverage of the fusee must increase exactly as the force of the mainspring decreases. In connection with the foregoing we quote the following from Hutton's "Mathematical Dictionary:"—"To correct the inequality of the spring it was very happily contrived to have the spring applied to the arms of levers, which are continually longer as the force of the spring is weaker; this foreign assistance, always increasing as it is most needed, maintains the action and effect of the spring in an equality."

The first procedure, therefore, in the examination of a watch before finally putting it together, will be to see if this adjustment of the mainspring is correct, because, if not, no watch can keep good time, for this reason: If the force of mainspring be greater at the first part, after having been fully wound up, than it is at its intermediate periods, the wheels will be accelerated in their motions, and hence the watch will gain time when first wound, and lose time when going down; and just the contrary will be the case if these conditions of the mainspring and fusee be reversed, for although the fusee and mainspring may be in exact correspondence to each other, either gaining or losing time at the commencement of action can be effected by a workman who understands the mode of adjusting the mainspring. In the next paper we intend devoting a small space to this important and interesting subject.

(*To be continued.*)

ARTIFICIAL SO-CALLED ORGANIC CONCRETIONS.

EARLY in the present year I gave in my "Microscopical Notes" an abstract of an interesting paper on "Molecular Coalescence," published in the *Quarterly Journal of Microscopical Science* for January, 1872. The current (July) number of the *Quarterly Journal* contains a lengthy article on the same subject by W. M. Orb, M.B., in which several new points are brought out, and much fuller details given of the processes followed.

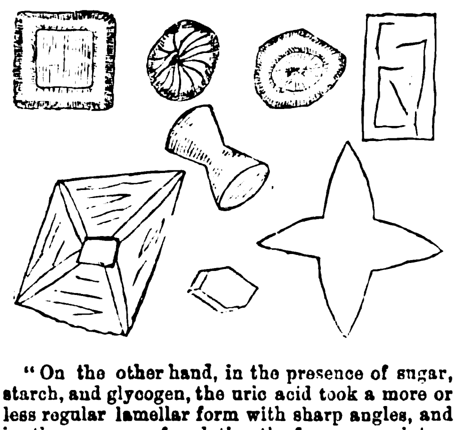
Mr. Orb, I think very justly, calls attention to the fact, well known to British microscopists, that Mr. Rainey published some notes on the subject as far back as 1858, and in the same year published a book "On the Mode of Formation of Shells of Animals, of Bone, and of several other structures by a process of Molecular Coalescence demonstrable by certain artifically formed products." Mr. Rainey makes calcium carbonate the starting point in his investigations. The following is Mr. Rainey's description of the method of obtaining the globular form (*Calcospherites*. See English Mechanic, January, 1872) of carbonate of lime.* "It consists in introducing into a two-ounce phial, about three inches in height, with a mouth about one inch and a quarter in width, half an ounce by measure of a solution of gum arabic saturated with carbonate of potash. The specific gravity of the compound solution should be 1·4068, when 1oz. will weigh 672grs. This solution must be perfectly clear; all the carbonate of lime which had been formed by the decomposition of the malate of lime contained in the gum, and also all the triple phosphate set free by the alkali, must have been allowed completely to subside. Next, two clean slides of the ordinary dimensions (3" × 1") are to be introduced with the upper end of one slide resting against that of the other, and with their lower ends separated as far as the width of the phial will permit; and, lastly, the bottle is to be filled up with a solution of gum arabic in common water, of specific gravity 1·0844, 1oz. of which will weigh 520grs. This solution also must be perfectly clear, having been strained through cloth and then left to stand some days to allow of the subsidence of all the floating vegetable matter. It must be carefully added to the alkaline solution that the two may be mixed as little as possible in this part of the process. The bottle must now be kept perfectly still, covered with a piece of paper to prevent the admission of dust, for three weeks or a month. The soluble salts of lime to be decomposed by the carbonate of potash are contained in the gum in combination with malic acid, and also in the common water. Ammoniaco-magnesian, or triple phosphate, is also contained in the gum and is set free by the alkali. Muriate of lime, dissolved in a solution of gum from which all the lime had been previously separated, would answer a similar purpose, provided the muriate were not in too great excess for the gum, in which case crystals of carbonate would be formed together with the globules, and the surface of the slide would be covered with coalescing patches of the latter. Also muriate of barytes, and muriate of strontia, when treated in the same manner as muriate of lime, furnish each a globular carbonate, the spherical

* It is, of course, understood that the following, and, indeed, pretty much of what I write here, is a more or less free abstract of Mr. Orb's article.

form of the latter being particularly perfect and beautiful. But muriate of magnesia, when decomposed in the same manner and under precisely the same conditions, does not furnish globules, but crystals of carbonate of magnesia evincing no tendency to become globular."

Mr. Rainey, working out step by step each new condition and appearance induced by variation in the composition of the fluid decomposed, and by the modifying influences of the introduction of additional matter as certain phosphates, proceeded to point out "that simple physical laws are capable of leading to the construction of many structural forms found in living bodies." He demonstrated this in the globular calculi, observed by him in the urine of the horse as early as 1849; in the shells of Crustacea and Mollusca; in bone, tooth, in the half-bony tendons of birds; and he is not stopped after exhausting those formations in which earthy matter takes a part, but he boldly applies his principles to the structure of the scleroηs tissue of vegetables, of starch globules, pigment cells, glomeruli, and of the lens of the eye.

Mr. Orb remarks that in 1870 he, himself, showed that the "great variety of forms assumed by uric acid in urine might, at least in part, be explained by the nature of the associated constituents in each case. It was found by experiment, for instance, that where uric acid was deposited in the presence of albumen it took the form of either small crystals with rounded angles, of dumb-bells, of sub-spherical bodies, or even of spheres.* (See Fig.)



"On the other hand, in the presence of sugar, starch, and glycogen, the uric acid took a more or less regular lamellar form with sharp angles, and in the presence of gelatine the forms were intermediate between the two. [See Fig.] In albuminous urine the acid was found always taking the form of short, stout, barrel-like crystals, with rounded sides and angles, or making approach to dumb-bell shape."

In face of these observations it occurred to Mr. Orb to apply a modification of Mr. Rainey's plan of experiment to the determination of some of the conditions under which dumb-bells might be formed, to fix with more certainty the relations between the octahedron and the dumb-bell of oxalate of lime; to try, in fact, to turn the one into the other.

"Some perfectly clear jelly prepared from isinglass was melted in a flat-bottomed jar in quantity enough to form a layer $\frac{3}{4}$in. deep. In this, whilst still liquid, a number of glass tubes, each about 4in. long, $\frac{1}{4}$in. in diameter, and open at both ends, were placed upright, so that each tube was immersed to the depth of nearly $\frac{3}{4}$in. After cooling the tubes were removed, and each was found plugged with firm clear jelly, so as to be thoroughly watertight. Six of these tubes were filled with a slightly alkaline solution of potassium oxalate, and placed in a weak solution (6grs. to 1oz.) of chloride of calcium, the level of the solution in the tubes being much higher than the level of the calcium fluid. The plug of jelly was thus interposed between the two solutions in the hope that diffusion slowly occurring the results of the mutual decomposition of the oxalate and calcium salt might be found after a time in the jelly. The experiment was performed in a room of the average temperature of 57 Fahr." The intention being to imitate as far as possible the conditions under which certain concretions are formed in the renal tubes. At the expiration of three months transverse sections of the plug were made at thirteen different points, the sections transferred to glass slides, the jelly melted with the slightest possible heat, and examined with a $\frac{1}{4}$in. objective. For the full results of the examination I have not space. It was found that the forms existing on the side of the oxalate were very different from those on the side of the calcium salt, and a remarkable series of gradations led easily from the one series to the other. Dr. Orb gives an excessively interesting series of drawings, too numerous to reproduce here, which will be found worthy of the most careful examination, and in themselves amply remunerate the student of biology for the cost of the number. The most interesting forms, perhaps, were produced under a variation of the experiment just described. "Acetic acid was added in considerable excess to the solution of oxalate of potash, and all the carbonic acid expelled. The solution was now used as before, and the plug was found, at the end of five days, white and opaque, with deposit in its lower portion adjoining the calcium solution. Above this it was almost clear, the acetic acid having, apparently in virtue of its greater diffusibility, driven back as it were—outstripped (?)—the calcium salt. At the calcic end were wheat sheaves, and the crystalline kind of dumb-bell, mixed with long, narrow-pointed, and very regular tablets; the octohedra were very few and small." Further experiments were performed, using in the tubes solution of oxalic acid (*a*), the calcium salt being as before, and (*b*) the calcium salt largely in excess of the oxalic acid. Solutions of oxalate of ammonium carefully purified, and of calcium chloride of known strength were also used. The formula of ammonium oxalate is given in Miller's "Elements of Chemistry" as—

$$(H_4N)_2C_2O_4, H_2O = 142.$$

Of calcium chloride, in the fusible form, as follows:—

$$CaCl_2, 6H_2O = 219.$$

From which it can be calculated that 100 parts of calcium chloride will be decomposed by 65 parts of ammonium oxalate. The solutions were, therefore, made to contain respectively 100grs. of calcium chloride and 65grs. of the ammonium oxalate in 4ozs. of distilled water.

Experiments were carried on—

1. With equivalents of the salts.
2. With 4 equivalents of oxalate to 1 equivalent of the chloride.
3. With 1 equivalent of oxalate to 4 equivalents of the chloride.

The results obtained were exceedingly interesting. In No. 3 the "wheat sheaves" were replaced by smaller, rounded, homogeneous dumb-bells of great beauty, and there were several other beautiful forms, as well as others more interesting than beautiful.

Further sets of experiments, involving the modifying influences of electricity, magnetism, and heat, were entered upon. Common horseshoe magnets of moderate power were at first made use of. "In some experiments, the plugged tubes being arranged as in the first experiment, the magnets were so placed that the lines of greatest deposit would run between their poles, in other cases, so that the length of the plug would be parallel to the line joining the poles. In other experiments little jars were partly filled with gelatine imbued with chloride of calcium, the poles being thrust into the gelatine whilst warm, and the jars on cooling filled up with solution of oxalate of ammonia. The general result was that there was an extraordinary increase in the size of all the forms where the plug or gelatine was subjected to the action of magnetism, but that there was no production of new germs or greater tendency to sphericity."

The influence of temperature was beautifully evident in tubes placed in the kitchen (temp. 55° to 65° Fahr.), the coalescence forms were three to four times as numerous as the crystalline. In the garden (27° to 45° Fahr.) this condition was more than reversed.

For notice of the experiments of the greatest biological interest there is now little space left.

In these experiments tubes stopped with albumen were used. The mode of stopping was very simple. "Beakers were filled to the depth of $\frac{3}{4}$in. with fresh white of an egg, the tubes were introduced and heat gradually applied by means of a water bath till the albumen was thoroughly coagulated. When this was carefully carried out with a temperature not exceeding 200° Fahr., the plugs were firm, homogeneous, and water tight, no leakage occurring after the tubes had been filled with water, and left for twenty-four hours. Oxalate of calcium deposited in these tubes at 50° to 60° Fahr., took almost entirely the coalescence form.

"When a plug was carefully examined, it was found firm and blueish in colour at the oxalic end, soft and yellow at the calcic. In the third next, the oxalate, no forms whatever of crystalline or coalescence order existed, but the albumen was remarkably fibrillated.* Below this appeared, in small numbers, large, perfect homogeneous spheres, isolated, refracting light energetically, and polarising with one perfect cross."†

Out of these arose a wider field of inquiry, which I can only very briefly summarise.

Phosphate of lime was taken:

64·4 Phosphate, 7·03 carb. calcium, as in bones of hawk.

59·6 phosphate, 7·3 carb. calcium, as in bones of man.

52·6 phosphate, 12·53 carb. calcium, as in tortoise.

57·3 phosphate, 4·9 carb. calcium, as in cod.

The first two were placed in hot-beds of different degrees of temperature, the hawk quantities being in the warmer; the others were left in a cool room, so that the temperature of about 85°, 75°, 60° Fahr. were severally obtained. It followed that in warmth or in cold, phosphate of lime was evenly distributed through the albumen in definite strata not forming crystals or spheres, but cementing the albumen to great hardness, particularly at the line of greatest density. Carbonate of lime, on the other hand, never failed to form spheres at the highest temperature used.

In the bone salt experiments a nearly uniform result was obtained. The carbonate of lime was subdued, as it were, by the phosphate, and an even sub-crystalline but continuous deposit was produced. The use of the phosphate as a cement and manipulator of the less tractable carbonate was well indicated. The relations between the mean temperature of the organism and the relative proportions of phosphate and carbonate were investigated, and, with the question of the influence of certain mineral medicines upon particular tissue, are deserving the farther investigation they will doubtless receive. H. P. H.

* The two latter I obtained in small quantities during some experiments on albuminous urine some months since. Macled tabular crystals I have not unfrequently obtained in presence of semi-decomposed epithelial matter.—H. P. H.

* Mr. Orb foot-notes a query—"Did this indicate combination?"

† Similar but small spheres occur in certain albuminous urine with calcium oxalate—temp. 60° to 80°.

HISTORICAL NOTES ON POISONING.

(Concluded from page 459.)

THE symptoms and signs which were accepted at that date [Roman empire] as evidence of poisoning are interesting in a medico legal point of view. They were, as may be supposed, sufficiently crude to inspire us with considerable doubt as to the reliability of many of the narrated cases of poisoning. That there were certain post-mortem appearances which were generally considered as evidences of death by poison, appears from the writings of Cicero, Tacitus, and others. Cicero speaks of "ea quæ solent esse indicia et vestigia veneni;" and in the account given by Suetonius of the death of Germanicus, who was poisoned by Piso, at the instigation of Tiberius, we find them enumerated as livid spots on the face and body, foam at the mouth, and the fact that the heart remained unconsumed when the rest of the body was burnt. It was also believed that worms did not become generated in the bodies of persons who died of poison. There were no judicial post-mortem examinations; and, in such inspections as were made, medical men were not specially employed. The body was simply exposed to the people, who were supposed to be able to form a sufficiently accurate judgment for themselves as to the cause of death. It is related by Dion Cassius that Nero, fearing lest his murder of Britannicus might be discovered, concealed the lividity of the face by a coating of chalk; but that a shower of rain washed away the chalk and displayed to the people the evidences of his fratricidal crime. It was not till the time of the Emperor Justinian, about the middle of the sixth century, that the aid of medical men was specially required in the judicial investigation of the questions which now fall to the province of the medical jurist. Even then, little room was left for the expression of an independent opinion, as the cases were for the most part decided on the authority of the learned Hippocrates.

The provisions of the Justinian code were incorporated in the capitularies of Charlemagne, and the foundations of State Medicine were laid. They were not yet, however, destined to be built upon. At the breaking up of the empire, there was a lapse into darkness worse than the first, and for many long years all progress was in a backward direction.

What little had been gained in medicine was carried off to Arabia or shut up in the monasteries. Much more might have been done by the monks, but the study of medicine was proscribed to them by several of the œcumenical councils of the twelfth century, as causing too great distraction from their religious duties. Superstition, bred of ignorance, was rampant, and led to results often far more disastrous than the worst of crimes. The art of poisoning had not been lost, however, as we have sufficient evidence to prove, though credulity and superstition often saw it where it did not really exist. The history of the Italian republics in the middle ages is replete with instances of poisoning and assassination.

Every one is acquainted with the history of the Borgias, and the long catalogue of crimes, in which poisoning figured conspicuously, which have been laid at the door of Pope Alexander VI. and his son Cæsar Borgia. Perhaps many of these have been considerably embellished by tradition, and many of the diabolical artifices to which they are said to have resorted may have only an apocryphal existence. Cæsar Borgia is said to have worn a ring containing a concealed point tipped with deadly poison; and a particularly cordial shake of the hand, under the guise of the warmest friendship, was, to the person so highly favoured, the grasp of death. That there is nothing inherently impossible in such an artifice what we know at the present day regarding poisons would give us many reasons to believe, however much we may doubt the credibility of the narratives. In later times, Philip II. of Spain was universally feared on account of the numerous villanies which he perpetrated by means of a poison which he called his "requiescat in pace." Pope Sixtus V., who ultimately fell a victim to this, used to say to the Spanish ambassador that Philip's "requiescat in pace" was the only thing he feared. The right of sanctuary (*jus asyli*), which was strenuously maintained by the Church, did much to shelter criminals both clerical and lay, and to render null and void the statutes enacted to check the frightful frequency of poisoning. Henry II. of England was one of the first to break through this privilege, and to bring to justice criminals of whatever class and from whatever place they had fled to for refuge. Burning alive and other cruel modes of death were the penalty of those convicted of this crime. While, therefore, real cases of poisoning were common and frequent, falsely imputed ones were not less so, and were productive of even greater evils.

The open neglect of all hygienic measures, the deluded reliance on absurd charms as prophylactic against all kinds of disease, and the mistaken ideas of mortifying the flesh, had much to do with the origination and propagation of those deadly epidemics which decimated the nations of the Middle Ages. The people, ignorant alike and superstitious, in most cases attributed these to wilful poisoning of the wells; and the occurrence of an epidemic was the signal for a murderous attack on the unfortunate Jews, who were generally accused of this crime. Many thousands of them were thus massacred. Even as late as 1831, when cholera broke out at St. Petersburg, a similar idea of poisoning the wells was entertained by the people.

A profound faith in universal antidotes against poison was characteristic of this age of the marvellous. This idea, however, did not originate with them, for it forms no inconsiderable part of the works of Nicander, Dioscorides, Galen, and others, and it continued to be spoken and treated of in many learned works up to a comparatively recent period in the history of medicine. One of the most celebrated of the ancient antidotes was that invented by Mithridates, and which was named after him. These *Mithridatiœ* and *Theriaca*, as they were termed, were variously modified at different periods. They consisted for the most part of an immense number of vegetable extracts and resins; and many works were written, specially devoted to the exact description and modes of compounding the various ingredients of these highly-prized alexipharmics. So late as the middle of the last century, Heberden wrote a special treatise showing their uselessness, and advocating their banishment from the pharmacopœias. More prized in the Middle Ages were the Bezoar Stones, first introduced by the Arabian physicians. So much were they valued, that they sold for ten times their weight in gold. These wonderful stones, of which there were two varieties—the oriental and the occidental—were nothing but the biliary calculi of different species of antelopes, goats, and camels. Amulets and charms of precious stones and coral, which blushed or turned pale when poison approached them; rings that became too hot to be worn; cups that cracked when poison was poured into them; and such-like, were equally relied on. Many other agents were employed, based on the idea of curing like by like, or on the equally scientific doctrine of Signatures, which saw, in whatever resembled the noxious substance in form or appearance, the proper antidote against it.

The promulgation of the "Constitutio Criminalis Carolina," in 1533, by the Emperor Charles V., was the dawn of a new era, and marks the commencement of the science of forensic medicine. The relations of medicine to jurisprudence were distinctly established, and medico-legal investigation by competent men was rendered imperative in the decision of numerous criminal and civil cases affecting the life and property of individuals. Numerous statutes were passed by various states, regulating and restricting the possession and sale of poisons, and stringent enactments were made against the poisonous adulteration of food and drink.

The use of poisons as medicinal remedies was also strongly condemned by many writers and teachers. Antimony was especially prohibited by the Universities of Paris and Heidelberg, and candidates for the degree of Doctor of Medicine were, about the middle of the sixteenth century, required to swear that they would never employ this substance in the treatment of disease. These regulations remained in force for many years. They were ostensibly for the purpose of preventing poisoning, but they were chiefly directed against the followers of Paracelsus, who used the mineral poisons largely as remedies. The attention of medical men now became directed to the scientific investigation of the nature and action of poisons, and of the means of detecting and checking their employment. Numerous memoirs on poisons and on subjects of legal medicine were written by distinguished men; and works specially treating of forensic medicine were written by Fortunatus Fidelis (1598), Paul Zacchias (about 1630), and others whom we regard as the fathers of the science. The foundation of a new physiology, chemistry, and allied sciences, led to a gradual emancipation from many absurd ideas regarding poisons.

Numerous exact experiments were made on the lower animals, and also on condemned criminals. A sense of humanity gradually put a stop to this latter mode of experimentation; but we, who have derived much valuable knowledge, though often obscured by absurd theories, from these experimenters, must not be too ready to find fault with them. In connection with this mode of experimentation, a name occurs which we commonly associate with a different employment; namely, that of Sir Christopher Wren.

Notwithstanding the general tendency to shake off mere tradition and subject everything to the canons of inductive research, yet many strange things retained their place in the works on forensic medicine in the seventeenth and eighteenth centuries. It was a very common belief, and accepted on the most slender evidence, that there were poisons in use so subtle that they might be conveyed in a letter which would prove fatal to the reader, or inhaled in the fragrance of a bouquet. We might to some extent credit these accounts, if we had grounds for supposing that the poisoners of old were skilful enough to isolate the zymotic poisons —the only poisons we know which can be carried in such a way. Prince Eugene is said to have received a poisoned letter, which, however, he suspected an immediately threw from him. To ascertain whether his suspicions were well founded, the letter was given to a dog, which was moreover fortified by an antidote. Notwithstanding this, the dog died. Marx, who relates the story, naïvely asks "Was not the dog poisoned by the antidote?" We might believe in poisoned gloves, but hardly in poisoned boots, poisoned saddles, and the like.

Pope Clement VIII. was said to have been killed by the fumes of a poisoned candle which was placed in his bedroom. Those who attributed his death to this cause, forgot, or did not know, that at the same time a brazier of burning charcoal was likewise placed in his holiness's apartment.

A belief in the existence of slow and secret poisons which could be prepared with such skill, and the dose calculated to such a degree of precision, as to cause death at any given period, according to the will of the poisoner, was more prevalent, and has not altogether passed away at the present day. It has descended from very ancient times. Theophrastus speaks of such a poison prepared from aconite which would produce its effects after two, three, or six months, or even after one or two years. The Carthaginians were said to have administered such a poison to Regulus, so that, whether he returned from his mission to Rome or not, he might not altogether escape. And it is related by Plutarch, that one of the Philips of Macedon caused such a poison to be administered to Aratus, King of Sicyon. This is said to have produced a gradual wasting of the whole body, accompanied by hæmoptysis. On one occasion, when he spat blood, Aratus, who believed he had been poisoned, exclaimed "This is a mark of the King's friendship!"

In more modern times the idea was founded on apparently better grounds, viz., on the effects attributed to the celebrated *aqua Tophana*. This poison derived its name from Tophana, a woman who resided at Naples in the latter part of the seventeenth century. It was sold in phials, which, in order to escape the scrutiny of the Government officials, were labelled "Manna of S. Nicholas," purporting to be an oily liquid of reputed supernatural virtues which was said to flow from underneath the tomb of S. Nicholas of Bari. The name "Manna of S. Nicholas" is familiar to all readers of "Kenilworth," though its mention there is somewhat of an anachronism. From four to six drops of this aqua or acquetta were said to be a fatal dose, and it was asserted that the dose could be so proportioned as to operate fatally at any fixed period after its administration. Tophana, who was convicted in 1707, and subsequently strangled by the orders of Charles VI., confessed to having been the means of destroying 600 lives. The wonderful effects ascribed to this poison led to many attempts to discover its composition. It was said to be a clear liquid, tasteless, odourless, and easily miscible in all kinds of food and drink. Halle, a writer on poisons, who was gifted with a marvellous amount of credulity, thought that it was a preparation from the foam of men tortured to death; and remarks, that if Italy could have been the parent of such wickedness, "then truly a seed of the forbidden fruit must have fallen in this garden of the devil!" The most probable of the many suppositions advanced regarding the composition of the *aqua Tophana* is that it was an arsenical solution. In support of this, Hoffman quotes a letter from Gasparelli, physician to the Emperor Charles, in which he asserts that he was informed by the Emperor himself (to whom Tophana confessed the secret of her preparation) that it was a solution of arsenic in an infusion of *cymbalaria* or toad-flax. The Abbé Gagliani and Ozanam assert that at least some of the preparations called *aqua Tophana* contained opium and cantharides. This, however, is not likely, if the *aqua Tophana* were really tasteless and odourless, as it was generally said to be. The accounts we have received of the effects which followed the administration of this poison would agree, in so far as they are trustworthy, with the symptoms of arsenical poisoning. The most likely explanation of the slow and subtle action ascribed to it, is that it was due to chronic poisoning caused by frequent administration. A similar explanation must be given of the almost equally celebrated *aqua mirabilis* of the Marchioness of Brinvilliers and the *poudres de succession* of La Voisin and Le Vigoureux.

The *aqua mirabilis* of the Marchioness of Brinvilliers was probably of a similar composition to the *aqua Tophana*. The career of this woman was one of the most remarkable in the history of poisoning. She carried on an intrigue with a young officer called S. Croix, which created such scandal that the father of the Marchioness caused S. Croix to be incarcerated in the Bastille. There he fell in with an Italian called Exili, from whom he learnt the art of secret poisoning. S. Croix, when liberated, instructed the Marchioness in the art which she afterwards practised with so little scruple. She is said to have assumed the character of a sister of mercy in order to try her nefarious mixtures on the unfortunate patients in the Hôtel Dieu. She subsequently made away with her father and brother. After a long career of crime, she was beheaded and burnt at Paris in 1676. The symptoms recorded in the case of her father and brother would confirm the opinion that arsenic was the chief constituent of her poisonous compounds. Closely connected with the Marchioness of Brinvilliers were two infamous women, named La Voisin and Le Vigoureux, the former of whom was a midwife in Paris. These women attained a great reputation as fortune-tellers, and were consulted by many eminent personages of both sexes regarding the probable time of death of their husbands or wives, or other obnoxious individuals. Their predictions were often marvellously verified, and no wonder, seeing that they had the fates in their own hand, and drove a wholesale trade in poisons. They were ultimately condemned and burnt alive by order of the Chambre de Poison or Chambre ardente instituted by Louis XIV. The poisons they made use of were called *poudres de succession*. To these, also, a slow and secret action was ascribed. Lead was said to form their principal constituent. From what we know, however, regarding acute and chronic lead-poisoning, we should be inclined to attribute the fatal effects to some more active agent, or possibly to the means employed to cure them. Most of the accounts of slow and secret poisoning are therefore manifestly fabulous, or are susceptible of such an explanation as given above. With the exception of the zymotic poisons and the hydrophobia-virus, which may long lie dormant in the system before producing their effects, but which we have no reason to believe were ever isolated or employed by the most skilled poisoners of old, we have nothing to warrant the assumption that such slow poisons ever existed except in the minds of the credulous. The existence, however, and frequent use of such poisons even at the present day, is maintained by a recent writer in a medical journal. He states that the Thugs of India possess and employ a slow poison called *tophayne*. And that poisons may be conveyed in letters which will prove fatal to the reader is considered probable, from the recent sudden death of two individuals after reading anonymous letters—one of these cases occurring in Canada, and the other, that of General Cugia, at the last Carnival in Rome.

Unless better evidence be brought forward than examples like these, we must regard conclusions from such data as manifestly worthless. Thanks to the knowledge which we now possess of the natural history of disease, and to the perfection of the means of detecting poisoning, together with the restrictions that are put on the sale of poisons, the crime is becoming more and more rare, and cannot, even in the most skilful hands, long remain undetected. Fortunately, those who have it most in their power are those who have been least guilty of it, with some few noted and universally execrated exceptions. Medical men have been in general true to their Hippocratic oath, and are ready to echo the sentiments of the surgeon in the army of Napoleon, who, when requested to poison 500 unfortunate invalid soldiers whom it was inconvenient to take with the army or to leave behind, indignantly exclaimed, "Neither my principles nor the dignity of my profession allow me to become an assassin!"

THE MANUFACTURE OF TEXTILE FABRICS AT POMPEII.

SOME interesting particulars of the ancient method of cleansing and finishing woven fabrics, as revealed by the ruins of Pompeii, are given by M. Beulé, who inspected the remains of a fulling and bleaching establishment in the buried city. The house in question was unearthed some time back, but the descriptions of its contents seem to have been confined to the pictures.

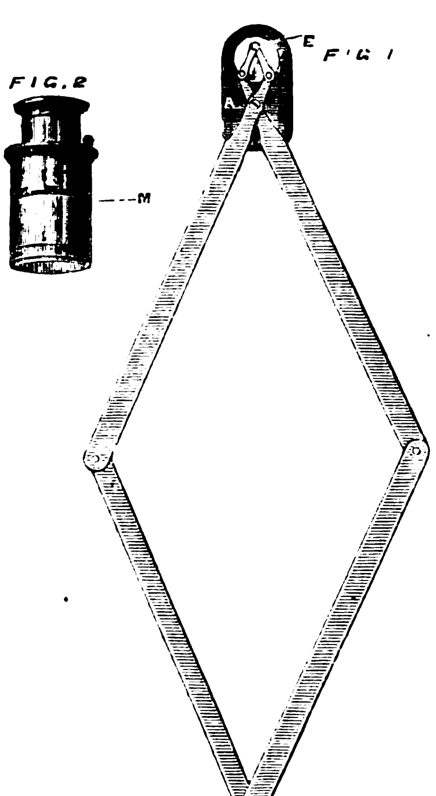
The largest and best executed paintings representative of the art were discovered in 1820, in the house of a fuller, opening on one side on the street of Mercury, and on the other on a street called after him, Fullonica. In the court a pillar covered with pictures was standing alongside a fountain. This pillar has been removed and deposited in the Naples Museum. In the lowest division, a woman, sitting, hands a piece of cloth to a little female slave. A workman, whose tunic is closely tied around the body, is looking at them, while at the same time carding a white cloak with a purple border, suspended from a stick. Another workman is in the act of sitting down alongside a crate of wicker-work on which the cloth is to be spread out; in one hand he holds a vase on which sulphur thrown on burning charcoal will develop a gas capable of bleaching the cloak. This is the same method, says M. Beulé, which is used to-day. On another face of the pillar arched niches contain large vats where the goods are soaked. Slaves standing in those vats trample the fabric with their bare feet in the same manner as Arabian women wash their linen by trampling them against the rocky bed of a stream; this is what the ancients called "the fuller's dance" (*saltus fullonicus*). The artist has painted with the same care the press with its two uprights, its two enormous screws, which were turned by means of cranks, in order to flatten the cloth beneath the planks which imparted the necessary finish. Finally, the drying chamber is shown by long sticks hanging on chains from the ceiling. The linen is spread out on them; a slave hands to a young woman an open fabric, while the wife of the fuller makes a note of it on her tablets. I have visited with particular curiosity the houses in Pompeii where these pictures had been gathered. I counted there in a court twenty-two tanks constructed of stone, and at different levels, so that the water could run from one into the other. Little benches in front of them served for the reception of the goods. At the other end of the court, seven smaller tanks served for fulling. The store-room, with traces of the planks, which were laid like rays radiating from a centre, the hearths, the drying chamber, may still be recognised. In other fullers' establishments, I have seen very thick sheet-lead lining the interior of vats made of cement. Sometimes, also, we find jars full of a greasy earth, which must be the fuller's earth of which Pliny speaks, and which contributed as much to the whiteness of the goods as the fumigation with sulphur or the urine which was collected in vases placed at the corners of the streets. Thus, despite the differences of time and processes, it has been established, to our surprise, that moderns are but little inventive, or, rather, that the ancients had already discovered all that was essential, rational, and suited to the requirements of the art.

DRAWING FROM THE MICROSCOPE.

AN easy method of making accurate drawings of objects seen in the microscope is almost a necessity for the student who wishes to make himself proficient in the use of his instrument, and is of the first importance to the beginner who desires to acquire a knowledge of the objects he examines. Independently of the fact that all real advance in the science hangs upon the multiplication and circulation of accurate representations of the forms and phenomena disclosed by the microscope to the eyes of skilled observers, the tyro, who may possibly be cut off from all communication with proficients to whom he could take his objects and have his difficulties explained by oral and ocular demonstration, will find that the power of making a drawing of an object exactly as seen will be of the greatest value to him in his endeavours to acquire a knowledge of what has been already accomplished, and a great assistance in his attempts to explore new fields; for a drawing is easily transmitted through the post, and coming into the hands of a microscopist who has already passed along the same road and through similar difficulties, he is enabled to remove the obstacle and explain away the perplexity of the student with a far larger amount of assurance and consciousness of correctness than would be possible from the most elaborate verbal description. In his treatise on "How to Work with the Microscope," Dr. Beale justly observes, "It may be truly said that no real advance in our knowledge of the minute structure of animal or vegetable tissues can be communicated to others, unless accurate drawings are made." Yet, as a matter of fact, how very few amongst even earnest students of the microscope can draw at all, and what a very small number have acquired the valuable art of drawing accurately. There are several "accessories" to the microscope, which are more or less useful in enabling the observer to make a truthful copy of what he sees, not the least valuable of which is Dr. Beale's neutral tint reflector, some particulars of which will be found at p. 331, Vol. XIII., and an improved method of using it at p. 386 of the same volume.

One of the latest inventions for rendering the copying of an object as seen in the microscope both accurate and easy, was recently described by Mr. Isaac Roberts, F. G. S., to the Royal Microscopical Society, and an illustration was published in their *Journal*, from the pages of which we reproduce a diagram of the little "micro-pantograph" he has

FIG. 2 FIG. 1



designed. With the appliances hitherto in use, it is questionable whether in many instances they do not increase the difficulty of making an accurate reproduction; but with this "accessory," almost any one can, after a few hours' practice, make an accurate copy of the most elaborate object, accomplishing this, moreover, with facility. The instrument consists essentially of two parallelograms, having their major and minor sides and angles respectively proportioned in all positions in which the instrument can be placed. The major and minor sides rotate freely about the common centre or fulcrum, which is fixed to the eyepiece of the microscope in the focus of the eye-lens. A pencil is attached to the major end-joint of the instrument, and a small glass disc ruled with a micrometer-lined cross is attached to the minor, or eyepiece, end-joint, in the position where pointers are placed. To see both cross and object at the same time similar focussing is necessary to that which is employed to see an object and a pointer. When drawing the hand merely moves a pencil over the paper, and at the same time and by the same action guides the micrometer cross-lines over the field where the object appears in the microscope. The drawing paper should, of course, be laid on an inclined table capable of adjustment to the height of the microscope employed, the top being also made movable to suit the angle at which the microscope is being used. In the illustration Fig. 1 represents the micro-pantograph, and Fig. 2 the form and approximate position of the slit into which the minor end of the micro-pantograph and its support shown at the top of Fig. 1 are inserted. In Fig. 1 E is a glass disc with micrometer cross-lines ruled upon it. It is cemented over a small hole drilled through the centre of the rivet forming the joint at the minor extremity. A is a centre, or fulcrum, around which the parts of the instrument freely move. N is a holder for a drawing pencil, placed over a hole drilled through the rivet forming the joint of the major end of the instrument. In Fig. 2 M is a slit for the insertion of the minor end of the micro-pantograph with its support shown behind E A in Fig. 1. The instrument being firmly fixed in position in the eyepiece to draw any object, it is only necessary to place the eyepiece in the microscope, adjust the drawing table to the height and inclination of the plane of the pantograph, and with the right-hand forefinger and thumb guide the pencil with slight pressure over the paper, at the same time looking through the eyepiece at the object and guiding the centre of the micrometer cross-lines over the respective parts of it; an accurate drawing of the object will thus be traced upon the paper.

Mr. Roberts has not patented this useful contrivance but freely presents it to all workers with, and students of, the microscope. Many of our readers will be able to construct the instrument for themselves, but, doubtless, our opticians will soon be in a position to supply it and adapt it to any form of microscope. For those, however, who may desire to make for themselves, it is only necessary to say that the length of the minor sides of the parallelogram within the eyepiece is ¾in.; of the major sides 5¾in., the instrument when extended to the full length measuring 12¼in.

NOTES OF COMMUNICATIONS TO THE ACADEMY OF SCIENCES, PARIS.*

INDUSTRIAL CHEMISTRY. — DECORATIVE PAINTING ON TIN.—Tinfoil is spread out upon a smooth surface, such as glass, the latter having been first moistened to aid the laying out of the foil and to maintain it in its position. The painting is then executed upon it in oil. This painting on tin, when dried and varnished, can be rolled up like ordinary paper-hangings, from which it essentially differs in possessing all the variety of tones and colouring that oil-paintings admit of. The tin groundwork constitutes a waterproof protection, and, on account of its great flexibility, will follow the various mouldings and contours of the object to be ornamented. To the latter should be applied a hydrofuge mixture, when it will be ready for the decorator. This method can replace ordinary gilding, as the gold can be applied in the workshop and the gilt tin fixed afterwards. The advantage of gilt tin over gilding on other metals is that it is inimical to oxidation; whereas it is known that gilding upon other metals, and notably upon zinc, deteriorates rapidly.—M. C. DANIEL.

[M. Dumas, one of the Commissaries appointed to report to the Academy on the above communication, was, with all who saw the remarkable specimens submitted, highly interested. He considered it of the greater importance to see an industry of this kind develop itself, as it has the sanction of long practice under a somewhat different form. The Chinese, in fact, employ painting upon tin for their furniture and lacquer work, and that which one commonly takes for gold on these objects is nothing but leaf tin covered with a yellow varnish.]

PHYSICS.—LIGHT OF THE VAPOUR OF IODINE.—Vapour of iodine presents a number of curious properties. The following is one that does not appear to have been previously noticed. This vapour at a high temperature gives out rays but little refrangible, furnishing a continued spectrum. Place in a tube of Bohemian glass a small crystal of iodine, and heat the tube strongly at a certain distance from the fragment; when sufficiently red, leave it to cool until almost invisible in the dark, the iodine then vaporizes rapidly. The coloured vapour, on arriving at the heated part, burns red in a very nice manner. By admitting an absorbing medium, the incandescence of this vapour can be produced in a very brilliant style. Seal in the interior of a glass tube a fine platinum spiral, which can be raised to a red heat by the electric pile; then introduce pure iodine into the tube, and seal the same after having expelled the air; volatilise the iodine, and establish the electrical communication. The incandescent platinum becomes surrounded with a vacillating flame, of which the colour is modified by absorption. It is a very rich red, and gives a fluted spectrum. The author expects to draw from these facts some interesting conclusions, but, before publishing them, purposes to submit them anew to experimental verification.—M. G. SALET.

METEOROLOGY.—RAIN OF SAND IN ITALY.—A fresh rain of sand fell in Italy on the nights of the 19th and 20th of April last. The same meteoric circumstances attended this as accompanied the shower of 10th March last. A heavy and sudden storm began

* Translated and abstracted for the ENGLISH MECHANIC

on the 15th April on the coasts of Scotland and Norway, attended with a great augmentation of heat all over Europe. The tempest traversed the west and centre on the 16th, and Italy on the 17th and 18th, directing itself towards Africa. On the night of the 19—20th, it returned upon Italy, charged with sand from the deserts of Africa, mixed with organic matter.—M. P. DENZA.

[We once witnessed a fall of blue clay and sand under similar circumstances at Zante, which laid about the streets, and discoloured the trees and bushes, and was about an inch thick on the deck of a man-of-war then in the harbour.—J. J. L.]

CHEMISTRY.—EFFECTS PRODUCED BY A CHASSEPOT BALL IN A CASE OF SUICIDE.—The lesions and derangements produced were such, that in the absence of other evidence, they might have been attributed to an explosible ball. The projectile presented a puffed up appearance, indicating a partial fusion. It seemed to have traversed the soft parts that it encountered without sensible loss of speed, and to have been brought up sharply by the vertebral column, where its impetus had been converted into heat. The author considers that we find realised herein the conditions pointed out by M. Melsens as necessary for lead to attain a temperature of 315°, its normal point of fusion.—M. ARNOULD THENARD.

PHYSICS.—OPTICAL PHENOMENA OBSERVED DURING A BALLOON ASCENT.—During a balloon voyage on the 8th June last, the ascent taking place from the establishment of M. Flaud, near the Champ-de-Mars, Paris, the following phenomena analogous to the Spectre of Ulloa, were observed. At 5.35 p.m. the balloon had passed the white cumuli that extended horizontally at the height of 1,900 metres. The sun was hot, and the expansion of the gas (hydrogen) determined the ascent towards more elevated regions; but as these could not be attained without danger, owing to the limited supply of ballast provided, the valves were used to descend. At this moment the aëronauts were sailing above a vast cloud, on which the sun projected a confused shadow of the balloon, which appeared to be surrounded by an aureola or glory, exhibiting the seven colours of the rainbow. Hardly had they time to look at the first phenomenon when they descended about 50 metres. They then passed very near the cumulus, which extended itself near the car and formed a screen of dazzling whiteness, of which the height was certainly not less than 70 to 80 metres. The shadow of the balloon now appeared near, very dark, and with great distinctness. The least details were visible, and the silhouettes of the voyagers were regularly displayed upon the silvery cloud, and when they raised their arms the movement appeared in the shadow. The shadow of the balloon was surrounded by a rather pale elliptic aureola, in which the seven colours of the spectrum distinctly appeared. Thermometer 14° Cent. Altitude nearly 1,900 metres.* Sky pure; sun hot. The cloud, upon the vertical wall of which the apparition was produced, was of considerable volume, and resembled a great block of snow brilliantly illuminated. There was a certain nebulosity surrounding the voyagers.—M. G. TISSANDIER.

JOHN J. LAKE.

THE MEDICINAL USE OF CARBOLIC ACID.

CARBOLIC ACID is very largely employed in the treatment of wounds and festering sores of all descriptions; but hitherto few experiments have been made with it as an internal remedy. There is good ground, however, for believing that in certain cases it will be found a very valuable therapeutic agent, and under these circumstances the *Lancet* describes some experiments which have been made by two French *savants* to ascertain in what doses it may be poisonous.

MM. Paul Bert and Jolyet, of Paris, have undertaken experiments to make out this point. Between forty-five and sixty grains will kill a dog of large size; nor should it be concluded that a man could bear a dose in proportion to his weight compared to that of the dog, as thirty grains of hydrochlorate of morphia have been injected into the jugular vein of a dog without killing him. Of course one-fourth of this dose would kill a man. The above-mentioned authors state that carbolic acid is a powerful poison, which, very imprudently, is left in the hands of anybody, either in solution or in the solid state. The former is the most dangerous, as some weak solutions for internal use are sold, as well as very strong ones intended for external use. Thus mistakes may easily occur. MM. Bert and Jolyet find that carbolic acid acts like strychnine on the excitability of the spinal marrow. It increases its sensibility, like strychnine, at first; but it diminishes that sensibility, or completely abolishes it, when the convulsive stage has exhausted the medulla. The phenomena resulting from carbolic acid are said by our authors to be quite similar to those produced by chloroform, chloral, ether, woorara, and the section of a motor nerve.

* A metre = 1yd. 0ft. 3·371in.

MECHANISM.*

(Continued from p. 480.)

IF we refer to what may be deemed an ever-present characteristic of continuous motion communicated by rolling, it will be seen in this—viz., that the curves used were of that class which returned into themselves. They are, in fact, completed curves, or portions of curves that may be completed, obeying a decided and a clearly-expressed law of formation as well as relation to each other. And we may notice further, that the shafts or axles on which these rolling curves are fixed, rotate. There is no other motion transferred by pure rolling than such as is expressed by the word "rotation." Some may say that motion communicated to a straight rack is a case of rolling, and that is not rotation. Practically it is not rotation; theoretically it is; for a rack is a straight line, and in the theory of mechanism straight lines are assumed to be the circumferences of circles with centres at infinite distances, for straight lines are really circles with infinity for a radius. Further, if "rolling" mechanism be examined, it will be noticed that the driver and follower are so connected that the precise extent of motion of the driver is of necessity transferred to the follower. In perfect rolling contact there is no escape from that law. The angular velocity, or the velocity of the shafts, may vary, but the length of the path of a point in the circumference of one wheel must be exactly equal to the length of the path of a point in the circumference of the other wheel. Bear in mind that there is a distinction between the angular velocity or the velocity of the shafts and the extent of travel of a point in the circumference of a wheel keyed on a shaft.

Further, the pathway in which the motion may be said to be transmitted is always in the line joining the two centres of rotation. The curves in contact move, but the pathway of communicated motion does not move. Remember, we are speaking of *pure* rolling contact. In this example of two wheels in rolling contact, the pathway in which motion is communicated is a line adjoining the two centres. As soon as the touching parts of the circumferences have left that line, they have left the pathway of communicated motion and ceased to communicate motion from the driver to the follower. The point in the pathway where the contact takes place may move. It may vibrate, as it were, in a line joining the centres of motion of the shafts, as in elliptic and eccentric wheels, or it may be fixed, as in circular wheels. But in all instances of pure rolling contact motion, equal lengths of the two contact surfaces cross that pathway in equal times.

Now, however, that motion is to be communicated by sliding, the relations between the moving pieces are very materially modified. Not only may the direction of the pathway in which the point of contact travels be ever varying, but the very idea of peripheries or circumferences rotating about the centres to which they are related, by some reentering law of curvature, vanishes. In rolling contact motions there are always peripheries; in sliding contact motions one or both of those peripheries disappear.

Let us see, then, how this preliminary alteration of affairs affects the mechanician in the case of rolling circles, ellipses, and lobe-wheels—by lobe-wheels are meant wheels based upon such figures as squares, with curves and teeth upon them (see Fig. 9, p. 480), of which there are some very beautiful photographs on the wall, well worth close inspection. It is cause for regret that, so little is mechanism appreciated as a study in England, that neither private enterprise nor the authorities in scientific museums have either exhibited or are possessed of copies of the originals from which many of the numerous photographs of mechanism in this room have been taken.

In the case of rolling circles, ellipses, and lobe-wheels, the velocities communicated depend on the ratio into which the point of contact divides the line connecting the centres of motion. This principle is applicable in all motions of pure mechanism. And there is a second condition. The freedom, perfection, and accuracy with which motion can be transferred are dependent upon the permanence of the line of direction in which the contact surfaces convey it. If the line of direction by which the motion is communicated varies, then accuracy in regard to the relations of the motions ceases. If the point is always in the same position in this line, then the velocity ratio of the shafts is constant, that is if, for example, one shaft makes ten revolutions, the other will make twenty; but if that point moves, the proportion of ten to twenty, or constant velocity ratio, fails.

You will find in this model (subject to the irregularities attendant upon all practical illustrations of pure rolling mechanism) there is on each wheel a piece of coloured paper, and as the wheels are turned round you see that these pieces come together again as at the first. The velocity ratio between the two is therefore constant. That point does not move. If, however, we take the case of these elliptical wheels (Fig. 11, p. 480) and bring them into contact at one point, you will observe that whilst the communication of motion by the rolling of the ellipses is perfect, the space passed through in that circumference and this circumference is the same. Equal travels have taken place in these elliptical wheels as regards the circumferences, but variable velocities in the shafts on which the wheels are keyed. Take, for example, these elliptical wheels, and see how the velocities of the shafts vary. There is a circle representing a section of the shaft divided into thirty parts. At the present moment the pointer is pointing to zero. While the wheel has gone half round, the shaft ought, according to the ordinary law, to have completed one half of a rotation, but you will find it is not so. The shaft has passed through twenty portions of the circle, but the other half rotation of the wheel takes the shaft through only ten portions.

Now, in these elliptic wheels without teeth, so long as pure rolling takes place, however varied may be the velocities of the circumferences of the cylindrical shafts, the circumferences of the wheels passed are equal. There is no evasion of that law; but assume they are in such circumstances that they are unequal, then one of the surfaces must have slid past the other. A sliding motion has entered into the mechanism which was not provided for at all. Perfection of workmanship and indestructibility of material can alone prevent a partial sliding in the very best of illustrative rolling contacts. What, therefore, cannot be averted must be accepted. Hence we must recognise rolling contact motions in connection with the motions consequent upon sliding, and we must therefore endeavour, as far as possible, to enlist the necessary sliding contact motions to aid in the promotion of rolling contact motions, the object being to impose an immutable law upon two pieces where one causes the motion of the other. As, for instance, in the case of clock-hands; if the minute hand did not move by an invariable connection with the hour hand, the clock would be very delusive. Since there is to be an immutable law between the two pieces, therefore, the uncertainties of sliding must be eliminated, whilst the presence of sliding must be recognised.

Now, put a piece of wood upon this rolling circle, and a pin or tracing pencil on the other; let the circles roll as before, and the pin mark a line upon the wood. Cut the wood to this line, and instead of the wheels rolling let arms from the centres carry the pencil-traced curve and a pin against its edge. The pressing and sliding action of the curve on the pin will cause the shafts to move as the rolling of the wheels did. Mathematicians can show the identity of the motions, and that they are the same as though communicated at the point in the line joining the centres. Were it not so, the preordained law of velocity-ratio would be broken.

The condition to be satisfied is that the motion be communicated exactly at the required point, and at no other.

The mechanician, or rather the mathematician—for we are now entering into that province which is forbidden ground, since the problem in this phase belongs to the mathematician—must determine the shapes of curves which may replace these rolling circles, the circles being entirely taken away; which curves shall so move in sliding contact that the line of pressure shall always intersect the line joining the centres of motion in the same point, or in a point whose law has been previously ordained. In the case of those elliptical wheels there is a law, and the point is continually varying. In the case of the circular wheels there is another law, and the point is constant. Although now trenching rather more on the province of mathematics than was originally intended, the conclusions to be drawn are so essential to the perfection of mechanism that a description of the principles which govern these conclusions must here be introduced.

Let us see why to use pure rolling contact for the communication of power is little more than theory, but to use it for the communication of velocity is practice, as those who were here on Monday last can testify. We had then the case of pure rolling contact for raising heavy weights; and if any of you go into the room at the Arsenal at Woolwich where large timber is sawn, and ask to be taken below where the driving machinery is, you will see a large circular saw—to the best of my recollection 4ft. or 5ft. in diameter—the rotation of which is accomplished by pure rolling contact. The saw is supported upon a simple shaft resting on two bearings. It is driven by two cones pressing against it. The cones have leather surfaces, with which they grip the saw, causing it to rotate, and in this case a high velocity is accomplished by pure rolling contact, and is utilised in the cross-cutting of baulks of timber.

Teeth on curves, or, as we usually call them, on wheels (although all curves can be made into wheels), are now the accepted mode for the communication of such motion as would take place if the rolling was perfect.

Let us see what should be the form of the teeth on curves, and how these teeth act and re-act upon each other.

(To be continued)

* By the Rev. ARTHUR RIGG, M.A., being the Cantor Lectures delivered before the Society of Arts.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly a possible.]

All communications should be addressed to the Editor of the English Mechanic, *31, Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. Passmore Edwards.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

**** In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

HARK BACK!—B. A. C. STARS—AND STAR ALTITUDES AND REFRACTION.

[4614.]—"Video" (query 12444, p. 471) should turn to Vol. XIII., p. 229, letter 1983; "H. Science" (query 12463, p. 471) to Vol. XI., p. 277; and "C. B." (query 12465, same page) either to Vol. III., p. 194, or to Vol. XIII., p. 153, letter 1839. "Excelsior," too (query 12482, p. 496), who inquires about the calculus, will find a curiously simple exposition of the elementary principles of the differential calculus and of its applications, in Vol. XII., pp. 361, 409, and 481, in a series of articles by Mr. Proctor. He will hence derive a notion of the extensive class of problems to the solution of which it is applied. As for the integral calculus, it is indispensable in the higher geometry, and is employed largely in dealing with the recondite subject of perturbations, &c., as also in certain branches of optics, and physics generally. If "Excelsior" will thoroughly master the ideas involved in Mr. Proctor's capital papers, he can go on to Todhunter's two books, his "Treatise on the Differential Calculus" and "Treatise on the Integral Calculus," published by Macmillan and Co. He, however, will scarcely get on without a tutor.

I may answer "C." (query 12518, p. 497) by telling him that 73 Ophiuchi is number 6155 in the British Association Catalogue; but that it is not 73 *Struve* Ophiuchi, as it is numbered 2281 in his list. Further, that Struve 2403 Draconis is B. A. C. 6410; that Struve 2878 Pegasi is not in the B. A. Catalogue at all; that 26 Pegasi is B. A. C. 7723; and, finally, that 36 Andromedæ is B. A. C. 250.

"Tyro" (query 12525, p. 497) asks a question which to answer in anything like detail would involve an employment of space scarcely permissible in a letter. I will, however, do what I can for him. I may, then, in the outset, explain that refraction tables are chiefly used in fixed observatories for the reduction of the observed *meridian* altitudes of objects to their true altitudes; and in a case of this sort we should, of course, for a star between the south point of the horizon and the zenith, add its declination to the co-latitude of the place of observation if such declination be north, or subtract it if it be south, to obtain its altitude at the instant of its transit. For example, what will be the meridian altitude of ι Pegasi at the time of its passage over the meridian, as seen from the Liverpool Observatory on the night of August 8? The latitude of our supposed observatory is 53° 24′ 4″, and its co-latitude, therefore, 36° 35′ 56″. If, then, to

36° 35′ 56″
we add 9 17 29, the star's declination north,

we get 45° 53′ 25″ as its actual meridian altitude.

The quantity to be added to this, from Bessel's tables, to obtain the apparent altitude "Tyro" can, of course, find for himself. He will do well to compute this correction for some mean height of the barometer for every degree from 0° to 90°, and then tabulate it against the degrees of north and south declination corresponding to particular ones of altitude for his own latitude. This is exceedingly simple. If, however, the star be at some distance from the meridian, its altitude may be computed by the following formula—

$$\tan. y = \cos. P \cot. \delta$$

$$\cos. z = \frac{\sin. \delta \sin. (y + \phi)}{\cos. y}$$

where z is the zenith distance of the star, P its hour angle from the meridian, δ its declination, and φ the latitude of the place. I need scarcely add that 90° − zenith distance = altitude. If "Tyro" possesses the smallest acquaintance with the use of trigonometrical tables, he will have no difficulty in computing an example from the above easy formula; but as for attempting to get "the *exact* allowance to be made in setting the circles of his equatoreal," that is a waste of time never perpetrated by the practical observer. As long as a star is sufficiently near the centre of the field for identification, it is the merest pedantic refinement and supererogation to insist upon its being absolutely in the line of collimation of the telescope. Besides, I question much if any ordinary equatorial mounting will admit of such hair-splitting accuracy.

A Fellow of the Royal Astronomical Society.

SOUND (OR UNSOUND) THEORY.

[4615.]—With reference to the query with which the letter (4607) of "The Harmonious Blacksmith" on p. 489 concludes, I must confess that (beyond the known fact that a confined column, or mass of air of definite length, vibrates rhythmically) I am unable to offer any satisfactory theoretical reason why a partly closed box should give greater resonance in connection with a vibrating string than a mere flat disc of wood employed as a sounding-board; but I have always understood and believed, that, as a matter of practice, it does. Of course, "The Harmonious Blacksmith" is familiar with the lecture-table experiment of increasing the sound emitted by a tuning-fork or bell by bringing it over the opening of a tube closed at the other end; and knows how enormously louder the resonant vibrations of the confined air cause the audible note of the fork to be. With his very great experience with stringed instruments, too, he must have had an opportunity of comparing the difference of quality in the tone of a guitar, which, like a violin, is a nearly closed box; and a banjo, which, I fancy, has no back at all. However, after all, *ars probat artificem.* "The proof of the pudding is in the eating;" and I cannot help wishing with "F. R. C. S." (let. 4598, p. 488), that our great musical contributor would have his funny fiddle constructed and played on, and furnish us with a full, true, and particular account of the result. It would be safer to theorise in the light of the knowledge thus acquired.

A Fellow of the Royal Astronomical Society.

A GIANT PLANET.

[4616.]—"Hyrab Sen" (let. 4573, p. 482) altogether misapprehends his position and my own. My theory is in no sense "on trial," merely because some one chooses to imagine objections to it, or because I consent to explain what it really is. I would point out, moreover, that in his remarks about my being "so great an authority," and again, "so great and potent an astronomer," he overlooks the fact that were I desirous of so asserting myself, I should refrain from making any explanatory remarks whatever in the correspondence columns of any journal, respecting the theories I have advanced. It is because I advocate a much greater degree of frankness than is at present usual among the students of science, and a much greater readiness to meet doubts and consider objections, though urged by the tyro, that I myself adopt a course so different from that which is commonly pursued. Such letters, and especially such rejoinders, as "Hyrab Sen's," make me doubt whether, after all, the better course would not be to yield to my natural tastes, and adopt the reticence of my fellow students of science. Certainly, that is the course which the consideration of my personal interests and convenience would suggest, and which I have long been urged to adopt by many for whose opinion I entertain a very high respect.

Let me at the outset point out that I should not be careful to defend my theory against "Hyrab Sen," even if he had attacked it. As a matter of fact, he is, for the most part, attacking points which do not belong to my theory at all, and have only been incidentally introduced into my essay on the subject.

As to the "midway" question, I reply that I used the expression midway rather than the technical term "geometrical mean," because it is proper to avoid technical terms in a popular essay. Again—having given the numbers, I did not proceed to explain in what sense I used the word, because it is *not* proper to insult one's readers. If it had occurred to me that any one would take *midway* to be synonymous with *half way*, or fail to see that 82,000 is not half way between 8,000 and 840,000, I should have explained the matter for his particular benefit, with many apologies to the rest of my readers.

I suppose it is quite useless to tell "Hyrab Sen" that when I speak of the light of Jupiter being seen through the cloudbelts which seem to us the densest, I mean that the clouds may not be close-packed, and that, from the satellites, Jupiter's real surface may be seen *between* the clouds (through the cloud-belts, not through the clouds themselves). I mention in my article that the best telescopes show a multitude of minute cloud-like objects over the ruddy equatorial zone.

As to a number of other ideas in "Hyrab Sen's" paper, he is as free to entertain them as I am to uphold the contrary—freer, indeed, a good deal—since I find myself fettered by some degree of acquaintance with the known facts of the case, whereas "Hyrab Sen" is apparently very little shackled in this way.

There was no petulance whatever in my remark that "I fancy 'Hyrab Sen' counts degrees Fahrenheit much as a schoolboy counts marbles." It is precisely as I expected. "Hyrab Sen" *does* think that degrees of heat may be counted up, multiplied, and divided, as marbles are counted by the schoolboy. And thus the 600th part of a temperature of 1200° Fahrenheit amounts, he imagines, to a temperature of 2° Fahrenheit! He may be aware, perhaps, that 1200° Fahrenheit correspond to 648·9° Centigrade; and according to his marble-counting method the 600th part of this temperature is 1·08° Centigrade, or nearly 34° Fahrenheit. So that the 600th part of a certain temperature may by the marble-counting method be shown to be either 2° or 34° Fahrenheit. I submit, therefore, that the method is open to objection.

His remark, that the method is similar to that which Sir John Herschel used in estimating the actual heat of the sun, is exquisite. For cool audacity, and rich though unconscious absurdity, it can only be paralleled by that astounding remark in the preface to a certain elementary compilation on astronomy, which announces that "the altogether admirable 'Popular Astronomy' from the pen of the Astronomer Royal" (a perfect masterpiece of popular writing) "may be looked upon as a sequel" to a book resembling the Astronomer Royal's work only in certain chapters which ought to be (but are not) adorned profusely with quotation marks. Sir John Herschel was a master on the subject "Hyrab Sen" is trying his "'prentis hand" upon—a Goliath where "Hyrab Sen" is not even a David—since, contemplating the great man's armour, he does not perceive that "*usum non habet*," and cannot even make a happy shot with his little sling and his well-counted marbles.

It is unfortunate that "Hyrab Sen's" method had not been thought of when Faye, Fizeau, St. Claire Deville, Becquerel, Vicaire, Vualle, and others, were maintaining before the Paris Academy of Sciences (as they still maintain) that the sun's heat does not exceed 10,000° Centigrade. "Hyrab Sen" might have come in triumphantly, first of all, with his known fact that the sun's heat is demonstrably thousands of times greater than that of red-hot iron, say 1,200° Fahrenheit—demonstrably, therefore, some millions of degrees Fahrenheit; but if that had not satisfied the Paris Academy he could have applied his marble-counting method to demolish the unhappy Frenchmen just as he supposes he has demolished me with it. Thus, the sun's heat, according to these benighted beings, is less than 18,000° Fahrenheit; but "the sun's rays at the earth's distance are spread over a sphere of the heavens which, roughly speaking, has a surface 47,000 times larger than the sun's; therefore, 18,000° ÷ 47,000, or less than ²/₅ths of a degree Fahrenheit, must be the amount of heat the sun imparts to the earth"—actually less, by "Hyrab Sen's" very own marble-counting method, than the heat which, by the same method, Jupiter is shown to supply to his outer satellite!

Now, perhaps, "Hyrab Sen" can guess why I "asked him the question" instead of "supplying a calculation myself." I gave him rope, so to speak, knowing how pleasingly he would use it. He had been so very eager to show his prowess and to demolish me, that I could not find it in my heart to pull him up until he had thoroughly shown his paces. With this desirable end in view I was quite willing to "bide a wee."

"With due deference to so great an authority," says "Hyrab Sen," "I decline to take Mr. Proctor's assertion," about luminous objects, "for granted, and though I know it is the orthodox scientific view that distance does not diminish brilliancy, I shall still persist in believing it does." Alas, for orthodox science! But probably "Hyrab Sen" understands the facts on which the accepted view is based as little as he does those which he urges against it. He may, after all, be converted some day. The orthodox may breathe again.

In trying to prove that "sunshine here is hundreds of times brighter than the light" of a body heated to redness, "Hyrab Sen" indulges in the remarks that "sunlight is demonstrably thousands of times brighter than moonlight." I take it that "sunshine here" is pretty nearly the same as sunshine at the moon, so that in comparing the luminosity of red-hot coke with that of the moon's disc, "Hyrab Sen" was comparing the former luminosity with sunshine here, and not with its thousandth part. I do not expect him to see this, however.

I quite understood "Hyrab Sen" to refer to Zöllner's results, which I certainly accept, in my essay, as the best yet extant. They are not what he supposes. He is all in a muddle on that part of his subject as throughout, and I really have not leisure to set him right. [I have always pitied poor Sisyphus.] Only let me remark that if, as he imagines, "there is no reason for supposing Jupiter to be a better reflector of light than Mars" (!), my case is proved; for we certainly get from Jupiter much more light than a globe of his size, constituted like Mars, would send us by reflexion. Of course, if Jupiter is a much better reflector of light than Mars, so much the smaller is the balance of inherent lustre.

But so far as "Hyrab Sen" is concerned, all this explanatory matter is thrown away. I cannot write further on the subject.

Richard A. Proctor.

REDUCTIONS BY *NAUTICAL ALMANAC* METHOD AND BY PROPORTIONAL LOGARITHMS.

[4617.]—In answer to "Aries" (let. 4612, p. 490), the *Nautical Almanac* method is altogether the most exact. The method given in nautical books is based on the assumption that the hourly change of declination is constant from one noon to the next. The *Nautical Almanac* method is based on the assumption that the *change* in the hourly change is constant.

Thus the sun's declination changes from 21° 0′ 40·4″ to 20° 49′ 9·3″ between Jan. 16, noon, and Jan. 17, noon, 1872, the change being − 11′ 31·1″. The rule in nautical books, when applied to find the declination at 4h., January 16 (or at noon, in longitude 60° west of Greenwich), amounts to taking ⁴/₂₄ths or ¹/₆th of this difference, or 1′ 55·2″, and subtracting it from 21° 0′ 40·4.″

[By the way, "Aries" either has very inaccurate tables, or is unfortunate in their use; for the diurnal prop. log. of 11′ 31″ is 8189, not 8198, and the arc corresponding to 1·0979 is 1′ 55″, not 1′ 57″. The arc corresponding to 1·0970 (the true sum) is 1′ 55·2″, as required. Again, in taking out the prop. log. of 20·4″, "Aries" has added, instead of subtracting, the prop. difference for 0·4″.]

Now, in the *Nautical Almanac* method, instead of assuming that the difference for 24h., or − 11′ 31·1″, is equally divided among the 24h., which would give an hourly difference of − 28 8″, we are given the hourly difference − 28·30″ at the beginning of the 24h., and − 29·29″ at the end. The difference between these or + 0·99″ is supposed to accrue uniformly during the 24h., giving an increase of ·04125″ per hour. Then, if we take the average for the beginning and end of each of the first four hours after noon January 16, and take *that* as the change during the hour, we get—

For the first hour, $-\frac{1}{2}$(28·30″ + 28·34125″).
For the second hour, $-\frac{1}{2}$(28·34125″ + 28·38250″).
For the third hour, $-\frac{1}{2}$(28·38250″ + 28·42375″).
For the fourth hour, $-\frac{1}{2}$(28·42375″ + 28·46500″).
Adding which, we have, for the four hours .... − 2 (28·30″ + 28·4650″).
= 1′ 53·5300″,

as by the *Nautical Almanac* rule, which is simply the just mathematical way of deducing the value of the above summation.

It will be obvious that we thus obtain a much nearer approximation to the true value than by a rule which does not take into account the hourly variation in the rate of change.

So with the other cases.

[I would strongly urge "Aries" and others to use the symbols °, ′, and ″, for degrees, minutes, and seconds of arc. The symbols m. and s. for *arcs* are as perplexing as the symbols ′ and ″ for *time*. Captain Noble did excellent service to science a few months ago by dwelling on this matter in a paper read before the R.A.S.]

RICHARD. A. PROCTOR.

THE GYROSCOPE.

[4618.]—IF "A., Liverpool" (let. 4594, p. 486), means that I do not understand *why* the second law of motion holds good, he is quite right. If, however, he means that I do not understand what the law means, I must simply say that he is mistaken.

His question "If a cannon ball be fired horizontally, how is the resistance to a change of plane of motion so nullified that it becomes of no effect whatever," is easily answered by a form of words which seems getting very much out of fashion—*I don't know*. (*Par parenthèse*, I may remark that the plane of motion is not changed. "A." doubtless means "line of motion." Still my reply is, *I've not the least idea*.)

Parkinson, the eminent mathematician, remarks of the second law of motion that "strictly speaking, it could only be proved by showing it to be true for every individual case that can occur, which is manifestly impracticable. But when the results of numerous and intricate calculations based upon it are invariably found to agree with observation, we arrive at a *moral conviction* of its truth."

Professor Nichol remarks, "There is, perhaps, no principle in philosophy on which so much vain logic has been expended, so that it might appear based on mathematical reasoning."

"A." is quite mistaken if he supposes that a weight can be swung by a string in a horizontal plane high as the point of support. It is no more possible to do this than to stretch a string so that it shall be strictly horizontal throughout its length.

RICHARD A. PROCTOR.

[4619.]—IF Mr. Proctor (let. 4587, p. 460) is "unable to spare the time for the *proper* discussion of this subject," would it not be better for him to let it alone altogether? I have that confidence in his intelligence and candour which assures me that if he could spare the time for the due consideration and discussion of the subject he would either at once admit that he has been in error or put forward a convincing demonstration of his accuracy. He is quite right as to the fact stated in the last sentence of his second paragraph, but neither I nor any one else has disputed that fact in the current discussion. The question was not whether the top falls slowly or quickly, but why it does not fall at all.

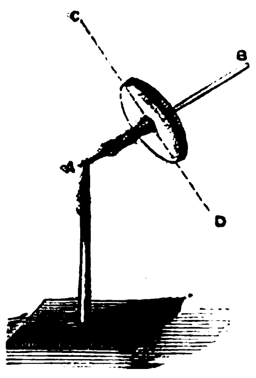
With reference to Mr. Proctor's third paragraph, I would recall to his recollection that at the former time he refers to, he himself put forward an explanation with diagrams. I have as yet contributed no explanation to the ENGLISH MECHANIC. I certainly contributed several letters on the former occasion, but all I claim to have done in them is to have shown that various proposed explanations, and amongst them Mr. Proctor's, were faulty. It strikes me as being a little cool for Mr. Proctor to advise that my explanation should not be published after he has himself made two attempts, which, to say the least, have not satisfied his readers.

Mr. Proctor's fourth paragraph is a random shot, which does not tell, for I have no new theory about nutation to bring forward. Mr. Proctor more than once reminds us that he has no doubt "mathematical analysis affords a complete account of all the phenomena of the gyroscope." I very much doubt, however, if he has been able to spare the time for the proper study of the analysis he refers to, for I cannot understand how, if he really had studied it, he could say as he does in reply to J. M. Taylor, that the motion of one particle under the action of gravity would tend to shift the plane in one direction and that of the opposite particle in precisely the opposite way, whereas the fact is that gravity tends to make both particles shift in precisely the same way—namely, in circular arcs having the point of support for their centre. The very first step towards an explanation is to point out that even if the top were not spinning, gravity would not make the several particles move vertically downwards, but in circular arcs round the point of support. In other words, gravity tends to produce rotation or turning about a horizontal axis passing through the point of support, and it is the effect of the combination of this rotation, or tendency to rotation, with the spinning motion of the top which is the subject of investigation.

Glasgow. E. H.

[4620.]—IF you can spare room for farther discussion on this subject, I trust you will consider the following worthy of insertion.

Since reading Mr. Taylor's letter (4510, p. 485), I have experimented on the weight of tops at rest, and when spinning vertically or at different angles, and I need hardly state that I detected or expected to detect the slightest difference in weight. I would, therefore, submit the following remarks to the notice of Mr. Taylor and others interested. I will first take the case of a top A B spinning in mid air, without the support A E, and consequently falling to the ground. Each particle has by the centrifugal force a tendency to move in the direction of the plane C D, at right angles to the axis A B, and having this tendency it must require a certain amount of force to overcome it before the angle of the plane C D can be altered; and, therefore, supposing the top to be spinning with sufficient rapidity, the axis must reach the ground in the same or parallel plane to that in which it commenced to fall, there being no other force except the slight resistance of the air to change its direction. But now spin the top and place it on the support A B, at any angle, and it will remain in that position as long as the rotation is quick enough to supply centrifugal force in the plane C D sufficient to withstand the effect of gravity, as it is evident the top cannot fall without altering the angle of C D. The whole of the weight is therefore borne by the support A E. L. H. O.

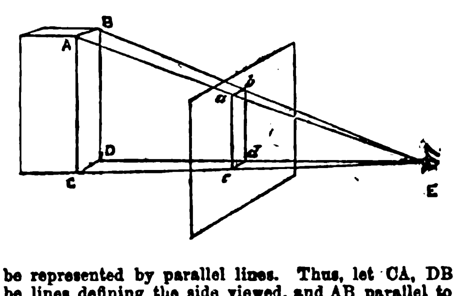


PERSPECTIVE.

[4621.]—ALTHOUGH you have decided to shelve this subject (rather early, by the way), I think you will admit that, as M. Paris (let. 4604, p. 489) charges me with begging the question, I am entitled to a reply. It shall be brief, however.

First, I by no means begged the question. The word vertical in my demonstration meant simply (as usual) perpendicular to the plane of the horizon—not lines apparently so, but lines actually so, like the sides of the supposed tower.

Secondly, it is not true that I am unable to grapple with Carpenter's difficulty; but that I am unable to admit that there is any difficulty in the matter. Of course the top of a tower (of equal breadth throughout) is farther from the sketcher than the base is; and, equally of course, it subtends a smaller visual angle, or is optically narrower. Nevertheless, its sides must be represented by parallel lines. Thus, let CA, DB be lines defining the side viewed, and AB parallel to CD. [That M. Paris may not suppose I am here begging the question, let me point out that AB and CD are the actual edges of a face of the tower; and that the parallelism spoken of is the real parallelism of these edges.] Let P be the plane of projection, E the eye. Then obviously the angle BEA is less than the angle DEC. Nevertheless, if $a\,b\,c\,d$ be the projection of ABCD, we have—



$$a\,b : \mathrm{AB} :: b\,\mathrm{E} : \mathrm{BE}$$
$$:: d\,\mathrm{E} : \mathrm{DE}$$
$$:: d\,c : \mathrm{DC}.$$

Hence $a\,b : d\,c :: \mathrm{AB} : \mathrm{DC} :: 1 : 1$. That is, $a\,b = d\,c$.

This method of proof can obviously be extended to the case where the tower is not looked at full front.

But my former proof is neater and more complete.

[I may just add, as another and complete proof that the vanishing-point of the sides of the tower (or of any plumb-lines) is the zenith, and that a line from the observer's eye to the zenith, being also vertical, cannot meet the vertical plane of projection. Hence there is no point on that plane (indefinitely extended) to which the projections of the tower's sides converge—in other words, they are parallel. *Q. E. D.*]

RICHARD A. PROCTOR.

[4622.]—THE enlarged appearance of the moon when on the horizon offers an example of pictorial perspective. What is called a harvest moon looks, perhaps, larger still, which may be owing to the colour with which the vapours prevalent on the surface of the earth at that season tinge it. However, at all times, whether white or red, the moon on the horizon appears considerably larger than what is sometimes called its natural size when seen at a considerable height in the heavens, and though it actually subtends no larger an angle, yet to produce the same effect in a picture, it must not be drawn in true (or linear) perspective, but considerably larger, *i.e.*, in pictorial perspective, to produce the effect of nature. It appears to me that this case is the same as that of distant mountains, though, from difference of colour, distance and the proportion of enlargement would be different. I believe that in any position, high or low, the moon is in a picture drawn considerably larger than its actual size subtended at the eye. This size is about 30′, and in a picture embracing an angle of 45°, and 12in. in width, this luminary in a moonlight scene should be about $\frac{1}{8}$in. in diameter. I think an artist would portray a full moon considerably larger than this, and a crescent moon larger still, in a picture of this size; and a harvest moon larger again. Pictorial perspective would demand this departure from exact linear perspective, and in a degree it would depend, perhaps, on the nature of the pigments used.

It may be a question whether we should call the natural size of the moon that which we view on the horizon or at a high altitude. In favour of the latter view it may be said that the natural size is that which we perceive when the moon is in the most usual position, *i. e.*, considerably above the horizon. In support of the former we may say that the natural size would be that which we perceive when looking in a horizontal direction, this being the most usual way of looking at distant objects, and I am inclined to think that this is the more correct mode of considering the question of the different apparent magnitudes of the moon, and also of the sun. I am, of course, speaking of their horizontal diameters, and not the vertical, which are more or less affected by refraction.

I once noticed a curious example of this apparent enlargement, in the case of a weathercock 4ft. long, which had been taken from the top of a steeple 200ft. high, and was resting against the foot of the tower, from which I was about 100 yards distant. In that situation it looked immense—at least three times its apparent length, when in its usual place on the steeple, which would then have been 120 yards distant from me, and ought, according to the strict rules of perspective, to have made it appear only 9in. short of the 4ft. instead of the apparent 82in. This is a very rough calculation, but the appearance was sufficiently striking to establish the fact I have mentioned.

While I am rambling, allow me to add a remark on let. 4538: While Mr. R. A. Proctor is, I need hardly say, correct in stating that the direction of motion of a swiftly-moving body changes slowly under the influence of gravity, the remarks of "G. M.," perhaps, to the same effect, are liable to an erroneous interpretation, which is of some importance, as they are intended to explain the matter to another. "G. M." writes: "'A.' is right in saying that a swiftly-moving body offers resistance to any force seeking to change the direction of its motion." The words "swiftly moving" are apt to mislead, as, if the swift motion were the cause of the resistance, which would be equally great in a slowly-moving body or a body at rest; and in the succeeding portion of the paragraph the mode in which the term "deflecting force of gravity" is used is liable to an erroneous interpretation, which the separation of the deflection from the force of gravity (which is the cause of deflection, while the variable horizontal velocity of the body is the cause of its variable amounts) would have obviated.

M. A.

[4623.]—OUR Arcadian friend, "The Welsh Shepherd," in let. 4566, p. 465, quitting his pipe and crook, takes up the pen to write me down an ass; of course, only a perspective ass. I doubt whether in these days of dear mutton and foot-and-mouth disease our shepherd is justified in leaving his flocks to wander at their own sweet will upon the breezy mountain with an impossible name to endeavour to convert me from my faith in Brewster. I do not ever swear in the words of any master, and I would have succumbed to (not conquered by) the Laputans cheerfully, had I not to my own satisfaction proved by experiment the truth of Sir David Brewster's opinion, that if we do not see the top of a square tower to be narrower than the base, it is owing to an optical illusion. It is possible, but not probable, that our friend, "The Welsh Shepherd," may be a greater authority in optical matters than Sir David; but since his letter placing me in the perspective pillory, *vice* Dr. Carpenter let off, reveals no original nor even noteworthy views, I may, perhaps, be allowed to pass his contradiction by. An ancient shepherd, a well-known co-respondent, was wont whenever he got the worst of a fight to take advantage of his patroness's nebulous conveyance, and to retire from the contest under a cloud. I have no wish to imitate my ancestor in this strategic movement, if I quote from Sir David Brewster's paper, in *Good Words* for 1862, what appears to bear upon the subject. Sir David notices a series of illusions relating to the vision of forms, such as plane surfaces and lines, mentioning the experiments of Bouguer, and applies the results to the architectural irregularities of the Parthenon and Theseum—upon which subject I should like our "E. L. G." to say something—adding, "The beauty and apparent symmetry of architectural forms must therefore depend on a certain class of optical illusions, which have not yet been sufficiently studied either by the architect or the man of science." I take the bearing of this to be that the Greeks built to counteract or increase, as required, the illusions of the eye. Sir David then proceeds to another class of ocular illusions called the Inversion of Perspective, and he writes as I quoted in my first letter: "This tendency of the eye to invert the perspective of rectangle prevents or diminishes that appearance of convergency on the plane face of a lofty square tower when we are standing not very far from the base. A photograph of the tower taken from the same spot would exhibit a painful convergency upwards, which is not seen by the eye;" but, as I have proved, may be detected in a moment by means of a plummet held at a short distance from the eye. And it must be so, for the whole of perspective is based upon the simple fact that all bodies appear to diminish in size as they recede, and the top of a building being more distant than the base, the side must narrow as it rises. I am at present residing in a rather lofty house offering tolerable facilities for trying this question. Before the pane of a window raking a street I hung a plummet, and the sides of the houses in "parallel perspective" converged as required. That the so-called horizontal lines, excepting *the* horizontal line, rose or dipped was too evident to need experimental verifying. The side of the house well represents the side of a square tower, and a plummet at a suitable distance (a sketching distance) showed very clearly the same thing. Mr. Proctor's demonstration begged the whole question. Of course, we all know the glass plate will show the rays in the cone or pyramid of vision to be vertical if they start vertical, and that is just what is denied by the anti-Laputans. As for "the rules of perspective being deductions from observations made upon the glass plate," that is sheer nonsense. Perspective rules were acted upon before a sheet of glass was made; and what is more, I very much doubt whether anybody ever did use a sheet of glass to verify or exemplify the rules. The fact is, the only true and pleasing perspective is oblique perspective. So much for lines; now let us take figures. Draw a number of people in a market place; let the picture embrace an angle of about 45°. I maintain, then, even on the same horizontal line the figures should differ in height, and any rifleman will see that at once; for as the figures at the point of sight must be nearer they must be bigger, a little, certainly, but still perceptibly bigger, or your picture will not look true. An angular measurement would show that they are so. For convenience, however, in parallel perspective we must in most cases disregard convergency, although when wishing to convey the appearance of great height I strongly advise it.

Now as to the compromise question. There is no illusion better known than that respecting the slope of mountains, and few people who look at steep mountain sides are aware how much less the inclination is than it appears to be. In painting mountain scenes the artist is justified in giving the apparent and not the real slope. Then as to colour: it is absolutely impossible to imitate the colours seen in nature, for they are the children of light, and we have only a dark surface for our brightest light, and dirty paints for the colours of the spectrum. If we can match a colour tolerably well, we must not do it, because to match one and not all would be to introduce a false note. Having no light, no decent colours, and what is still worse, never the true complementary colours, we can only produce something suggesting what is seen in nature by never representing any one thing very truthfully. Whenever this rule is forgotten, we receive a shock to our pictorial nerves, as we do when an artist paints to the "life" a cold round of beef on a tablecloth spread upon "suggested" grass. M. Paris.

[The above letter was in type before the note at foot of let. 4605, p. 489, appeared.]

UPWARD DEFLECTION OF BULLETS, &c.

[4624.]—None of your correspondents appear to have hit the nail on the head. I, therefore, send the following extract from a work by General Hay:—

"There is another point of great importance with regard to the range of elongated projectiles. It is asserted by Sir W. Armstrong and others that at certain low elevations the range of an elongated projectile is greater in the atmosphere than in vacuo, and the following is the explanation given by the former of this apparent paradox: 'In a vacuum the trajectory would be the same whether the projectile were elongated or spherical, so long as the angle of elevation and the initial velocity were constant; but the presence of a resisting atmosphere makes this remarkable difference, that while it greatly shortens the range of the round shot, it actually prolongs that of the elongated shot, provided the angle of elevation does not exceed a certain limit—viz., about 6°. This appears at first very paradoxical, but it may be easily explained. The elongated shot, if properly formed, and having sufficient rotation, retains the same inclination to the horizontal plane throughout its flight, and consequently acquires a continually increasing obliquity to the curve of its flight. Now, the effect of this obliquity is that the projectile is in a measure sustained upon the air, just as a kite is supported by the current of air meeting the inclined surface, and the result is that its descent is retarded, so that it has time to reach to a greater distance.'" T. S. Usborne.

EDIBLE MUSHROOMS OF ITALY.

[4625.]—In England, though fungi are abundant and various, only two are used as articles of food, and these two are, perhaps, the least savoury of the edible mushrooms. The reason of this exclusiveness appears to depend principally on the ease with which the common and fairy-ring mushrooms can be distinguished from their poisonous congeners. On the Continent, and especially in Italy, various kinds of delicious mushrooms are constantly to be found in the market, and form a pièce de resistance in all the fare bills of the restaurants, be they of the better or of the lowest class. The best and most easily recognisable fungus is certainly the porcino (*Boletus edulis*), a very compact, full-flavoured, and nourishing mushroom. When full grown it is about 8in. in diameter, with a brown cap, and pale sulphur-coloured gills (resembling in texture fine brain coral). The stem is very firm, and measures 8in. in circumference. Raw, the smell is like cedar wood; cooked, the taste and smell are like the finest paté de foies gras. The usual mode of cooking is to slice the porcino very fine, stew for a short time in butter or oil, and then add parsley and garlic (chopped), salt and pepper, to liking. So "meaty" is the flavour of this mushroom that it serves to flavour potatoes, rice, &c., as well as a meat stew would do. The next in the order of culinary merit is the "reale" (*Amanita Cesarea*). This curious fungus at its first appearance on the ground looks exactly like an egg. In twenty-four hours the white top splits open and discloses the bright orange cap, which then presents the

FIG. 1

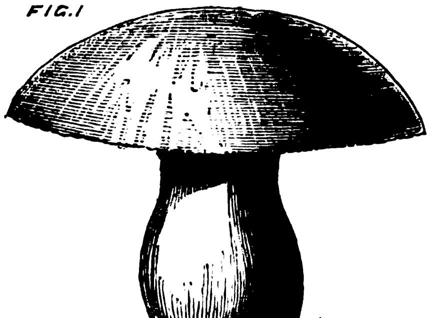


FIG. 4

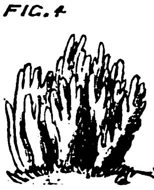

FIG. 2

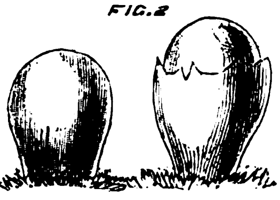

FIG. 3

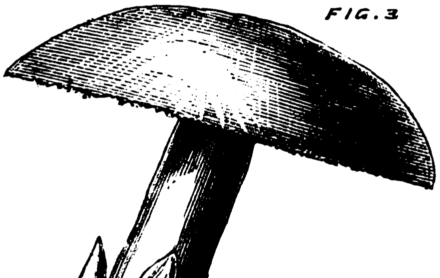

appearance of the yolk of an egg (boiled hard) laying in its white. In another twenty-four hours the stalk has shot up, carrying with it the yellow cap, which expands until its diameter is about 6in. Fried, the taste of this singularly beautiful mushroom is almost indistinguishable from that of a good egg. Both this and the former are largely used in the manufacture of Italian pickles. They are also preserved for winter use by immersion in strong brine. Besides these, the common puff ball (*Lycoperdon*), the "fingers" (*Mannine*), are also much used.

Most of these are found in England. I have myself eaten the *Boletus edulis*, gathered at Wimbledon, in the strip of wooded land which now forms the Wimbledon Wood. Puff balls are also abundant there.

The annexed figures give an idea of the peculiar forms of these Italian fungii. Fig. 1 is the porcino; Fig. 2, the reale; Fig. 3, the same fully expanded; and Fig. 4, the *Mannine*. S. Bottone.

THE HARP.

[4626.]—Many beautiful things perish that it would be desirable to preserve. The piano, which, after all, is a harp in a box, in fact, an improved dulcimer in its best forms, is indeed a miracle of human ingenuity and ability. I do not at all purpose to set up the harp in opposition to it. I want the harp to live as well as the piano, and it has merits which commend it to that distinction. For the price of one good piano you may have, perhaps, a score of harps, gladdening as many families and as many performers. A well-made harp will last four times as long as a well-made piano. It can be carried about. It can be taken into the garden, or from one chamber to another. The harper begins by tuning his instrument, which, therefore, is always in tune when played upon. The pianoforte player, however, unhappily does not know how to tune his instrument. Fancy, then, the effect in a piece of music of even one string out of tune. But oftentimes there are many strings so; in the country or in a colony, therefore, the instrument (speaking of the piano) too often falls far short of being the comfort which it ought to be, which, under like circumstances, a harp would prove. But even in towns the piano is very often out of tune. The player, let us only reflect, is not taught to tune his instrument. In other respects tuners are not always at hand. Economy keeps many persons from sending for them, and learners are too often condemned to play on discordant instead of accordant instruments. The result is painful to the listener, and tends to injure the learner's ear, as no performance can possibly prove satisfactory on a tuneless or partially tuneless instrument; in fact, the money paid to pianoforte tuners, too often needed afresh when their backs are just turned, would do more than meet the interest on the money that a harp might cost. A good performance on a good piano in perfect order is, indeed, a treat. Nevertheless, its sister the harp, which I would bespeak in especial for dwellings which cannot afford a good piano—and any other is not worth having—is capable of yielding results which the piano, whatever may be its perfections otherwise, cannot realise.

On the thirty-six string harp the rule is to take the fifteenth string, counting from the top down, as the key-note, and make it G by means of a tuning fork. Lest the wires should not bear this tension in the upper octaves, the fourteenth string may be tuned as G in the first instance, thereby reducing the tension throughout. When the harp, however, is strung with sufficiently fine and well-tempered wire, it will bear the full concert pitch, the more so as I believe this pitch has of late been reduced. And I may here mention at once that the eight lowest strings consist of No. 18 wire, the next six of 20 wire, the next seven of 22 wire, the next seven of 24 wire, and all the rest of 25 wire brass or steel. The strings are secured at one end to a common turned perforated wire pin, with square shoulders to yield a purchase to the key, and a second pin with a notch on it to serve as a bridge, for all the world like an Erard harp, that may be seen in any music-shop window. The lower end of the wire, secured to a bit of wood about an inch long and a quarter inch wide, is first attached.

The advantage of taking the fifteenth string as the keynote is that the highest note at the top is G and the last note in the bass is also G. In some of Egan's improved harps, however, two additional strings below low G were added, making thirty-eight in all, and thus rendering the instrument more complete. I have one of Egan's harps. Egan himself is now no more, but I found one of his workmen in York-street, Dublin. His daughters were seamstresses, and this workman resided with them. He offered to supply a superior harp for £10. An equally effective but not so handsome an instrument may be constructed for a considerable less sum. By looking at the French harp a constructor might borrow many hints as to the pins and general arrangement. The wire strings at their lower ends are passed through holes which must either be made in a metal plate, else triangular bits of tin must be thrust into the wood above the aperture, to bear the immediate stress of the string. Apertures also must subsist in the back of the sounding box to permit the introduction of the hand and the proper adjustment, which is easily managed, of the lower end of the string.

The key of G with one sharp—viz., F♯, is the only key in which the Irish wire harp, in fact, is played. Possibly the Welsh arrangement of multiple strings might suit. I do not myself think it would suit, and, as for pedals, they are out of the question along with wire strings. In tuning the Irish or wire harp the octaves are first tuned in unison, beginning with G, fifteen strings down, then tuning the octaves up and down correctly. The fifths must then be arranged, then the thirds. The F♯, however, it must be recollected, only accords with the fifth below. But any tyro in the art of music and, *à fortiori*, any professor of music, can set this matter right. The music would have to be arranged for the key of G. Irish performers always play the treble with the left hand, the bass with the right. On the French harp the treble is played with the right hand, as on the piano. But this is of no particular moment. Any harp music in the key of G will suit the wire harp, and any professional man is competent to instruct players. The fingering, so far as I know, is the same in respect to all harps.

In regard to the Irish or wire-harp, the length of the pole or pillar is some 5ft. or so from base to summit. Its length depends on the length of the soundboard or box, and that again on the length and curvature of the comb. The lowest G string is 4ft. 6in. long, the next G is 3ft., the next G 1ft. 8in., the next G 10½in., the next G 7in., and the highest G 3in. The length of the soundbox is about 4ft., its breadth below 13in., and depth 7½in.; above its breadth is 3½in., its depth 2½in. The comb is 2ft. in direct length; but it has a vertical as well as lateral curvature or slew, which adds to the absolute length. Its depth is from 3½in. to 4in., and its thickness about 1½in. It is, furthermore, built in vertical sections, breaking-joint (say) of oak or mahogany, so as to add to its strength and permanence. The pillar may be of oak, the soundboard or box of pine. The soundbox is tapered from bottom to top, the front is rectangular, the back curved. But in the copy which I have of King Brian's harp, and which must have been jewelled at the end of the comb, the back is rectangular as well as the front. The whole, speaking of Brian's harp (the belly excepted), is richly carved, and all the harps have an ovolo or chamfer running along the upper edge on both sides. On the whole, the Irish or wire harp is capable of very sweet effects; of quick as well as slow music, diminuendo and crescendo passages alike; of shakes, arpeggios, and harmonics; and even in the key of G, that in which it is commonly (I might say always) played, it is capable of producing almost every sweet and gracious cadence fitted to cheer and solace, so far as music is fitted to do so, the heart of man. Ixion.

[4627.]—I may add to "Vertumnus's" reasons for the harp (ancient or modern) having fallen into disuse, the following:—A person having learnt to play on that instrument must either carry it over his shoulder or employ a man to convey it for him, if he ever wanted to exhibit his skill in other houses than his own. I began to learn the harp, but discontinued doing so for this reason, none of my friends possessed such an instrument, while no one was without a pianoforte. It's not "convaynient!" F. F. C.

AN IMPROVED BEEHIVE.

[4628.]—In continuation of my letter (4187, p. 251), and as a reply to our friend, E. T. Grays' letter (4371, p. 354), I herewith give answers to his questions, and comply with his desire as regards the promised honey-taking machine, accompanied by other small necessaries.

1. If the bees are in a hive, procure an empty straw hive or box, turn the hive with the bees in upside down, and place the empty one over; then by a continuous tapping or knocking on the undermost hive the bees will at once ascend into the upper one. As soon as this has taken place, and you are satisfied that the queen has ascended, remove the upper hive gently, at the same time putting a cloth over to avoid letting the bees out again. Set the hive in an upright position while you prepare as follows. If possible cut some of the combs out of the old hive, and as near as possible fit them into the new frames, then place six frames in the stock-room (three over and three under), procure a piece of oilcloth (say 2ft. by 3ft.), lay this on the ground close behind the new hive, then bring the hive or box with the bees in, and quickly and carefully remove the cloth, and in the same moment strike the hive sharp down on the oil-cloth, when all except a dozen or so will lay on the oil-cloth. Take hold of the two sides of the oil-cloth, and tumble the mass of bees into their new house. Place the window in its position and close the door; leave them to arrange themselves quietly, looking at them in about six hours' time to see that all is right, when you will most likely find them clustered and building new combs. When a swarm is obtained the proceedings are the same, only easier.

2. It might be an improvement, though not necessary, and would be more expensive; my bees have wintered over when there has been 10° below zero of frost, in hives of wood 1in. thick.

3. There is no advantage in having longer frames. In the improved hive there is ample space for brood; better have more hives in better order than larger ones in disorder.

4. As regards loss of heat, I have not noticed anything of this sort; but in Woodbury low, broad hives, I have had my bees destroyed, and lots of honey in the hive, the area having been too great for them to travel over in the severe cold. In the improved hive the partition boards being closed, and the honey-room filled with warm material, is sufficient.

The honey-taking machine will be easily understood by referring to drawing (Figs. 1 and 2), showing side and end elevation. A is a revolving, upright shaft, worked by means of the bevel wheels E, and handle D, or simply by handle F, where wheels cannot be procured; B is the can in which the honey is caught when driven out by the centrifugal force as shown. The can is 8in. deep. The frame, with comb and honey in, is laid flat on a perforated plate, which is supported by small angles of tin-plate, 2in. from the top of the can, as shown. The four distance-pieces pass through holes made to correspond, so that the comb rests flat on the perforated plate. The holes in the plate are five-sixteenths of an inch in diameter, and the seven-thirty-second part of an inch from centre to centre. C is a sliding weight to balance the can and honey on the pin or centre H; the dotted lines show the can in repose, when not revolving. The speed is about 100 to 150 revolutions for the can; this drains the combs thoroughly, and the frame and comb can at once be replaced in the hive to be filled again.

Figs. 3 and 4 show a contrivance I have, which may suit others, for diminishing or closing the entrance of hives as the winter approaches. I is a revolving square on the centre O', fixed the sliding door K, which is shown down, or covering to the entrance, except for one bee to pass at a time, when K is raised as high as the slots L will allow. I can be turned to suit any of the three sizes of opening, or in winter can be closed entirely, except the perforations. The dotted lines show the entrance behind K. This simple contrivance saves all trouble of narrowing the entrance by means of stones, sticks, &c., as one often sees, and to the great annoyance of the bees. The whole slide is of zinc, and is neat and effectual.

Figs. 5 and 6 show a frame fork for taking out and setting frames into the improved hive, and the mode of using will be easily understood by looking carefully at the sketches.

Fig. 7 is a very useful little tool. I call it a guide layer. It is used as follows:—Small pieces of clean wax are put in at P, until half full, it is then held over a candle or lamp at R until the wax is melted, when we take a frame and draw the nose S along the middle inside, thus leaving a small string of wax as a guide for the bees to build by. This I have found much simpler and better than gumming or glueing strips of old comb or wood as a guide inside frames, and the bees build much more accurate from this mode, and prefer frames with this sort of foundation. In a hive where I tried three frames (one prepared thus, a second with a strip of comb carefully glued on, and a third with a thin strip of wood one-sixteenth of an inch square glued on. On the first they built a beautiful comb at once; the second they did not rest until they had peeled every morsel off; and the third they took no notice of, and on removing the second and third, and giving them frames prepared by the guide layer, they commenced and built beautifully.

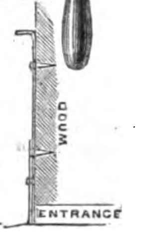

FIG. 6

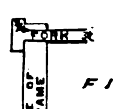


It may interest some, and, perhaps, encourage others, who have a silent doubt about the improved hives, when I state that up to the middle of July there has been 95lb. of honey taken from one hive this year. I have little doubt that before the season is over the same hive will yield 10lb. more, and 25lb. will then be left for winter use. Thus the hive will in one season yield 105lb. saleable honey, or a total of 130lb. collected in one season.

It would be interesting if our friend Mr. Abbott would give us a few lines on the best mode of supefying bees by means of chloroform.

Also, can any bee-keeper say or explain why bees are so vicious at the time of collecting honey from buckwheat? At all other times I can tumble them about as I like, but while buckwheat is in season there is no going near them without a head-dress.

Nyborg, Denmark. Bee-Keeper.

LIGURIAN BEES.

[4629.]—Having become a reader of the English Mechanic, and finding that the subject of bee-keeping is widely interesting to your readers, I venture to give you an instance of success which to me is surprising.

Having kept black bees in Woodbury hives for four years with but indifferent results, as good, though, as I supposed our locality admitted of, I suddenly became ligurianised, and early in the spring applied to Mr. Abbott, of Hanwell, for a ligurian swarm. It arrived on April 28. Wretched weather followed, when I "tickled not their nostrums with a feather," as Tom Hood says, but their palates with "soothing syrup," of which they had about 4lb. to keep them in heart and hope till brighter times. As soon as fine weather returned, not wishing to pauperise the little community I left them to shift for themselves. It was not long before the hive was well filled, and they seemed to have an emigration scheme in contemplation which, however, was given up in consequence of some rising young bees, soon after I had placed on a Woodbury super, discovering that their house had a story more than the community generally supposed. This additional space was filled by about July 10, when the bees commenced hanging outside very thickly. On the 15th the super was removed, containing eight splendid combs, thick, white, and all sealed, and weighing 44lb. without the honey board. Tare about 4lb. I now tried the weight of the hive (straw Woodbury, but you may guess my dismay, not unmingled with satisfaction, at finding my weighing apparatus not equal to the occasion—60lb. being its limit, and my hive weighing more. No need to feed, clearly, and thinking that perhaps more could be done, a bell-glass, 7in. in diameter and 7in. high, was placed on next morning. This contained a good-sized piece of new but dirty empty comb. This super to-day (July 26) is filled with comb, all stored and nearly half-sealed. When finished it will weigh 10lb. net. The sweets of bee-keeping ought to be honey and sugar. If all swarms behaved like this one, bee-keepers would get a little of both.

Avenue House, Acton, W. F. Cheshire.

CO-OPERATIVE STORES.

[4630.]—Mr. R. R. Smith produces (in letter 4570, p. 465) excellent reasons, though not new to me, for calling things by their own names, and against calling them by other things' names, and against the endless mutual delusions, superstitions, and knaveries, and polluting debasements of soul thence bred. If a tenth of 3s. 8d. be assumed, as he assumes it to be, in this particular case, the just remuneration for the work described, then this neither denotes 10 per cent., nor 5, nor 15, nor any particular percentage to be more proper than another, or proper at all, to be charged "upon the cost price." It would simply denote, if his facts were a true average specimen of the business (which of course they are not), that a farthing *a parcel* was a shopman's just due—the same for a half-ounce parcel as for a half-stone, or half-quarter. Of course this is not the case, and whoever gets a parcel, large or small, from the shopman for a farthing over the wholesale value of its contents, robs him. But to be robbed is what one who reasons no better, and has no worthier aims, is made for; and what we must always, while he is such, hope and pray, for God's and man's sake, and soul's and bodies', and society's, and everything's sake, may continue to be his lot till its lesson is learnt.

As for his difficulty about coinage, if he could get and read an American pamphlet called "Equitable Commerce," or some others by its author, Josiah Warren, of Massachusetts, he would find that any coinage difficulty has been and would be soon solved, wherever there are labourers reasonably sober and in earnest, by their leaving the metal coin to those who desire it. None can make it necessary to commerce or life, where labourers are wise and in earnest. It is one of the grossest of superstitions, though taught even in universities, that coined money was either invented to facilitate, or ever did facilitate, exchanges. It was invented with no such aim, but solely for paying taxes; and its use in commerce anywhere has been purely accidental, secondary, and unneeded. The works of Mr. James Taylor, and even his small pamphlet entitled "Political Economy Illustrated by Sacred History" (Seeleys, 1852), establish this very clearly. Indeed, great commercial nations, as Egypt, Assyria, China, attained their highest refinement and power without using coin. The two former had no coin till their conquerors, the Persians (its first inventors), imposed it; and in all ancient lands it was the badge of conquest. The Old Testament *shekel* was a weight, and no coin to be reckoned by tale, till after the captivity.

While the most mischievous superstitions, as this of the utility of coin, are left untouched, attempts are made on every side to dub as "superstitions," and so to hide away, such damning and unalterable truths as the essential defilement in the touch of all "trade" as now understood; that is, all remuneration by percentages on anything, or rather, by *unfixed, unpublished* profits, instead of definite and publicly known fees or wages, a fixed fee for a fixed service. It is the height of at once absurdity and immorality to set forth (as I have seen the *Examiner* newspaper do) that there can be any trader, as the word is now taken, any of the class Adam Smith defined (Book I., chap. 6) as receiving "profits of stock," whether the poorest or the wealthiest in England, who is not a lower creature than any not so receiving—any professional man or labourer, the poorest. He is as essentially a lower order of creature, as a fox is lower than a S. Bernard's dog; nay, more so, because he is not, *quà* trader, a creature of God. The Creator has made men, maps them to be labourers, and professional men, and even, in a more limited sense, made kings, and with still more limitation we may say, slaves, slaveowners and even landowners; but He has made none a trader (*i.e.*, "profits-of-stock" receiver, or of *dead* stock, in the senses so carefully defined by Adam Smith in the above chapter), nor anywhere made it necessary there should be any such person; especially not any with dark receipt thereof—that is, in concealed or *unpublic* amounts, great or small. *That* is the black polluting element affecting the shop and all connected with it, the darkness of the opaque till, not transparent like the professional man's. The *choosing* of that opacity—choosing darkness rather than light—is what constitutes the "trader" essentially a baser being; not defiled by what entereth into the man, but by what cometh out of the man, his *choice*. This is why we have a degraded caste, not in the vaguer sense the word may be applied to the outwardly ragged, but degraded in soul, polluted and polluting—a truth it is worse than useless to hide, since it must survive and rule both the rise and destruction of twenty "nations of shopkeepers." And a degraded class means, observe, a class that *ought not to exist*—one whose existence all godly men must seek to make more and more difficult, till, by God's blessing, it is made *impossible*. This is why I hold, and have always held since being of an age to even look at Adam Smith's book or its subject, that combination against the trader class, and for the restraint of "trade" as now defined, is the only *religious* act possible to us English of these days, the only worship of the Almighty; because the only work really for, and *not against* His creatures. In all other so-called philanthropies, and godlinesses, and faiths old or new, from an "Order of S. Benedict" to one of Comte, the 85 "Christianities," the priesthoods, dumb on all living iniquity as bees alighted on honey, beating the air, and prodding only at dead Satans, I can see only the live Satan's laughing-stocks and very welcome allies. Show me a body of men that are making less "profits of stock" possible—an Antonio of whose acts a Shylock might complain "he doth bring down the rate of usance here in Venice," action that tends to a lessening the gross source of "Schedule D" income-tax, or, in short, makes but one penny of "profits of stock" grow where twopence grew before—and *there*, I hold, is Divine Service, but nowhere else in this many-altared land and day of ours. Every workman who is combining with no fellows to prepare any such union as I described in let. 3044 (No. 348), but looking to have always an "employer" (or worse, to *be* one), or lazily swallowing, as creed, respectability's fundamental assumption, that one man's capital must employ other men with none, and that employer and labourer must be two men, is by every day, whether of work or "strike," only riveting the chains of his brethren, and children if any, strengthening the hands of their devourers—*i.e.*, the enemies of mankind, "ghostly and bodily," as our catechism saith, and furthering, to the utmost that in him lies, the reign of all iniquity and misery. And every one, workman or not, who is combining with no others to supersede the butcher, the baker, and every adventure-shop in succession, by establishing shops and shopkeepers of their own (each the customers' own property and hired servant) in some such way as I described in let. 4080, is one who, hitherto, I hold, had better for mankind not have been born, even if he have given us more than Peabody.

God's servant Etienne Leclaire is gone, and according to the *Pall Mall Gazette* some officer from Versailles appointed to succeed him, and so the "Maison Leclaire," to be stereotyped, probably as a kind of almshouse, at the point to which he had brought it, with a permanent "Devil bribe" (let. 3044, rule 3) of 25 per cent. Now, of course, wherever there shall be a competition of divers Maisons Leclaire, which there must be in each trade or manufacture, in every place that is to become anything but a social hell and permanent trap-door to hell below—the first factory of men good enough to keep their capital together by a 20 per cent. bribe will undersell those that need 25, and thus, competition in righteousness, instead of in dark pelf-filching, will gradually bring down the "rate of usance," which means bringing down all evil, and advancing all good. The writer (let. 4570) complains of a wrong mode of competition making traders worse. Pray, who has *chosen the ground* of competition? E. L. G.

ARTIFICIAL MANURES.

[4631.]—I am much obliged to Mr. Allen (let. 4565, p. 465), for the notice he has taken of my letter on this subject (p. 381); but I beg to assure him that the "heresies" it contains were put forth for a purpose—a purpose which will be partly served, if I can obtain the attention of chemists and others, who may be able to experiment on the question whether plants require nitrogenous manures. I think one of the first "facts" in connection with agriculture which I learned to appreciate, was that the most valuable manures at present known are those containing nitrogen—and that for cheapness and ease of application the salts of ammonia were the best. Since then, however, many facts have been brought to my notice, which, though not exactly converting me from an opinion, the truth of which has been proved over and over again in practice, suggest the idea that by some means or other, yet to be discovered, plants may be made or induced to obtain all the nitrogen they require from the abundance of the atmosphere. An interesting article from the pen of Mr. G. E. Davis, on p. 400, of Vol. XIII., contains the particulars of some experiments in this connection and a clear statement of the hypothesis. I presume that he has been too busy of late to make further investigations, which must of necessity occupy much time. M. Deherian (see p. 314, *ante*) also propounds a theory to account for the fact that plants do contain more nitrogen than was contained in the manured earth; but Mr. Davis's paper is the more complete, and I commend it to the attention of Mr. Allen and others interested.

I expected to be severely censured for the heresies in my letter, but at present they seem to have fallen on unprepared ground. The one idea which underlies the vague notions I have hitherto formed, is that some "manure" may possibly be discovered, which will enable the plant to absorb nitrogen from the atmosphere; if any one can turn on a little "light" or knock the idea on the head, I shall be obliged.

In reply to Mr. J. M. Taylor (let. 4527, p. 438), I have had no experience with the manure obtained by Moule's system; but I have seen the extraordinary results obtained by the use of the sewage tank. Blood manure seems an excellent thing for roses, at all events. But I commend to his attention the article on p. 219 *ante* on the experiments at Blennerhassett farm, and the reports of those carried on by the public spirited enterprise of Mr. Lawes at Rothamsted. At the latter place, plots of ground have been fertilised with various manures, and crops of corn grown upon them for twenty-eight years in succession. In the table published in the *Gardeners' Chronicle* the average production for the last twenty years is given, together with the yield of last year (the 28th season). The weight of the grain per bushel is not a matter of much moment here, where space is an object, but it is worthy of note that the highest weight (60lb. per bushel) was obtained only from corn grown on land fertilised with farmyard manure (14 tons per acre). The best yield from *artificial* manures during the twenty years' average was obtained from a compound of the sulphates of potash, soda, magnesia (200lb., 100lb., 100lb.), 3½ cwt. of superphosphate, and 600lb. of ammonia-salts (sulphate and muriate equal parts), per acre. This manure produced on an average of twenty years 38¼ bushels of corn per acre, as opposed to 36¾ bushels obtained from a similar manure in which the 600lb. of ammonia-salts was replaced by 550lb. of nitrate of soda. The other ingredients of the two manures were exactly the same, be it understood, so that the ammonia manure gave 1½ bushel more than the nitrate of soda manure; but here it must be pointed out that the 550lb. of nitrate of soda is equivalent to only 400lb. of ammonia-salts, and on looking to the experiment in which only that quantity of ammonia-salts was employed (the other ingredients being the same), I find that the yield was only 35¼ bushels, or exactly 1½ bushel *less* than the soda manure. But now comes the clincher. In the 28th season the yield from the manure containing 400lb. of ammonia salts had fallen to 22¼, that from the 600lb. to 27⅛, while that from the nitrate of soda manure had only fallen to 34½ bushels, giving the latter an advantage of 12¼ bushels per acre (2lb. extra per bushel as well) over the manure containing an equal amount of nitrogen in the shape of 400lb. ammonia salts, and an advantage over even the 600lb. ammonia manure of 7 bushels. Nor is this all. The yield of straw which in the twenty years had shown an average of 35⅜ and 41⅜ cwts. per acre, for the 400lb. and 600lb. ammonia-salts, and 41½ for the 550lb. nitrate of soda manure, had fallen in the 28th season to 27½ and 35⅛ for the ammonia manures, but had actually increased to 43¾ for the nitrate of soda manure. Nor even is this all? When 550lb. of nitrate of soda *alone* was tried against its equivalent, as far as nitrogen is concerned, of 400lb. ammonia-salts alone, the yield was 26 bushels against 22¼ from the latter—the average result for twenty years; but when the 28th season is reached the nitrate of soda gives 17⅜ bushels to 10½ from the ammonia salts. On another plot, however, ammonia-salts (400lb.) equalled the 550lb. nitrate of soda (taking into consideration the weight of the grain) during the twenty years, but fell off to 10 bushels in the 28th season. The weight of straw produced by the nitrate of soda also had the advantage during the twenty years, and was about double that from the ammonia in the 28th season.

Those old-fashioned farmers who look to the manure heap for fertilising materials, and keep cattle in sufficient number, will "take heart again" when they find that the plot manured with "farm yard," at the rate of 14 tons per acre yielded 35¾ bushels (60lb.) per acre (¾ more than the compound containing 400lb. of ammonia salts), and was not merely the *only manure* which kept up its average to the 28th season, but stands out prominently as the one manure which gave an increase over the 20-year average, the figures being for last year 39 bushels of 60lb. corn with 40½ cwt. of straw. This letter is however, running to a greater length than the editor will like, but I must mention one thing that bears on my "heresy." One plot "unmanured continuously" for 28 years actually yielded last year 10½ bushels per acre, or *three-eighths of a bushel more* than the best of the two plots annually supplied with 400lb. of ammonia salts gave during the 28th season. The difference was actually greater, for the corn from the unmanured plot weighed 2lb. per bushel more than the other. To avoid misunderstandings, I mention again that the 28th season means last year, whilst the average has been struck for the 20 years ending 1871. I shall be glad of any information on the subject, but I have said enough for the present, and only wish to observe that my "heresy" has at least as good a foundation as many of the dogmas we have recently had in the English Mechanic.

Saul Rymea.

THE COMING STRUGGLE.

[4632.]—The editor of the *Meteorological Magazine* has just announced the fear that signs are impending of a "coming struggle" between the authorities of the observatories at Greenwich and Kew, which, if ripened into actual hostilities, would seriously impede the progress of Science! The Astronomer Royal has, it appears, pronounced the magnetical and meteorological observations at Greenwich to be "the best in the world;" while of the Kew observations the editor of the *Meteorological Magazine* remarks that "practically it has no published results by which it can be judged." If so great a disparity exists between the two observatories, we ask in the name of Science, where is there room for struggle? Will the younger sister seek to put a stop to the continuous and systematic course of meteorological observations carried on at the far older observatory, or will the elder sister seek to render nugatory the efforts of the more recent establishment? "To sum up the whole argument," says the editor of the *Meteorological Magazine*, "we consider the two observatories have essentially divergent objects: Greenwich, the continuity of observation and information respecting secular changes; Kew, the verification of instruments and original physical research."

The most important subject for consideration is the serious impediment to the progress of meteorological science likely to result from a struggle between the two observatories. May we not ask ourselves the following question: What if the authorities at Greenwich and Kew be at issue with each other, are we to consider that meteorology will suffer to the extent supposed? If Greenwich be the model meteorological establishment, which it undoubtedly is, can it supply the data, *except for one station*, for elucidating those questions in meteorology which have led to the appointment of the Meteorological Committee and the establishment of the Meteorological Office? The science of meteorology needs a broader basis than either the observations at Greenwich or Kew can supply; and even with regard to the secular changes which Greenwich from its long-continued series of observations is best able to elucidate it is necessary to remark that such elucidation can only have reference to the spot on the earth's surface on which the instruments are planted. With the machinery in daily work at the Meteorological Office the most splendid results may be realised. There may be and doubtless is room for great improvement, but if ever meteorology is elevated into a science of induction and prevision, as her elder sister astronomy, it must be by the employment of a large number of observers at distant stations forwarding their observations to head-quarters three or four times a day. So far as observation is concerned, an establishment of the nature of the Meteorological Office is better calculated for elucidating the meteorology of a country than an isolated series of observations at a single station. Nevertheless, for determining the numerical values of the meteorological elements the Greenwich observations are unrivalled. It is generally admitted that meteorology is but in its infancy. Now, an infant needs nursing, and it is a sorry sight to see the nurses leaving the infant to do the best it can while they settle their differences as to the best mode of nursing it. It is to be hoped that no difference will arise between two of the principal meteorological establishments of the country; but, to use a homely phrase, the Committee and the Office will give "a strong pull and a long pull, and will pull altogether," to advance the science which they cultivate.

W. R. Birt.

PIGS, RABBITS, AND SHELL-FISH.

[4633.]—I have been waiting with some degree of impatience, hoping to see this question taken up and exhaustively examined by some of your medical readers; but save the short reply of Mr. Bottoza, which gave what I may call the chemical view of the question, we have had nothing more than the hackneyed phrases which have been used almost from time immemorial in condemnation of pigs, rabbits, and shell-fish. I confess that I was slightly astonished when I read the remarks of "Sarah" on p. 283, because, although I had heard remarks in disparagement of rabbits and shell-fish, I had no idea that besides being "coarse and impure diet" they exercised a "vile and lowering influence on the mind," and consequently are the cause of much "crime and misery" among the lower orders. Looking through spectacles of a different tint to "Sarah's" one might be inclined to suspect that much of the "crime and misery" was originated by insufficient supplies of food, which cheap rabbits and shell-fish would go a long way to counteract. Be this as it may, however, "lobster" has had to answer for a great many evils shrewdly laid at its door, and so has the salmon, the king of fish; but how either of these articles of food can be capable of producing a lowering influence on the mind I do not understand, although I quite appreciate the force of Byron's lines—

> Who'd pique themselves on intellect, whose use
> Depends so much upon the gastric juice.

A great point seems to be made of the wisdom which forbad the Jews to partake of pork, while other specimens of the self-same wisdom seem to be utterly ignored—for instance, the blood question. But as a matter of fact, man was permitted to eat all kinds of animal food which he lusted after for some years before the laws detailed in Deuteronomy were promulgated; and besides, the pig is looked upon as an unclean animal unfit for human food by other Eastern nations (was this wisdom, too?), but was certainly used in Palestine for some purpose or other between B.C. and A.D. 29. But into this "wisdom" part of the question as affects the Jews I do not care to go. I imagine there may be climatic reasons why the pig is not suited for food in hot countries; for it is very certain that he is a favourite source of animal provender in northern and cold regions. The cause of this general favouritism is the very simple fact that of all domestic animals, the hog (*Sus scrofulosus*) is able to accommodate himself to circumstances, and to put up with the very "narrowest" of these without becoming thin and melancholy. He will live and thrive on all kinds of food, animal and vegetable; his stomach will digest what other and probably "choicer" animals cannot swallow without danger. He is very prolific, and readily fattens on good food; and from China to the western prairies of America he forms a girdle round the earth, and is eaten alike by the most refined and the most debased of nations. By what process a pig can turn barleymeal into unwholesome flesh is for his opponents to explain; for given a healthy pig fed on wholesome materials, and can any one say that he is more liable to disease than the domestic ox or sheep? (Will "Arotes" say what the "ravages" caused by a pork diet in the Crimean army were? I think the illness there was due to "short commons.") Of course the omnivorous disposition of a half-starved pig will lead him to partake of garbage which will do him no good; but I doubt whether piggy ever had a more deadly disease than rinderpest, pleuro-pneumonia, or foot-and-mouth, and even the Tænia does him less harm than "flukes" do sheep. But piggy is accused of causing consumption (!), skin-diseases, scrofula; he is said to furnish us with round and thread-worms, and the tape-worm—several correspondents writing as if there were but one species of Tænia. I do not feel compelled to offer evidence in refutation of the first three charges at present, because I think the boot is on the other leg, and evidence should first be offered in support. But as regards the charge relating to intestinal worms I beg to point out that a very unnecessary degree of alarm has been spread abroad—or more correctly, perhaps, a *highly necessary* degree, if the public will only make their alarm felt; for so long as pork is alone credited with the origin of "worms" the alarm is mischievous, but if all the likely sources of that and similar nuisances are taken into consideration it cannot fail to be productive of good. Many of your correspondents who would shudder at the idea of contracting tapeworm from eating pork, drink a glass of London water with gusto. But listen now, to what Dr. Cobbold says. He has been speaking of the Russian Cossacks, who to a man act as hosts to the *beef* tapeworm (*Tænia mediocanellata*), and he proceeds: "Fortunately, the adult parasite seldom does serious injury to the bearer; but the larvæ of some of these tapeworms are dangerous, and it is against them, therefore, that we should be especially on our guard. Thus, if you or I were to drink a glass of water containing two or three eggs of the *Tænia solium*, whose larvæ reside in the pig (and we might very well do that, for if there were 1,000 eggs in this tumbler of water you would not see the slightest trace of them with the naked eye) they would become transformed in our interior into cysticerci; and, as they have an awkward habit of betaking themselves to the vital organs, especially the brain, it necessarily follows that they would give rise to serious symptoms." Now, although the *T. solium* is a difficult guest to get rid of, I think I would prefer to play host to the adult, than be a developing-place for its eggs and the habitat of its larva. Besides the *T. solium* and *T. mediocanellata*, there is the *T. echinococcus* and *T. cœnurus*. The *T. echinococcus* resides in its adult state in the dog, but in its larval condition inhabits the ox, sheep, the deer tribe, the horse, the ass, and *man*, to whom it is really of *surpassing interest* (Dr. Cobbold), occasioning the death of some hundreds of our fellow subjects every year. "I take leave to assert, on evidence which I have been at some pains to obtain, that every year 200 or 300 persons die in England in consequence of their having swallowed the eggs of the *Tænia echinococcus*." (Dr. Cobbold).

The *T. cœnurus*, the larva of which is found in the brain of the "staggery" sheep, becomes adult in the alimentary canal of the dog, and is propagated by thousands. The rabbit also acts as host to the *cœnurus*. But enough is as good as a feast. I should not have devoted so much space to Mr. Pig, were it not for an announcement that large quantities of pork are coming from America, which will enable dealers to retail it at 6d. a pound, at which price it will doubtless meet with a large sale. To guard against parasitic worms—cook thoroughly; to guard against unwittingly hatching eggs, mix alcohol with that glass of pure (!) water drawn from any source into which sewage or the drainage water of fields can flow. Thus ends piggy: a great deal of bad meat can be found at market, but no more in proportion than of beef and mutton, and unless your readers can advance better reasons (?) than those already published, I think pork will still be an article of diet in this country.

But what shall we say of the rabbit? What has he done, or what can he do? Well, the rabbit is no worse off than the hare—though the *domestic* rabbit is, probably, like all other animals which man has brought into subjection, more liable to disease than the hare. The flesh of the rabbit is certainly digestible, and though I have heard that it is at times poisonous, in consequence of the animal eating some herb, I beg leave to doubt whether any serious results can be traced to the employment of rabbits as food.

Shell-fish are rightly or wrongly looked upon by many with suspicion; but large numbers of lobsters and crabs, and immense quantities of mussels and periwinkles, are annually consumed without the consumers exhibiting any ill effects. It is true that persons have been poisoned through eating the lungs of both crab and lobster; but surely that fact should not condemn their use as food, any more than an attempt to digest a bullock's hide would put a veto on beef. If the lobster is condemned, why not the shrimp? Mussels are also accused of causing dangerous illnesses, but it is very certain that millions of tons are consumed for food. Probably when spawning, in May, June, and July, they are unwholesome, and the byssus invariably should be removed. Oysters have been always looked upon as a delicate and nourishing food. Cockles are largely eaten, and so are whelks. Shell-fish live on wholesome food, and why their flesh should not be wholesome too I really do not know. The Italians call them the "fruit of the sea;" and, after all, the choice of fish to eat and to reject depends entirely on the flavour of the flesh. Salmon itself is unwholesome, if not positively deleterious, at one period of the year, although that has the requisite fins and scales which the eel (the most delicate-fleshed fish) is supposed not to possess. Why does not "Sarah" condemn the eel—especially the conger—as "vile and lowering?" What shall we say of the ordinary fowl, and the duck, the latter of which will eat almost any offal, and is very nice with green peas I think, "Sarah?" And yet let the duck have a "fishy" taste, and oh, what unwholesome "diet." Depend upon it, the human stomach is capable of extracting nourishment from other flesh and other fish and other fowl than we wot of. The French eat frogs and snails—and consider them delicacies. We eat crayfish and periwinkles. Tastes differ. That is all. SAUL RYMEA.

EYEPIECES.

[4634.]—WITH his accustomed kindness "F.R.A.S." has replied to my note on the subject of eyepieces. I beg to thank him, and at the same time to add somewhat to my query, the further to elucidate this important subject. I assume the image from a parabolic mirror to be truly ~~reflected from~~ the flat or prism; if this be received through the medium of a Huyghenian eyepiece, it will, I apprehend, be somewhat distorted, for the eyepiece is not aplanatic, *ergo*, the image is imperfect. If, however, the Huyghenian eyepiece is applied to the refractor, the object-glass, being imperfectly corrected, receives the necessary correction from this eyepiece, hence the comparatively admirable definition (minus secondary spectrum) of a Dallmeyer instrument. My idea of substituting a complete magnifying instrument in lieu of a non-achromatic eyepiece is not new, but I consider that it has never been efficiently tried.

To "F. R. A. S.'s" obvious objection of want of light, I submit that a wide-angled objective gives an extraordinary amount of light, in spite of the numerous surfaces (that is, six more than an ordinary eyepiece), and I fancied that if sufficient light came through a narrow slit and the numerous prisms of the spectroscopes from a second or third magnitude star, such a blazing object as the sun's corona or the moon would give sufficient. I alluded to the moon, as, if her details could be more effectually solved, we might gain some insight into the difficult subject of the early history of the sphere we live upon. Although I was aware of the law which renders her not the best subject for my purpose, the magnification of the atmosphere is a bar to all forms of eyepieces, and is, in my humble estimation, the fruitful cause of the many wonderful discoveries, spectroscopic and telescopic, we get in popular scientific papers. The late Mr. Ross was of opinion that an achromatic eyepiece was yet wanting to complete the microscope; this has not yet been attained, and I have, after numerous experiments, come to the same conclusion as Mr. Ross. For delicate observations I have long since discarded B, C, and D eyepieces, for I find the acute curves destroy the definition of the finest objectives utterly. I depend upon the A's and lengthened tube for amplification.

"F. R. A. S." will observe that these views are at variance with his observations as to the power Browning's mirrors will bear; he will not, I hope, consider this as a contradiction, but simply that my ideas of perfection are unreasonably beyond attainment at present. BETSY SUMMERCITY.

HEATING BY HOT AIR.

[4635.]—THE idea of heating plant houses by means of hot air is not by any means new, but I believe that Mr. Housman is the first who has carried out in a successful manner. He exhibited a model of his apparatus at the recent show at Birmingham, and has drawn renewed attention to the subject in a letter to the *Journal of Horticulture*. I send an extract in order that your readers may understand the principles of the system, and express their opinions on it.

Believing, he says, that the time has now arrived for a reconsideration of the question whether hot-air heating may not, in many instances, successfully compete with hot-water heating; and having during some years past practically succeeded with a method of air-heating, I was induced to exhibit a model of my system at the late Royal Horticultural Show at Birmingham. I have reason to think that it received some notice from persons well qualified to give an opinion on its merits, and I write this with a desire that the expression of such opinion should be elicited. I am far from claiming superiority in every case; in fact, where a "town" of glass has to be warmed from one source of heat, I see no likelihood of the agency of water being superseded. But for buildings placed in a range, or heated separately, I think from the hot-air system many advantages may be secured which are not obtainable, at least not readily obtainable, from the hot water.

Conceding that some equivalent must be found for the large heated surface of moderate temperature, which is an admitted necessity for successful culture, I submit that such an equivalent may be found in the cooling effects of rapid currents of moist air passing over a gill stove highly heated. It is when circumstances are favourable to the inducing of such rapid currents that I claim the balance of advantage for the hot-air system. If, after constructing a firebox in such a manner that the fire shall not impinge upon metal, we dome it over with a box of wrought iron 3ft. square, we shall have, in addition to the brickwork, a heating surface of 45 square feet. By adding gills, 12 on each side, and 3in. deep, we increase the surface to 185 square feet; and if we can subject this extended surface to the refrigerating effects of a moist current of air rushing over it with many times the velocity of the currents from the ordinary hot-water pipes, we have the means of effecting our object—viz., the delivery of large quantities of not too fervid air. This object once attained, advantages belonging to the system become apparent. The air flue, which, unlike the old smoke flue, requires no special care in its construction, delivers its heat through slides, which by a simple adjustment apportion the supply at will, or they can be made to shut it off altogether—no mean advantage when sun heat meets fire heat on a fickle day. The air so admitted is fresh air, bearing with it the healthful influences of the outer atmosphere, and causing, by the velocity of its incoming, the aërial perturbation so grateful to plant life, and for every gallon of fresh air admitted a like quantity is expelled; so, assuming the area of inlet to be 4 square feet, a like area of outlet will be required, and this is necessarily equivalent in a house 60ft. long to ½in. of top air always left on.

If this system can be brought into successful operation in a small way, it will be just the thing for amateurs growing stove-plants, or for service in the greenhouse on occasions. E. C. G.

"JACK OF ALL TRADES."

[4636.]—HAVING returned to old quarters, I think a letter of thanks is due to the many kind friends who have been so liberal with their donations to keep afloat a fast sinking craft, and have done their best to make me say "Jack's" alive again. I wish I could say "Jack's" himself again, but that is a question of time, and I here take the opportunity to say to all who have done so, May they find friends as kind in time of need! I cannot wish that it might be so, for that would be wishing them a vast amount of suffering for experimenting; but should they ever suffer any of these ills that flesh is heir to, I have every reason to believe the Smedley system recommendable both from its simplicity and efficacy, and should be glad to see it more largely introduced into our private life. I mean upon the self-help principle for assistance (see "Domestic Hydropathy," by T. Preston; Cassell, Petter, and Galpin). It could be arranged at little expense, and I should be glad to assist any who may feel disposed to go further into this treatment, and give my ideal plan of how this may be carried out. Not wishing to occupy too much of our valuable space, I again tender my grateful thanks to all my ENGLISH MECHANIC friends. JACK OF ALL TRADES.

NEW MATERIAL IN ORGAN BUILDING.

[4637.]—ENTHUSIAST to the utmost limit I will allow "Sucram" (let. 4579) to be; but it is cruel as well as useless to send amateurs on a wrong tack. How could a pipe of such material be tuned or voiced? "The Harmonious Blacksmith" long ago mooted the question that a cylinder of any other material than metal would answer. With all respect to him, I am a doubter: the different proportions of metal composition make all the difference in the ring of the pipe, and all the enthusiasm in the world won't bring that quality out of paper. You might get a medium as good as wood, but would it be worth the trouble? The cat may be as good as the king; but, with all the crowning of might and mystery, she still will be the cat. I have said before that pipe-making cannot be done by the ordinary run of amateurs; it must be learned at the bench, and there the amateur must go for his lessons. Perhaps it would be worth "Sucram's" while to try a metal top and foot to a wood cylinder. The question is, how will it work? The use of the cone must sooner or later interfere with it.

HENRY USSHER, B.A., M.B.

CONDENSATION OF STEAM IN PIPES.

[4638.]—MR. TURTON (let. 4542, p. 461) will find, on inquiry, that though the problem of converting high pressure steam into high pressure air is not fully solved, a very large percentage of usefulness is got out of compressed air, and by the ordinary compression pump suitably applied. For a pump to do next to nothing half its stroke is a serious defect, and how this defect should be inherent in every form of pump, I would like Mr. Turton to show. To solve the problem, Mr. Turton supposes as probable the application of the principle of the injector. But before "A. W. E." (let. 4457) tries this, or any other application in which steam has to be used with compressed air, I think something definite should be known as to how the two comport themselves when used together or mixed. How can this information be got? Will an answer to the following query lead to it? If so, perhaps some able correspondent will give it. There are two cylinders of the capacity of one cubic foot each, attached by an inch pipe, with a tap to connect them when required. One contains steam at 50lb. pressure, the other compressed air at 70lb. When the two are connected, what takes place? What change in the steam, the air, and the pressure? OHIO.

IS THE MOON SPHERICAL?—To MR. W. R. BIRT.

[4639.]—I SAY "No"—and pledge myself to prove it.

CH. RABACHE.

ANTIQUITY OF MAN.

[4640.]—I beg to inform "F.R.A.S." (let. 4405, p. 380) that I have no theory on the subject, but am simply looking for information. It is indifferent to me personally whether man has been 8,000 or 100,000 years upon the earth, but I should like to know which is nearest the truth. I have not Lyell's book by me for reference, but what I gathered from it was that he gave fair evidence from records of excavations in Switzerland and elsewhere for an antiquity, on a rough calculation which did not assume to be correct to within three or four centuries, of between 7,000 and 8,000 years. This is all I could find reasonably fair proof of. Anything further, as the conjectural period of 100,000 years or much more, was too much founded on guesses, theories, opinions, and too little upon actual evidence, to be relied on.

From the accounts I have read or received from scientific men of cave explorations in England, as for instance, those lately made at Settle, it seems as if the relics of the primitive cave men go to no great depth, evidencing no very long tenure of the cave to be measured by thousands of years, but soon cease and are succeeded below by bones of wild beasts alone without trace of human occupation. Of course, for all this goes to prove there may have been men in existence elsewhere, though not in these particular caves, many thousands of years ago; if so, let us have real proof of their existence, apart from conjecture and mere theory. I by no means affirm that the lower stratum of human remains in the Settle cave must have been those of the race destroyed by the Deluge; but I thought it well to direct "our" readers' notice to the coincidence which undoubtedly exists between the term assigned by calculation to the end of that primitive occupancy of the cave, and the date of the Deluge according to the older and probably truer version of the Mosaic account, that of the Septuagint. J. M. G. Brookwood.

THE ORGAN (EXPRESSION *A LA MAIN*).

[4641.]—In No. 328 I addressed to "Adept" a query (8291) concerning the probable consequences of carrying out my old crotchet of inclosing each pipe of an organ-rank in a separate swell-box, to be opened by the manuals for the above purpose. Considering it is now more than a year since the date of "Adept's" last contribution (in No. 322), perhaps some other "organic" expert will kindly afford me the required information; for, if practicable, it seems the least objectionable method of producing the greatly-to-be-desired effects.

I also addressed a query (8307) concerning the earliest known application of percussion to harmonium or other free reeds, to which a reply would confer an obligation on me.

The Harmonious Blacksmith.

ROTARY ENGINE.

[4642.]—I question whether the engine of Joseph William Fennell (let. 4552) would return a higher duty than the ordinary valveless rotary. There is the same defect in it as in all rotaries—viz., the packing, or rather the non-packing of the piston. In Joseph William Fennell's arrangement this could be altered, and the engine made as good as a reciprocating engine. For instance, for the packing of the rim of D there should be a square piece of brass $\frac{3}{8}$in. thick; this is to be forced up against the casing by means of a screw, and the same with the sides of piston D; two plates, same thickness, forced against sides by a left and right hand screw. These are all to move in guides; it would make a very effective water motor. P. W. H. J.

[4643.]—The engine described and illustrated (let. 4552, p. 462) is a revival of an old idea of mine. About five years ago I registered a similar invention to this, but gave up the idea of patenting it, as an engineer to whom I showed my sketch pointed out to me that the valves would make a most objectionable noise, and moreover would not stand the wear and tear. A practical rotary movement to the steam-engine is almost as illusory as perpetual motion and the philosopher's stone. Minds great and small have applied themselves to the solution of the difficulty, and some most ingenious contrivances have resulted, but nothing, however, which is likely to displace the piston movement.

Philip E. Masey.

ROUND SHOULDERS AND CURVED SPINES.

[4644.]—As the attention of your readers has recently been called to various contrivances for remedying the above defects, I send for insertion two photographs of a simple contrivance I have just brought out for a similar purpose. The photos. represent a back-board and spine-chair, for the use of children who have weak frames and round shoulders, contracted chests, and curved spines. This contrivance has for its object a perfectly plain and hard surface to rest the spine and shoulders upon, the head and seat being eased by a thin cushion. The trunk of the body, in these positions, grows straight and regular, and the weak muscles, that cannot give the necessary resistance in a vertical position, regain their wonted strength and prevent curvature, while the shoulders are pressed into their normal position, throwing the chest open, and free for the expansion of the lungs and organs of the chest. All children while growing should lie down some time daily, and more especially those that are weakly. It is the custom in some families and schools for the children to lie on a plain backboard, a little inclined, but with the plain board the lying becomes very trying. This irksome feeling is obviated in the above contrivance by the rest and resistance given to the spine; while lying, the child keeps its position, all weariness is relieved, and the whole body rests together. When the child is tired of lying on the back-board it can be raised into an inclined back-board chair. In this position, the rest it offers to any weakly frame is a luxury, the spine being relieved from the vertical position gets the rest it cannot get in a vertical chair. The body of the child being at ease, the mind can peruse its lessons without fatigue and restlessness. Some weakly children lie on stuffed cushions and mattresses. This should not be when there is no disease of the spine, because the prominent round shoulder would imbed itself in the mattress, and the child grows deformed while it lies; but in the case of diseased spines, where there must be no pressure, the same positions are necessary as with weak spines. A thin mattress to fit the back of the chair makes the contrivance valuable to all sufferers, child or adult, or it makes an excellent easy chair in ordinary household use.

The ancients paid more attention to muscular training and the lying on perfectly hard surfaces than we do. We, as a rule, lie on soft surfaces, which have a tendency to relax, instead of brace and consolidate the muscular structure.

As the contrivance I have offered for the information of your readers is one which has for its object the remedying of defects in the human structure, if I shall not be trespassing too much upon your space I would trace some of these effects to their cause. Those who are occupied with the affairs of everyday life, and scarcely see anything outside their own business, would scarcely credit the amount of decrepit humanity there is in the world, more especially among the youthful and infant members of our race. Children with curved and diseased spines, hip diseases, round shoulders, narrow chests, shrivelled and paralysed limbs, and undeveloped frames abound. Some of them, with fair medical and mechanical treatment, grow out of their afflictions; others are beyond the reach of human skill, and grow up burdens to themselves and their parents. One cannot be constantly coming in contact with such cases without tracing many of them to their origin. They arise from the following causes: Girls becoming mothers when not yet out of their teens; youths becoming fathers before their physical structure is matured; intermarrying of blood relations, from which follows idiotcy, imbecility, deformity; reckless lives of youth; drunkenness and gluttony in parents; bad nursing, artificial nursing; everything contrary to the common laws of our being, and to what God intended.

Many afflictions arise from no fault on the part of parents, but from hidden causes; while, on the other hand, the most healthy children have been rendered cripples for life, through carelessness; and thousands of children are annually rendered cripples by intrusting them to the care of nurse-girls, who cannot take care of themselves. Here, then, is a mighty evil that stares us in the face, and one which no Act of Parliament can grapple with, but which must be met by our individual selves.

Physical deformities are bad, but mental deformities are far worse. And if there was ever an age of mental deformity, this is one, in which the most valuable gifts of God to man—namely, health and common sense—are sacrificed to fashion. High heels and narrow boots—cramped feet, enlarged joints, weak ankles, and broken legs; unprotected heads, apologies for bonnets—neuralgia and diseases of the brain; tight lacing—contracted chest, diseased hearts, and sudden death; Grecian bends—pains in the stomach; nostrums for the skin, being made "beautiful for ever," going to parties undressed—asthma, pleurisy, consumption; poisoning and colouring the food to suit the eye, living to eat instead of eating to live. Both sexes are equally to blame. I think you will agree with me when I say the grandest science of our existence is to know our true selves and how to live.

James Gillingham.

THE FORCE OF GRAVITY AT OR NEAR TO THE SURFACE OF THE EARTH.

[4645.]—Taking 16,008,324ft., to one second of time, as the force at a certain latitude or point on the earth's surface by which heavy bodies freely fall, or are attracted. Turning the decimal fraction 0·008324 into the semi-transverse diameter of an ellipsis, by the addition of unity—thus, 1·008324, the logarithm of which equals 0·0036001, the application of this value will soon appear.

The force of gravity on the equator at or near to the surface is equal to the value of the logarithm 1·20276554 = 15·950178ft., and that on the pole is equal to the value of the logarithm 1·20710546, equal to 16·110369ft., which is the force in one second of time, by which bodies are attracted at or near to the surface on the polar point.

The two values, equatorial and polar, being added together, and the square root extracted thus, $1{\cdot}20276554 + 1{\cdot}20710546 = \sqrt{2{\cdot}4098710} = 1{\cdot}2049355 = 16{\cdot}03007$ feet. This is the force of gravity at a point very near to the latitude of 45°, equal to the tangent of 44° 56′ 46·35″. The force of gravity, as measured or calculated from the mean distance of the moon, is equal to the logarithm 1·2077201; which, being divided by the logarithm 0·0036001, thus, $\frac{1{\cdot}2077201}{0{\cdot}0036001} = 1{\cdot}2041200 = 16$ft., which is the force of gravity in one second of time, at a point on the earth's surface, precisely at 45° of latitude. And dividing the value, as found from the mean distance of the moon, thus, $\frac{1{\cdot}2077201}{1{\cdot}2049355} = 0{\cdot}0027846$, and $0{\cdot}0036001 - 0{\cdot}0027846 = 0{\cdot}0008155$, and $1{\cdot}2049355 - 0{\cdot}0008155 = 1{\cdot}2041200 = 16$ft. to one second of time, equal to the force of gravity on or near to the surface of the earth, "exactly" at latitude 45°.

It is clearly evident, from the foregoing calculation, that the force of gravity, being "less" than 16ft. in one second of time at the equator, and "more" than 16ft. at the pole in the same time, that somewhere between the points that force or attractive power must be 16ft. in one second of time, and that point is 45° latitude. Veritas.

CENTRIFUGAL FORCE.

[4646.]—With all due respect to your numerous correspondents who use the term, notwithstanding all the text-books in existence, at the risk of raising a sharp discussion, I, in conjunction with some of our most eminent professors, maintain that there exists no such force as "centrifugal force." Who can prove there is?

C. H. W. B.

THE BEARING-REIN.

[4647.]—I am glad to find that there are gentlemen not above being thought effeminate, as they undoubtedly will be, by those who countenance the use of this instrument of torture. I have never before seen it applied with such terrific severity as is now being done; and, if people had not become hardened and accustomed to the sight, I believe it would not be tolerated for a single week. I could introduce "Philo" to a different sight to that of London, where I think he would soon be convinced that the coachmen are the principal and almost the only offenders. I only this morning saw a young horse (and they are the greatest sufferers) in such a distressed state that I believe if it had been a poor man's he would have been mobbed. I called a friend's attention to it, who at once said, "I should not have noticed it, I was looking at the ladies; the fellow ought to have six weeks on the treadmill." I could show "Philo," in a day, about 150 hackney carriages, and not one of the horses attached to them wearing the torture-rein; about a dozen pairs of handsome animals drawing parties of the exclusive upper ten, all apparently happy together; then about 100 pairs very uncomfortably but not terrifically reined, reminding one of a man with his arm in a sling; then about 20 in such a state that one need not to be ashamed to weep for them. It verily is an unpardonable cruelty. Space forbids my alluding to the use of *blinders* I must call them, as they are now fitted so that a horse can scarcely know whether it is daylight or dark.

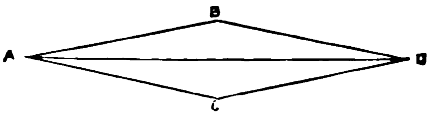
Old Ploughman.

REFLECTION.

[4648.]—It must be remembered that a piece of metal, or other reflecting surface, bent in the way suggested is only concave in one direction, and thus the image of a circular object produced at the focus is no longer circular, but a long oval, so that the light covers a much larger space, and is therefore less concentrated. Then, to correct this distortion and waste of light, it is proposed to use another cylindrical mirror or lens, which, if of similar power to the first, would just produce the result now obtained by a single mirror of spherical (or rather parabolic) surface, a waste of light and complication of apparatus without any corresponding advantage. The germ of good contained in "E. B. F.'s" suggestion (let. 4602, p. 488) has already been utilised in the Cassegrain reflecting telescope. In this, the rays reflected by the objective speculum are caught on a small convex mirror, and reflected back to the lenses constituting the eyepiece. In this construction the magnifying power is less than in the Gregorian or Newtonian telescopes; but the image is more distinct, as but one image is formed, and the two mirrors have a tendency to correct each other's spherical aberration. In fact, the Cassegrain telescope is among reflectors what the Galilean telescope or opera-glass is among refractors. Alfred H. Allen.

PARALLELOGRAM OF FORCES.

[4649.]—IF "F. R. A. S." and Mr. Proctor have not time to fully explain my difficulty, perhaps they will kindly indicate the direction our studies must take to fathom this puzzling subject. It cropped up thirty years ago in a Glasgow publication, since then I have seen nothing published to bridge over the difficulty. Some years ago I submitted it to one of the ablest professors in the Andersonian University, and in the opinion of all the class, including myself, he shirked it completely, telling us we had got beyond our depth, &c. If the lines A B, A C meet in a very acute angle, and represent two equal forces in magnitude and direction, then the diagonal A D will give the resultant in



direction and magnitude; therefore a body under the joint action of the two forces must reach D in the same time that it would have reached B or C under the action of a single force; but A D is nearly double of A B, therefore the body must go along A D with nearly a double velocity. But the theory of projectiles informs us that to produce a double velocity requires the expenditure of a fourfold force, but in this and similar cases we have a double velocity from a double force. If the parallelogram of forces and this law of quadruple force can be shown to be in harmony, it will be highly gratifying to many besides myself.

MARINE ENGINEER.

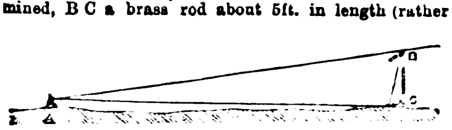
DRAINING MINES OF WATER.

[4650.]—IN 1869, at the time of the Exeter Meeting of the British Association, I met a French gentleman who submitted to the late Sir Charles Fox the plan of a new process for raising liquids to any height at a trifling cost. Though a number of engines are actually supplied according to this principle in France. Sir Charles Fox declined the communication. I understand that 2,000 gallons of water can be raised to the required height in half an hour's time by this means, at a cost of about 7 cubic feet of coal or petroleum gas. No engine is needed, only proper tanks and pipes.

A. J. DAYMAN.

JUDGING DISTANCES.

[3651.]—I OBSERVE that most, if not all, of our rifle matches take place at distances which have been previously ascertained, either by measurement or more likely by the aid of trigonometry. Most of our range measurers require two observations and a base line. In actual skirmishing the rifleman would require to judge the distance for himself, and to facilitate this object is the aim of judge of distance drill. Were it not for the resistance of the air a ball would pursue a parabolic path; the resistance of the air causes a higher trajectory to be described, as the velocity becomes less from atmospheric resistance, and the ball therefore falls more from the action of gravity in passing over a given distance than if it moved in vacuo. Considering, however, the case of a parabolic path, if the ball falls a distance of a inches in the first 100 yards, it will fall 4 a inches in the first 200 yards, 9 a in 300 yards, and so on—the fall under the influence of gravity varying as the square of the distance. Thus it will be seen that the error of mistaking 200 yards for 100, an error which I may observe is not likely to occur, is not so serious as mistaking 400 yards for 300. In the former case the ball would hit the target a inches too low so far as this error was concerned, in the latter it would hit it 16 a to 7 a or 9 a inches too low, and besides this, the latter mistake is one more likely to be made, and the object is more difficult to hit at 400 yards. In the case of artillery practice there is the great advantage that the gunner, seeing where the shot strikes, after a few shots succeeds in getting the range. I have heard of telescopes for judging the distances of objects looked at through them. I should like some information on this subject. I presume there is a micrometer in the focus of the eyeglass, or perhaps the principle of Monsieur de Rocon's telescope is used—viz., a piece of Iceland spar (this mineral has the property of double refraction) is slid along a wire in the axis of the telescope until the observed object, the size of which must be known, appears with the two images touching each other. Could the principle of the sextant be rendered available—viz., that a ray of light impinging on two plane mirrors, inclined at an angle A°, is diverged 2A° from its previous direction. Thus, let A be an object whose distance is to be determined, B C a brass rod about 5ft. in length (rather



more), having two mirrors, C and B, attached to it, inclined to each other at a very small angle, C being immovable; the half of B is silvered as in the sextant, and it must slide very steadily along the rod; the rod is graduated; a ray coming from A falls on the mirror C, and is reflected to the mirror B, and reflected again to the eye; the eye at B sees the object A, also through the unsilvered part of the mirror B; the mirror B is slid down along the rod until the two images coincide. Suppose A C 500 yards or 1,500ft., and B C 5ft., then angle B A C = $\frac{5}{1,500} = \frac{1}{300}$ nearly, referred to its circular measure, the unit of circular measure or an arc equal to the radius being about 57°, inclination of the mirrors equal half of angle B A C = $\frac{1}{600}$, or about the tenth of a degree. I should like the opinions of correspondents on this idea. Could the mirror B be made to slide so steadily on the rod as not to vary its inclination appreciably to the mirror A? This seems the practical difficulty.

PHILANTHROPIST.

GREATLY ELONGATED PROJECTILES FOR RIFLED GUNS.

[4652.]—As it is obvious the longer a projectile be made, whose weight remains the same, the smaller its diameter must become, and consequently the smaller the calibre of the gun from which it is expelled, it has occurred to me that it may be well worth while to inquire if a yet further saving both in the weight of the gun and the powder charge might not be effected by improving the form of the projectile so that the required range may be obtained without imparting to it so high a velocity.

The advantages of increase of range, at least in rifled muskets, are very questionable. The ranges of the better kinds now in use are so great that they enable "Christians" to "do good to those who (try to) despitefully use them" at 1,200 yards, a distance at which a man 6ft. high appears smaller than a peppercorn held 1ft. from the eye. There can, however, be no two opinions of the economy and military advantages of reducing the calibre and weight of the musket, also that of the powder charge, if that be possible without diminishing the velocity of the projectile at useful ranges, say up to 800 or 1,000 yards, and much, if it all, increasing the height of the trajectory.

It has occurred to me that these advantages might be obtained by exactly the same means by which we enable a given force to move a ship more rapidly through the water—viz., by making the thing to be moved of a form which is less resisted. No doubt a cylindriconoidal shot is much less resisted than a spherical bullet of the same weight, and a projectile five or seven diameters long, than one only 2½ or 3 times longer than the calibre, but a projectile of the former proportions is objectionable on the ground that its centre of gravity is not sufficiently forward, consequently its tendency to turn over and travel with its latter end foremost has to be resisted by making it spin with great velocity. This can only be done by augmenting the twist of the rifling, which certainly increases that obstruction all rifling must cause to the shot's expulsion from the gun.

FIG. 1

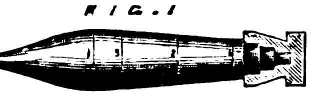


FIG. 2

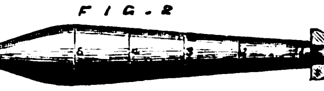


I suspect Mr. John Scott Russell would have but little faith in a naval architect who proposed to build a boat in the form of a cylinder with one end pointed or rounded and its stern a flat disc, which is just the form of an ordinary rifle shot whose bows resemble a bluff Dutchman, and whose square "starn" must needs pull a good deal of water after it. A Thames wager boat, like those in which the Oxford and Cambridge crews compete, has not only a fine entrance, but also a fine run, the first to remove the water out of its path slowly, and consequently easily, the latter to leave the water behind without pulling much of it after the boat like one with a square "starn" does. I need hardly remark the cylindriconoidal shot is not exactly the "solid of least resistance;" for this we require both a fine entrance and a fine "run," such as I have drawn in the illustrations.

To keep a projectile like that represented in its proper position in the chase of the gun, it would seem that some means of temporarily supporting its latter end is needful. For this purpose I have designed the rather peculiar "sabot" shown in section. The use of any sabot, however light, is open to the objection that more powder must be burned than would be required if it were possible to do without it, for it is obvious you must burn enough to expel not only the shot, but also its shoe. Against this objection we have the advantage of the greatly diminished atmospheric resistance consequent on the fine run of the projectile, the consequence of which must be that, as its velocity will be much less reduced at long ranges, it can hardly be needful to impart to it so high a velocity before it leaves the gun, hence I expect that, notwithstanding we have to expel the sabot also, no more, perhaps even less, powder will be required.

If the specific gravity of the sabot be much less than that of the projectile, that difference, together with greater atmospheric resistance to the sabot caused by its form, will, I think, soon cause the latter to be left behind, the projectile, after separating from it, proceeding on its course unincumbered thereby. Were the recess in the sabot which receives the projectile a mere conical hole, I fear the latter would be jammed therein by the force of the explosion, and fail to become separated, so I have designed a series of cylindrical compartments, affording altogether, including the bottom of the smallest one, four surfaces at right angles with the axis of the projectile, and I think if rather thick paper washers be inserted at the bottom and between the annular surfaces to prevent contact adhesion will be prevented.

The best material for the sabot would be something at once sufficiently strong not to be destroyed by the explosion, which is as light as possible. Should metal be found necessary, probably aluminium would be best, it being very light, but I fear too costly. Every known kind of glass or earthenware would, I think, be too brittle. Bone, wood, or yet better, papier-mâché, which is far stronger than any wood of whose fibres it is composed, might serve if the explosion did not destroy it. That it would survive, I doubt, although the pressure of the gases would not be so great as usual, because, as less velocity would have to be imparted to the projectile, a smaller powder charge would suffice. Perhaps a yet further saving in the weight of powder might be effected by forming the periphery of the largest part of the projectile to fit the grooves of the rifling, a thing by no means difficult to effect with compressed leaden shot. I think this would save that small proportion of the powder whose force is now only employed in forcing the cylindrical surface of the projectile into the grooves, and thereby altering its form to fit them. This portion of the powder cannot assist the expulsion of the projectile, because its force has already been expended in doing other work, and it can't do its "work" twice. Were the work of shaping the projectile done before it was introduced into the gun, the whole force of the explosion would be available for expelling the projectile just as it is in great guns where projectiles have ribs cast on them to fit the rifling. I think it must be admitted that if you want to expel either a projectile from a gun or a fellow human being from your house, putting obstacles in his way is not the way to facilitate that process. Spiral grooves must needs be obstacles to expulsion, but are necessary to send him "spinning" on his way.

To those who have not realised the magnitude of what Cæsar calls the "impedimenta" of a modern army, the saving of, perhaps, 20 per cent. in the weight of the powder charge of a soldier's musket may seem of little importance. It represents, however, a good many tons in the weight to be carried, often over very inferior roads, and some not few thousands of pounds in military expenditure. I may further remark that (*cæteris paribus*) the more powder you burn before the shot is expelled from the gun the greater the recoil, a thing which—in the case of old "Brown Bess"—was "no joke," but, like the writer, "terribly in earnest," as our soldiers (and their bruised shoulders) could testify. Besides, if only four-fifths as much powder be burned, may we not hope to reduce the weight of the musket some 2lb., or even more, considering its calibre will be lessened, to the great comfort of the many muscular Christians whose rather unpleasant duty it is to carry it when the thermometer stands at 120° in the sunshine, doing which, like the venerable "Brown Bess" recoil, is no joke, I "kalkalate." Certainly, I don't know from experience, because, when a young man, being a man of peace, I listened not to the voice of the "charmer"—in the guise of a recruiting sergeant—when, quoting Shakespeare, that charmer said, "List, O list!" neither have I played at soldiering like most volunteers do. N.B.—Few of them do anything else in the military line than play. The play, however, greatly resembles hard work. Whether "Le jeu ne vaut pas la chandelle," is another question.

THE HARMONIOUS BLACKSMITH.

P.S.—May I take the liberty of inviting the criticisms of "Artillery Captain," and other experts on this my last shot, which I hope will not quite miss its mark. Perhaps it would be yet more likely to hit it if made more taper towards the first shoulder, or, yet better, if that could be dispersed with altogether, thereby reducing its diameter to something less than half the calibre at that part, also enabling us to extend the length of the hinder part to five diameters instead of 3½, and reducing the length of the sabot one-fourth. See Fig. 2. The proportions of this projectile being altered as above suggested, its centre of gravity would be so far forward that it could hardly turn over during its flight, even if the twist of the rifling, and its consequent velocity of rotation, were but small. Excessive twist is very objectionable, for it induces the stripping of soft leaden projectiles, but so long as these be made of equal diameter throughout, behind their heads, a great twist is a necessity to prevent them from turning over during their flights, and the longer they be made the more they resemble "Oliver Twist" in asking for more (twist).

THE HARMONIOUS BLACKSMITH.

Science and Art Department.—The examination of students' works has just been concluded. From 397 night classes 56,016 works have been received. From 114 Schools of Art 73,226 works have been sent up, making a grand total of 129,242 drawings, models, or paintings, executed in the year ending April last. This is an increase over 1871 of 19,051 works. These works were first submitted to a preliminary examination, each school being taken separately, by a Committee of Examiners who awarded 1,100 third grade prizes, and at the same time selected from the mass 1,208 of the best and most advanced works for reference to the national competition, in which all the Schools of Art in the country compete with one another. Ten gold, twenty-five silver, and sixty bronze medals have been awarded, together with a number of prizes of books. The prize works of this competition, together with as many of the other competing works as space could be found for, are now exhibited at the South Kensington Museum, where they will remain open to inspection until September.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[11554.]—**Pedestrian Tour.**—How to make a pair of comfortable waterproof shoes out of a pair of old trousers: Cut out of your old cloth as many pieces as you require for the thickness of your soles. Boil equal parts of resin and tallow together, and soak the pieces in them. Scrape the substance off the surface and join your soles together, pressing them with a hot iron. This will make them adhere together. Heels are made in like manner. Over your soles lay any kind of cloth or canvas you please, of the right dimensions. Screw it round the border of the soles with brass screws, and your shoes are made. They may be made to tie or button on, to taste. I have never been better shod than on this principle.—C. R.

[11632.]—**Debility.**—If "Cordwainer's" friend cannot procure the bean at the herbalist's, he can obtain the pills of most chemists. Sold under the appellation of Edward Douglas's nervous pills.—E. Parker.

[12002.]—**Aquarium.**—"H. O'B." says, "Don't collect eels or other running water animals, because such cannot be kept alive in still water." As far as my experience goes small eels live very well in aquariums, and I know that the finest specimens I have ever caught, or seen caught, were taken from ponds in which the water was certainly not running.—Saul Rymea.

[12054.]—**The Needle Lock.**—I am very glad that my note on this subject has produced a reply from "Q. Yorke," especially as the query appeared to be likely to join the "lost" in the unanswered column. I never said the needle lock was "unpickable"—probably no lock ever made really is, but the needle lock can only be "picked" with a key made for it. It is, too, *one* of the best locks ever made, from that very fact. "Force" does not enter into the question at all, for we do not employ locks to resist "force," but to prevent doors or boxes being opened by *every* curious or nefarious individual. I have yet to see the lock capable of resisting "force" when applied by the skilled hands of an accomplished thief. As a matter of fact gentlemen of this character do not waste time and ingenuity in picking locks; they either force them off or cut them out, unless silence happens to be a sine quâ non. The lock that does not yield to gentle force, very frequently has its fastenings removed by a well understood process, and if the exact position of these is not known a wide sweep is taken and the piece to which the lock is secured cut out. The needle lock will not bear rough treatment, but those I have seen have answered very well. Like all other locks it is not proof against the splendid tools (qua tools) which your first-class burglar uses. It is just a question of the insertion of a bar in the keyhole, a few turns of a nut on a screw, and the back of the lock, if not the whole of it, is forced off.—Saul Rymea.

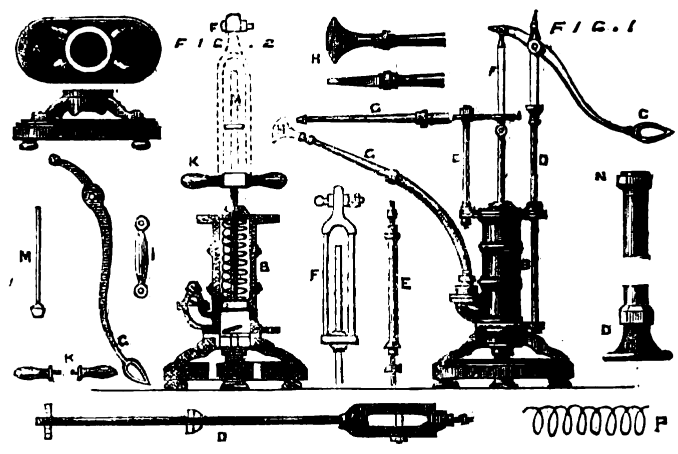
[12057.]—**Defective Sewing Machine** (U.Q.).—Make the recess in the hook deeper, that the spool may retain its position. Now, it gets hampered by dropping down between the shield and hook, and jams the thread.—Jack of All Trades.

[12063.]—**Tambour Frame** (U.Q.).—Make it the same as the ordinary sampler frame, either with two morticed rails and stiles with holes in for stretching, or four lathes with holes in and pins; or, if for large work, a square frame with a strip of canvas nailed upon the frame with webbing and snap-headed brass nails. To this the material upon which you wish to work is stretched and tacked, a reef being taken in to suit the size.—Jack of All Trades.

[12064.]—**Diameter of Screw** (U. Q.).—This is a query I cannot understand. Will J. A. Adams be more explicit?—Jack of All Trades.

[12067.]—**Portable Force Pump** (U. Q.).—Some time ago, when paying a visit to Dowgate Dock (Morewood & Co.'s old place), I saw just the thing that would suit "W. M." It was very portable, and consisted of a moderate-sized galvanized bucket, with a small pump fixed in the centre, furnished with brass fittings. Branch has plain flats, and rose with india-rubber hose, and at what I thought a very reasonable price.—Jack of All Trades.

[12067.]—**Portable Force Pump** (U. Q.).—This pump is convertible in case of fire, or for garden purposes. It will need but little explanation. I have shown in diagrams the connected and disconnected parts: by following the letters nothing can be misunderstood. It will be seen by reference that I have not introduced for garden purposes the ordinary rose for watering purposes, but one similar to a singeing apparatus, as used by farriers, as being the best-suited, so as not to destroy the most tender blossom of flowers or plants. The only letters I shall mention will be those marked M, arm of piston disconnected; N, hose and union joint or screw; O, bell-shaped nozzle at the end



of suction hose, or fastened by union joint to bottom of pump barrel. To render this pump compact, as well as portable and convertible, I have carefully arranged every part. The supply of water may be drawn from pond or portable cistern.—Joseph William Fennell.

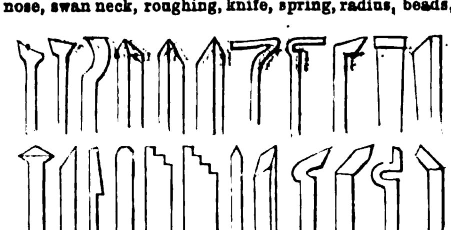
[12071.]—**American Drill Chuck** (U.Q.).—Tap the chuck to fit the lathe spindle.—P. W. H. J.

[12071.]—**American Drill Chuck** (U.Q.).—Yes; you may expand it over a gas-jet sufficient for that without injury.—Jack of All Trades.

[12075.]—**Fruit Syrups** (U.Q.).—There are various ways; some are chemicals coloured with cochineal, &c., while others are the pure juice, to every pint of which one pound of sugar is added. Some are boiled and clarified with eggs, while others are left to stand until clear, sugar being then added without boiling.—Jack of All Trades.

[12076.]—**Polishing Slate Clocks** (U.Q.).—Take a piece of flannel or list, with spirits of wine, and see whether it has been lacquered, if so wash the lacquer off and use copal varnish. Sometimes these are oiled before lacquering, which is the cause of it, and a mistake.—Jack of All Trades.

[12082.]—**Turning Tools used for Metals** (U. Q.).—These are hook tools, heel tools, diamond nose, side, L, three square skimmers, bolt head, planishers, for all classes of brass work, and filed for quirks, hollows, and beads of various sizes, for standard tools as well as gravers, chisel nose, round nose, all of which vary according to your work. Those are used for hand turning for slide-rest. They consist of round nose, swan neck, roughing, knife, spring, radius, beads,



hollows, &c. The sketch will give a general idea. Take them in rotation, as mentioned; the last is the Scotch, and is not to be beaten for rough work, and, in fact, general use for surfacing or boring tools; but though you may have the forms given, and make them, it is another thing to use them.—Jack of All Trades.

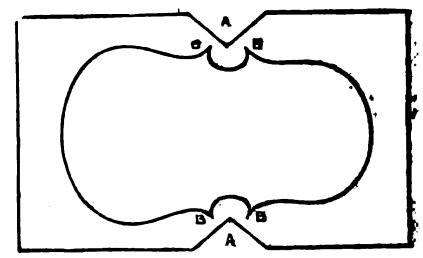
[12083.]—**Polishing the Edges of Glass** (U Q.)—This is done in many instances with a cork wheel, and fine or flour emery, putty powder, powdered pumice, or cowcup.—Jack of All Trades.

[12085.]—**Cricket Bats** (U. Q.).—A cricket bat requires no staining; age is the only seasoning which is serviceable. Polishing is a drawback, and makes it more of an ornamental than a useful toy. The face of a bat should on no account be polished, for then oil cannot penetrate, and no bat can be of much use for any length of time without constant oiling.—W. M. Colles.

[12085.]—**Cricket Bats** (U. Q.).—Can be stained with a weak solution of bichromate of potash, spirit, and turmeric, and polished with pale polish or a coating of bright.—Jack of All Trades.

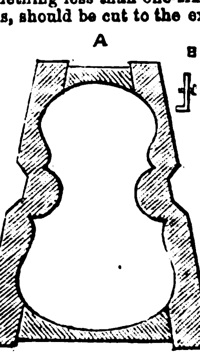
[12087.]—**Violin** (U.Q.).—Heat is the means of bending sides of violin. If the wood is wetted it is apt to recover its straight form on cooling. The violin makers use "curling tongs." For the amateur I suggest the following mode:—Heat a piece of round iron (an urn-heater will answer), nip the cooler in the vice, bend a piece of tin and put over the heated end. If the prepared slip of wood is held down upon the tin, shifting it as required, it may be carefully beat (dry) to the required shape, and will retain its form.—Suffolk Amateur.

[12087.]—**Violin** (U.Q.).—Get a piece of wood (pine will do) large enough to cut out the shape of your violin, and as thick as the depth, say 1¼in. Cut out the shape with a fret-saw, and you will then have a framework to begin with (see sketch), A A. Cut out so that you can use a hand-screw or small cramp to fetch up the block when glueing the sides. In cutting the frame cut the corners BBBB well in, and wide enough to take two pieces the thickness of the sides of the violin, but don't cut it too wide. Now get your sides and fit them in the frame. You can bend them to their shape on a round piece of iron made warm, not hot, and held in the vice. Now don't be in a hurry when bending the sides, because there is plenty of time, and if the iron gets cold you can warm it again. If the sides do not bend readily, wet the upper side a little, only don't try to bend it all at once; do it little by little, and it will gradually come to its proper place. When the sides are fit you can prepare the blocks, six in number, one for each corner, and one for each end. Be careful in fitting the blocks, and get them to bed well. When fit you may proceed to glue the sides in; block up two corners first, one at each side; when set do the others, and then the ends. See that the glue has not fastened the sides to the frame, or you will have a job to get it out. When the blocks are set, put some strips of wood at each edge inside; cut the strips in lengths to reach from block to block, and bend them in the same way as the sides over the iron. The strips are best made of split wood, you can then work them either way; they must be about ¼in. in depth, and



about one-sixteenth of an inch in thickness outside, and tapering off inside. When finished you taper them after fixing them in their places. Prepare one side of the strip, and fix it tightly into its place, each end just catching on a block; when they are all in and set finish off inside, making all perfectly smooth; level the edges and the blocks, and it is then ready for the back. If you don't understand this write again, and I will endeavour to explain, though I could have shown you all about it in less than one-half the time it has taken me to write this.—J. R. F.

[12087.]—**Violin** (U.Q.).—I will relate how the job was done by me with perfect success. A frame of deal is first made of the exact shape of the outline of the violin, out of two pieces of deal ⅝in. thick, fixed together face to face, with ⅛in. blocks between, so as to make the whole depth 1¼in., the usual depth of the ribs. The wood for the latter having been reduced to something less than one-sixteenth of an inch in thickness, should be cut to the exact lengths of each rib, and steeped in warm water for a short time, then bent on an Italian iron such as laundresses use—viz., an iron tube on a stand into which red-hot heaters are put from time to time to keep up the heat. To press down the strips on the iron use a piece of wood with the end hollowed to fit the curve of the iron; whilst the wood is still warm place it in the frame, and fix it in its place with small flat pieces of wood having a head at one end projecting at right angles; press the head tight to the rib so as to make it sit close to the frame, and drive a small tack through the flat part into the face of the frame, and when all the ribs are bent and secured in this way, set it aside to dry; afterwards glue a small block of wood into each angle of the ribs, and also some strips of deal, about ¼in. deep, and one-sixteenth of an inch thick, round the top and bottom edges of the ribs, to strengthen them. I inclose sketch of frame, &c. A, frame; B, wood clip.—Vexed Violinist.



[12087.]—**Violin** (U.Q.).—Boil them, and bend upon and between blocks.—Jack of All Trades.

[12088.]—**Cleaning Jewellery** (U.Q.).—Sal-ammoniac and urine are said to give the desired effect.—Jack of All Trades.

[12091.]—**Plums (U.Q.).**—Disease is said to be caused by the large roots getting down into hungry soil, more especially if your bottom is red gravel. I have seen trees treated thus: Undermine the roots and cut off the tap-root. Grub out if you can, with as little injury to the surface roots as possible, and fill in with old mortar, or, what is better, powdered oyster shells. The trees must be lopped in proportion. I have seen trees that have been served like this—which bore no fruit before, but plenty of bloom; and others that have borne fruit to a great extent, but which never came to perfection—cured and become splendid trees by this treatment—pears, plums, apples, walnuts, gooseberries, vines, &c. There is a nice little work called the "Cottager's Calendar," by Preston, price 3d.—JACK OF ALL TRADES.

[12103.]—**Staining Glass (U.Q.).**—These are plated glasses, that are only coloured on one side. This plated glass is acted upon by hydrofluoric acid upon the coloured side; in fact, it is etching upon glass, the acid dissolving the coloured glass and leaving the other clear for colours. See Indices for "Glass Painting," by "Sable."—JACK OF ALL TRADES.

[12107.]—**Recipe for Greasy Strapping (U.Q.).**—I know of nothing but hot water, which will drive the grease out.—JACK OF ALL TRADES.

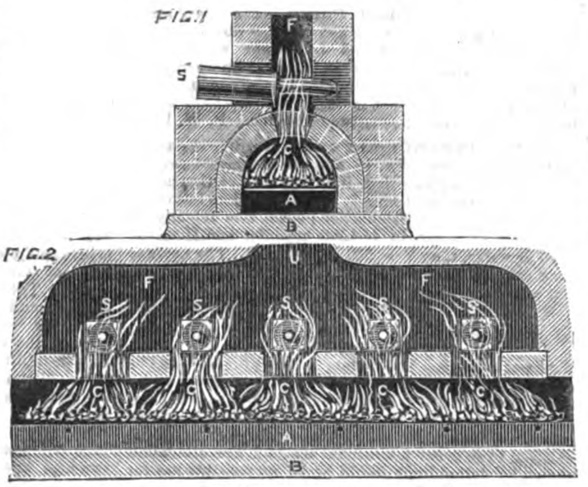
[12107.]—**Recipe for Greasy Strapping (U.Q.)**—When strapping gets so greasy as not to be pieced with the ordinary belt punch and lace, there is no help for it, it must be got rid of. Avoid all very greasy strappings, as they do not carry power well, and are apt to slip if the grease is in excess.—P. W. H. J.

[12109.]—**Old Locomotive Tubes (U.Q.).**—They are generally very brittle, and must be thoroughly cleansed inside and out, then heated very nearly red hot, and slacked in water. Fill them either with pitch, resin, or lead before bending.—JACK OF ALL TRADES.

[12095.]—**Hardening Steel Shafts (U. Q.)**—With a few fire-bricks build a furnace after the following sketch:—Fig. 1, end view; Fig. 2, section through A F; S S S, shafts; bricks are left out here and there in the crown of arch, and the same through flue F. At right angles place the ends of shafts through, and lute in with loam; rest the other ends upon trestles. Heat to a bright blood red, and slack in a good depth of water, at 80° or 90°, plunging them in perpendicularly, and let them remain until perfectly cold.—JACK OF ALL TRADES.

[12119.]—**Pump for Colliery (U.Q.).**—I should fancy a centrifugal pump would answer your purpose.—JACK OF ALL TRADES.

[12119.]—**Pump for Colliery.**—I don't exactly understand "One in Need." He says that he has to bring 500 galls. 200 yards, but does not say to what height it is to be raised. If it were on a level or on an incline downwards towards shaft there would be no need of a pump, so I am forced to the conclusion that it has to be raised. If this is only a few feet, a centrifugal pump would do best. It would only require a very small one for that quantity of water, in fact, if "One in Need" is anything of a mechanic, he could make one himself. The wheel could be entirely of brass, and casing of sheet iron. One of about 8in. diameter would do, of course a less one would do, but I think that that would be most serviceable. But I cannot say positively anything concerning it until I have further particulars. I want to know description of mine—whether it is driven in the side of the hill or not, or whether, if it has a shaft, it has a regular set of pumps. A plan and section of mine would make things clearer.—P. W. H. J.



[12155.]—**The Suspended Shilling.**—The statement that a suspended shilling will strike the hours can hardly be taken as a fact. I have cured one person of the fallacy by requesting him, instead of looking at the shilling and thereby, as it were, mesmerising himself, to watch his arm and observe that it does not move. I should expect that your correspondent is equally open to a cure.—SUFFOLK AMATEUR.

[12172.]—**Constipation.**—Let "H. S. A." try the following: 40 grains powdered rhubarb, 24 grains ipecacuanha made into 24 pills. One to be taken thrice daily with a little good exercise. Continue for two or three weeks. If no benefit arises the remedy is not hurtful.—SUFFOLK AMATEUR.

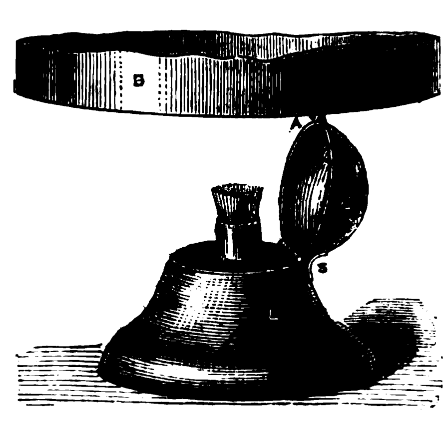
[12180.]—**Seasoning Pear Wood.**—If A. H. Cooke keeps his pear wood in a hay-loft he will find it soon spoilt. Choose a place which has a cool draught, the hay-loft is likely to be the exact reverse, strip the bark to allow the wood to dry. Pear wood is used for turning and cabinet work.—SUFFOLK AMATEUR.

[12184.]—**Brown Varnish for Baskets.**—Use "brown hard;" too cheap to make it profitably.—E. M.

[12187.]—**Repolishing Chimney-piece.**—Polish with Tripoli, and then with putty powder and felt; don't use too much water.—E. M.

[12205.]—**Double Rocket (Hesperis.)**—In answer to the above as to the best method of propagating the same, S. Bottone (page 415) says: "Best from seed sown in the autumn to bloom next year." I hope that S. Bottone will excuse my asking if he has raised the double rocket from seed himself, or if he speaks from the information of others. I have grown the double rocket for the last twenty years, and I never found it to produce a single seed. I have looked at several works on horticulture as to the method of propagating this plant, and find no mention made of seed. They give the usual method of propagating by division of the roots after the plants are done flowering or by cutting.—ABEL.

[12213.]—**Coffee.**—I have lately seen a self-acting apparatus like that described on page 416. In the one I saw, however, the two vessels (which were of earthen-



ware) instead of being above one another were placed at the extremities of a brass rod balanced like a see-saw. The chamber containing water, which I will call the boiler, is closed at the top with the exception of a hole which is plugged by a cork, and by which the boiler is filled. One end of a bent tube passes through the cork, and almost touches the bottom of the boiler; the other end, which is provided with a metal strainer like the rose of a watering-can, nearly reaches the bottom of the coffee chamber. The spirit-lamp L, which heats the water, has a lid E which acts as an extinguisher, and is closed by a spring S. When the boiler B is full, it is weighed down by the water, and a projection A on its bottom catches the extinguisher and holds it up. When the water boils, it is forced up the tube by the steam into the vessel containing the coffee, and the latter being now weighed down raises the boiler, and, by thus releasing the extinguisher, puts the lamp out; the steam in the boiler now condenses, and the coffee flows back to the boiler, and may be drawn from the latter by a tap. I inclose a sketch of the lamp, and bottom of boiler.—GLATTON.

[12215.]—**Fettling Materials.**—Marbella, blue billy, and ilmenite are merely impure oxides of iron. Ilmenite is titaniferous iron, blue billy is the refuse of the pyrites used in sulphuric acid making. I don't know the peculiarity of marbella.—J. B. C.

[12217.]—**Violin Tuning.**—I tune my second string to A by fork, then screw up the first until it chords in harmony with the second. W. M. Meek will easily hear when the E and A blend by the beauty of the tone; the third and fourth I tune in the same way, all off the second string; that is, I screw them up until I obtain the sweetest chord. It is nonsense to talk of tuning to a certain key, all scales are played off one tuning.—JOHN HOPKINS.

[12236.]—**Glowworms** should be found in plenty now. The beetle comes out fully developed rarely later than June. They are found in most country places in sheltered spots, where there is perpetual dampness, not wetness.—SAUL RYMEA.

[12244.]—**To Harden Lead or Zinc Type.**—It seems as if Mr. Sharpley would not obtain the information he requires. I know of no compound type-metal which is sufficiently fusible to cast in moulds and yet able to resist the heat of gas for hours. Surely, if Mr. Sharpley spoils a lead type every half-hour, brass *must* be cheaper. Why not try cast iron? or are the letters too small to get good types in this metal.—E. M.

[12249.]—**High Pressure Fire-Box Boiler.**—In reply to "495," the plates of the shell are to be $\frac{3}{8}$in. thick, double riveted, and best Staffordshire iron. The ends to be same kind of iron $\frac{3}{4}$in. thick, having two strengthening pieces $\frac{5}{8}$in. thick, and 5in. wide, riveted diagonally across from about the crown of the tube to the shell, and the stays mentioned in my first letter pass through shell and strengthening pieces and screwed up. By the use of Galloway's tubes you might make the boiler move over 40 h-p., but I think that it would be best to do without them, and add them afterwards as you find your power insufficient. Thus you will always be able to increase your power without putting an additional boiler down. If I had calculated for Galloway's tubes at first, I might have made the boiler considerably smaller. The tubes are to be set at an angle of 10° with the vertical line. There are to be 35 of them set in two parallel rows, at a distance of 1ft. from each other in the line; they are to be about 2in. wide at bottom and 4in. at top, internal, and about $\frac{3}{8}$in. thick with flanges. The bridge is to be a brick and a half thick at top, and two bricks at bottom. The firebars to be of cast iron. I need not particularise Hopkinson's valve, because, of course, you will obtain it direct from the maker. I would merely stipulate that the diameter of the top safety valve should be $6\frac{3}{4}$in. diameter.—P. W. H. J.

[12255.]—**Hair.**—The best wash is: Rose-water, 8oz.; glycerine, $\frac{1}{2}$oz., sulphur, 1drm., sugar of lead, $\frac{1}{2}$drm.: mix. To be used daily till the head is clean, and then occasionally. Proved.—M. W. G.

[12258.]—**Old Violin.**—The label "Chetianus Amates Camonensis, 1640," does not indicate value apart from its genuineness. I cannot find any mention of such a maker of violins. The Amatis of Cremona most known are Andreas, Hieronymus, Antonius and Nicolaus, to whom may be added Josephus of Bologna.—SUFFOLK AMATEUR.

[12267.]—**Cabinet for Birds' Eggs.**—"C. T. B." will find that a miniature chest of drawers will be the most suitable receptacle for specimens of eggs, &c.—W. M. COLLES.

[12293.]—**Lighthouses.**—Mr. Hey must apply to the Trinity Board, Tower-hill, E.C., when, if successful, he will have to go through a course of tuition on Blackwall Wharf, and finally pass an examination by the Trinity engineer.—LAND'S END.

[12299.]—**Tar Pavement.**—There are one or two points of importance in the construction of this kind of causeway that appear to have been overlooked in "Philo's" reply. One is, the regulation of the size of hard materials to mix with the gas-tar; and another, the necessity of securing perfect adhesion between them and the tar itself, so as to make the mass to a certain extent homogeneous and prevent its breaking up from any cause. In the process which I have watched, and which is very successfully adapted to provide for the heavy wear and tear of exposed railway platforms, the following particulars seemed noteworthy:—Firstly, the securing a perfectly firm foundation of hard-rammed chalk, building rubbish, or other "hard core," the thickness to be proportioned to the anticipated traffic and to the character of the soil beneath—*i. e.*, with regard to firmness or tendency *per contra* to "settle" under continued pressure. If the soil be of a very yielding character, it must be excavated to a sufficient depth and replaced by the foundation stuff, well rammed as aforesaid. The hard material for the path may consist of gravel stones or of shingle from the sea beach, broken stone, or anything similar; but it must be double riddled, so as to exclude all pieces above or below certain dimensions. The limit of useful size appears to be from $\frac{1}{2}$in. diameter as the minimum, up to 1in. or $1\frac{1}{2}$in. The next object is to thoroughly dry this material, so as to obtain perfect adhesion of the tar when applied to it. For this purpose the stone is carefully roasted, in this way: A thin layer of the stone is spread, and upon this a fire of cinders is lighted. When it is burning well a small quantity of the stone is scattered upon it; and when this is thoroughly hot more cinders, and again more stone, and so on, until the whole of your material forms an incandescent heap. When it has thus remained a sufficient time to have every particle of moisture expelled from it, it becomes (as may well be supposed), very "thirsty," and will suck in any fluid applied, so as thoroughly to incorporate it. But first the hot stuff must be again sifted to get rid of all the ashes and dust; and this must be done quickly, in order not to lose the benefit of the high temperature. As fast as it is sifted and thrown out of the sieve by one man, another pours upon it the prepared tar from a long ladle, and another rapidly turns the heap over and over, so that every scrap of stone gets a thoroughly good coating and soaking with the tar, but not in excess of the quantity required to secure adhesion and firm texture. These processes, it is obvious, must be carried on, not upon the site of the intended pathway, but at a short distance from it; and the tar, or mixture of tar and pitch, should be placed in a tub or half-cask sunk to a level with the ground in the vicinity of the roasting heaps, and thence may be conveniently ladled out as described. The tarred stone is then barrowed to the path, upon which it is evenly spread to a thickness of a couple of inches or so, the top being arranged with proper "pitch" for surface-drainage. It is then rolled with heavy rollers; and in corners or against walls, where the rollers cannot penetrate, it is thumped down with flat-bottomed rammers. After this, a surface coating of drying stuff, which may consist of coarse sand or lime rubbish, or, better still, the small chips and dust from a stone-mason's yard, must be sprinkled evenly over it, and the rolling and thumping repeated. If, from intense heat, or excess of tar, the latter should still tend to "sne" up on pressure, further coatings of the drying stuff may be applied from time to time as required. And, if not objectionable for any reason, a thin coating of the same may be left loose on the surface for a time, to prevent any possibility of damage to even the most delicate of "understandings" by direct contact with the tar. The peculiarity of paths well made on this principle is that—like

A woman, a dog, and a walnut tree,
The more you beat 'em the better they be.

They improve continuously with "wear and tear;" will stand a considerable amount of even rough usage; and, agreeably elastic at first, they finally settle down to a rock-like firmness. In making barn and other floors under cover in this way, a larger proportion of pitch, or of real asphalte, appears to be required; and the broken Derbyshire spar (crystalline sulphate of lime) is used with good effect and great advantage in establishing a firm and pleasant surface.—G. W. K. L.

[12311.]—**Hydraulic.**—The questions are easily answered. Pumps expel only the water which stands above the lower end of the pipe; never that which is under it. The action of the pump piston is to create a vacuum, which is immediately filled up by the descending liquid. The water flows in, not by "attraction" but by atmospheric pressure. This pressure is also called gravity, and incorrectly considered as centripetal. Hard water, being of greater density, occupies the bottom of the well; it cannot ascend, if not forced upwards, which it is not. On the contrary, the soft water ascends in proportion as a vacuum is produced under the piston: it descends first by atmospheric pressure acting on its surface. The place occupied by the pump is of no consequence whatever. It is always the upper water which descends to the pipe's mouth, in obedience to atmospheric pressure, and fills up the vacuum. Should not this take place, no water would ascend at all.—C. R.

[12329.]—**Practical Mechanics.**—What do the several correspondents who have written upon this subject require? Mr. Anderson's Cantor Lectures were given pretty fully, and at the present time the Rev. A. Rigg's Cantor Lectures are appearing just as fully. Both these series of lectures are upon the subject—Applied Mechanics. As for books upon the subject, I agree with your correspondent "Caer Glon" that they are unsatisfactory; but it is probable that before long something better will be published. Meanwhile, let me advise all students to follow some such plan as this: Get to see a machine at work, seek out the point where the power is applied, then see where this power is carried to, and how. If this be done, the student will soon feel himself progressing in knowledge. It would be rendering me personally an important service, and I believe many others also, if correspondents would state exactly where they are at fault, and what they desire to know in this subject of applied mechanics.—C. H. W. B.

[12341.]—**Moths.**—Finely ground white pepper dusted on the carpet and under will banish them, but may banish you, too, if your nose is much given to sneezing. Try snuff.—M. A. B.

[12344.]—**Disappearance of Art.**—If there be no remains of the mechanical arts found in Egypt, Assyria, &c., does it not argue that they never existed there? Imagine that in the course of time the power of England waned, and the mechanical arts were lost, what would become of the vast accumulations of that indestructible material, iron, existing in the form of ponderous bridges, cranes, girders, steam hammers, marine, loco, and land engines, &c.? Their debris at least (if not their actual forms) would last many thousand years. This query and 12374, "Ancient Wrought Iron," open out a field of very curious inquiry. Many thanks to S. Bottone and to "J. C. L." for their answers to 12188.—LXXXVIII.

[12346.]—**Gearing Waggon Wheels.**—In my reply to the above query (p. 469) there is a slight mistake. It ought to be thus—

25 : 2 : : 10 (arm
2
———
25) 20·0 (·8in., or $^8/_{10}$ of an in. out of straight line.
20 0

—Luffra.

[12347.]—**Stroke.**—The stroke of an engine is twice the radius of the circle described by crank-pin. It can be ascertained from an actual engine by turning the fly-wheel round until the piston-rod is as far in as it will go, and the engine is on the dead centres. Then tie a piece of string tightly round the piston-rod, close to the top of stuffing-box. Now turn the fly-wheel until the piston-rod is as far out as it will go, then measure distance between top of stuffing-box and string, which will be the length of stroke. The weight of fly-wheel for the Boulton and Watt engines as given by Watt, is found by this rule. Multiply the number of horse-power of the engine to which it is to be applied by 2,000, and divide the product by the square of the velocity of the circumference of the wheel in feet per second, the quotient is the weight of the wheel in cwts. Thus, the weight of a fly-wheel for an engine of 20 horse-power is 90·4 cwts., supposing it is 18ft. diameter, and to revolve 22 times per minute. The modern rule, as given in "Molesworth's" for weight of rim, is this: Let D = mean diameter of wheel in feet, P = total average pressure on piston in lb., and S = stroke in feet. Then W = weight of rim in cwts. $= \frac{P\ S}{45\ D}$, and sectional area of rim in sq. in. $= \frac{11{\cdot}42\ W}{D}$, and D = stroke × $3\frac{1}{2}$ or 4 generally. For engines with high expansion or irregular loads, multiply W, as found above, by 1·5. Some engineers have the diameter from 3 to 5 times stroke of engine, and from 6 to 8 cwt. per horse-power, ¼ of which weight is weight of boss and arms. This rule gives the fly-wheel about 3 to 6 times the average momentum of piston and other reciprocating parts.—P. W. H. J.

[12348.]—**Spanish Pronunciation.**—Erratum.—The word *blancho*, as given in the tenth line of my answer to "E. L. G." in our English Mechanic of July 19th, 1872, ought to be *blanco*: the error is typographical.—Wm. Wray.

[12351.]—**Underground Telegraph Wires in Cities.**—The soil is dug out to the proper depth, a bed is made at the bottom sufficiently large to receive the wires and allow of their being isolated. These wires are stretched out at proper distances by means of a disc of perforated sheet iron, through which they pass; three or four yards are drawn out at the time. When the wires are thus stretched out and fixed, melted bitumen, or common resin, is poured in so as to completely envelop and isolate them. This done the work is complete, and the earth is covered in. Such wires never need repair, and are free from all influence of atmospheric electric perturbation.—C. R.

[12352.]—**Centrifugal Pump.**—It appears to me that if "Rat-Tat" tried a pump constructed upon his idea, which is only a modification of the spray apparatus, he would find that if the aperture for the exit of the raised water were anywhere between the steam nozzle and surface of water that the air would rush in instead of the water coming up, and if the water is to pass nozzle as the smoke and air in locomotives does, the water would be blown into spray and the steam condensed instantly.—A., Liverpool.

[12352.]—**Centrifugal Pump.**—The plan mentioned in the latter part of answer of "Rat-Tat" has been tried and not found to answer as well as with the centrifugal. The reason is that to pump or eject a large body of water is attended by the condensation of the steam, if it is not in larger volume than would be required for a well-constructed engine.—P. W. H. J.

[12352.]—**Centrifugal Pump.**—I will first answer last part of query—viz., to find the number of revolutions. I shall suppose that it is Appold's or Gwynne's, as these are the most largely employed. The following is the formula for calculation:—Let V = velocity of periphery of pump in feet per minute, and H = the head of water, then V = 550 + 550 $\sqrt{H}$. The average head can be estimated at 9ft. Of course, this is not correct, but is near enough, and easy to deal with. Then V = (550 + 550 × 3) ft. = 2200ft. ∴ Number of revolutions per minute $= \frac{2200}{3{\cdot}1416 \times 2}$ = about 350 revolutions per minute. The leather belt mentioned would be exposed to a strain of 530lb. Theoretically, 8in. and a fraction would drive it well, but I think that it is an advantage to have one 10in. broad, as there would be much less danger of straps breaking, through not being exposed to so great a tensional strain. The alteration shown by dotted lines would be of no possible use for so short a length of strap. If it were a long strap, then it would be useful, on account of the weight of the strap increasing the adhesion, but even then it would hardly be worth while. The small pulley marked *c* on drawing (which, by the way, is not described) would increase the adhesion considerably, and so lessen risk of breakage. If "Teachable" had sent description of chain, it would have been possible to have seen whether it was really proportioned for the strain. Another way of getting over this difficulty is to increase the velocity of the pulley *c*, and lessening its diameter. This would have the effect of decreasing tensional strain on the chain. It would be the best and surest plan, but would entail considerable cost. Either diameter of spur-wheel *a* would have to be increased; or, what is much cheaper, if possible, the diameter of the pinion *b* would have to be diminished. At all events, try the strap first with present arrangements.—P. W. H. J.

[12352.]—**Centrifugal Pump.**—I have seen a woven leather belt (Hurn, patentee) driving a 16 horse-power engine and centrifugal pump to perfection. One of these woven belts has been driving the engine at the Royal Gas Factory, Woolwich Arsenal, upwards of three years to my knowledge. Inspect the belt and judge for yourself.—Mechanic.
